The best strategy to prevent delayed CINV—nausea and/or vomiting occurring 24 or more hours after chemotherapy—is to control acute CINV.²⁴ Aprepitant, dexamethasone and metoclopramide have demonstrated efficacy in preventing delayed CINV, whereas the results with SSRIs are inconsistent.²³

Patients receiving cisplatin and other agents are at highest risk to experience delayed CINV. The addition of aprepitant in the recommended three-drug combination on the day of cisplatin administration and additional doses of aprepitant and dexamethasone on the 2 days after cisplatin administration improved the control of vomiting as compared with patients who received the dexamethasone alone postchemotherapy, the standard of care prior to the availability of aprepitant.^{14,15} Current practice guidelines recommend administration of aprepitant and dexamethasone on the 2 days following the administration of chemotherapy of high emetic risk.^{2,23}

The incidence of delayed CINV following chemotherapy agents of moderate emetic risk is less-well defined. The current recommendation is to give single-agent dexamethasone or an SSRI to patients in this group, except to patients who are receiving an anthracycline and cyclophosphamide for whom single-agent aprepitant is recommended for the 2 days following chemotherapy.²³ Other practice guidelines offer alternate recommendations for the prophylaxis of delayed CINV after regimens of moderate emetic risk.^{2,24}

Management of delayed CINV has challenged practitioners. With the addition of aprepitant, the number of patients not experiencing delayed emesis after cisplatin chemotherapy increased from 51% to 72% as compared with dexamethasone,^{14,15} and from 49% to 55% in patients receiving an anthracycline plus cyclophosphamide, as compared with twice-daily ondansetron,²⁰ but the problem has not been

eliminated. The availability of palonosetron, an injectable SSRI with a prolonged serum half-life and higher receptor binding affinity, may offer another option for prophylaxis of delayed nausea and vomiting. Given once every 7 days,²⁵ palonosetron was found to protect more patients from delayed emesis than either ondansetron or dolasetron in adult patients receiving chemotherapy of moderate emetic risk,^{26,27} but the studies were not designed to determine superiority.

CLINICAL CONTROVERSY

Is one SSRI more efficacious than another in preventing CINV associated with chemotherapy regimens of high emetic risk? Current practice guidelines²³ state that SSRIs have equivalent safety and efficacy and are interchangeable based on current literature. Triple-drug therapy that includes dexamethasone and aprepitant is the current standard of care, but head-to-head trials of palonosetron versus dolasetron or granisetron or ondansetron, in combination with dexamethasone and aprepitant, have not been reported.

POSTOPERATIVE NAUSEA AND VOMITING

Postoperative nausea and vomiting (PONV) complicates surgical procedures for approximately 25% to 30% of patients undergoing anesthesia.²⁸ Factors to be considered for PONV prophylaxis and treatment include risk factors, potential morbidity, potential adverse events associated with antiemetics, antiemetic efficacy, and costs. Most patients undergoing an operative procedure do not require preoperative prophylactic antiemetic therapy and universal PONV prophylaxis is not cost-effective. Table 37-8 summarizes the risk factors for PONV. Prophylaxis and treatment of PONV should adhere to consensus guidelines.²⁹ Other strategies to reduce baseline PONV risk factors among patients at highest risk, in addition to prophylactic antiemetics, include use of regional anesthesia, propofol, supplemental oxygen, and hydration, as well as avoiding nitrous oxide, volatile anesthetics, and opioids. Total intravenous anesthesia reduced the risk of PONV similar to the prophylactic administration of a single antiemetic.³⁰

Prophylaxis of PONV

Although the optimal management of PONV is not known, patients at highest risk of vomiting should receive prophylactic antiemetics. Patients at low risk for PONV are unlikely to benefit from prophylaxis and may potentially experience adverse reactions from the medications. Cyclizine, dexamethasone, dolasetron, droperidol, granisetron, metoclopramide, ondansetron, and tropisetron are effective as compared with placebo for the prophylaxis of PONV.³¹ Table 37-9 summarizes the doses for prophylactic antiemetics from the consensus guidelines.²⁹ Patients at moderate risk for PONV should receive one prophylactic antiemetic, whereas those at high risk should receive two prophylactic antiemetic agents from different classes.^{29,30} Optimal dosing of agents used in combination has not been determined.

TABLE 37-9 Recommended Prophylactic Doses of Antiemetics for Postoperative Nausea and Vomiting

Drug	Adult Dose (IV)	Pediatric Dose (IV)	Timing of Dose ^a
Dolasetron	12.5 mg	350 mcg/kg up to 12.5 mg	At end of surgery
Granisetron	0.35–1 mg		At end of surgery
Ondansetron	4–8 mg	50–100 mcg/kg up to 4 mg	At end of surgery
Tropisetron	5 mg		At end of surgery
Dexamethasone	5–10 mg	150 mcg/kg up to 8 mg	At induction
Droperidol	0.625–1.25 mg	50–70 mcg/kg up to 1.25 mg	At end of surgery

^aBased on recommendations from consensus guidelines; may differ from manufacturer's recommendations.

From Gan et al.²⁹

Dexamethasone is an effective, inexpensive prophylactic agent when administered either alone or in combination with other antiemetic drugs before the induction of anesthesia.^{30–32} Droperidol is one of the most effective agents for PONV prophylaxis, but concerns about the development of torsade de pointes severely limit its use.³³ With equivalent efficacy and safety profiles, acquisition cost was the primary factor that differentiated the SSRIs from each other.²⁹ SSRIs are most effective when given at the end of surgery.

Aprepitant was recently approved for the prevention of PONV at a dose of 40 mg given orally within 3 hours prior to induction of anesthesia.²¹ Whether it will be used as monotherapy or in combination with other prophylactic agents is yet to be determined.

Treatment of PONV

Most patients given a drug to prevent PONV will not benefit from it and 1 to 5 of every 100 patients given PONV prophylaxis may experience a mild adverse reaction such as headache, sedation, or dry mouth.³¹ If a patient develops nausea and/or vomiting despite prophylaxis, treatment options are limited. Use of the same drug for treatment is ineffective when it was used for prophylaxis.³⁴

SSRIs in doses of dolasetron 12.5 mg, granisetron 0.1 mg, ondansetron 1 mg or tropisetron 0.5 mg are recommended in patients who experience PONV despite prophylactic dexamethasone or when no prophylactic agent was used.²⁹ Treatment doses of SSRIs, when an SSRI was used as prophylaxis, are not recommended until 6 hours after surgery.³⁴ Patients who experience PONV after receiving prophylactic treatment with a SSRI plus dexamethasone should receive a rescue dose from a different drug class such as a phenothiazine or droperidol.³⁵

■ RADIATION-INDUCED NAUSEA AND VOMITING (RINV)

Nausea and vomiting associated with radiation therapy is not well understood. It is neither as predictable nor as severe as CINV, and many patients receiving radiation therapy will not experience nausea or vomiting. Risk factors associated with the development of RINV include the site of radiation, the dose, dose rate, and area of the body to be irradiated.

8 Patients receiving single-exposure, high-dose radiation therapy to the upper abdomen, or total- or hemibody irradiation, should receive prophylactic antiemetics for RINV.

Prophylaxis of RINV

Four radiotherapy-induced emesis risk groups have been defined by the Antiemetic Subcommittee of the Multinational Association of Supportive Care in Cancer (MASCC) and the ASCO antiemetic practice guidelines.^{2,23} Both groups recommend preventive therapy with a SSRI and dexamethasone in patients who are receiving total-body irradiation (high emetic risk). The efficacy of oral granisetron 2 mg and ondansetron 8 mg was demonstrated in 34 patients who underwent hyperfractionated total-body irradiation.³⁶ Patients undergoing radiation therapy procedures with moderate to low emetic risk should receive a SSRI prior to each fraction.

■ DISORDERS OF BALANCE

A variety of clinical conditions may be associated with vertigo and dizziness. The etiology of these complaints may include diseases that are infectious, postinfectious, demyelinating, vascular, neoplastic, degenerative, traumatic, toxic, psychogenic, or idiopathic. Symptoms of imbalance perceived by the patient present a particular clinical challenge. Whether associated with a minor or complex disorder, motion sickness may be associated with nausea and vomiting.

Although much progress has been made in the management of other illnesses associated with emesis, motion sickness represents an area in which newer agents have provided little benefit. Beneficial therapy for patients in this setting can most reliably be found among the antihistaminic–anticholinergic agents. However, the precise mechanisms of action of these agents are currently unknown. Neither the antihistaminic nor the anticholinergic potency appears to correlate well with the ability of these agents to prevent or treat the nausea and vomiting associated with motion sickness. When used for their depressant effects on labyrinth excitability, these agents produce variable efficacy and safety profiles. Oral regimens of antihistaminic–anticholinergic agents given one to several times each day may be effective, especially when the first dose is administered prior to motion.

Scopolamine is commonly used to prevent nausea or vomiting caused by motion. The usefulness of scopolamine in preventing motion sickness was enhanced with the development of the transdermal system (patch) that increased patient satisfaction and decreased untoward side effects. A review of 12 randomized, controlled studies showed that scopolamine provided better protection from motion-induced sickness than did placebo, but was not superior to antihistamines and combinations of scopolamine and ephedrine.³⁷

■ ANTIEMETIC USE DURING PREGNANCY

As many as 75% of pregnant women experience nausea and vomiting to some degree during the first trimester of pregnancy. The severity of the symptoms varies considerably, from mild nausea to incapacitating nausea and vomiting. The etiology of nausea and vomiting of pregnancy (NVP) is not well understood. For the majority of women, these symptoms are self-limited, although approximately 1% to 3% develop hyperemesis gravidarum, a serious condition marked by severe physical symptoms and/or medical complications requiring hospitalization. In its most severe state, hyperemesis gravidarum may result in volume contraction, starvation, and electrolyte abnormalities.

Initial management of NVP often involves dietary changes and/or lifestyle modifications. Nonpharmacologic interventions for NVP include ginger³⁸ and acupressure, although efficacy trials for acupressure are lacking. Persistent nausea and/or vomiting leads to the consideration of drug therapy at a time when teratogenic potential of each agent must be considered.

Table 37–10 summarizes the NVP treatment recommendations from the American College of Obstetricians and Gynecologists (ACOG).³⁹ A comprehensive review of treatment options for NVP was published.⁴⁰ Pyridoxine (10 to 25 mg 1 to 4 times daily), with or without doxylamine (12.5 to 20 mg 1 to 4 times daily), is recommended as first-line therapy. If symptoms persist, addition of an histamine₁-receptor antagonist such as dimenhydrinate (50 to 100 mg orally or rectally every 4 to 6 hours as needed), diphenhydramine (25 to 50 mg orally or 10 to 50 mg intravenously [IV] every 4 to 6 hours as needed), or meclizine (25 mg orally every 4 to 6 hours as needed) is recommended. Dopamine antagonists can also be added if symptoms continue (metoclopramide 5 to 10 mg IV every 8 hours as needed; promethazine 12.5 to 25 mg IV every 4 hours as needed; prochlorperazine 5 to 10 mg orally every 6 hours as needed).

Patients with persistent NVP or who show signs of dehydration should receive intravenous fluid replacement with thiamine. Ondansetron 2 to 8 mg orally/IV every 8 hours as needed may alleviate NVP, but the only randomized, controlled trial of intravenous ondansetron showed it to be no more effective than promethazine for treatment of severe NVP.⁴¹ Corticosteroids should be reserved for patients with refractory NVP or hyperemesis gravidarum; methylprednisolone 16 mg orally/IV every 8 hours for 3 days followed by a 2-week taper is recommended. This regimen may

TABLE 37-10 Treatment Recommendations for the Management of Nausea and Vomiting of Pregnancy

Recommendations	Recommendation Grades ^a
The severity of nausea and vomiting of pregnancy (NVP) may be decreased by taking a multiple vitamin at the time of conception.	A
First-line pharmacotherapy for the treatment of NVP should consist of pyridoxine (vitamin B ₆) or pyridoxine + doxylamine.	A
Treatment of NVP with ginger has shown beneficial effects and can be considered as a nonpharmacologic option.	B
Antihistamine H ₁ -receptor blockers, phenothiazines, and benzamides have been shown to be safe and efficacious in cases of refractory NVP.	B
Early treatment of NVP is recommended to prevent progression to hyperemesis gravidarum.	B
Treatment of severe NVP or hyperemesis gravidarum with methylprednisolone may be efficacious in refractory cases; however, the risk profile of methylprednisolone suggests it should be a treatment of last resort.	B
Intravenous hydration should be used for the patient who cannot tolerate oral liquids for a prolonged period or if clinical signs of dehydration are present.	C
Correction of ketosis and vitamin deficiency should be strongly considered.	C
Dextrose and vitamins, especially thiamine, should be included in the therapy when prolonged vomiting is present.	C
Enteral or parenteral nutrition should be initiated for any patient who cannot maintain weight because of vomiting.	C

^aStrength of recommendations: A = good and consistent scientific evidence. B = limited or inconsistent scientific evidence. C = consensus and expert opinion.

be repeated if necessary, but treatment should not exceed a total of 6 weeks.

■ ANTIEMETIC USE IN CHILDREN

Practice guidelines recommend that a corticosteroid plus SSRI should be administered to children receiving chemotherapy of high or moderate emetic risk.²³ The best doses or dosing strategies for children (by age, weight, or body surface area) have not been clearly established. Standard adult doses of SSRIs may not provide consistent antiemetic protection in children due to wider interpatient variations in metabolism and clearance.⁴²

For nausea and vomiting associated with pediatric gastroenteritis, emphasis should be placed on rehydration measures rather than on pharmacologic intervention. Promethazine suppositories were the most commonly prescribed antiemetic for pediatric gastroenteritis in a survey of physicians, despite the lack of prospective trials for this agent.⁴³ In 2004, the Food and Drug Administration reviewed all cases (125) of serious adverse events that involved children (age range: birth to 16 years) who had received any formulation of promethazine. Serious outcomes, including death, occurred with all routes of administration (oral, rectal, and parenteral) at doses ranging from 0.45 to 6.4 mg/kg. Subsequently, a black box warning was added to the promethazine labeling that included a contraindication for use of any product containing promethazine in children younger than age 2 years and a strengthened warning with regard to use in children 2 years of age or older.⁴⁴

■ PHARMACOECONOMIC CONSIDERATIONS

There are many important variables to consider when attempting to document the overall costs of using a medication in a particular

medical situation. Medication costs alone cannot begin to explain the true pharmacoeconomic outcome associated with the use of antiemetic drugs. For example, the costs associated with an unexpected hospital admission because of vomiting after an outpatient surgical procedure quickly offset the savings related to the selection of an inexpensive antiemetic drug. In this and other similar situations, it is economically and clinically important to develop antiemetic protocols based on appropriate decision analysis and clinical outcomes in order to optimize drug product selection. The clinical practice guidelines that have been previously described are valuable tools when developing institution-specific antiemetic protocols. The availability of new, more expensive agents will only increase the costs associated with the prophylaxis of CINV and PONV. The need to control antiemetic costs for health systems is universal and formulary management strategies have been described.⁴⁵

EVALUATION OF THERAPEUTIC OUTCOMES

In accordance with the information presented concerning age and clinical condition, individualized therapy is possible through drug selection and dosage adjustment. Monitoring criteria for drug therapy should include the subjective assessment of the patient's severity of nausea, as well as objective parameters, such as changes in patient weight, the number of vomiting episodes each day, the volume of vomitus lost, and evaluation of fluid, acid–base balance, and electrolyte status, with particular attention to serum sodium, potassium, and chloride concentrations. In addition, evaluation of renal function may become important, particularly in patients with volume contraction and progressive electrolyte disturbances. Specific parameters include daily urine volume, urine specific gravity, and urine electrolyte concentrations. Physical assessment of patients should include evaluation of mucous membranes and skin turgor, because dryness of these tissues may be indicative of significant volume loss.

ABBREVIATIONS

ASCO: American Society of Clinical Oncology
 CINV: chemotherapy-induced nausea and vomiting
 CTZ: chemoreceptor trigger zone
 NK₁: neurokinin₁
 NVP: nausea and vomiting of pregnancy
 PONV: postoperative nausea and vomiting
 RINV: radiation-induced nausea and vomiting

WILLIAM J. SPRUILL AND WILLIAM E. WADE

KEY CONCEPTS

- 1 Diarrhea is caused by many viral and bacterial organisms. It is most often a minor discomfort, not life-threatening, and it is usually self-limited.
- 2 The four pathophysiologic mechanisms of diarrhea have been linked to the four broad diarrheal groups, which are secretory, osmotic, exudative, and altered intestinal transit. The three mechanisms by which absorption occurs from the intestines are active transport, diffusion, and solvent drag.
- 3 Management of diarrhea focuses on preventing excessive water and electrolyte losses, dietary care, relieving symptoms, treating curable causes, and treating secondary disorders.
- 4 Bismuth subsalicylate is marketed for indigestion, relieving abdominal cramps, and controlling diarrhea, including traveler's diarrhea, but may cause interactions with several components if given excessively.
- 5 Underlying causes of constipation should be identified when possible and corrective measures taken (e.g., alteration of diet or treatment of diseases such as hypothyroidism).
- 6 The foundation of treatment of constipation is dietary fiber or bulk-forming laxatives that provide 10 to 15 g/day of raw fiber.
- 7 Irritable bowel syndrome (IBS) is one of the most common gastrointestinal disorders. It is characterized by lower abdominal pain, disturbed defecation, and bloating. Many nongastrointestinal manifestations also exist with IBS. Recent studies have found that visceral hypersensitivity is a major culprit in the pathophysiology of the disease.
- 8 Diarrhea-predominant IBS should be managed by dietary modification and when diet changes alone are insufficient to promote control of symptoms, by drugs such as loperamide.
- 9 Several drug classes are involved in the treatment of the pain associated with IBS, including tricyclic compounds and the gut-selective calcium channel blockers.

DIARRHEA

Diarrhea is a troublesome discomfort that affects most individuals in the United States at some point in their lives and can be thought

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

of as both a symptom and a sign. Usually diarrheal episodes begin abruptly and subside within 1 or 2 days without treatment. This chapter focuses primarily on noninfectious diarrhea, with only minor reference to infectious diarrhea (see Chap. 117 for a discussion of gastrointestinal infections). Diarrhea is often a symptom of a systemic disease and not all possible causes of diarrhea are discussed in this chapter. Acute diarrhea is commonly defined as <14 days' duration, persistent diarrhea as more than 14 days' duration, and chronic diarrhea as more than 30 days' duration.

To understand diarrhea, one must have a reasonable definition of the condition; unfortunately, the literature is extremely variable on this. Simply put, diarrhea is an increased frequency and decreased consistency of fecal discharge as compared to an individual's normal bowel pattern. Frequency and consistency are variable within and between individuals. For example, some individuals defecate as often as three times per day, whereas others defecate only two or three times per week. A Western diet usually produces a daily stool weighing between 100 and 300 g, depending on the amount of nonabsorbable materials (mainly carbohydrates) consumed. Patients with serious diarrhea may have a daily stool weight in excess of 300 g; however, a subset of patients experience frequent small, watery passages. Additionally, vegetable fiber-rich diets, such as those consumed in some Eastern cultures, such as those in Africa, produce stools weighing more than 300 g/day.

Diarrhea may be associated with a specific disease of the intestines or secondary to a disease outside the intestines. For instance, bacillary dysentery directly affects the gut, whereas diabetes mellitus causes neuropathic diarrheal episodes. Furthermore, diarrhea can be considered as acute or chronic disease. Infectious diarrhea is often acute; diabetic diarrhea is chronic. Congenital disorders in gastrointestinal ion-transport mechanisms are another cause of chronic diarrhea.¹ Whether acute or chronic, diarrhea has the same pathophysiologic causes that help identification of specific treatments.

EPIDEMIOLOGY

The epidemiology of diarrhea varies in developed versus developing countries.^{2,3} In the United States, diarrheal illnesses are usually not reported to the Centers for Disease Control and Prevention (CDC) unless associated with an outbreak or an unusual organism or condition. For example, the acquired immune deficiency syndrome (AIDS) has been identified with protracted diarrheal illness. Diarrhea is a major problem in daycare centers and nursing homes, probably because early childhood and senescence plus environmental conditions are risk factors. Although an exact epidemiologic profile in the United States is not available through the CDC or published literature, chronic diarrhea affects approximately 5% of the adult population and ranges from 3% to 20% in children worldwide.⁴ In developing countries, diarrhea is a leading cause of illness and death in children, creating a tremendous economic strain on healthcare costs.

1 Most cases of acute diarrhea are caused by infections with viruses, bacteria, or protozoa and are generally self-limited.⁵ Although viruses are more commonly associated with acute gastroenteritis, bacteria are responsible for more cases of acute diarrhea.⁶

Evaluation of a noninfectious cause is considered if diarrhea persists and no infectious organism can be identified, or if the patient falls into a high-risk category for metabolic complications with persistent diarrhea. Common causative bacterial organisms include *Shigella*, *Salmonella*, *Campylobacter*, *Staphylococcus*, and *Escherichia coli*. Food-borne bacterial infection is a major concern, as several major food poisoning episodes have occurred that were traced to poor sanitary conditions in meat-processing plants. Acute viral infections are attributed mostly to the Norwalk and rotavirus groups.

PHYSIOLOGY

In the fasting state, 9 L of fluid enters the proximal small intestine each day. Of this fluid, 2 L are ingested through diet, while the remainder consists of internal secretions. Because of meal content, duodenal chyme is usually hypertonic. When chyme reaches the ileum, the osmolality adjusts to that of plasma, with most dietary fat, carbohydrate, and protein being absorbed. The volume of ileal chyme decreases to about 1 L/day upon entering the colon, which is further reduced by colonic absorption to 100 mL daily. If the small intestine water absorption capacity is exceeded, chyme overloads the colon, resulting in diarrhea. In humans, the colon absorptive capacity is about 5 L daily. Colonic fluid transport is critical to water and electrolyte balance.

Absorption from the intestines back into the blood occurs by three mechanisms: active transport, diffusion, and solvent drag. Active transport and diffusion are the mechanisms of sodium transport. Because of the high luminal sodium concentration (142 mEq/L), sodium diffuses from the sodium-rich gut into epithelial cells, where it is actively pumped into the blood and exchanged with chloride to maintain an isoelectric condition across the epithelial membrane.

Hydrogen ions are transported by an indirect mechanism in the upper small intestine. As sodium is absorbed, hydrogen ions are secreted into the gut. Hydrogen ions then combine with bicarbonate ions to form carbonic acid, which then dissociates into carbon dioxide and water. Carbon dioxide readily diffuses into the blood for expiration through the lung. The water remains in the chyme.

Paracellular pathways are major routes of ion movement. As ions, monosaccharides, and amino acids are actively transported, an osmotic pressure is created, drawing water and electrolytes across the intestinal wall. This pathway accounts for significant amounts of ion transport, especially sodium. Sodium plays an important role in stimulating glucose absorption. Glucose and amino acids are actively transported into the blood via a sodium dependent cotransport mechanism. Cotransport absorption mechanisms of glucose-sodium and amino acid-sodium are extremely important for treating diarrhea.

Gut motility influences absorption and secretion. The amount of time in which luminal content is in contact with the epithelium is under neural and hormonal control. Neurohormonal substances, such as angiotensin, vasopressin, glucocorticoid, aldosterone, and neurotransmitters also regulate ion transport.

PATHOPHYSIOLOGY

2 Four general pathophysiologic mechanisms disrupt water and electrolyte balance, leading to diarrhea, and are the basis of diagnosis and therapy. These are (a) a change in active ion transport by either decreased sodium absorption or increased chloride secretion; (b) change in intestinal motility; (c) increase in luminal osmolality; and (d) increase in tissue hydrostatic pressure. These mechanisms have been related to four broad clinical diarrheal groups: secretory, osmotic, exudative, and altered intestinal transit.

Secretory diarrhea occurs when a stimulating substance either increases secretion or decreases absorption of large amounts of water and electrolytes. Substances that cause excess secretion include vasoactive intestinal peptide (VIP) from a pancreatic tumor, unabsorbed dietary fat in steatorrhea, laxatives, hormones (such as secretion), bacterial toxins, and excessive bile salts. Many of these agents stimulate intracellular cyclic adenosine monophosphate and inhibit Na^+/K^+ -adenosine triphosphatase (ATPase), leading to increased secretion. Also, many of these mediators inhibit ion absorption simultaneously. Clinically, secretory diarrhea is recognized by large stool volumes (>1 L/day) with normal ionic contents and osmolality approximately equal to plasma. Fasting does not alter the stool volume in these patients.

Poorly absorbed substances retain intestinal fluids, resulting in osmotic diarrhea. This process occurs with malabsorption syndromes, lactose intolerance, administration of divalent ions (e.g., magnesium-containing antacids), or consumption of poorly soluble carbohydrate (e.g., lactulose). As a poorly soluble solute is transported, the gut adjusts the osmolality to that of plasma; in so doing, water and electrolytes flux into the lumen. Clinically, osmotic diarrhea is distinguishable from other types, as it ceases if the patient resorts to a fasting state.

Inflammatory diseases of the gastrointestinal tract discharge mucus, serum proteins, and blood into the gut. Sometimes bowel movements consist only of mucus, exudate, and blood. Exudative diarrhea affects other absorptive, secretory, or motility functions to account for the large stool volume associated with this disorder.

Altered intestinal motility produces diarrhea by three mechanisms: reduction of contact time in the small intestine, premature emptying of the colon, and bacterial overgrowth. Chyme must be exposed to intestinal epithelium for a sufficient time period to enable normal absorption and secretion processes to occur. If this contact time decreases, diarrhea results. Intestinal resection or bypass surgery and drugs (such as metoclopramide) cause this type of diarrhea. On the other hand, an increased time of exposure allows fecal bacteria overgrowth. A characteristic small intestine diarrheal pattern is rapid, small, coupling bursts of waves. These waves are inefficient, do not allow absorption, and rapidly dump chyme into the colon. Once in the colon, chyme exceeds the colonic capability to absorb water.

Etiologic Examination of the Stool

Stool characteristics are important in assessing the etiology of diarrhea. A description of the frequency, volume, consistency, and color provides diagnostic clues. For instance, diarrhea starting in the small intestine produces a copious, watery or fatty (greasy), and foul-smelling stool; contains undigested food particles; and is usually free from gross blood. Colonic diarrhea appears as small, pasty, and sometimes bloody or mucoid movements. Rectal tenesmus with flatus accompanies large intestinal diarrhea.

CLINICAL PRESENTATION

Table 38–1 outlines the clinical presentation of diarrhea and Table 38–2 shows common drug-induced causes of diarrhea. A medication history is extremely important in identifying drug-induced diarrhea. Many agents, including antibiotics and other drugs, cause diarrhea or, less commonly, pseudomembranous colitis. Self-inflicted laxative abuse for weight loss is popular.

Most acute diarrhea is self-limiting, subsiding within 72 hours. However, infants, young children, the elderly, and debilitated persons are at risk for morbid and mortal events in prolonged or voluminous diarrhea. These groups are at risk for water, electrolyte, and acid–base disturbances, and potentially cardiovascular collapse and death. The prognosis for chronic diarrhea depends on

TABLE 38-1 Clinical Presentation of Diarrhea

General
<ul style="list-style-type: none"> Usually, acute diarrheal episodes subside within 72 hours of onset, whereas chronic diarrhea involves frequent attacks over extended time periods.
Signs and symptoms
<ul style="list-style-type: none"> Abrupt onset of nausea, vomiting, abdominal pain, headache, fever, chills, and malaise. Bowel movements are frequent and never bloody, and diarrhea lasts 12 to 60 hours. Intermittent periumbilical or lower right quadrant pain with cramps and audible bowel sounds is characteristic of small intestinal disease. When pain is present in large intestinal diarrhea, it is a gripping, aching sensation with tenesmus (straining, ineffective, and painful stooling). Pain localizes to the hypogastric region, right or left lower quadrant, or sacral region. In chronic diarrhea, a history of previous bouts, weight loss, anorexia, and chronic weakness are important findings.
Physical examination
<ul style="list-style-type: none"> Typically demonstrates hyperperistalsis with borborygmi and generalized or local tenderness.
Laboratory tests
<ul style="list-style-type: none"> Stool analysis studies include examination for microorganisms, blood, mucus, fat, osmolality, pH, electrolyte and mineral concentration, and cultures. Stool test kits are useful for detecting gastrointestinal viruses, particularly rotavirus. Antibody serologic testing shows rising titers over a 3- to 6-day period, but this test is not practical and is nonspecific. Occasionally, total daily stool volume is also determined. Direct endoscopic visualization and biopsy of the colon may be undertaken to assess for the presence of conditions such as colitis or cancer. Radiographic studies are helpful in neoplastic and inflammatory conditions.

the cause; for example, diarrhea secondary to diabetes mellitus waxes and wanes throughout life.

TREATMENT

Diarrhea

PREVENTION

Acute viral diarrheal illness often occurs in daycare centers and nursing homes. As person-to-person contact is the mechanism by which viral disease spreads, isolation techniques must be initiated. For bacterial, parasite, and protozoal infections, strict food handling, sanitation, water, and other environmental hygiene practices can prevent transmission. If diarrhea is secondary to another illness, controlling the primary condition is necessary. Antibiotics and bismuth subsalicylate are advocated to prevent traveler's diarrhea, in conjunction with treatment of drinking water and caution with consumption of fresh vegetables.

DESIRED OUTCOME

3 If prevention is unsuccessful and diarrhea occurs, therapeutic goals are to (a) manage the diet; (b) prevent excessive water, electrolyte, and acid-base disturbances; (c) provide symptomatic relief; (d) treat curable causes; and (e) manage secondary disorders causing diarrhea (Figs. 38-1 and 38-2).

Clinicians must clearly understand that diarrhea, like a cough, may be a body defense mechanism for ridding itself of harmful substances or pathogens. The correct therapeutic response is not necessarily to stop diarrhea at all costs.

NONPHARMACOLOGIC MANAGEMENT

Dietary management is a first priority in the treatment of diarrhea. Most clinicians recommend discontinuing consumption of solid

foods and dairy products for 24 hours. However, fasting is of questionable value, as this treatment modality has not been extensively studied. In osmotic diarrhea, these maneuvers control the problem. If the mechanism is secretory, diarrhea persists. For patients who are experiencing nausea and/or vomiting, a mild, digestible, low-residue diet should be administered for 24 hours. If vomiting is present and uncontrollable with antiemetics (see Chap. 37), nothing is taken by mouth. As bowel movements decrease, a bland diet is begun.

Feeding should continue in children with acute bacterial diarrhea. Fed children have less morbidity and mortality, whether or not they receive oral rehydration fluids. Studies are not available in the elderly or in other high-risk groups to determine the value of continued feeding in bacterial diarrhea.

Water and Electrolytes

Rehydration and maintenance of water and electrolytes are primary treatment goals until the diarrheal episode ends. If the patient is volume depleted, rehydration should be directed at replacing water and electrolytes to normal body composition. Then water and electrolyte composition are maintained by replacing losses. Many patients will not develop volume depletion and therefore will only require maintenance fluid and electrolyte therapy. Parenteral and enteral routes may be used for supplying water and electrolytes. If vomiting and dehydration are not severe, enteral feeding is the less costly and preferred method. In the United States, many commercial oral rehydration preparations are available (Table 38-3).

Because of concerns about hypernatremia, physicians continue to hospitalize patients and intravenously correct fluid and electrolyte deficits in severe dehydration. Oral solutions are strongly recommended.^{7,8} In developing countries, the World Health Organization Oral Rehydration Solution (WHO-ORS) saves the lives of millions of children annually.

During diarrhea, the small intestine retains its ability to actively transport monosaccharides such as glucose. Glucose actively carries sodium with water and other electrolytes. Because the WHO-ORS has a high sodium concentration, physicians have been reluctant to

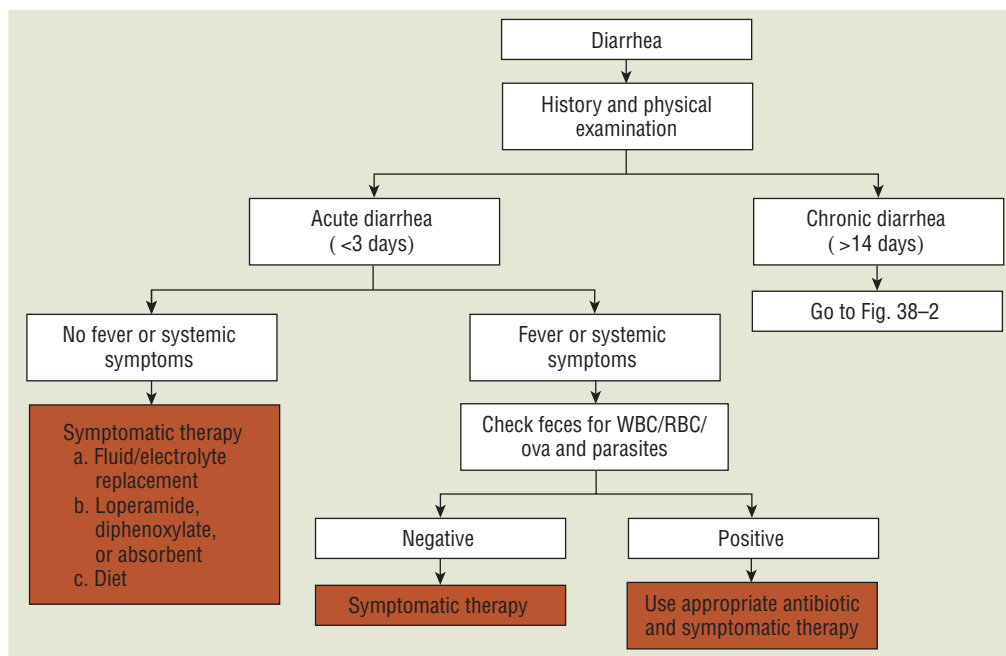

FIGURE 38-1. Recommendations for treating acute diarrhea. Follow these steps: (a) Perform a complete history and physical examination. (b) Is the diarrhea acute or chronic? If chronic diarrhea, go to Fig. 38-2. (c) If acute diarrhea, check for fever and/or systemic signs and symptoms (i.e., toxic patient). If systemic illness (fever, anorexia, or volume depletion), check for an infectious source. If positive for infectious diarrhea, use appropriate antibiotic/anthelmintic drug and symptomatic therapy. If negative for infectious cause, use only symptomatic treatment. (d) If no systemic findings, then use symptomatic therapy based on severity of volume depletion, oral or parenteral fluid/electrolytes, antidiarrheal agents (see Table 38-4), and diet. (RBC, red blood cells; WBC, white blood cells.)

use it in well-nourished children. Yet controlled comparative studies describe more favorable results with the WHO-ORS than with parenteral fluids.⁹ The recommended WHO-ORS (see Table 38-3) has now been reformulated to have a lower osmolality, sodium content, and glucose load. Rice-based oral solution is also a hypototically active substrate that elutes glucose without increasing stool or urine outflows. Rehydration of infants with acute diarrhea using a rice-based solution is effective.⁹ Decreased stool output and greater absorption and retention of fluid and electrolytes also results. In summary, oral rehydration solution is a lifesaving treatment for millions afflicted in developing countries. Acceptance in developed countries is less enthusiastic; however, the advantage of this product in reducing hospitalizations may prove its use as a cost-effective alternative, saving millions of dollars in healthcare expenditures.

■ PHARMACOLOGIC THERAPY

Various drugs have been used to treat diarrheal attacks (Table 38-4). These drugs are grouped into several categories: antimotility, adsorbents, antisecretory compounds, antibiotics, enzymes, and intestinal microflora. Usually these drugs are not curative but palliative.

Opiates and Their Derivatives

Opiates and opioid derivatives (a) delay the transit of intraluminal contents or (b) increase gut capacity, prolonging contact and absorption. Enkephalins, which are endogenous opioid substances, regulate fluid movement across the mucosa by stimulating absorptive processes. Limitations to the use of opiates include an addiction potential (a real concern with long-term use) and worsening of diarrhea in selected infectious diarrhea.

Most opiates act through peripheral and central mechanisms with the exception of loperamide, which acts only peripherally. Loperamide is antisecretory; it inhibits the calcium-binding protein calmodulin, controlling chloride secretion. Loperamide, available as

2-mg capsules or 1 mg/5 mL solution (both are nonprescription products), is suggested for managing acute and chronic diarrhea. The usual adult dose is initially 4 mg orally, followed by 2 mg after each loose stool, up to 16 mg/day. Used correctly, this agent has rare side effects, such as dizziness and constipation. If the diarrhea is concurrent with a high fever or bloody stool, the patient should be referred to a physician. Also, diarrhea lasting 48 hours beyond initiating loperamide warrants medical attention. Loperamide can also be used in traveler's diarrhea. It is comparable to bismuth subsalicylate for treatment of this disorder.¹⁰

Diphenoxylate is available as a 2.5-mg tablet and as a 2.5 mg/5mL solution. A small amount of atropine (0.025 mg) is included in the product to discourage abuse. In adults, when taken as 2.5 to 5 mg three or four times daily, not to exceed a 20-mg total daily dose, diphenoxylate is rarely toxic. Some patients may complain of atropinism (blurred vision, dry mouth, and urinary hesitancy). Like loperamide, it should not be used in patients who are at risk of bacterial enteritis with *E. coli*, *Shigella*, or *Salmonella*.

Difenoxin, a diphenoxylate derivative also chemically related to meperidine, is also combined with atropine and has the same uses, precautions, and side effects. Marketed as a 1-mg tablet, the adult dosage is 2 mg initially, followed by 1 mg after each loose stool, not to exceed 8 mg/day.

Paregoric, tincture of opium, is marketed as a 2 mg/5 mL solution and is indicated for managing both acute and chronic diarrhea. It is not widely prescribed today because of its abuse potential.

Adsorbents

Adsorbents are used for symptomatic relief. These products, many not requiring a prescription, are nontoxic, but their effectiveness remains unproven. Adsorbents are nonspecific in their action; they adsorb nutrients, toxins, drugs, and digestive juices. Polycarbophil absorbs 60 times its weight in water and can be used to treat both diarrhea and constipation. It is a nonprescription product and is

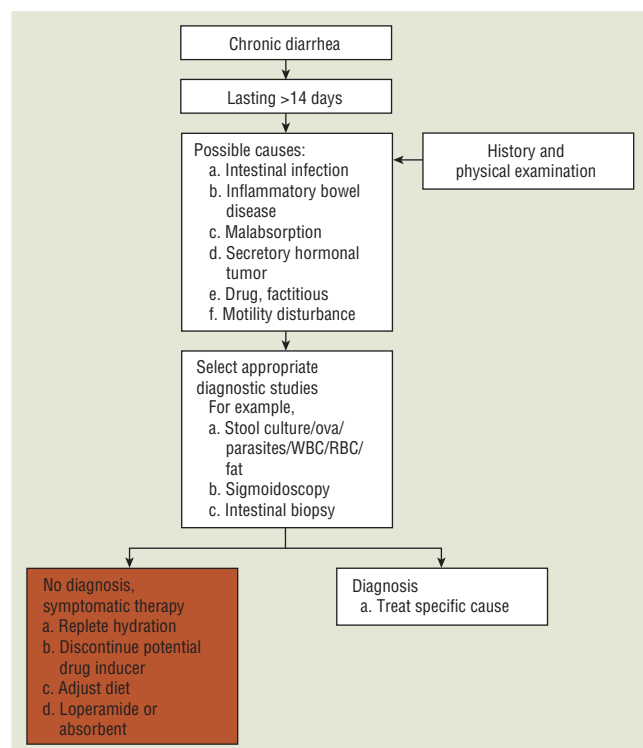

FIGURE 38-2. Recommendations for treating chronic diarrhea. Follow these steps: (a) Perform a careful history and physical examination. (b) The possible causes of chronic diarrhea are many. These can be classified into intestinal infections (bacterial or protozoal), inflammatory disease (Crohn's disease or ulcerative colitis), malabsorption (lactose intolerance), secretory hormonal tumor (intestinal carcinoid tumor or vasoactive intestinal peptide-secreting tumor [VIPoma]), drug (antacid), factitious (laxative abuse), or motility disturbance (diabetes mellitus, irritable bowel syndrome, or hyperthyroidism). (c) If the diagnosis is uncertain, selected appropriate diagnostic studies should be ordered. (d) Once diagnosed, treatment is planned for the underlying cause with symptomatic antidiarrheal therapy. (e) If no specific cause can be identified, symptomatic therapy is prescribed. (RBC, red blood cells; WBC, white blood cells.)

sold as a 500-mg chewable tablet. This hydrophilic nonabsorbable product is safe and may be taken four times daily, up to 6 g/day in adults. See Table 38–4 for selected antidiarrheal preparations.

Antisecretory Agents

Bismuth subsalicylate appears to have antisecretory, antiinflammatory, and antibacterial effects. As a nonprescription product, it is

marketed for indigestion, relieving abdominal cramps, and controlling diarrhea, including traveler's diarrhea. Bismuth subsalicylate dosage strengths are a 262-mg chewable tablet, 262 mg/5 mL liquid, and 524 mg/15 mL liquid. The usual adult dose is 2 tablets or 30 mL every 30 minutes to 1 hour up to 8 doses per day.

4 Bismuth subsalicylate contains multiple components that might be toxic if given excessively to prevent or treat diarrhea. For instance, an active ingredient is salicylate, which may interact with anticoagulants or may produce salicylism (tinnitus, nausea, and vomiting). Bismuth reduces tetracycline absorption and may interfere with select gastrointestinal radiographic studies. Patients may complain of a darkening of the tongue and stools with repeat administration. Salicylate can induce gout attacks in susceptible individuals.

Bismuth subsalicylate suspension has been evaluated in the treatment of secretory diarrhea of infectious etiology as well. In a dose of 30 mL every 30 minutes for 8 doses, unformed stools decrease in the first 24 hours. Bismuth subsalicylate may also be effective in preventing traveler's diarrhea.

Octreotide, a synthetic octapeptide analog of endogenous somatostatin, is proven effective for the symptomatic treatment of carcinoid tumors and other peptide-secreting tumors, dumping syndrome, and chemotherapy-induced diarrhea.¹¹ It has had limited success in patients with AIDS-associated diarrhea and short-bowel syndrome, does not appear to have an advantage over various opiate derivatives in the treatment of chronic idiopathic diarrhea, and has the disadvantage of being administered by injection.¹² Metastatic intestinal carcinoid tumors secrete excessive amounts of vasoactive substances, including histamine, bradykinin, serotonin, and prostaglandins. Primary carcinoid tumors occur throughout the gastrointestinal tract, with most in the ileum. Predominant signs and symptoms experienced by patients with these tumors are attributable to excessive concentrations of 5-hydroxytryptophan and serotonin. The totality of their clinical effects is termed the carcinoid syndrome. Paroxysmal vasomotor attacks characterize carcinoid syndrome, most notably sudden red to purple flushing of the face and neck. These attacks are often caused by emotional outbursts or by ingestion of food or alcohol. Some patients have a violent, watery diarrhea with abdominal cramping. Initially, diarrhea might be managed with various agents such as codeine, diphenoxylate, cyproheptadine, methysergide, phenoxymethamine, or methyl dopa. But octreotide has more recently been considered first-line therapy.

Octreotide blocks the release of serotonin and many other active peptides, and has been effective in controlling diarrhea and flushing. It is reported to have direct inhibitory effects on intestinal secretion and stimulatory effects on intestinal absorption. Non-gastrin-secreting adenomas of the pancreas are tumors associated with profuse watery diarrhea. This condition has been referred to as Verner-Morrison's

TABLE 38-4 Selected Antidiarrheal Preparation

Antimotility	Dose Form	Adult Dose
Diphenoxylate	2.5 mg/tablet 2.5 mg/5 mL	5 mg four times daily; do not exceed 20 mg/day
Loperamide	2 mg/capsule 1 mg/5 mL	Initially 4 mg, then 2 mg after each loose stool; do not exceed 16 mg/day
Paregoric	2 mg/5 mL (morphine)	5–10 mL one to four times daily
Opium tincture	5 mg/mL (morphine)	0.6 mL four times daily
Difenoxin	1 mg/tablet	2 tablets, then 1 tablet after each loose stool; up to 8 tablets/day
Adsorbents		
Kaolin–pectin mixture	5.7 g kaolin + 130.2 mg pectin/30 mL	30–120 mL after each loose stool
Polycarbophil	500 mg/tablet	Chew 2 tablets four times daily or after each loose stool; do not exceed 12 tablets/day
Attapulgate	750 mg/15 mL 300 mg/7.5 mL 750 mg/tablet 600 mg/tablet 300 mg/tablet	1200–1500 mg after each loose bowel movement or every 2 hours; up to 9000 mg/day
Antisecretory		
Bismuth subsalicylate	1050 mg/30 mL 262 mg/15 mL 524 mg/15 mL 262 mg/tablet	Two tablets or 30 mL every 30 min to 1 h as needed up to 8 doses/day
Enzymes (lactase)	1,250 neutral lactase units/4 drops 3,300 FCC lactase units per tablet	3–4 drops taken with milk or dairy product 1 or 2 tablets as above
Bacterial replacement (<i>Lactobacillus acidophilus</i> , <i>Lactobacillus bulgaricus</i>)		2 tablets or 1 granule packet three to four times daily; give with milk, juice, or water
Octreotide	0.05 mg/mL 0.1 mg/mL 0.5 mg/mL	Initial: 50 mcg subcutaneously One to two times per day and titrate dose based on indication up to 600 mcg/day in two to four divided doses

syndrome, WDHA (watery diarrhea, hypokalemia, and achlorhydria) syndrome, pancreatic cholera, watery diarrhea syndrome, and vasoactive intestinal peptide-secreting tumor (VIPoma). Excessive secretion of VIP from a retroperitoneal or pancreatic tumor produces most of the clinical features. Excessive VIP is isolated in about half of patients, along with numerous other peptide hormones (peptide histidine methionine [PHM], serotonin, somatostatin, gastrin, and glucagon). Surgical tumor dissection is the treatment of choice. In nonsurgical candidates, the profuse watery diarrhea and other symptoms commonly encountered are managed with octreotide.

The dose of octreotide varies with the indication, disease severity and patient response.¹¹ For managing diarrhea and flushing associated with carcinoid tumors in adults, the initial dosage range is 100 to 600 mcg/day in two to four divided doses subcutaneously for 2 weeks. For controlling secretory diarrhea of VIPomas, the dosage range is 200 to 300 mcg/day in two to four divided doses for 2 weeks. Some patients may require higher doses for symptomatic control. Patients responding to these initial doses may be switched to Sandostatin LAR Depot, a long-acting octreotide formulation. This product consists of microspheres containing the drug. Initial doses consist of 20 mg given intramuscularly intragluteally at 4-week intervals for 2 months. It is recommended that during the first 2 weeks of therapy the short-acting formulation also be administered subcutaneously. At the end of 2 months, patients with good symptom control may have the dose reduced to 10 mg every 4 weeks, while those without sufficient symptom control may have the dose increased to 30 mg every 4 weeks. For patients experiencing recurrence of symptoms on the 10-mg dose, dosage adjustment to 20 mg should be made. It is not uncommon for patients with carcinoid tumors or VIPomas to experience periodic exacerbation of symptoms. Subcutaneous octreotide for several days should be reinstituted in these individuals. In so-called carcinoid crisis,

octreotide is given as an intravenous infusion at 50 mcg/h for 8 to 24 hours.

Because octreotide inhibits many other gastrointestinal hormones, it has a variety of intestinal side effects. With prolonged use, gallbladder and biliary tract complications such as cholelithiasis have been reported. Approximately 5% to 10% of patients complain of nausea, diarrhea, and abdominal pain. Local injection pain occurs with about an 8% incidence. With high doses, octreotide may reduce dietary fat absorption, leading to steatorrhea.

Two other somatostatin analogs, lanreotide and vapreotide, have been studied.¹³ Lanreotide, not currently available in the United States but available in Europe, is indicated for patients with carcinoid tumors in a dose of 30 mg intramuscularly (as a depot) every 14 days. If necessary the dose can be increased to 30 mg intramuscular every 7 to 10 days. Vapreotide is an orphan drug that is indicated for pancreatic and gastrointestinal fistulas as well as esophageal variceal bleeding.

Miscellaneous Products

Lactobacillus preparations such as Lactinex granules are considered probiotics agents that contain bacteria or yeast, such as lactic acid bacteria are dietary supplements that have been used for many years in hopes of replacing colonic microflora. This supposedly restores normal intestinal function and suppresses the growth of pathogenic microorganisms. However, a dairy product diet containing 200 to 400 g of lactose or dextrin is equally effective in producing recolonization of normal flora. The dosage of lactobacillus preparations varies depending on the brand used and lactobacillus preparations should be administered with milk, juice, water, or cereal. Intestinal flatus is the primary patient complaint experienced with this modality.

Anticholinergic drugs such as atropine block vagal tone and prolong gut transit time. Drugs with anticholinergic properties are present in many nonprescription products. Their value in controlling diarrhea is questionable and limited because of side effects. Angle-closure glaucoma, selected heart diseases, and obstructive uropathies are relative contraindications to the use of anticholinergic agents.

Lactase enzyme products are helpful for patients who are experiencing diarrhea secondary to lactose intolerance. Lactase is required for carbohydrate digestion. When a patient lacks this enzyme, eating dairy products causes an osmotic diarrhea. Several products are available for use each time a dairy product, especially milk or ice cream, is consumed.

CLINICAL CONTROVERSY

Long-term use of oral opiates is not routinely recommended for several pharmacologic reasons. Some opioids such as morphine and codeine have the tendency to cause constipation by slowing down the peristaltic action of the bowels, which can also result in a functional ileus. This effect can be minimized by administering laxatives and/or stool softeners in patients who require long-term opiate therapy. Prokinetic agents may also be helpful in treating opiate-related constipation.

Investigational Drugs

Several new classes of compounds are undergoing clinical trials for efficacy in acute diarrhea.¹⁴ Enkephalins are endogenous opiate compounds in the gut that have antisecretory and proabsorptive activity in the small intestine. They promote sodium and chloride reabsorption via stimulation of a nonadrenergic, noncholinergic neurotransmitter. Enkephalinase inhibitors, compounds that slow down the enzymatic (i.e., enkephalinase) breakdown of endogenous enkephalins found in the small intestines. They exert an antisecretory effect without affecting GI motility or CNS-related effects/side effects. One specific compound, originally called acetorphan but now referred to as racecadotril, has been extensively tested in humans and found to be equal to other opiate anti-diarrheals such as loperamide, while causing less GI motility side effects such as abdominal bloating, pain, and constipation.^{15,16} Racecadotril is currently licensed only in France and a few other developing countries with a high incidence of childhood diarrhea, but it is expected to be approved by other countries as well in the near future.

Vaccines are a new therapeutic frontier in controlling infectious diarrheas, especially in developing countries.^{17,18} An oral vaccine for cholera is licensed and available in other countries (Dukoral from SBL Vaccines) appears to provide somewhat better immunity and have fewer adverse effects than the previously available parenteral vaccine. However, the CDC does not recommend cholera vaccines for most travelers, nor is the vaccine available in the United States.

Oral *Shigella* vaccine, although effective under field conditions, requires 5 weekly oral doses and repeat booster doses, thereby limiting its practicality for use in developing nations. With about 1,500 serotypes for *Salmonella*, a vaccine is not currently available for humans. There are two newer typhoid vaccine formulations, one a parenteral inactivated whole-cell vaccine and the other an oral live-attenuated (Ty21a) vaccine that is administered in 4 doses on days 1, 3, 5, and 7, to be completed at least 1 week before exposure. Rotavirus vaccine is effective in infants and children; and is administered as a three-oral-dose sequence. A rotavirus vaccine program has been formed to reduce child morbidity and mortality from diarrheal disease by accelerating the availability of rotavirus vaccines appropriate for use in developing countries.

EVALUATION OF THERAPEUTIC OUTCOMES

General Outcomes Measures

Therapeutic outcomes are directed toward key symptoms, signs, and laboratory studies. Constitutional symptoms usually improve within 24 to 72 hours. Monitoring for changes in the frequency and character of bowel movements on a daily basis in conjunction with vital signs and improvement in appetite are of utmost importance. Also, the clinician needs to monitor body weight, serum osmolality, serum electrolytes, complete blood cell counts, urinalysis, and culture results (if appropriate).

Acute Diarrhea

Most patients with acute diarrhea experience mild to moderate distress. In the absence of moderate to severe dehydration, high fever, and blood or mucus in the stool, this illness is usually self-limiting within 3 to 7 days. Mild to moderate acute diarrhea is usually managed on an outpatient basis with oral rehydration, symptomatic treatment, and diet. Elderly persons with chronic illness and infants may require hospitalization for parenteral rehydration and close monitoring.

Severe Diarrhea

In the urgent/emergent situation, restoration of the patient's volume status is the most important outcome. Toxic patients (fever, dehydration, hematochezia, or hypotension) require hospitalization, intravenous fluids and electrolyte administration, and empiric antibiotic therapy while awaiting culture and sensitivity results. With timely management, these patients usually recover within a few days.

CONSTIPATION

Constipation is a commonly encountered medical condition in the United States for which many patients initiate self-treatment. One reason constipation continues to be a frequent problem in this country is lack of adequate dietary fiber. Another unfortunate problem is that many people have misconceptions about normal bowel function, and think that daily bowel movements are required for health and well being. Others believe that the lack of a daily bowel movement contributes to the accumulation of toxic substances or is associated with various somatic complaints. These misconceptions often lead to the inappropriate use of laxatives by the general public.

Constipation does not have a single, generally agreed upon definition. When using the term, the lay public or healthcare professional may be referring to several difficult-to-quantify variables: bowel movement frequency, stool size or consistency, and such symptoms as the sensation of incomplete defecation. Stool frequency is most often used to describe constipation; however, the frequency of bowel movements used to define constipation is not well established.

Normal people pass at least 3 stools per week. Some of the definitions of constipation used in clinical studies include (a) less than 3 stools per week for women and 5 stools per week for men despite a high-residue diet, or a period of more than 3 days without a bowel movement; (b) straining at stool greater than 25% of the time and/or 2 or fewer stools per week; or (c) straining at defecation and less than 1 stool daily with minimal effort. These varying definitions demonstrate the difficulty in characterizing this problem. An international committee defined and classified constipation on the basis of stool frequency, consistency, and difficulty of defecation.^{19,20}

Functional constipation is defined as two or more of the following complaints present for at least 12 months in the absence of laxative use: (a) straining at least 25% of the time; (b) lumpy or hard stools at least 25% of the time; (c) a feeling of incomplete evacuation at least 25% of the time; or (d) two or fewer bowel movements in a week. Rectal outlet delay is defined as anal blockage more than 25% of the time and prolonged defecation or manual disimpaction when necessary.

EPIDEMIOLOGY

A systematic review of the epidemiology of constipation in North America reported a prevalence range for constipation of 1.9% to 27%, with the most reported estimates ranging from 12% to 19%. Prevalence estimates by gender were female-to-male ratio of 2.2:1.²¹ Results from 42,375 participants of the National Health Interview Survey on Digestive Disorders demonstrated that there is not an age-related increased incidence of infrequent bowel movements; however, there is an age-related increased incidence of laxative use.²² The frequency of subjects reporting two or fewer bowel movements per week was 5.9% for those younger than 40 years of age; 3.8% for subjects 60 to 69 years of age; and 6.3% for subjects older than 80 years of age. In a prospective study of 3,166 people older than 65 years of age in a Florida community,²³ 26% of women and 15.8% of men reported recurrent constipation. Factors found to correlate with self-reported constipation were age, sex (higher frequency in females), total number of drugs taken, abdominal pain, and hemorrhoids.

PATHOPHYSIOLOGY

5 Constipation is not a disease, but a symptom of an underlying disease or problem. Approaches to the treatment of constipation should begin with attempts to determine its cause. Disorders of the GI tract (irritable bowel syndrome or diverticulitis), metabolic disorders (diabetes), or endocrine disorders (hypothyroidism) may be involved. Constipation commonly results from a diet low in fiber or from use of constipating drugs such as opiates. Finally, constipation may sometimes be psychogenic in origin.²⁴ Each of these causes is discussed in the following sections.

Constipation is a frequently reported problem in the elderly, probably the result of improper diets (low in fiber and liquids), diminished abdominal wall muscular strength, and possibly diminished physical activity. However, as previously stated, the frequency of bowel movements is not decreased with normal aging. In addition, diseases that may cause constipation, such as colon cancer and diverticulitis, are more common with increasing age. Table 38–5 lists common causes of constipation in specific disease states.

Drug-Induced Constipation

Use of drugs that inhibit the neurologic or muscular function of the GI tract, particularly the colon, may result in constipation (Table 38–6).

The majority of cases of drug-induced constipation are caused by opiates, various agents with anticholinergic properties, and antacids containing aluminum or calcium. With most of the agents listed in Table 38–6, the inhibitory effects on bowel function are dose dependent, with larger doses clearly causing constipation more frequently.

Opiates have effects on all segments of the bowel, but effects are most pronounced on the colon. The major mechanism by which opiates produce constipation has been proposed to be prolongation of intestinal transit time by causing spastic, nonpropulsive contractions. An additional contributory mechanism may be an increase in electrolyte absorption.

All opiate derivatives are associated with constipation, but the degree of intestinal inhibitory effects seems to differ between agents. Orally administered opiates appear to have greater inhibitory effects

TABLE 38-5 Possible Causes of Constipation

Conditions	Possible Causes
GI disorders	Irritable bowel syndrome
	Diverticulitis
	Upper GI tract diseases
	Anal and rectal diseases
	Hemorrhoids
	Anal fissures
	Ulcerative proctitis
	Tumors
	Hernia
	Volvulus of the bowel
	Syphilis
	Tuberculosis
	Helminthic infections
	Lymphogranuloma venereum
	Hirschsprung's disease
Metabolic and endocrine disorders	Diabetes mellitus with neuropathy
	Hypothyroidism
	Panhypopituitarism
	Pheochromocytoma
	Hypercalcemia
	Enteric glucagon excess
Pregnancy	Depressed gut motility
	Increased fluid absorption from colon
	Decreased physical activity
	Dietary changes
	Inadequate fluid intake
	Low dietary fiber
	Use of iron salts
	CNS diseases
Neurogenic causes	Trauma to the brain (particularly the medulla)
	Spinal cord injury
	CNS tumors
	Cerebrovascular accidents
	Parkinson's disease
	Ignoring or postponing urge to defecate
Psychogenic causes	Psychiatric diseases
	See Table 38–6

than parenterally administered products. Orally administered enkephalins (endogenous opiate-like polypeptides) are recognized to have antimotility properties.

CLINICAL PRESENTATION

Table 38–7 shows the general clinical presentation of constipation.

TABLE 38-6 Drugs Causing Constipation

Analgesics
Inhibitors of prostaglandin synthesis
Opiates
Anticholinergics
Antihistamines
AntiParkinsonian agents (e.g., benzotropine or trihexyphenidyl)
Phenothiazines
Tricyclic antidepressants
Antacids containing calcium carbonate or aluminum hydroxide
Barium sulfate
Calcium channel blockers
Clonidine
Diuretics (non-potassium-sparing)
Ganglionic blockers
Iron preparations
Muscle blockers (D-tubocurarine, succinylcholine)
Nonsteroidal antiinflammatory agents
Polystyrene sodium sulfonate

TABLE 38-7 Clinical Presentation of Constipation**Signs and symptoms**

- It is important to ascertain whether the patient perceives the problem as infrequent bowel movements, stools of insufficient size, a feeling of fullness, or difficulty and pain on passing stool.
- Signs and symptoms include hard, small, or dry stools, bloated stomach, cramping abdominal pain and discomfort, straining or grunting, sensation of blockade, fatigue, headache, and nausea and vomiting.

Laboratory tests

- A series of examinations, including proctoscopy, sigmoidoscopy, colonoscopy, and barium enema, may be necessary to determine the presence of colorectal pathology.
- Thyroid function studies may be performed to determine the presence of metabolic and endocrine disorders.

TREATMENT**Constipation****■ GENERAL APPROACH TO TREATMENT**

The patient should be asked about the frequency of bowel movements and the chronicity of constipation. Constipation occurring recently in an adult may indicate significant colon pathology such as malignancy; constipation present since early infancy may be indicative of neurologic disorders. The patient also should be carefully questioned about usual diet and laxative regimens. Does the patient have a diet consistently deficient in high-fiber items and containing mainly highly refined foods? What laxatives or cathartics has the patient used to attempt relief of constipation? The patient should be questioned about other concurrent medications, with interest focused on agents that might cause constipation.

For most patients who complain of constipation, a thorough physical examination is not required after it is established that constipation (a) is not a chronic problem, (b) is not accompanied by signs of significant GI disease (e.g., rectal bleeding or anemia), and (c) does not cause severe discomfort. In these circumstances, the patient may be referred directly to the first-line therapies for constipation described in the next section (mainly bulk-forming laxatives and dietary fiber with occasional use of saline or stimulant laxatives). Table 38–8 presents a general treatment algorithm for the management of constipation.

6 The proper management of constipation requires a number of different modalities; however, the basis for therapy should be dietary modification. The major dietary change should be an increase in the amount of fiber consumed daily. In addition to dietary management, patients should be encouraged to alter other aspects of their lifestyles if necessary. Important considerations are to encourage patients to exercise (achieved even by brisk walking after dinner) and to adjust bowel habits so that a regular and adequate time is made to respond to the urge to defecate. Another general measure is to increase fluid intake. This is generally recommended and believed beneficial, although there is little objective evidence to support this measure.

If an underlying disease is recognized as the cause of constipation, attempts should be made to correct it. GI malignancies may be removed via surgical resection. Endocrine and metabolic derangements should be corrected by the appropriate methods. For example, when hypothyroidism is the cause of constipation, cautious institution of thyroid-replacement therapy is the most important treatment measure.

As discussed earlier, many drug substances may cause constipation. If a patient is consuming medications well known to cause constipation, consideration should be given to alternative agents. For some medications (e.g., antacids), nonconstipating alternatives

TABLE 38-8 Constipation Treatment Algorithm**History**

- Drug induced
- Laxative abusers

Symptoms seen with chronic constipation

- Fluid and electrolyte imbalances (hypokalemia)
- Protein-losing gastroenteropathy with hypoalbuminemia
- Syndromes resembling colitis

Select appropriate diagnostic studies

- Proctoscopy
- Sigmoidoscopy
- Colonoscopy
- Barium enema

Diagnosis

1. Treat specific cause
2. No diagnosis, symptomatic therapy
 - A. Bulk-forming agents
 - B. Dietary modification
 - C. Alter lifestyle (exercise)
 - D. Increase fluid intake
 - E. Discontinue potential drug inducer

exist. If no reasonable alternatives exist to the medication thought to be responsible for constipation, consideration should be given to lowering the dose. If a patient must remain on constipating medications, then more attention must be given to general measures for prevention of constipation, as discussed in the next section.

■ NONPHARMACOLOGIC THERAPY**Dietary Modification and Bulk-Forming Agents**

The most important aspect of therapy for constipation for the majority of patients is dietary modification to increase the amount of fiber consumed. Fiber, the portion of vegetable matter not digested in the human GI tract, increases stool bulk, retention of stool water, and rate of transit of stool through the intestine. The result of fiber therapy is an increased frequency of defecation. Also, fiber decreases intraluminal pressures in the colon and rectum, which is thought to be beneficial for diverticular disease and for irritable bowel syndrome. The specific physiologic effects of fiber are not well understood. Patients should be advised to include at least 10 g of crude fiber in their daily diets.²⁶ Fruits, vegetables, and cereals have the highest fiber content. Bran, a by-product of milling of wheat, is often added to foods to increase fiber content and contains a high amount of soluble fiber, which may be extremely constipating in larger doses. Raw bran is generally 40% fiber. Medicinal products, often called “bulk-forming agents,” such as psyllium hydrophilic colloids, methylcellulose, or polycarbophil, have properties similar to those of dietary fiber and may be taken as tablets, powders, or granules (Table 38–9).

A trial of dietary modification with high-fiber content should be continued for at least 1 month before effects on bowel function are determined. Most patients begin to notice effects on bowel function 3 to 5 days after beginning a high-fiber diet, but some patients may require a considerably longer period of time. Patients should be cautioned that abdominal distension and flatus may be particularly

TABLE 38-9 Dosage Recommendations for Laxatives and Cathartics

Agent	Recommended Dose
Agents that cause softening of feces in 1–3 days	
Bulk-forming agents/osmotic laxatives	
Methylcellulose	4–6 g/day
Polycarbophil	4–6 g/day
Psyllium	Varies with product
Polyethylene glycol 3350	
Emollients	
Docusate sodium	50–360 mg/day
Docusate calcium	50–360 mg/day
Docusate potassium	100–300 mg/day
Lactulose	15–30 mL orally
Sorbitol	30–50 g/day orally
Mineral oil	15–30 mL orally
Agents that result in soft or semifluid stool in 6–12 h	
Bisacodyl (oral)	5–15 mg orally
Senna	Dose varies with formulation
Magnesium sulfate (low dose)	<10 g orally
Agents that cause watery evacuation in 1–6 h	
Magnesium citrate	18 g 300 mL water
Magnesium hydroxide	2.4–4.8 g orally
Magnesium sulfate (high dose)	10–30 g orally
Sodium phosphates	Varies with salt used
Bisacodyl	10 mg rectally
Polyethylene glycol-electrolyte preparations	4 L

troublesome in the first few weeks of fiber therapy, particularly with high bran consumption. In most cases these problems resolve with continued use.

Bulk-forming laxatives have few adverse effects. The only major caution in the use of bulk-forming laxatives is that obstruction of the esophagus, stomach, small intestine, and colon has been reported when the agents have been consumed without sufficient fluid and in patients with intestinal stenosis.

Surgery

In a small percentage of patients who present with complaints of constipation, surgical procedures are necessary because of the presence of colonic malignancies or GI obstruction from a number of other causes. In each case, the involved segment of intestine may be resected or revised. Surgery may be required in some endocrine disorders that cause constipation, such as pheochromocytoma, which requires removal of a tumor.

Biofeedback

The majority of patients with constipation related to pelvic floor dysfunction can benefit from electromyogram-guided biofeedback therapy.²⁵ The value of biofeedback in children with chronic constipation has not been well demonstrated.²⁶

■ PHARMACOLOGIC THERAPY
Drug Regimens of Choice

Treatment and prevention of constipation should consist of bulk-forming agents in addition to dietary modifications that increase dietary fiber.²⁷ A variety of products are available that provide adequate bulk. Whichever agent is chosen, it should be used daily and continued indefinitely in most patients, particularly those with chronic constipation.

For most persons with acute constipation, infrequent use (less than every few weeks) of laxative products is acceptable. Acute constipation may be relieved by the use of a tap-water enema or a glycerin

suppository; if neither is effective, the use of oral sorbitol, low doses of bisacodyl or senna, or saline laxatives (e.g., milk of magnesia) may provide relief. If laxative treatment is required for longer than 1 week, the person should be advised to consult a physician to determine if there is an underlying cause of constipation that requires treatment with other modalities.

For some bedridden or geriatric patients, or others with chronic constipation, bulk-forming laxatives remain the first line of treatment, but the use of more potent laxatives may be required relatively frequently. Fiber should be avoided in bedridden patients who are cognitively impaired.²⁵ When other than bulk-forming laxatives are used, they should be administered in the lowest effective dose and as infrequently as possible to maintain regular bowel function (more than 3 stools per week). Agents that may be used in these situations include bisacodyl, senna, milk of magnesia, and sorbitol or lactulose. Mineral oil should be avoided, particularly in bedridden patients, because of the risk of aspiration and lipoid pneumonia. Some patients with chronic constipation may present with fecal impactions. Before vigorous oral laxatives can be used, the impaction needs to be removed using mechanical methods, including tap-water or saline enemas and digital extraction.

In the hospitalized patient without GI disease, constipation may be related to the use of general anesthesia and/or opiate substances. Most orally or rectally administered laxatives may be used in these situations. For prompt initiation of bowel evacuation, either a tap-water enema, glycerin suppository, or oral milk of magnesia are recommended.

With infants and children, constipation may occur commonly. In patients with persistent problems, the underlying etiology may be neurologic, metabolic, or secondary to anatomic abnormalities. Management of constipation in this age group should consist of dietary modification with an emphasis on high-fiber foods.

For acute constipation in most age groups, a tap-water enema or glycerin suppository may be helpful. Occasional use of milk of magnesia or an anthraquinone laxative in low doses is justified as well.

Drug Classes

The traditional classification system for laxatives and cathartics by suspected mode of action is not very useful, as this is not clearly understood for many agents. In general, most of these products induce bowel evacuation by one or more of the mechanisms associated with the etiology of diarrhea, including active electrolyte secretion, decreased water and electrolyte absorption, increased intraluminal osmolarity, and increased hydrostatic pressure in the gut. Laxatives convert the intestine from primarily an organ that absorbs water and electrolytes to an organ that secretes these substances.

The various classes of laxatives are discussed in this section. These agents are divided into three general classifications: (a) those causing softening of feces in 1 to 3 days (bulk-forming laxatives, docusates, and lactulose); (b) those that result in soft or semifluid stool in 6 to 12 hours (diphenylmethane derivatives and anthraquinone derivatives); and (c) those causing water evacuation in 1 to 6 hours (saline cathartics, castor oil, and polyethylene glycol-electrolyte lavage solution).

Emollient Laxatives

Emollient laxatives are surfactant agents, docusate in its various salts, which work by facilitating mixing of aqueous and fatty materials within the intestinal tract. They may increase water and electrolyte secretion in the small and large bowel. These products are generally given orally, although docusate potassium has also been used rectally. These products result in a softening of stools within 1 to 3 days of therapy.

Emollient laxatives are ineffective in treating constipation, but are used mainly to prevent this condition. They may be helpful in situations in which straining at stool should be avoided, such as

after recovery from myocardial infarction, with acute perianal disease, or after rectal surgery. It is unlikely that these agents would be effective in preventing constipation if major causative factors (e.g., heavy opiate use, uncorrected pathology, or inadequate dietary fiber) are not concurrently addressed.

Although docusates are generally safe, a few adverse effects have been noted. They may increase the intestinal absorption of agents administered concurrently and alter toxic potential.

Lubricants

Mineral oil is the only lubricant laxative in routine use. This agent, obtained from petroleum refining, acts by coating stool and allowing for easier passage. It inhibits colonic absorption of water, thereby increasing stool weight and decreasing stool transit time. Mineral oil may be given orally or rectally in a dose of 15 to 45 mL. Generally, the effect on bowel function is noted after 2 or 3 days of use.

Mineral oil is helpful in situations similar to those suggested for docusates: to maintain a soft stool and to avoid straining for relatively short periods of time (a few days to 2 weeks); however, it possesses a much greater potential for adverse effects and its routine use should be discouraged. Mineral oil may be absorbed systemically and can cause a foreign-body reaction in lymphoid tissue. Also, in debilitated or recumbent patients, mineral oil may be aspirated, causing lipoid pneumonia.²⁸ Mineral oil may decrease the absorption of fat-soluble vitamins (A, D, E, and K) with chronic use by causing retention in the GI tract. Finally, even when given orally, mineral oil may leak from the anal sphincter, causing pruritus and soiling of clothing.

Lactulose and Sorbitol

Lactulose is a disaccharide that is used orally or rectally. It is metabolized by colonic bacteria to low-molecular-weight acids, resulting in an osmotic effect whereby fluid is retained in the colon.²⁹ The fluid retained in the colon lowers the pH and increases colonic peristalsis. Lactulose is generally not recommended as a first-line agent for the treatment of constipation because it is costly and not necessarily more effective than such agents as sorbitol or milk of magnesia. It may be justified as an alternative for acute constipation, and has been particularly useful in elderly patients. Occasionally, the use of lactulose may result in flatulence, cramps, diarrhea, and electrolyte imbalances.³⁰ Sorbitol, a monosaccharide, exerts its effect by osmotic action and has been recommended as a primary agent in the treatment of functional constipation in cognitively intact patients.²⁵ It is as effective as lactulose and much less expensive.

Diphenylmethane and Anthraquinone Derivatives

Bisacodyl, the only remaining diphenylmethane derivative with the withdrawal of phenolphthalein, exerts its therapeutic effect by stimulating the mucosal nerve plexus of the colon. Bisacodyl exhibits significant interpatient variability in effective dose, with doses that cause no effect in one patient resulting in excessive cramping and fluid evacuation in others. Bisacodyl is not recommended for regular daily use but can be used intermittently (every few weeks) to treat constipation or as a bowel preparation before diagnostic procedures in which cleansing of the colon is necessary. Bisacodyl may sometimes cause severe abdominal cramping as well as significant fluid and electrolyte imbalances with chronic use.

Senna or sennosoids are the only remaining anthraquinone derivatives after removal of cascara sagrada and casanthrone (cascara extracts). Laxative effects are limited to the colon, and stimulation of the Auerbach plexus may be involved. As with bisacodyl, senna is only recommended for intermittent use and daily use should be strongly discouraged.

Saline Cathartics

Saline cathartics are composed of relatively poorly absorbed ions such as magnesium, sulfate, phosphate, and citrate, which produce their effects primarily by osmotic action in retaining fluid in the GI tract. Magnesium stimulates the secretion of cholecystokinin, a hormone that causes stimulation of bowel motility and fluid secretion. These agents may be given orally or rectally. A bowel movement may result within a few hours after oral doses and in 1 hour or less after rectal administration.

These agents should be used primarily for acute evacuation of the bowel, which may be necessary before diagnostic examinations, after poisonings, and in conjunction with some anthelmintics to eliminate parasites. Such agents as milk of magnesia (an 8% suspension of magnesium hydroxide) may be used occasionally (every few weeks) to treat constipation in otherwise healthy adults. Saline cathartics should not be used on a routine basis. The enema formulations of these agents may be useful in fecal impactions.

As with most laxatives, these agents may cause fluid and electrolyte depletion. Also, magnesium or sodium accumulation may occur when magnesium-containing cathartics are used in patients with renal dysfunction or when sodium phosphate is used in patients with congestive heart failure.

Castor Oil

Castor oil is metabolized in the GI tract to an active compound, ricinoleic acid, which stimulates secretory processes, decreases glucose absorption, and promotes intestinal motility, primarily in the small intestine. Castor oil usually results in a bowel movement within 1 to 3 hours of administration. Because the agent has such a strong purgative action, it should not be used for the routine treatment of constipation.

Glycerin

Glycerin is usually administered as a 3-g suppository and exerts its effect by osmotic action in the rectum. As with most agents given as suppositories, the onset of action is usually less than 30 minutes. Glycerin is considered a very safe laxative, although it may occasionally cause rectal irritation. Its use is acceptable on an intermittent basis for constipation, particularly in children.

Polyethylene Glycol-Electrolyte Lavage Solution

Whole-bowel irrigation with polyethylene glycol-electrolyte lavage solution (PEG-ELS) has become popular for colon cleansing before diagnostic procedures or colorectal operations.

Four liters of this solution is administered over 3 hours to obtain complete evacuation of the GI tract. The solution is not recommended the routine treatment of constipation and its use should be avoided in patients with intestinal obstruction.

Lubiprostone

The FDA recently approved the first new drug in a class called “chloride channel activators,” which are designed to act locally in the gut to open chloride channels on the GI luminal epithelium, which, in turn, stimulates chloride-rich intestinal fluid secretion and accelerates GI transit time and delays gastric emptying.³¹ Lubiprostone (Amitiza), is approved for “chronic idiopathic constipation in adults” at a recommended dose of one 24-mg capsule twice daily with food. Clinical trials have shown a significant increase in spontaneous bowel movements versus placebo.³² Common adverse effects include headache (13%), diarrhea, and nausea, as a result of delayed gastric emptying, which were more prominent with twice-daily dosing.

Other Agents

Tap-water enemas may be used to treat simple constipation. The administration of 200 mL of tap water by enema to an adult often results in a bowel movement within 30 minutes. Soap-suds enemas are no longer recommended as their use may result in proctitis or colitis.

Prevention

For certain groups of patients, such as those recovering from myocardial infarction or rectal surgery, straining at defecation is to be avoided. The basis of preventive therapy in these patients should be bulk-forming laxatives. Additionally, the use of docusate is popular, although its effectiveness is debated. In pregnant patients, constipation may result because of alterations in anatomy or iron supplementation. As described earlier, bulk-forming laxatives and docusates should be the first line of prevention.

LAXATIVE ABUSE SYNDROME

Misconceptions about normal bowel patterns and the effect of laxatives have contributed to a syndrome of laxative abuse that is relatively common in the United States. The availability of laxatives as chocolates or gums conveys to the public that the use of these agents is without adverse consequences. Abuse of laxatives has occurred traditionally in persons trying to maintain daily bowel function, but more recently has extended to others who use laxatives for the purpose of controlling weight. In either case, the consistent abuse of strong laxatives and cathartics may lead to serious illness.

Laxative abuse for the purpose of maintaining daily bowel function begins with misconceptions about the frequency, quantity, or consistency of stools. With the use of strong purgatives, the colon may be so thoroughly cleansed that a bowel movement may not occur normally until a few days later. This delay reinforces the need for more purgatives and the cycle of laxative dependence is begun. Eventually the patient may require daily laxatives to maintain bowel function. A variation of laxative abuse is seen in persons who use them as a means of weight loss.

The laxative abuser may present with contradictory findings of diarrhea and weight loss. In addition, long-term abusers of laxatives lend to have vomiting, abdominal pain, lassitude, weakness, thirst, edema, and bone pain (caused by osteomalacia). With prolonged use of laxatives a number of serious illnesses may arise, including fluid and electrolyte imbalances (including acid-base imbalances and hypokalemia), protein-losing gastroenteropathy with hypoalbuminemia, and syndromes resembling colitis.

The determination of laxative abuse syndrome can be difficult because many laxative abusers vigorously deny laxative use. Middle-aged women tend to be the most common laxative abusers. The chronic laxative abuse problem should be addressed by a combination of measures, including psychiatric evaluation, dietary modification with reliance on bulk-forming laxatives, and specific guidelines to the patient for the withdrawal of stimulant laxatives.

EVALUATION OF THERAPEUTIC OUTCOMES

The ultimate goal of treatment for constipation is alteration of lifestyle (particularly diet) to prevent further episodes of constipation. Short-term goals include alleviation of acute constipation with relief from symptoms. For patients with chronic constipation, the goals are more long-term and include use of proper diet and decreased reliance on laxatives. Effective treatment of constipation requires the patient to become more knowledgeable about the causes of constipation, proper diet, and appropriate use of laxatives.

IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS) is a gastrointestinal syndrome characterized by chronic abdominal pain and altered bowel habits in the absence of any organic cause. It is the most commonly diagnosed gastrointestinal condition.

EPIDEMIOLOGY

The prevalence of IBS is approximately 10% to 15% based on North American and European population-based studies; however, there is a wide variation in prevalence by individual country.^{33–36} IBS affects men and women, young patients, and the elderly. However, younger patients and women are more likely to be diagnosed with IBS. A systematic review estimated that there is an overall 2:1 female predominance in North America.³⁴ Although only 15% of those affected actually seek medical attention, IBS is the cause of between 25% and 50% of all referrals to gastroenterologists.³⁷

PATHOPHYSIOLOGY

Although the exact pathophysiologic abnormalities with IBS are still being actively investigated, it is currently thought that IBS results from altered somatovisceral and motor dysfunction of the intestine from a variety of causes. Abnormal central nervous system processing of afferent signals may lead to visceral hypersensitivity, with the specific nerve pathway affected determining the exact symptomatology expressed. This visceral hypersensitivity is a neuroenteric phenomenon that is independent of motility and psychological disturbances.²⁷ Factors known to contribute to these alterations include genetics, motility factors, inflammation, colonic infections, mechanical irritation to local nerves, stress, and other psychological factors.

Serotonin-Type Receptors

The enteric nervous system contains a significant percentage of the body's 5-hydroxytryptamine (serotonin, 5-HT).³⁸ Two types of serotonin exist within the gut: serotonin type 3 (HT₃) and serotonin type 4 (HT₄), which are responsible for secretion, sensitization, and motility.³⁹ Previous studies show that there is an increase in the postprandial levels of 5-HT in those who suffer from diarrhea predominant IBS when compared with nonsufferers.³⁸ Therefore, stimulation and antagonism of these serotonin receptors has become a focused area for research on new drug therapies for both diarrhea- and constipation-predominant disease.

CLINICAL PRESENTATION

7 Irritable bowel syndrome presents as either diarrhea-predominant or constipation-predominant disease and can be defined as lower abdominal pain, disturbed defecation (constipation, diarrhea, or an alternating pattern of both), and bloating in the absence of structural or biochemical factors that might explain these symptoms (Table 38–10). Because IBS can consist of a variable number of signs and symptoms, two diagnostic criteria “check lists” are commonly used to aid in the workup of a patient suspected of having IBS. The Manning criteria was first proposed in 1978, whereas the Rome criteria was initially proposed in 1999 and revised as recently as 2006 by an international working group in an effort to help standardize the diagnostic criteria used in clinical research protocols. Table 38–11 shows the symptom criteria for both of the Manning⁴⁰ and Rome III⁴¹ symptom-based criteria.

Additional diagnostic steps that can be taken include sigmoidoscopy or colonoscopy; examination of the stool for occult blood and ova and parasites; complete blood cell count; erythrocyte sedimentation rate; and fecal occult blood test.

TABLE 38-10 Clinical Presentation of Irritable Bowel Syndrome**Signs and symptoms**

- Lower abdominal pain
- Abdominal bloating and distension
- Diarrhea symptoms, >3 stools/day
- Extreme urgency
- Mucus passage
- Constipation symptoms, <3 stools/wk, straining, incomplete evacuation
- Psychological symptoms such as depression and anxiety

Nongastrointestinal symptoms

- Urinary symptoms
- Fatigue
- Dyspareunia

Other concurrent conditions

- Fibromyalgia
- Functional dyspepsia
- Chronic fatigue syndrome

Reduced health-related quality of life

tation rate; and serum electrolytes. In some cases, radiographic imaging studies, such as computed tomography scans or barium swallows or enemas, may also be necessary if the findings of the above assessment are not typical for IBS.⁴²

TREATMENT

Irritable Bowel Syndrome

■ GENERAL APPROACH TO TREATMENT

The treatment approach to IBS is based upon the predominant symptoms and their severity (Fig. 38-3). Milder, less frequent episodes can be managed with dietary restrictions and a higher-fiber diet, with addition of bulk-forming laxatives, if necessary. More persistent disease may require as-needed uses of various antispasmodic or antidiarrheal agents such as loperamide. Lastly, the most-severe forms of this disease may call for pharmacologic agents directed specifically at the underlying neurohormonal imbalance, such as the 5-HT₄ agonists, such as tegaserod, or the 5-HT₃ receptor antagonists, such as alosetron.

CLINICAL CONTROVERSY

The newer serotonin receptor agonists and antagonists tegaserod and alosetron act on GI-specific serotonin receptors to treat constipation-predominant and diarrhea predominant IBS, respectively. However, both drugs are currently only indicated for women. Efficacy and safety in men has not been established because the initial manufacturer's sponsored clinical trials contained insufficient numbers of men with IBS to provide the necessary statistical power to prove efficacy and safety. Ongoing studies should determine if these drugs are indicated in men.

Alosetron, a 5-HT₃ receptor antagonist, was withdrawn from the U.S. market in 2000 as a result of serious adverse effects, including severe constipation and ischemic colitis that did not appear in the initial clinical trials. It was reintroduced in 2002 and is now limited to an FDA-approved restricted-use program in lower initial doses, and requires extensive postmarketing surveillance. Results of these trials are necessary to definitively determine alosetron's true safety profile, especially with regard to its association with or causation of fatal ischemic colitis.

TABLE 38-11 Symptom-Based Criteria for Irritable Bowel Syndrome**The Manning criteria⁴⁰**

Chronic or recurrent abdominal pain for at least 6 months and two or more of the following:

1. Abdominal pain relieved with defecation
2. Abdominal pain associated with more frequent stools
3. Abdominal pain associated with looser stools
4. Abdominal distension
5. Feeling of incomplete evacuation after defecation
6. Mucus in stools

Rome III diagnostic criteria for irritable bowel syndrome⁴¹

Recurrent abdominal pain or discomfort at least 3 days per month in the last 3 months associated with 2 or more of the following:

1. Relieved with defecation
2. Onset associated with a change in frequency of stool
3. Onset associated with a change in form (appearance) of stool

■ CONSTIPATION-PREDOMINANT DISEASE

In the constipation-predominant patient, dietary fiber may be beneficial. Patients should be instructed to begin with 1 tablespoonful of fiber with 1 meal daily and gradually increase the dose to include fiber with 2 and 3 meals a day until the desired outcome is achieved. End points that the patient should aim for include bulkier and more easily passed stools. For patients unable to tolerate dietary

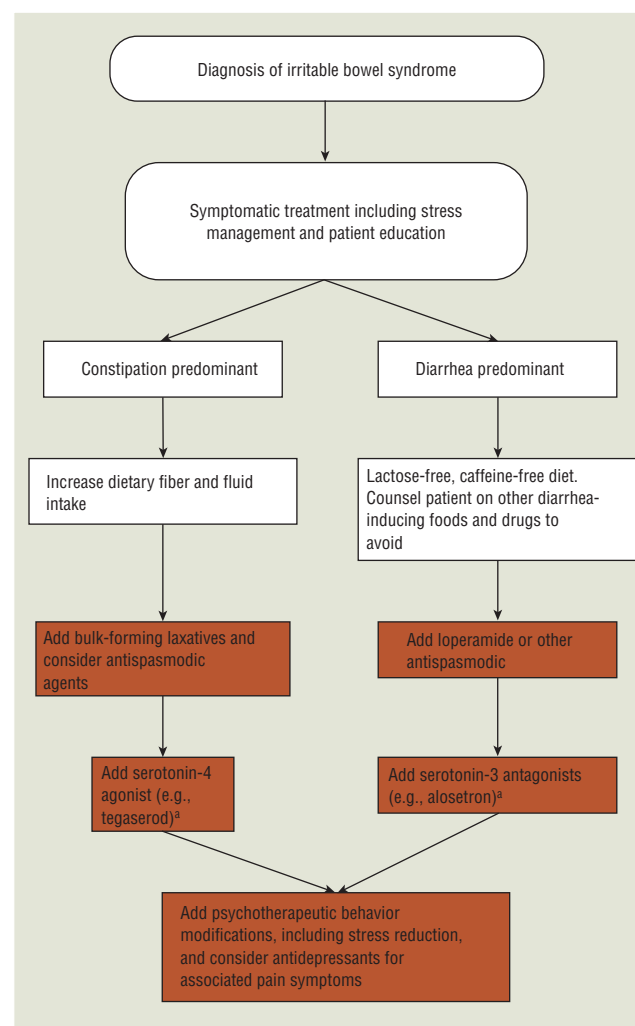

FIGURE 38-3. A general stepwise approach to the management of both constipation- and diarrhea-predominant irritable bowel syndrome. ^aConsider manufacturer sponsored patient access program.

bran, bulking agents such as psyllium may be substituted.³⁰ Laxative use is not encouraged in these patients, and it should only be used in the smallest dose for the least amount of time in cases of severe constipation.

The 5-HT₄ partial agonist tegaserod was the first therapy approved by the FDA specifically for short-term, intermittent treatment of constipation-predominant IBS.⁴² Tegaserod was suspended from marketing in early 2007 at the request of the FDA due to an analysis of clinical trial data showing a small, yet significant, increase in ischemia events (MI < CVA, and unstable angina) in patients with pre-existing cardiovascular disease and/or cardiovascular risk factors. In July 2007, the drug's manufacturer, Novartis, began tegaserod (Zelnorm®) restricted access program to patients in the United States via either a manufacturer sponsored FDA-approved investigational new drug (IND) protocol or through the FDA via an emergency INID protocol. Tegaserod is a serotonin derivative that activates 5-HT₄ receptors on the neurons in the gastrointestinal tract, increasing GI motility and decreasing visceral sensations. It is approved as 2-mg or 6-mg doses given twice daily 30 minutes prior to a meal with water for up to 12 weeks.⁴³ Stimulation of the 5-HT₄ receptors by tegaserod increases gastric secretions and promotes motility, with improvement in symptoms generally occurring within the first week of therapy. Currently this therapy is only approved for use in women, as efficacy and safety in men has not been established because of inadequate numbers of men enrolled in clinical trials to date.⁴⁴ In addition, length of effective therapy has only been approved for 12 weeks⁴⁵; however, tegaserod may provide safe and effective therapy for up to 12 months.^{44,46} Diarrhea was the most common adverse effect, resulting in drug discontinuation in 1.6% of study subjects.

■ DIARRHEA-PREDOMINANT DISEASE

8 For patients in whom diarrhea is the primary complaint, avoidance of certain food products may be necessary. Caffeine, alcohol, and artificial sweeteners (sorbitol, fructose, and mannitol) are known to irritate the gut and produce a laxative effect. Lactose intolerance should be considered in certain patients; however, the prevalence of this condition may be exaggerated.

Herbal medicines or teas often contain senna, which may produce diarrhea. In patients with disease persistence following dietary modification, loperamide may be used for episodic management of urgent diarrhea, or in situations in which the patient wishes to avoid the possibility of an acute onset of symptoms.⁴³ This drug decreases intestinal transit, enhances water and electrolyte absorption, and strengthens rectal sphincter tone. Some patients may require continuous therapy, and careful dosage titration can usually be undertaken to prevent the development of constipation. Bile acid sequestrants such as cholestyramine may be useful in patients with diarrhea related to idiopathic bile acid malabsorption or following cholecystectomy.⁴²

Diarrhea-predominant IBS caused by excessive stimulation of the 5-HT₃ receptor can be relieved by the drug alosetron. Alosetron was the first truly effective treatment for diarrhea-predominant IBS. However, in November 2000 it was voluntarily withdrawn from the market because of severe GI adverse effects, including 113 reported cases of serious constipation and 8 cases of possible ischemic colitis and death. This decision was met with a great public outcry, as many who had suffered for years had experienced relief for the first time. Because this drug was highly effective in many patients, the FDA approved restricted use of alosetron in June 2002. Alosetron is now available via an FDA-approved restricted-use program in conjunction with GlaxoSmithKline as detailed at <http://www.lotronex.com>. It is now indicated, in lower initial doses of 0.5 mg twice daily, for women with diarrhea-predominant symptoms of longer than 6 months' duration that are not relieved by conventional therapy. Healthcare providers must use extreme caution in therapy with this drug, and must follow strict FDA-mandated guidelines.

Use of Antidepressants in IBS

Tricyclic antidepressants have shown some benefit in treatment of diarrhea-predominant IBS associated with moderate to severe abdominal pain, by modulating perception of visceral pain, altering GI transit time, and treating underlying comorbidities.^{47,48} Selective serotonin reuptake inhibitors are less-well studied, with only one report with paroxetine showing some improvement in stool passage and "well being" but no decrease in abdominal pain.⁴⁹

Figure 38–3 shows a general stepwise approach to the management of both constipation and diarrhea-predominant irritable bowel syndrome.

■ PAIN IN IBS

9 Select patients with IBS suffer significant pain associated with their disease. Data supporting the use of antispasmodic agents in these patients are conflicting.^{50,51} In these cases, a trial of low-dose antidepressant therapy is indicated, especially if pain is associated with eating. Both tricyclic antidepressants and serotonin reuptake inhibitors produce analgesia, and may relieve depressive symptoms if present. Preprandial doses of drugs containing anticholinergic properties may suppress pain (and/or diarrhea) associated with an overactive postprandial gastrocolonic response. Tricyclic antidepressants should be avoided in patients with pain and constipation. In addition, psychotherapy, including cognitive behavioral therapy, relaxation therapy, and hypnotherapy, has been shown to decrease IBS symptoms.⁵²

■ DRUG CLASSES CURRENTLY UNDER INVESTIGATION FOR THE TREATMENT OF IBS

Probiotics (see Diarrhea above) such as *Lactobacillus* and *Bifidobacterium* reduced IBS symptoms in several investigation trials.^{53,54} Another 5-HT₃ antagonist, cilansetron, has demonstrated similar efficacy to that of alosetron in phase II trials and enrolled enough male patients to show benefit in males as well. This drug is currently in phase III trials. In addition, other compounds being evaluated include neurokinin₁ (NK1) and neurokinin₃ (NK3) receptor antagonists, gut-selective calcium channel blockers, cholecystokinin receptor antagonists, and agents capable of stimulating motilin receptors (motilin mimetics).⁵⁵

■ EVALUATION OF THERAPEUTIC OUTCOMES

IBS is usually classified as constipation-predominant, diarrhea-predominant, or IBS with abdominal pain and bloating. Therapeutic goals in IBS should focus on the patient's primary complaint. Dietary and drug therapy goals should focus on end-organ treatment to relieve abdominal pain (antispasmodic drugs) or disturbed bowel habits (antidiarrheals and bulk-forming agents). Additionally, severe symptoms from central nervous system dysregulation should be treated with antidepressants, psychotherapy, relaxation/stress management, cognitive behavior treatment, and/or hypnosis aimed at specific affective disorders.⁵⁵ Lastly, the serotonin receptor agonists and antagonists can be used in carefully selected patients whose symptoms are not adequately controlled with other agents. The American Gastroenterology Association recommends that patients with severe IBS consider psychological treatments such as psychotherapy, relaxation/stress management, and/or cognitive behavior treatment.

ABBREVIATIONS

5-HT: serotonin

IBS: irritable bowel syndrome

ORS: oral rehydration solution

PEG-ELS: polyethylene glycol-electrolyte lavage solution

PHM: peptide histidine methionine

VIP: vasoactive intestinal peptide

KEY CONCEPTS

- 1 Cirrhosis is a severe, chronic, irreversible disease associated with significant morbidity and mortality. However, the progression of cirrhosis secondary to alcohol abuse can be interrupted by abstinence. Consequently, it is imperative for the clinician to educate and support abstinence from alcohol as part of the overall treatment strategy of the underlying liver disease.
- 2 Patients with cirrhosis and portal hypertension should be considered for endoscopic screening and patients with varices should receive primary prophylaxis with β -adrenergic blockade therapy.
- 3 When nonselective β -adrenergic blocker therapy is used to prevent rebleeding, it is essential that the dose be titrated to achieve a heart rate goal of 60 beats per minute (beats/min) or a heart rate that is 25% lower than the baseline heart rate.
- 4 Octreotide is the preferred vasoactive agent employed in the medical management of variceal bleeding. Endoscopy employing endoscopic band ligation is the primary therapeutic tool in the management of acute variceal bleeding.
- 5 The combination of spironolactone and furosemide is the recommended initial diuretic therapy for patients with ascites.
- 6 All patients who have survived an episode of spontaneous bacterial peritonitis should receive long-term antibiotic prophylaxis.
- 7 The mainstay of therapy of hepatic encephalopathy involves therapy to lower blood ammonia concentrations, and includes diet therapy, lactulose, and antibiotics alone or in combination with lactulose.

Chronic liver disease and exposure to hepatotoxic substances causes damage to normal liver tissue resulting in an inflammatory response and abnormal collagen secretion. The initial result of this inflammation and collagen secretion is hepatic fibrosis.¹ Fibrosis, defined as the excessive accumulation of proteins, such as collagen, in the liver's extracellular matrix, is currently considered a wound-healing response to chronic liver injury. If fibrotic liver disease advances, collagen bands progress to bridging fibrosis and eventually frank hepatic cirrhosis.² The word *cirrhosis* is derived from the Greek *kirrhos*, meaning orange-colored, and refers to the yellow-orange hue of the cirrhotic liver seen by the pathologist or surgeon. Cirrhosis is defined histologically based

on three criteria: diffuse disease, presence of fibrosis, and replacement of normal liver architecture by abnormal nodules.³ As fibrotic tissue replaces normal hepatic parenchyma, resistance to blood flow results in the clinical problems of portal hypertension and the development of varices and ascites. Hepatocyte loss and intrahepatic shunting of blood result in diminished metabolic and synthetic function which leads to hepatic encephalopathy and coagulopathy.

1 While cirrhosis has many causes (Table 39–1), in the United States, excessive alcohol intake and hepatitis B and C are the most common causes.^{1,3} This chapter elucidates the pathophysiology of cirrhosis and the resultant effects on human anatomy and physiology. Treatment strategies for managing the most commonly encountered clinical complications of cirrhosis are discussed.

EPIDEMIOLOGY

The exact prevalence of cirrhosis is unknown, with nearly 30% to 40% of diagnoses being made on autopsy.³ Cirrhosis is responsible for more than 26,000 deaths each year in America and chronic liver disease is currently ranked twelfth among the leading causes of death in the United States.⁴ Acute variceal bleeding and spontaneous bacterial peritonitis are among the immediately life-threatening complications of cirrhosis. Associated conditions causing significant morbidity include ascites and hepatic encephalopathy. Approximately 50% of patients with cirrhosis develop ascites during 10 years of observation and half of the cirrhotic patients who develop ascites will die within 2 years of diagnosis.⁵

PATHOPHYSIOLOGY OF CIRRHOSIS

Any discussion of cirrhosis must be based on a firm understanding of hepatic anatomy and vascular supply. Conceptually, the liver can be thought of as an elaborate blood filtration system receiving blood from the hepatic artery and the portal vein (Fig. 39–1) with portal blood originating from the mesenteric, gastric, splenic, and pancreatic veins. Blood enters the liver via the portal triad which contains branches of the portal vein and hepatic artery, bile ducts, and lymphatic and nerve tissue. It then drains through the sinusoidal spaces of the hepatic lobule (Fig. 39–2), which are lined by the workhorses of the liver, the hepatocytes. Individual hepatocytes are arranged in plates 1 cell thick, expanding from the portal veins to the terminal hepatic venules. The six or more surfaces of each individual hepatocyte either make contact with adjacent hepatocytes, border the bile canaliculi, or are exposed to the sinusoidal space. Filtered blood travels into the terminal hepatic venules, also called central veins, and then empties into larger hepatic veins and eventually into the inferior vena cava. The hepatic lobule can be subdivided into three functional zones based on relative oxygen supply. The hepatic artery supplies oxygen-rich blood to the portal triad. Hepatocytes at

TABLE 39-1 Etiology of Cirrhosis

Chronic alcohol consumption
Chronic viral hepatitis (types B, C, and D)
Metabolic liver disease
Hemochromatosis
Wilson disease
α_1 -Antitrypsin deficiency
Nonalcoholic steatohepatitis ("fatty liver")
Cholestatic liver diseases
Primary biliary cirrhosis
Secondary biliary cirrhosis (possible causes: gallstones, strictures, parasitic infection)
Primary sclerosing cholangitis (associated with ulcerative colitis and cholangio-carcinoma)
Budd-Chiari syndrome
Severe congestive heart failure and constrictive pericarditis
Drugs and herbals
Isoniazid, methyl dopa, amiodarone, methotrexate, phenothiazine, estrogen, anabolic steroids, black cohosh, Jamaican bush tea

the periphery therefore receive a higher level of oxygen than the cells near the terminal hepatic venules.⁶

In areas of hepatocellular injury, regardless of the nature of the inciting agent, hepatic stellate cells undergo an abnormal transformation. Stellate cells normally reside in the sinusoidal space and are involved in the storage of retinoids like vitamin A. However, when hepatic injury occurs, stellate cells in the affected areas begin to resemble fibroblasts, express contractile proteins, and become a major source of collagen and other matrix proteins that proliferate

FIGURE 39-1. The portal venous system.

FIGURE 39-2. The hepatic lobule. 1, 2, and 3 indicate the three functional zones based on relative oxygen supply (1 being the highest).

during fibrosis, eventually causing the permanent hepatic scarring characteristic of cirrhosis.¹ The progressive deposition of fibrous material within the sinusoids disrupts the normal blood flow through the hepatic lobule. Resistance to portal blood flow increases as fibrous tissue accumulates resulting in persistent and progressive elevations in portal blood pressures or portal hypertension.

Changes occur in cirrhosis to the vasodilatory and vasoconstricting mediators that regulate the hepatic sinusoidal blood flow. A decrease in the production of nitric oxide, which acts as a vasodilator, and an increase in the levels of endogenous vasoconstrictors, such as endothelin, combine to increase the resistance to blood flow through the sinusoidal space. Concurrently, there also appears to be an increase in the blood flow to the splanchnic vasculature through a nitric oxide-mediated effect on the splanchnic arteriole.^{7,8} These pathophysiologic changes mark the current and past targets of pharmacologic therapy for the treatment of portal hypertension and prevention of variceal bleeding.

In summary, cirrhosis results in elevation of portal blood pressure because of fibrotic changes within the hepatic sinusoids, changes in the levels of vasodilatory and vasoconstrictor mediators, and an increase in blood flow to the splanchnic vasculature.

ANATOMIC AND PHYSIOLOGIC EFFECTS OF CIRRHOSIS

Cirrhosis and the pathophysiologic abnormalities that cause it result in the commonly encountered problems of ascites, portal hypertension, esophageal varices, hepatic encephalopathy, and coagulation disorders. Other, less commonly seen problems in patients with cirrhosis include hepatorenal syndrome, hepatopulmonary syndrome, and endocrine dysfunction.

ASCITES

Ascites, from the Greek *askos*, meaning water bag or wineskin, is the pathologic accumulation of lymph fluid within the peritoneal cavity. It is one of the earliest and most common presentations of cirrhosis.⁹ More than 50% of cirrhotic patients develop ascites within 10 years of diagnosis.⁵ The mechanism for the development of ascites is multifactorial. Recent theory states that severe portal hypertension and hepatic insufficiency lead to splanchnic arterial vasodilation and decreased peripheral resistance. The resulting systemic hypotension causes increased activity of the sympathetic nervous system and renin-angiotensin-aldosterone system, which causes increased sodium and water retention and vasoconstrictor production (Fig. 39-3). Although vascular resistance is increased in most major vascular territories (kidney, brain, skin, and muscle) by this increase in vasoconstrictor release, the splanchnic vasculature does not seem to have the same response. Instead, splanchnic arterial dilation occurs and causes a rapid inflow of arterial blood into the liver and other splanchnic organs. Hydrostatic pressure increases leading to excessive splanchnic lymph production and leakage. The leaked fluid accumulates in the abdominal cavity, forming ascites, which is continuously perpetuated by ongoing sodium and water retention by the kidneys.¹⁰

PORTAL HYPERTENSION AND VARICES

The most important clinical sequelae of portal hypertension are the development of varices or alternative routes of blood flow from the portal to the systemic circulation, bypassing the liver (see Fig. 39-1). Varices decompress the portal venous system and return blood to the systemic circulation. Varices can occur at any level of the gastrointestinal tract; however, the route with the most clinical significance is through the left gastric vein with the development of esophageal varices. Patients with cirrhosis are at risk for variceal bleeding when

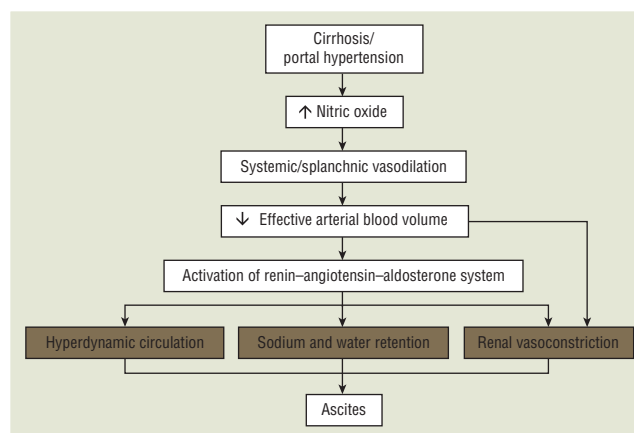

FIGURE 39-3. Pathogenesis of ascites.

portal venous pressure is 12 mm Hg greater than vena cava pressure.⁷ Hemorrhage from varices occurs in 25% to 40% of patients with cirrhosis, and each episode of bleeding carries a 25% to 30% risk of death.¹¹ Rebleeding is common following initial hemorrhage, especially within the first 72 hours. More than 50% of recurrent bleeding episodes occur within the first 10 days of the initial bleed and risk returns to baseline after 6 weeks.¹¹ The risk of bleeding from esophageal varices is related to the tension on the variceal wall, which, in turn, is related to portal vein pressure and, ultimately, to the degree of cirrhosis.⁷ It should be apparent from this understanding that the primary strategy for the treatment of esophageal varices is the reduction of portal hypertension by pharmacologic and surgical approaches.

HEPATIC ENCEPHALOPATHY

Hepatic encephalopathy (HE) can be defined as a central nervous system disturbance with a wide range of neuropsychiatric symptoms, and which is associated with hepatic insufficiency and liver failure.^{12,13} Symptoms of HE are thought to result from an accumulation of gut-derived nitrogenous substances in the systemic circulation as a consequence of decreased hepatic functioning and shunting through porto-systemic collaterals bypassing the liver. Once these substances enter the central nervous system, they cause alterations of neurotransmission that affect consciousness and behavior.¹² Ammonia is the most commonly cited culprit in the pathogenesis of HE, but glutamate, benzodiazepine receptor agonists, and manganese have also been recognized as potential causes.^{12,13} Arterial ammonia levels are increased commonly in both acute and chronic liver disease, but an established correlation between blood ammonia levels and mental status does not exist.¹² Despite this, interventions to lower blood ammonia levels remain the mainstay of treatment for HE.

HE is now categorized as type A, B, or C, based on nomenclature developed by the 11th World Congress of Gastroenterology. Type A is HE induced by acute liver failure; type B is a result of portal-systemic bypass without associated intrinsic liver disease; and type C is HE that occurs in patients with cirrhosis. The duration and characteristics of HE are classified as episodic, persistent, and minimal. Episodic HE occurs spontaneously or is precipitated by a clinical factor, such as gastrointestinal bleeding. Recurrent HE is defined by two episodes of spontaneous or precipitated HE occurring within 1 year, and the hallmark of persistent HE is chronic cognitive deficits that decrease a patient's quality of life. Minimal HE refers to cirrhotic patients who do not suffer clinically overt cognitive dysfunction, but who are found to have cognitive impairment on psychological studies.¹³ HE associated with chronic liver failure has a gradual onset, is commonly associated with known precipitating factors, and has a poor prognosis with the need for long-term treatment of the underlying liver disease.¹²

COAGULATION DEFECTS

Complex coagulation derangements can occur in cirrhosis. These defects include a reduction in the synthesis of clotting factors, excessive fibrinolysis, disseminated intravascular coagulation, thrombocytopenia, and platelet dysfunction. Vitamin K-dependent clotting factors, including factor VII, are affected early and occur with sufficient frequency and rapidity that the prothrombin time is a standard component of the Child-Pugh scoring system discussed in the following section. In fact, a reduction in clotting factor VII is so common in end-stage liver disease that it affects 75% to 85% of patients.¹⁴ The presence of activated clotting factors in cirrhosis creates a low-grade disseminated intravascular coagulation-like state with fibrinolysis. In addition, the portal hypertension of cirrhosis is accompanied by a qualitative and quantitative reduction in platelets with mild to moderate thrombocytopenia occurring in 49% to 64% of patients with end-stage liver disease.¹⁴ The net effect of these events is the development of bleeding diathesis.

CLINICAL PRESENTATION

Cirrhotic patients may present in a variety of ways, from asymptomatic patients with abnormal laboratory tests noted on routine blood tests to acute life-threatening hemorrhage in an emergency room. The approach to a patient with suspected liver disease begins with a thorough history and physical examination. Table 39–2 describes some of the typical presenting characteristics of patients with cirrhosis.^{3,15} Clinical jaundice is often a late manifestation of cirrhosis and its absence does not exclude the diagnosis.

A thorough history of alcohol or drug use, with the input of family and friends is important, as the patient often underestimates the amount of alcohol consumed. Family history can also provide clues regarding problems such as hemochromatosis. The social history provides information regarding potential occupational exposures to toxic agents. A history of acute pain and fever may indicate an obstructive process caused by gallstones, or an inflammatory condition such as viral or alcoholic hepatitis.

The classic clinical signs of cirrhosis, such as palmar erythema, spider angiomas, and gynecomastia, are neither sensitive nor specific for this disease.^{15,16} Only a combination of physical and laboratory findings provides a reasonable indicator of liver disease. A decreased albumin level was the most common finding in patients with cirrhosis, but was nonspecific and occurred in a variety of conditions. An elevated prothrombin time was the single most reliable manifestation of cirrhosis. The combination of thrombocytopenia, encephalopathy, and ascites was found in just over half of cirrhotics, but had the highest predictive value.¹²

TABLE 39-2 Clinical Presentation of Cirrhosis

Signs and symptoms
Asymptomatic
Hepatomegaly, splenomegaly
Pruritus, jaundice, palmar erythema, spider angiomas, hyperpigmentation
Gynecomastia, reduced libido
Ascites, edema, pleural effusion, and respiratory difficulties
Malaise, anorexia, and weight loss
Encephalopathy
Laboratory tests
Hypoalbuminemia
Elevated prothrombin time
Thrombocytopenia
Elevated alkaline phosphatase
Elevated aspartate transaminase (AST), alanine transaminase (ALT), and γ -glutamyl transpeptidase (GGT)

LABORATORY ABNORMALITIES

There are no laboratory or radiographic tests of hepatic function despite the commonly ordered *liver function tests*. These commonly measured markers are substances produced by the liver and released into the bloodstream during hepatocellular injury, and are more correctly termed *liver dysfunction tests*. True liver function tests that assess the ability of the liver to eliminate substances that undergo hepatic metabolism, such as the ¹⁴C-aminopyrine breath test, are limited by complexity and availability.

Routine liver tests include alkaline phosphatase, bilirubin, aspartate transaminase (AST), alanine transaminase (ALT), and γ -glutamyl transpeptidase (GGT). Additional markers of hepatic synthetic activity include albumin and prothrombin time. Liver function tests are often the first step in the evaluation of patients who present with symptoms or signs suggestive of cirrhosis. Liver function tests are typically elevated in chronic inflammatory liver disease such as hepatitis C, but may be normal in patients with a previous toxic exposure or resolved infectious process such as hepatitis B.

The use of liver function tests in the diagnosis and management of cirrhosis is discussed in the following sections. It is useful to group the tests into two broad categories: markers of hepatocyte damage, such as the transaminases, and markers of hepatocellular synthetic function, such as prothrombin time and albumin.

Aminotransferases

The aminotransferases, AST and ALT, are enzymes located in the cytoplasm of hepatocytes and their levels are elevated with hepatocellular injury. The degree of elevation and rate of rise in aminotransferase serum levels is helpful in suggesting possible etiologies. The highest levels are typically seen in acute viral, ischemic, or toxic liver injury.¹⁷ In contrast, alcoholic liver disease resulted in AST elevations of only 6 to 7 times the upper limit of normal in 98% of patients in a landmark study by Cohen and Kaplan.¹⁸

The ratio of AST to ALT also provides information in patients with suspected alcoholic liver disease. Seventy percent of patients with alcoholic liver disease had ratios greater than 2 compared to only 4% of patients with viral hepatitis.¹⁸

Alkaline Phosphatase and γ -Glutamyl Transpeptidase

Elevated serum levels of alkaline phosphatase and GGT occur as a result of the bile flow obstruction that accompanies conditions such as primary biliary cirrhosis, primary sclerosing cholangitis, drug-induced cholestasis, gallstone disease, and autoimmune cholestatic liver disease. Neither alkaline phosphatase nor GGT are found solely in the liver, and elevations in either of these biomarkers can occur in a variety of disease states, affecting other bodily tissues. However, the combination of an elevation in alkaline phosphatase level with a concomitant elevation in GGT level is considered to be both a sensitive and specific marker of cholestatic liver disease.¹⁷

Child-Pugh Classification and Mayo End-Stage Liver Disease Score

The Child-Pugh classification system has gained widespread acceptance as a means of quantifying the myriad effects of the cirrhotic process on the laboratory and clinical manifestations of this disease.¹⁹ Recommended drug-dosing adjustments for patients in liver failure, when available, are normally based upon the Child-Pugh score. The newer Mayo End-Stage Liver Disease (MELD) scoring system is now the accepted classification scheme used by the United Network for Organ Sharing (UNOS) in the allocation livers for transplantation.²⁰ The Child-Pugh classification system employs a combination of physical and laboratory findings (Table 39–3),

TABLE 39-3 Criteria and Scoring for the Child-Pugh Grading of Chronic Liver Disease

Score	1	2	3
Bilirubin (mg/dL)	1–2	2–3	>3
Albumin (mg/dL)	>3.5	2.8–3.5	<2.8
Ascites	None	Mild	Moderate
Encephalopathy (grade)	None	1 and 2	3 and 4
Prothrombin time (seconds prolonged)	1–4	4–6	>6

Grade A, <7 points; grade B, 7–9 points; grade C, 10–15 points.

whereas the MELD score calculation takes into account a patient's serum creatinine, bilirubin, international normalized ratio (INR), and etiology of liver disease, omitting the more subjective reports of ascites and encephalopathy used in the Child-Pugh system. The MELD scoring calculation is as follows²¹:

$$\text{MELD score} = 0.957 \times \text{Log}_e(\text{creatinine mg/dL}) + 0.378 \times \text{Log}_e(\text{bilirubin mg/dL}) + 1.120 \times \text{Log}_e(\text{INR}) + 0.643$$

These classification systems are important because they are used to assess and define the severity of the cirrhosis, and as a predictor for patient survival, surgical outcome, and risk of variceal bleeding.

CLINICAL CONTROVERSY

The Child-Pugh classification system has been used for decades to quantify liver impairment in patients with cirrhosis. A problem with this system is that it relies on subjective scoring components related to ascites and encephalopathy, leading to the possibility of interpretation differences and scoring disparities. UNOS now employs the MELD scoring system, which relies solely on objective laboratory measurements, to stratify the severity of a patient's liver dysfunction and assist with transplant allocation. Controversy surrounds whether or not the Child-Pugh scoring system should be abandoned for the more objective MELD scoring system to describe the severity of a patient's liver dysfunction, assist with clinical decision making, and eventually guide drug dosing.

Bilirubin

Bilirubin is a breakdown product of hemoglobin derived from senescent red blood cells. Elevations of the serum bilirubin are common in end-stage liver disease and obstruction of the common bile duct caused by gallstones or malignancy; however, there are other causes of an elevated bilirubin (Table 39-4).

TABLE 39-4 Etiology of Hyperbilirubinemia

Etiology	Diagnosis
Unconjugated bilirubin	
Excessive production	Hemolysis
Immature enzyme systems	Jaundice of newborn
	Jaundice of prematurity
Inherited defects	Gilbert syndrome
	Crigler-Najjar syndrome
Drug effects	
Conjugated bilirubin	
Impaired intrahepatic excretion	
Hepatocellular disease	Hepatitis, cirrhosis, drugs
Intrahepatic cholestasis	Drugs, pregnancy
Congenital	Dubin-Johnson syndrome
	Rotor syndrome
Obstruction	
Extrahepatic	Calculus, stricture, neoplasm
Intrahepatic	Sclerosing cholangitis, cirrhosis, neoplasm

**FIGURE 39-4.** Interpretation of liver function tests. (CT, computed tomography; DDX, differential diagnosis.)

When cirrhosis has been established, the degree of bilirubin elevation has prognostic significance and is used as a component of the Child-Pugh and MELD scoring systems for quantifying the degree of cirrhosis.

Figure 39-4 describes a general algorithm for the interpretation of liver function tests. The algorithm first separates the tests into two categories based on the underlying pathology (pattern of elevations): obstructive (alkaline phosphatase, GGT, and bilirubin) versus hepatocellular (AST and ALT). If a hepatocellular pattern predominates, the magnitude of elevation provides diagnostic assistance. If the degree of elevation is ≥ 20 times normal, the etiology is likely a result of drugs or other toxins, ischemia, or acute viral hepatitis. Elevations < 20 times normal have a broad differential. Unfortunately, most liver enzyme abnormalities will fall into a mixed pattern, providing limited diagnostic assistance.

Albumin and Coagulation Factors

Albumin and coagulation proteins are markers of hepatic synthetic activity and are therefore used to estimate the level of functioning hepatocytes in cirrhosis. They are both used in the Child-Pugh system for liver disease and the INR is used in the MELD scoring system as a marker of coagulation. Albumin levels can be affected by a number of factors, including the patient's nutritional status, acute illnesses, which result in redistribution of albumin, and protein losses from renal and intestinal sources.

Coagulation factors I, II, V, VII, VIII, IX, X, XI, XII, and XIII are synthesized in the liver and, when circulating levels of factors I, V, VII, IX, and X are sufficiently reduced, the prothrombin time (PT) becomes prolonged. PT prolongation is related to the severity of liver disease and decreased synthetic activity in the liver. The PT is used as one of the prognostic factors found in the Child-Pugh scoring system. Likewise, the INR, which is calculated based upon the PT, is used in the MELD system.²² The PT has also been used in acute liver disease as an outcome measurement in acetaminophen overdose and acute alcoholic hepatitis.²³

Thrombocytopenia

Thrombocytopenia (generally defined as a platelet count less than 150,000) is a common feature of chronic liver disease found in 30% to 64% of cirrhotic patients. The etiology of thrombocytopenia in liver disease is multifactorial involving primarily splenomegaly caused by portal hypertension with pooling of platelets in the spleen. A decrease in thrombopoietin as a consequence of decreased

hepatic synthesis occurs, as well as an immune-mediated destruction of platelets. Additionally, bone marrow suppression may exist related to alcohol, folate deficiency, and drug therapies, and lead to thrombocytopenia associated with the cirrhotic process.²²

ENDOSCOPIC AND RADIOGRAPHIC ABNORMALITIES

The use of imaging techniques can provide useful information regarding the presence of liver disease and portal hypertension. The modality chosen is often determined by the clinical presentation. Examples include the use of ultrasound for the detection of gallstones and biliary duct abnormalities in patients presenting with acute pain and jaundice, or endoscopic retrograde cholangiopancreatography (ERCP) for patients with known choledocholithiasis. Upper endoscopy can be used to detect the presence of esophageal or gastric varices as an indicator of portal hypertension. Computed tomography is a sensitive means of detecting hepatic metastases and is used for directing liver biopsy.

LIVER BIOPSY

Liver biopsy plays a central role in the diagnosis and staging of liver disease. However, for the diagnosis of cirrhosis, percutaneous liver biopsy has a significant false-negative rate because of the presence of regenerating nodules within the liver.

TREATMENT

Cirrhosis

■ GENERAL APPROACHES TO TREATMENT

The clinical manifestations of cirrhosis are protean and it is difficult to provide overall management guidelines. General approaches to therapy should include:

1. Identifying and eliminating, where possible, the causes of cirrhosis (e.g., alcohol abuse).
2. Assessing the risk for variceal bleeding and beginning pharmacologic prophylaxis when indicated. Reserve prophylactic endoscopic therapy for patients with contraindications or intolerance to β -adrenergic blockers. Endoscopic therapy is also appropriate for patients suffering acute bleeding episodes. Variceal obliteration with endoscopic techniques is the recommended treatment of choice in patients with acute bleeding.
3. Evaluating the patient for clinical signs of ascites and managing with pharmacologic therapy (e.g., diuretics and paracentesis). Careful monitoring for spontaneous bacterial peritonitis should be used in patients with ascites who undergo acute deterioration.
4. Monitoring for hepatic encephalopathy, which is a common complication of cirrhosis that requires clinical vigilance and treatment with dietary restriction, elimination of central nervous system depressants, and therapy to lower ammonia levels.
5. Monitoring frequently for signs of hepatorenal syndrome, pulmonary insufficiency, and endocrine dysfunction is necessary.

■ DESIRED OUTCOMES

The desired therapeutic outcomes can be viewed in two categories: *resolution of acute complications*, such as tamponade of bleeding and resolution of hemodynamic instability for an episode of acute variceal hemorrhage; and *prevention of complications*, through lowering of portal pressure with medical therapy using β -adrenergic blocker therapy, or supporting abstinence from alcohol. Treatment

end points and desired therapeutic outcomes are presented for each of the recommended therapies discussed.

■ PORTAL HYPERTENSION AND VARICEAL BLEEDING

Portal hypertension is characterized by an increased gradient between the portal venous and central venous pressures which leads to esophageal and gastric varices. Once the gradient increases above 12 mm Hg, variceal bleeding can occur causing a potentially life-threatening complication of cirrhosis.¹¹ Mortality from the first incidence of variceal bleeding is approximately 50%.²⁴ In one study, varices arose in 5% of cirrhotic patients within 1 year and in 28% within 3 years. The 2-year risk of variceal bleeding was 12% and the 30-day mortality of variceal bleeding ranged from 20% to 29%. Progression was predicted by the Child-Pugh scoring system.²⁵

■ MANAGEMENT OF PORTAL HYPERTENSION AND VARICEAL BLEEDING

The management of varices involves three strategies: (a) primary prophylaxis (prevention of the first bleeding episode); (b) treatment of acute variceal hemorrhage; and (c) secondary prophylaxis, prevention of rebleeding in patients who have previously bled.⁸

Primary Prophylaxis

β -Adrenergic Blockade The mainstay of primary prophylaxis is the use of nonselective β -adrenergic blocking agents such as propranolol or nadolol.¹¹ These agents reduce portal pressure by reducing portal venous inflow via two mechanisms: a decrease in cardiac output through β_1 -adrenergic blockade and a decrease in splanchnic blood flow through β_2 -adrenergic blockade.²⁶

Meta-analysis of 12 trials assessing the effectiveness of the β -adrenergic blockers propranolol and nadolol demonstrated the effectiveness of these agents in the prevention of bleeding over a median follow up of 2 years and a trend toward a reduction in mortality. The average reduction in the incidence of initial bleeding achieved by nonselective β -adrenergic blockade is approximately 25%. Benefit was proven irrespective of variceal size or the presence of ascites.²⁷ Nadolol reduces the rate of growth of small esophageal varices in patients with cirrhosis.²⁸ However, β -adrenergic blocker therapy does not prevent the formation of first varices and prophylactic therapy is not recommended until an assessment of esophageal varices is made.^{7,26} Once started, β -adrenergic blocker therapy should be continued for life unless it is not tolerated.²⁹

Treatment Recommendations: Variceal Bleeding—Primary Prophylaxis

② All patients with cirrhosis should be screened for varices upon diagnosis and all patients found to have varices, regardless of variceal size, should receive prophylaxis therapy with a ③ nonselective β -adrenergic blocker.⁷ Initiate therapy with oral propranolol 10 mg three times daily or nadolol 20 mg once daily and titrate to a reduction in the resting heart rate of 20% to 25%, an absolute heart rate of 55 to 60 beats/min, or the development of adverse effects. Patients with contraindications or intolerance to β -adrenergic blockers should be considered for alternative prophylactic therapy.³⁰ Endoscopic band ligation (EBL) is superior to both β -adrenergic blockers and nitrates for preventing first bleeding.^{31–36} Because EBL does not improve survival and long-term benefits are still uncertain, use of EBL for primary prophylaxis should be reserved for patients with contraindications or intolerance to β -adrenergic blockers.⁷ Nitrates are no longer recommended as alternative therapy for primary prophylaxis against variceal bleeding in patients with intolerance to β -adrenergic blockers.⁷ Additionally, there is insufficient evidence to recommend

use of nitrates in addition to β -adrenergic blockers in an attempt to further lower portal pressure.^{7,37} At this time, there is also insufficient evidence to support the use of other agents which decrease hepatic resistance and blood flow such as carvedilol, prazosin, irbesartan, or losartan in the management of portal hypertension.⁸ Nonselective β -adrenergic blocker therapy remains the mainstay of therapy in portal hypertension patients with known varices to avoid first variceal bleeding.

■ ACUTE VARICEAL HEMORRHAGE

Variceal hemorrhage typically presents with hematemesis or melena. Important risk factors include active alcohol abuse, use of nonsteroidal antiinflammatory agents or aspirin, or previous variceal hemorrhage.³⁰ It is important to note, however, that variceal bleeding secondary to portal hypertension can occur in patients without signs of liver disease; for example, in patients with portal vein thrombosis. The initial assessment should determine the severity of the bleeding, severity of other organ dysfunction, and the severity of the liver disease.³⁰

Management of Acute Variceal Hemorrhage

Initial treatment goals include (a) adequate fluid resuscitation; (b) correction of coagulopathy and thrombocytopenia; (c) control of bleeding; (d) prevention of rebleeding; and (e) preservation of liver function. Prompt stabilization and aggressive fluid resuscitation of patients with active bleeding is followed by endoscopic examination. General resuscitation measures should be applied in the initial management of variceal hemorrhage. Airway management is critical in patients with variceal hemorrhage because of depressed reflexes and/or combative behavior associated with drug and alcohol use. The endoscopic approach to bleeding also requires a quiet and cooperative patient, and elective intubation for airway control and adequate sedation is often necessary. Clinical practice guidelines approved by the American College of Gastroenterology recommend esophagogas-

troduodenoscopy (EGD) employing endoscopic injection sclerotherapy (EIS) or endoscopic band ligation (EBL) of varices as the primary diagnostic and treatment strategy for upper GI tract hemorrhage secondary to portal hypertension and varices.³⁸

Fluid resuscitation involves colloids initially and subsequent blood products after blood bank matching procedures are completed. Packed red blood cells, fresh-frozen plasma, and platelets may be employed both as volume expanders and corrective therapy for underlying clotting abnormalities. Vasoactive drug therapy (somatostatin, octreotide, or terlipressin) to stop or slow bleeding is routinely used early in patient management to allow stabilization of the patient and to permit endoscopy to proceed under more favorable conditions. Antibiotic therapy to prevent sepsis should also be implemented early, especially for patients with signs of infection or ascites. Figure 39-5 presents an algorithm for the management of variceal hemorrhage.

Drug Therapy

Drugs employed to manage acute variceal bleeding include octreotide or somatostatin, vasopressin, and terlipressin (triglycyl-lysine vasopressin). These agents work as splanchnic vasoconstrictors thus decreasing portal blood flow and pressure.^{39,40}

Somatostatin and Octreotide Somatostatin is a naturally occurring 14-amino-acid peptide with a half-life of 1 minute, necessitating continuous intravenous infusion; octreotide is its more potent synthetic octapeptide analog with a half-life of 10 to 22 minutes, which can be dosed via intravenous infusion or subcutaneous injection. Somatostatin and octreotide decrease splanchnic arterial blood flow with a subsequent decrease in portal inflow through inhibition of vasodilatory gastrointestinal peptides including glucagon, vasoactive intestinal peptide, calcitonin gene-related peptide, and substance P. Somatostatin and octreotide are associated with few side effects.⁴¹ Unlike vasopressin, systemic vasoconstriction and elevations in blood

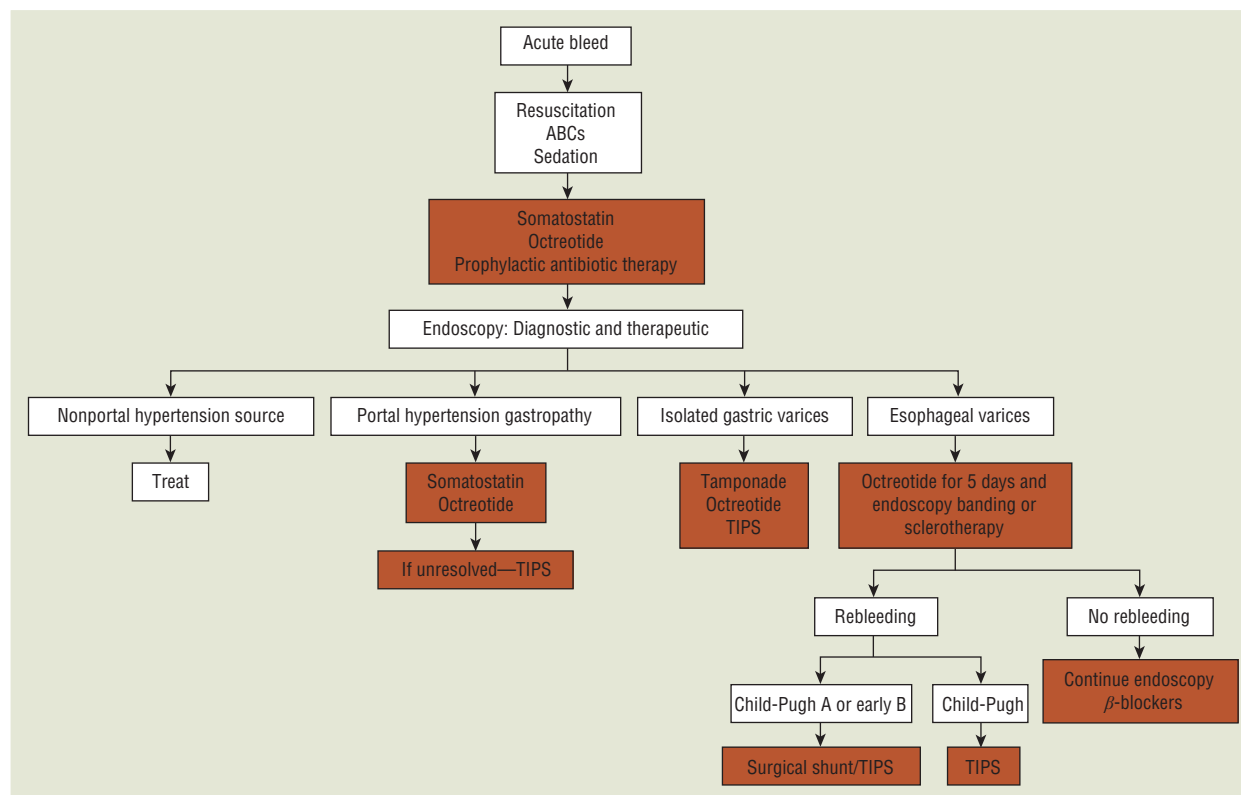

FIGURE 39-5. Management of acute variceal hemorrhage. (TIPS, transjugular intrahepatic portosystemic shunt.)

pressure are not seen because the vasoconstriction that occurs with somatostatin and octreotide is selective for the mesenteric circulation. Clinical trial data with somatostatin and octreotide are somewhat conflicting. For somatostatin, meta-analysis of clinical trials has been performed for studies comparing the drug with both placebo and vasopressin. Somatostatin controlled bleeding better than vasopressin, and had a superior side effect profile, but, oddly, was not found to control bleeding better when trials comparing the drug to placebo were analyzed.^{42,43} A meta-analysis of 13 studies comparing octreotide with terlipressin, vasopressin, or placebo found improved control of bleeding with octreotide over each of the other three therapeutic options. Efficacy was similar to sclerotherapy with fewer side effects than terlipressin or vasopressin.⁴⁴

Vasopressin (also known as antidiuretic hormone) is a potent, nonselective vasoconstrictor that has been recommended for many years for the management of acute variceal bleeding. Vasopressin reduces portal pressure by causing splanchnic vasoconstriction, which reduces splanchnic blood flow. Unfortunately, the vasoconstrictive effects of vasopressin are nonselective—the vasoconstriction produced is not restricted to the splanchnic vascular bed. Potent systemic vasoconstriction occurs in the coronary and mesenteric circulation as well, resulting in hypertension, severe headaches, coronary ischemia, myocardial infarction, and arrhythmias. A meta-analysis of 15 randomized controlled clinical trials of vasopressin for variceal hemorrhage demonstrated that vasopressin was significantly more effective than no treatment; however, control of hemorrhage was achieved in only 50% of the bleeding episodes.⁴² Adverse effects were reported in 45% of patients, and vasopressin was discontinued in 25% of patients secondary to adverse effects. To minimize adverse effects associated with the peripheral vasoconstriction secondary to vasopressin, and to further lower portal pressure, the combination of vasopressin and intravenous nitroglycerin has been evaluated.⁹ The combination trended toward improved control of hemorrhage with reduced side effects when compared to vasopressin alone. However, with the recent addition of safer and equally effective treatment alternatives, vasopressin, alone or combined with nitroglycerin, can no longer be recommended as first-line therapy for the management of variceal hemorrhage.³⁰

Terlipressin (Glypressin), a triglycyl-lysine vasopressin, is a synthetic prodrug of vasopressin with intrinsic vasoconstrictor activity that was developed in an attempt to provide an analog of vasopressin with lower toxicity. It is the preferred drug in Europe for acute variceal bleeding, is the only drug shown to reduce mortality, but is not currently available in the United States.³⁰

The glycyl residues are enzymatically cleaved *in vivo*, resulting in the slow conversion into lysine vasopressin. This process results in the availability of lysine vasopressin with a longer half-life, permitting intermittent intravenous dosing every 4 hours.³⁰ Terlipressin produces a marked and sustained reduction in portal pressure, effectively controls variceal bleeding, and causes few side effects even among patients with initial treatment failure with standard somatostatin therapy.^{45,46} Its prolonged biologic effect allows intravenous administration as an intermittent infusion every 4 hours, whereas somatostatin requires administration as a continuous intravenous infusion.⁴⁷ Terlipressin is better tolerated and equally effective as compared to sclerotherapy.⁴⁵ Cirrhotic patients with active bleeding are at high risk of infection and sepsis secondary to aspiration, the placement of multiple intravascular access devices, sclerotherapy, translocation, and defects in humoral and cellular immunity.³⁰ Prophylactic antibiotic therapy to reduce the risk of sepsis during episodes of bleeding is reported to decrease the incidence of rebleeding and to increase short-term survival.⁴⁸ Prophylactic antibiotic therapy should be instituted upon admission for variceal bleeding.⁷ All patients with variceal hemorrhage should be screened for infection and pan cultured. Patients should be evaluated at admission and

observed throughout therapy for signs and symptoms of spontaneous bacterial peritonitis.⁴⁹

Endoscopic Interventions: Sclerotherapy and Band Ligation

4 The American College of Gastroenterology published clinical practice guidelines in 1997 recommending EGD employing EIS or EBL of varices as the primary diagnostic and treatment strategy for upper GI tract hemorrhage secondary to portal hypertension and varices.³⁸ Since that time, the Baveno IV Consensus Report was published stating that EBL is the recommended form of endoscopic therapy for acute variceal bleeding, although EIS may be employed if ligation is technically difficult.⁷ EIS involves injection of 1 to 4 mL of a sclerosing agent into the lumen of the varices to tamponade blood flow. EBL consists of placement of rubber bands around the varix through a clear plastic channel attached to the end of the endoscope. After the rubber bands are in place, the varix will slough off after 48 to 72 hours. Endoscopic approaches can successfully stop bleeding in up to 95% of cases, but rebleeding may occur in 50% of cases.³⁰

Various clinical trials have been completed comparing the effectiveness of EBL, EIS, and drug therapy to control variceal bleeding. In a meta-analysis of 15 trials comparing EIS with vasoactive drug therapy, the rates of treatment failure and mortality were found to be similar between treatment strategies, while EIS was related to significantly more adverse effects as compared to somatostatin.⁵⁰ In a trial comparing EBL and somatostatin, EBL was found superior at controlling bleeding and adverse effects were similar.⁵¹ A meta-analysis of 13 randomized controlled trials comparing EBL, EIS, and vasoactive drug therapy found EBL to be the most effective treatment option with EIS and drug therapy being equally effective, but significantly less effective than EBL.⁵² Endoscopic injection of the tissue adhesive *n*-butyl 2-cyanoacrylate has been found to control active bleeding as well as EBL, and was associated with a lower rate of rebleeding in one trial.⁵³

Interventional and Surgical Treatment Approaches

If standard therapy fails to control bleeding (after two failed endoscopic procedures, further attempts are unlikely to be of benefit) a salvage procedure, such as balloon tamponade, transjugular intrahepatic portosystemic shunting (TIPS), or surgical shunting is necessary. Sengstaken-Blakemore tubes are balloon devices designed to tamponade gastric and esophageal varices that can be effective in 70% to 90% of cases of variceal bleeding.³⁰ However, these devices have a 10% to 30% complication rate and will be ineffective if the bleeding source is nonvariceal, a situation which occurs in 10% to 50% of patients with portal hypertension.³⁰ Balloon tamponade should be reserved as a temporizing measure until a TIPS procedure or surgical shunt can be performed.⁴⁹

In patients with acute variceal bleeding refractory to pharmacologic or endoscopic therapy, a decrease in portal pressure through use of the TIPS procedure is effective in controlling bleeding and preventing rebleeding.⁵⁴ The TIPS procedure involves the placement of one or more stents between the hepatic vein and the portal vein (Fig. 39–6). This procedure is widely used because it provides an effective decompressive shunt without laparotomy, and can be employed regardless of Child-Pugh score. Survival rates with TIPS in patients refractory to endoscopic treatment are comparable to rates achieved with portacaval shunts.³⁰ Patients undergoing TIPS experience a 30% incidence of encephalopathy, and approximately 50% of shunts malfunction.⁴⁹

Various surgical shunts have been developed and are effective for the prevention of recurrent variceal hemorrhage in patients refractory to β -adrenergic blockade and endoscopy.⁴⁹

FIGURE 39-6. Transjugular intrahepatic portosystemic shunt (TIPS).

Treatment Recommendations: Variceal Hemorrhage

Patients require prompt resuscitation with colloids and blood products to correct intravascular losses and to reverse existing coagulopathies. **4** Drug therapy with octreotide or somatostatin should be initiated early to control bleeding and facilitate diagnostic and therapeutic endoscopy. Based on availability, octreotide is preferred. Therapy is initiated with an IV bolus of 50 to 100 mcg and is followed by a continuous infusion of 25 mcg/h, up to a maximum rate of 50 mcg/h. Monitor patients for hypo- or hyperglycemia, especially patients with diabetes, and assess for cardiac conduction abnormalities. Vasopressin is no longer recommended for control of variceal bleeding. Endoscopy is recommended in any patient with upper gastrointestinal bleeding caused by ruptured varices. EBL is the recommended form of endoscopic therapy but EIS may also be employed and an additional endoscopic therapy option is injection of the tissue adhesive *n*-butyl 2-cyanoacrylate.⁷ Antibiotic prophylaxis is recommended if ascites is present and EIS is planned. Appropriate choices include a third-generation cephalosporin (e.g., ceftazidime or ceftriaxone), a penicillin/ β -lactamase inhibitor combination (e.g., piperacillin-tazobactam), or a fluoroquinolone (e.g., ofloxacin). Surgical shunts and TIPS are employed as salvage therapy in patients who have failed repeated endoscopy and vasoactive drug therapy.

Secondary Prophylaxis: Prevention of Rebleeding Because the risk of rebleeding after initial control of variceal hemorrhage can approach 80%, and rebleeding significantly increases the risk of death, it is inappropriate to simply observe patients for evidence of further bleeding. Traditionally, pharmacologic therapy using β -adrenergic blockers was recommended as the initial approach for prevention of rebleeding. Combination therapy with β -adrenergic blockers and chronic EBL to eradicate varices has been recognized as the likely best treatment option for secondary prophylaxis of variceal bleeding.⁷ Alternatives for the secondary prevention of rebleeding include surgical or interventional shunting.

Drug Therapy. Drug therapy of variceal hemorrhage is less expensive, offers fewer serious complications, and is usually preferred by patients. In patients without contraindications, β -adrenergic blocking agents should be the initial step in secondary prophylaxis, along with EBL.^{7,30} A meta-analysis of 11 randomized controlled clinical trials demonstrated a significant 21% reduction in rebleeding with β -blockers as compared to untreated controls, and a 5.4% improvement in the 2-year overall survival rate.⁵⁵ Secondary prophylaxis with β -adrenergic blockade therapy also resulted in a significant 7.4% reduction in death as a consequence of rebleeding. Propranolol was used in 10 trials; nadolol was used in one trial. Patients treated with β -adrenergic blocking agents experienced significantly more adverse

events, 22% versus 9% compared to untreated controls,⁵⁵ with 5.7% requiring discontinuation of β -adrenergic blockade therapy.

When considering the benefits associated with β -adrenergic blockers, it is important to appreciate that at least 30% of cirrhotic patients will not achieve a reduction in portal pressures sufficient to prevent bleeding even with adequate β -adrenergic blockade.³¹ Use of a long-acting β -blocker (such as nadolol) is usually recommended to improve compliance, and gradual, individualized dose escalation may help to minimize side effects. Ideally, portal pressure monitoring can help to assess the response to β -adrenergic blocker therapy and identify nonresponders earlier in the treatment course. A decrease in hepatic venous pressure gradient (HVPG) to <12 mm Hg or a reduction of more than 20% from baseline are considered therapeutic targets.⁸

CLINICAL CONTROVERSY

The procedure for measuring portal pressures is invasive, expensive, and not available in most facilities. Additionally, the cost-effectiveness of this approach (baseline and posttherapy) has not been compared with simply monitoring heart rate reduction with β -blockers.⁵⁶ However, for patients who fail to achieve sufficient reductions in portal pressure with β -blocker therapy alone, combination therapy with nitrates may more effectively lower portal pressure potentially reducing bleeding rates.⁵⁷ Controversy currently surrounds whether or not routine HVPG monitoring should be employed in secondary prophylaxis patients so as to better identify those with insufficient portal pressure lowering on standard β -adrenergic blocker therapy who may potentially benefit from the addition of nitrate therapy.

Comparisons of β -adrenergic blocker therapy alone with EIS suggest that less variceal rebleeding is seen with EIS, but this benefit is offset by an increase in complications.⁵⁸ However, β -adrenergic blocker therapy in combination with nitrates is more effective than EIS at lower risk of rebleeding with fewer side effects.⁵⁹ Several studies have been conducted comparing EIS with EBL at preventing rebleeding. EBL is safer and more effective at decreasing the rate of recurrent bleeding. EBL requires fewer sessions to obliterate varices and improves survival as compared to EIS.^{60–62} Combined drug therapy with nadolol plus isosorbide mononitrate was more effective than EBL at preventing rebleeding than EBL with a lower rate of major complications.⁵⁷ More studies are required to make combination therapy with a β -adrenergic blocker and a nitrate the definitive choice over EBL for prevention of rebleeding. Current guidelines suggest that a combination of drug therapy and EBL is likely the best therapeutic choice for secondary prophylaxis at this time.

Shunting. When drug therapy and endoscopy fail, alternatives include TIPS placement or shunt surgery. Regular documentation of patency and the requirement of repeat procedures make it an unsuitable long-term solution. In patients with well-compensated hepatic function (Child-Pugh grade A or B) surgical shunting is an excellent option.

Treatment Recommendations: Secondary Prophylaxis The preferred initial approach to secondary prophylaxis is currently unsettled with both pharmacotherapy and interventional procedures being accepted means. Endoscopic therapy using either EIS or EBL and pharmacologic therapy are both effective in reducing the risk of rebleeding. As a consequence of decreased complications, bleeding, and possibly mortality, EBL has emerged as the endoscopic treatment of choice.^{60–62} **4** Either EBL alone or the combination of EBL with pharmacologic therapy can be considered appropriate initial therapy. Pharmacologic therapy should be initiated with a nonselective β -blocker such as propranolol 20 mg three times a day, or nadolol at a dose of 20

TABLE 39-5 Evidence-Based Table of Selected Treatment Recommendations: Variceal Bleeding in Portal Hypertension

Recommendation	Grade
Prevention of variceal bleeding	
Nonselective β -blockers should be initiated in patients with medium or large esophageal varices	1A
EBL should be offered to patients who have contraindications or intolerance to nonselective β -blockers	5D
Treatment of variceal bleeding	
Antibiotic prophylaxis should be instituted on admission	1A
Vasoactive drugs should be started as soon as possible, prior to endoscopy, and maintained for 2–5 days	1A
EBL is the recommended form of endoscopic therapy for acute esophageal variceal bleeding and should be used in conjunction with vasoactive drug therapy	1A
Secondary prophylaxis of variceal bleeding	
Nonselective β -blockers, EBL, or both should be used for prevention of recurrent variceal bleeding	1A

EBL, endoscopic band ligation.

Recommendation Grading: Level of Evidence 1 = highest; 5 = lowest and Grade of Recommendation: 1 = strongest; D = weakest.

Data from DeFranchis R. *Updating consensus in portal hypertension. Report of the Baveno III consensus workshop on definitions, methodology and therapeutic strategies in portal hypertension. J Hepatol* 2000;33:846–852.

to 40 mg once daily, and titrated weekly to achieve a goal heart rate of 55 to 60 beats/min or a heart rate that is 25% lower than the baseline heart rate. Assessment of portal pressures can identify nonresponders for whom combination therapy with β -blockers and nitrates may be attempted to achieve portal pressure gradients <12 mm Hg. Monitor patients for evidence of heart failure, bronchospasm, and glucose intolerance, particularly hypoglycemia in patients with insulin-dependent diabetes. Table 39–5 summarizes the evidence-based treatment recommendations regarding portal hypertension and variceal bleeding.

■ ASCITES AND SPONTANEOUS BACTERIAL PERITONITIS

Patients with cirrhosis fail to maintain normal extracellular fluid volumes secondary to abnormal sodium and fluid retention and an impaired capacity to eliminate water.⁹ The classic physical examination findings of ascites are a distended abdomen with a fluid thrill or shifting dullness. The development of ascites in patients with cirrhosis is an indication of advanced liver disease and is a poor prognostic sign. The principal therapeutic goal for patients with ascites is to improve the patient's sense of well-being and quality of life by minimizing respiratory difficulties, loss of appetite, and discomfort from abdominal distension or leg swelling. Treatment of ascites is expected to have little effect on survival, however.⁶³ Pleural effusions are common, and in some cases can be the primary manifestation of the fluid retention. Workup includes a history and physical examination, laboratory tests to assess liver function, abdominal ultrasound to rule out hepatocellular carcinoma, endoscopy to evaluate esophageal and gastric varices, abdominal paracentesis with analysis of ascitic fluid, and a complete evaluation of circulatory and renal function. Treatment of ascites has risks. Depending on the treatment approach and the goals selected, significant adverse reactions can occur, including electrolyte disturbances, acid–base abnormalities, hepatic encephalopathy, hypovolemia, and renal insufficiency.

Spontaneous bacterial peritonitis (SBP), infection of preexisting ascitic fluid, in the absence of any evidence of a primary intraabdominal source of infection, is a common complication in patients with ascites, developing in 10% to 25% of patients followed prospectively for at least 1 year.⁹ The pathogenesis of SBP is unknown, but presumably results from altered gut permeability (cirrhosis permits enteric organisms direct access to the bloodstream via the

portosystemic collaterals), suppression of the reticuloendothelial system, and bacterial overgrowth of the ascitic fluid. Ascitic fluid offers a favorable growth medium as a result of leukocyte dysfunction and decreased ascitic fluid defenses as a result of a decreased albumin content.⁶⁴ Consequently, most episodes of SBP are caused by gram-negative Enterobacteriaceae, with *Escherichia coli* the most commonly isolated. The clinical presentation of SBP can vary from patients who present with all of the signs and symptoms of peritonitis, including fever, leukocytosis, abdominal pain, hypoactive or absent bowel sounds, and rebound tenderness, to those patients who have no signs or symptoms at all. For this reason, a diagnostic paracentesis with analysis of ascitic fluid should be performed in all patients admitted with ascites and in patients with cirrhosis who suddenly deteriorate.^{5,9} Spontaneous bacterial peritonitis is diagnosed when ascitic fluid cell counts show an absolute polymorphonuclear (PMN) leukocyte count of ≥ 250 cells/mm³.⁶⁴

Management of Ascites and Spontaneous Bacterial Peritonitis

The following treatment guidelines for the management of adult patients with ascites and spontaneous bacterial peritonitis were developed and approved by the Practice Guidelines Committee of the American Association for the Study of Liver Diseases (AASLD).⁵

Ascites In adult patients with new-onset ascites as determined by physical examination or radiographic studies, abdominal paracentesis should be performed and ascitic fluid analysis should include a cell count with differential and a serum-ascites albumin gradient (SAG). If infection is suspected, ascitic fluid cultures should be obtained at the time of the paracentesis. The SAG can accurately determine whether ascites is a result of portal hypertension or another process. If the SAG is >1.1 g/dL, portal hypertension is present with 97% accuracy.⁵ If the SAG is <1.1 g/dL, with similar certainty, the patient does not have portal hypertension. This is important because patients without portal hypertension will not respond to salt restriction and diuretics. The treatment of ascites secondary to portal hypertension is relatively straightforward and includes abstinence from alcohol, sodium restriction, and diuretics. This strategy is effective in approximately 90% of patients. Fifteen percent of patients will respond to dietary sodium restriction alone, and an additional 75% of patients will respond to the addition of diuretics.⁶⁵

1 Abstinence from alcohol is an essential element of the overall treatment strategy. Abstinence from alcohol can result in improvement of the reversible component of alcoholic liver disease and normalize portal pressures in some patients.⁵ Even in those patients with cirrhosis from another cause (e.g., autoimmune hepatitis) abstinence from alcohol can reverse alcohol-related effects and result in substantial improvement of the underlying liver disease. Patients with cirrhosis not caused by alcohol have less reversible liver disease, and by the time ascites is present, given the poor prognosis, these patients may be best managed with liver transplantation rather than protracted medical therapy.⁵

Beyond avoidance of alcohol, the primary treatment of ascites caused by portal hypertension and cirrhosis is salt restriction and oral diuretic therapy.⁵ Fluid loss and weight change depend directly on sodium balance in these patients. To monitor them appropriately, evaluation of urinary sodium excretion, using a 24-hour urine collection, is recommended.⁵ However, severe hyponatremia, serum sodium <120 mEq/L, does warrant fluid restriction; rapid correction of asymptomatic hyponatremia (patients with cirrhosis usually are not symptomatic until their serum sodium concentrations are <110 mEq/L) is not recommended.

Diuretic Therapy 5 The AASLD practice guidelines recommend that diuretic therapy be initiated with the combination of spirono-

lactone and furosemide. At one time, spironolactone was commonly recommended for initial therapy as a single agent. However, because of the likelihood for development of drug-induced hyperkalemia with spironolactone when used as monotherapy, the drug is now only recommended for use as a lone diuretic agent in patients with minimal fluid overload.⁵ If tense ascites is present, paracentesis should be performed prior to institution of diuretic therapy and salt restriction.⁵ For patients who respond to diuretic therapy, this approach is preferred over the use of serial paracenteses.⁵ In patients with refractory ascites, serial paracenteses may be employed. Albumin infusion postparacentesis is controversial, but reasonable for extraction volumes exceeding 5 L.⁵ Laboratory tests for renal function and electrolytes need to be monitored during therapy. Liver transplantation should be considered in patients with refractory ascites. For patients who are not transplant candidates and who fail repeated paracentesis because of loculated ascites, TIPS or peritoneal venous shunts may be considered. Both of these procedures have significant complication rates and are not recommended for the routine treatment of ascites.⁵

Spontaneous Bacterial Peritonitis Relatively broad-spectrum antibiotic therapy that adequately covers the three most commonly encountered pathogens (*E. coli*, *Klebsiella pneumoniae*, and *Streptococcus pneumoniae*) is warranted in patients with documented or suspected SBP.⁵ Delaying antibiotic therapy while awaiting evidence of a positive ascitic fluid culture is not recommended and can result in overwhelming infection and death.⁵ In some patients, signs and symptoms of infection are present such as fever, abdominal pain, and encephalopathy at the bacterascites stage (i.e., signs and symptoms are present before the PMN count in the ascitic fluid is elevated). In these patients, signs and symptoms of infection justify empiric antibiotic therapy until culture results are known, regardless of the PMN count in the ascitic fluid.⁵

Cefotaxime, or a similar third-generation cephalosporin, is considered the drug of choice for SBP.⁵ Cefotaxime is more effective than aztreonam or the combination of ampicillin and tobramycin.⁹ A 5-day course of antibiotic therapy was as efficacious as 10 days of therapy in a randomized trial involving 100 patients with SBP.⁶⁶ Fluoroquinolone antibiotics provide good activity against the usual pathogens encountered in SBP, excellent oral bioavailability, and high penetration into ascitic fluid. Ofloxacin 400 mg every 12 hours administered orally is equivalent to intravenous cefotaxime for treatment of SBP in patients without vomiting, shock, significant hepatic encephalopathy, or serum creatinine over 3 mg/dL.⁶⁷ For many patients, oral ofloxacin therapy offers a simple, cost-effective alternative to intravenous therapy with third-generation cephalosporins.

Secondary bacterial peritonitis, ascitic fluid infection caused by a treatable intraabdominal source, can masquerade as SBP and should be considered when multiple or atypical organisms are cultured, a very high ascitic fluid PMN count is seen, or in patients who fail to respond to appropriate antibiotic therapy. A dramatic clinical response is typical of uncomplicated SBP once treatment is initiated. A followup paracentesis revealing a PMN count that continues to rise despite antibiotic therapy can be helpful in detecting secondary peritonitis.⁵

⑥ Antibiotic therapy for the *prevention* of SBP should be considered in all patients who are at high risk for this complication, including those who have experienced a prior episode of SBP or variceal hemorrhage, and those with low-protein ascites (<1 g/dL). Patients with gastrointestinal hemorrhage should receive short-term (7 days) norfloxacin twice daily or trimethoprim-sulfamethoxazole to prevent SBP. An intravenous quinolone can be used for patients actively bleeding.⁵ Patients who survive an episode of SBP should receive long-term prophylaxis with norfloxacin or trimethoprim-sulfamethoxazole.⁵ It may also be appropriate to provide antibiotic prophylaxis (either short-term or long-term) to those

patients with ascites and no gastrointestinal bleeding, a total ascitic protein <1 g/dL, and a serum bilirubin >2.5 mg/dL.⁵ Antibiotic prophylaxis should be limited only to patients in one of the above high-risk groups as selective intestinal decontamination does promote the growth of resistant gut flora. Additionally, prophylaxis regimens should be continued long-term only in patients who have survived an episode of SBP or possibly in those with ascites whose total ascitic protein is <1 g/dL and serum bilirubin is >2.5 mg/dL.⁵

Treatment Recommendations: Ascites and Spontaneous Bacterial Peritonitis

Adult patients admitted to the hospital with new-onset ascites should have an abdominal paracentesis performed to establish the serum-ascites albumin gradient, the ascitic fluid PMN count, and to obtain ascitic fluid cultures. Patients who drink alcohol should be strongly discouraged from further alcohol use. ⑤ Sodium restriction to 2,000 mg/day, together with spironolactone and furosemide, is the mainstay of therapy. Diuretic therapy should be initiated with single morning doses of spironolactone 100 mg and furosemide 40 mg administered orally with the goal of a 0.5-kg maximum daily weight loss. Titrate diuretic therapy using the 100-mg:40-mg ratio, to a maximum daily dose of 400 mg spironolactone and 160 mg furosemide. This combination ratio is used because it usually maintains normokalemia. Fluid restriction, unless the serum sodium is <120 mEq/L, and bedrest are not recommended. Monitor urinary sodium excretion using a 24-hour urine collection, and monitor serum potassium and renal function frequently. Avoid rapid correction of asymptomatic hyponatremia in patients with cirrhosis. If tense ascites is present, a 4- to 6-L paracentesis should be performed prior to institution of diuretic therapy and salt restriction. For patients who respond to diuretic therapy, this approach is preferred over the use of serial paracenteses. Discontinue diuretic therapy in patients who experience encephalopathy, severe hyponatremia (serum sodium <120 mEq/L) despite fluid restriction, or renal insufficiency (serum creatinine >2 mg/dL). Serial paracenteses may be considered for patients with refractory ascites with albumin infusion postparacentesis when volumes exceeding 5 L are removed.

Patients with documented SBP, positive ascitic fluid cultures, or ascitic fluid PMN count ≥ 250 cells/mm³, regardless of symptoms, should receive broad-spectrum empiric antibiotic therapy with cefotaxime 2 g every 8 hours, or a similar third-generation cephalosporin, plus albumin 1.5 g/kg within 6 hours of admission and 1 g/kg on day 3. Patients with ascitic fluid PMN counts <250 cells/mm³, but with signs and symptoms of infection (abdominal pain, tenderness, fever, encephalopathy, renal failure, acidosis, or peripheral leukocytosis), should also receive empiric antibiotic treatment with cefotaxime 2 g every 8 hours, or a similar third-generation cephalosporin. Short-term prophylaxis should be considered for the prevention of SBP in patients with low-protein ascites (<1 g/dL) and in patients with variceal hemorrhage.⁵

⑥ All patients who have survived an episode of SBP should receive long-term antibiotic prophylaxis.⁵ Table 39–6 summarizes the evidence-based treatment recommendations regarding ascites and SBP.

HEPATIC ENCEPHALOPATHY

The clinical manifestations of HE vary widely.⁶⁸ Patients with minimal HE often experience only minor motor and attentional deficits and compensate on their own without the need for therapy. Those with persistent HE who have more significant deficits that impact activities of daily living can benefit from intervention.¹²

The prevalence of HE among cirrhotics is variable but may be found in up to 70% of patients.¹³ To determine the severity of HE, a grading system that relates neurologic and neuromuscular signs can

TABLE 39-6 Evidence-Based Table of Selected Treatment Recommendations: Ascites and Spontaneous Bacterial Peritonitis

Recommendation	Grade
Ascites	
Initial therapeutic paracentesis should be performed in patients with tense ascites	II-3
Sodium restriction of 2,000 mg/day should be instituted, as well as oral diuretic therapy with spironolactone and furosemide	I
Diuretic-sensitive patients should be treated with sodium restriction and diuretics rather than serial paracentesis	III
Refractory ascites	
Serial therapeutic paracenteses may be performed	III
Postparacentesis albumin infusion of 8–10 g/L of fluid removed can be considered if more than 4–5 L are removed during paracenteses	II-2
Treatment of SBP	
If ascitic fluid PMN counts are greater than 250 cells/mm ³ , empiric antibiotic therapy should be instituted (cefotaxime 2 g every 8 hours)	I
If ascitic fluid PMN counts are less than 250 cells/mm ³ , but signs or symptoms of infection exist, empiric antibiotic therapy should be initiated while awaiting culture results	II-3
Ofloxacin 400 mg twice daily may be substituted for cefotaxime in patients without vomiting, shock, grade II or higher encephalopathy, or serum creatinine greater than 3 mg/dL	I
If ascitic fluid PMN counts are greater than 250 cells/mm ³ and clinical suspicion of SBP is present, 1.5 g/kg albumin should be infused within 6 hours of detection and 1 g/kg albumin infusion should also be given on day 3	I
Prophylaxis against SBP	
Twice-daily norfloxacin or trimethoprim-sulfamethoxazole should be used for 7 days to prevent SBP in cirrhosis patients with gastrointestinal hemorrhage; intravenous quinolone therapy may be used in active bleeding	I
Patients who survive an episode of SBP should receive long-term prophylaxis with either daily norfloxacin or trimethoprim-sulfamethoxazole	I
Short-term or long-term prophylaxis may be justified in patients with ascites whose ascitic total protein is less than 1 g/dL or whose serum bilirubin is greater than 2.5 mg/dL	I

PMN, polymorphonuclear leukocyte; SBP, spontaneous bacterial peritonitis.

Recommendation Grading: I = randomized controlled trials; II-1 = controlled trials without randomization; II-2 = cohort or case-control analytic studies; II-3 = multiple time series, dramatic uncontrolled experiments; III = opinions of authorities, descriptive epidemiology.

Data from Runyon BA. Management of adult patients with ascites due to cirrhosis. *Hepatology* 2004;39(3):841–856.

be used (Table 39–7). Presently, the primary substances thought to be involved in the development of HE are ammonia, manganese, and the γ -aminobutyric acid (GABA)–benzodiazepine receptors.^{12,68}

Management of Hepatic Encephalopathy

Episodic HE usually develops in a clinically stable cirrhotic patient as the result of an acute precipitating event.¹² Table 39–8 lists the most

commonly encountered precipitating factors and suggests general treatment alternatives.^{12,13,68} Table 39–9 describes the treatment goals for patients with HE and contrasts the differences between episodic and persistent HE. The general approach to the management of HE is to first identify and treat any precipitating factors, which often results in prompt resolution of the encephalopathy. The development of mental status changes in cirrhosis is associated with increased morbidity and mortality.¹² However, universal treatment of patients with subclinical HE is not recommended because the consequences of motor and attention deficits are considered minor, and prevention of progression to more severe HE has not been studied.¹²

Treatment approaches for episodic and persistent HE include (a) reducing ammonia blood concentrations by dietary restrictions and drug therapy aimed at inhibiting ammonia production or enhancing its removal and (b) inhibition of the GABA–benzodiazepine receptors. Additionally, treatment for persistent HE should include avoidance and prevention of precipitating factors in an effort to avoid acute decompensation.¹²

Hyperammonemia **7** Despite criticisms of the ammonia hypothesis, treatment interventions to reduce ammonia blood concentrations are beneficial in patients with HE.¹² Decreasing ammonia blood concentrations by limiting its availability and production, or by enhancing its metabolism, remains a mainstay of therapy for patients with both episodic and persistent HE.¹²

Decreasing ammonia blood concentrations can be attempted by reducing ammonia production or by decreasing the availability of ammonia in the colon. Limiting dietary protein acutely usually results in a lowering of ammonia concentrations and improvement in HE.

Guidelines for nutritional support of patients with liver disease have been published by the European Society for Parenteral and Enteral Nutrition.⁶⁹ Protein withdrawal is a cornerstone of treatment for patients during acute episodes of HE. However, prolonged restriction can lead to malnutrition and poorer prognosis among HE patients.^{12,70} Therefore, once successful reversal of HE symptoms is achieved, protein is added back to the diet initially with 0.5 to 0.6 g/kg per day and advanced by 0.25 to 0.5 g/kg per day every 3 to 5 days until either a target of 1 to 1.5 g/kg per day is reached or progression of HE occurs.⁶⁹ Vegetable-source protein may be preferable to animal-source protein because it contains fewer aromatic amino acids (phenylalanine, tryptophan, and tyrosine) and methionine which, when elevated in the serum, can worsen the symptoms of HE.^{12,69,70} Also, the higher fiber content of vegetable protein increases colonic transit time and lowers colonic pH secondary to its fermentation by colonic bacteria.^{12,69} Most patients will tolerate at least 1 g/kg per day of standard proteins without becoming encephalopathic.⁷⁰ Branched-chain amino acid formulations may provide a better tolerated source of protein in those patients with protein intolerance.¹² Bowel cleansing using cathartics or lactulose enemas (see below) results in rapid removal of ammonia substrate from the colon and may be combined with dietary intervention to help patient eliminate ammonia and tolerate dietary protein.

TABLE 39-7 Grading System for Hepatic Encephalopathies

Grade	Level of Consciousness	Personality/Intellect	Neurologic Abnormalities	Electroencephalogram Abnormalities
0	Normal	Normal	None	None
Minimal	Normal	Normal	Psychological only	None
1	Inverted sleep patterns/restless	Forgetful, mild confusion, agitation, irritable	Tremor, apraxia, incoordination, impaired handwriting	Triphasic waves
2	Lethargic, slow responses	Disorientation for time, amnesia, decreased inhibitions, inappropriate behavior	Asterix, dysarthria, ataxia, hypoactive reflexes	Triphasic waves
3	Somnolent but arousable, confused	Disorientation for place, aggressive	Asterix, hyperactive reflexes, Babinski sign, muscle rigidity	Triphasic waves
4	Coma/unarousable	None	Decerebrate	Delta activity

TABLE 39-8 Portosystemic Encephalopathy: Precipitating Factors and Therapy

Factor	Therapy Alternatives
Gastrointestinal bleeding	
Variceal	Band ligation/sclerotherapy Octreotide
Nonvariceal	Endoscopic therapy Proton pump inhibitors
Infection/sepsis	Antibiotics Paracentesis
Electrolyte abnormalities	Discontinue diuretics Fluid and electrolyte replacement
Sedative ingestion	Discontinue sedatives/tranquilizers Consider reversal (flumazenil/naloxone)
Dietary excesses	Limit daily protein Lactulose
Constipation	Cathartics Bowel cleansing/enema
Renal insufficiency	Discontinue diuretics Discontinue nonsteroidal antiinflammatory drugs, nephrotoxic antibiotics Fluid resuscitation

The use of lactulose, a nonabsorbable disaccharide (and Lactinol, which is not available in the United States), is standard therapy for both acute and chronic HE.¹² Lactulose, when administered orally, passes through the gastrointestinal tract and reaches the colon unchanged.^{12,71} For patients unable to take lactulose orally or via tube administration, it may be administered as an enema.¹² Lactulose increases osmotic pressure in the colon and also undergoes fermentation by gut flora resulting in production of organic acids which lower colonic pH. Together, these actions increase peristalsis and exert a cathartic effect.⁷¹

Acidification of the colon through lactulose administration lowers ammonia levels in the blood in several ways: (a) it supplies carbohydrate to the gut thereby decreasing amino acid breakdown; (b) it changes bacterial flora metabolism in the gut reducing protein degradation; (c) it supplies energy for the growth of the bacterial mass in the gut (nitrogen-containing compounds are used in this growth process and therefore expended); and (d) it decreases bacterial urea degradation.⁷¹ Lactulose also enhances the net movement of ammonia from the blood into the bowel.¹² More than 30 clinical trials have demonstrated the efficacy of lactulose in the management of acute HE, and more than 20 studies support its use in chronic HE.¹⁵ Clinical improvement is noted in approximately 86% of patients with acute HE, and in approximately 77% of patients with chronic HE.

Inhibiting the activity of urease-producing bacteria by using neomycin or metronidazole can decrease production of ammonia.^{72,73} Neomycin at doses of 3 to 6 g daily can be given for 1 to 2 weeks during an acute episode of HE.¹² For persistent HE, a dose of 1 to 2 g daily could be used with periodic renal and annual auditory monitor-

ing.¹² Despite poor absorption, chronic use of neomycin can lead to irreversible ototoxicity, nephrotoxicity, and the possibility of staphylococcal superinfection. As such, neomycin should not be considered first-line therapy for HE. In patients with an inadequate response to lactulose alone, combination therapy with neomycin may be tried.¹² Metronidazole 250 mg twice daily may also produce a favorable clinical response in HE.¹² However, neurotoxicity caused by impaired hepatic clearance of the drug may be problematic.¹²

It has been speculated that ammonia generated by *Helicobacter pylori* in the stomach is associated with precipitating or worsening HE in patients with cirrhosis.⁷⁴ However, a prospective clinical trial showed no significant improvement in mental status or serum ammonia levels in patients with HE who underwent *H. pylori* eradication.⁷⁵ Consequently, routine eradication of *H. pylori* is not recommended.¹²

Enhancing ammonia removal by stimulating its detoxification by supporting alternative metabolic pathways can reduce blood ammonia concentrations. L-Ornithine L-aspartate stimulates residual hepatic urea cycle activity and promotes peripheral glutamine synthesis.⁷⁶ The effectiveness of intravenous L-ornithine L-aspartate at reducing blood ammonia and improving the clinical symptoms of hepatic encephalopathy in cirrhosis patients has been studied and proven to be effective in patients with grade 1 and grade 2 HE with clinical response rates similar to those of lactulose.⁷⁷ Oral L-ornithine L-aspartate is effective at reducing blood ammonia and improving clinical symptoms in patients with grade 2 HE.⁷⁸

Zinc is a cofactor of urea cycle enzymes and can be deficient in cirrhotic patients, especially in cases of malnourishment. Both supportive and nonsupportive studies evaluating the efficacy of zinc replacement at decreasing ammonia levels and improving symptoms of HE have been published.¹² In a controlled trial in cirrhotic patients with mild HE, the administration of zinc sulfate 600 mg/day for 3 months resulted in increased urea formation and lower ammonia levels, along with improvement in psychological test scores.⁷⁹ Zinc supplementation is recommended for long-term management in patients with cirrhosis who are zinc deficient.¹²

Inhibition of GABA–Benzodiazepine Receptors The GABA-receptor complex is the primary inhibitory neural network within the central nervous system. An enhanced GABAergic tone and an increased amount of endogenous benzodiazepines have been postulated to contribute to HE.¹² Based on evidence of an increase in benzodiazepine receptor ligands in patients with hepatic encephalopathy, flumazenil has been evaluated for the treatment of HE. Among five prospective, placebo-controlled trials, three reported benefit with flumazenil, whereas two found no difference when compared to placebo. With dosages of 0.2 to 15 mg IV, response rates were variable, ranging from 17% to 78%; improvements, however, were often transient.⁸⁰ Flumazenil, which is only available in an intravenous dosage form, may be considered for short-term therapy in refractory patients with suspected benzodiazepine intake, but cannot be recommended for routine clinical use.

Treatment Recommendations: Hepatic Encephalopathy

Treatment recommendations depend on the type of HE being managed, episodic HE, persistent HE, or minimal HE. The general approach to the management of HE is to first identify patients with acute episodic HE and then to provide aggressive management of any precipitating events (see Table 39–8). When the precipitating event has been discovered and appropriate therapy initiated, steps to rapidly reverse the encephalopathy should be implemented. Remember that the altered sensorium associated with HE itself is associated with increased morbidity and mortality.

⑦ The mainstay of therapy of HE involves measures to lower blood ammonia concentrations, and includes diet therapy, lactu-

TABLE 39-9 Treatment Goals: Episodic and Persistent Hepatic Encephalopathy (HE)

Episodic HE	Persistent HE
Control precipitating factor	Reverse encephalopathy
Reverse encephalopathy	Avoid recurrence
Hospital/inpatient therapy	Home/outpatient therapy
Maintain fluid and hemodynamic support	Manage persistent neuropsychiatric abnormalities
	Manage chronic liver disease
Expect normal mentation after recovery	High prevalence of abnormal mentation after recovery

lose, and antibiotics, alone or in combination with lactulose. Other adjunctive therapies include zinc replacement in patients with zinc deficiency.

In patients with episodic HE, protein is withheld or limited to 10 to 20 g/day while maintaining the total caloric intake, until the clinical situation improves. Titrate protein based on tolerance, increasing intake in increments of 10 to 20 g/day every 3 to 5 days to a total of 1 to 1.5 g/kg per day. In patients with persistent HE, restrict protein to 40 g/day. Consider the addition of dietary fiber to animal-source protein diets.

In episodic HE, lactulose is initiated at a dose of 45 mL orally every hour (or by retention enema, 300 mL lactulose syrup in 1 L water, held for 60 minutes) until catharsis begins. The dose is then decreased to 15 to 45 mL orally every 8 to 12 hours (enemas every 6 to 8 hours) and titrated to produce two to three soft, acidic stools per day. Patients are maintained on this regimen to prevent recurrence of episodic HE. Monitor electrolytes periodically, follow patients for changes in mental status, and titrate to the number of stools as above.

Antibiotic therapy with either metronidazole or neomycin is reserved for patients who have not responded to diet and lactulose therapy, where the combination may provide additive effects and improved clinical response. Zinc acetate supplementation at a dose of 220 mg twice daily is recommended for long-term management in patients with cirrhosis who are zinc deficient.

Other adjunctive therapies that may be considered for patients refractory to standard therapy include L-ornithine L-aspartate or flumazenil 0.2 mg up to 15 mg IV. Universal treatment of patients with minimal HE is not recommended; however, therapy to improve performance of daily activities, or in patients with more significant deficits, may be considered with close monitoring for adverse effects. Finally, supportive measures to manage the underlying liver failure need to be implemented.

■ SYSTEMIC COMPLICATIONS

In addition to the more common complications of chronic liver disease discussed above, a number of other complications can occur, including hepatorenal syndrome, hepatopulmonary syndrome, coagulation disorders, and endocrine dysfunction.

Hepatorenal syndrome, functional renal failure in the setting of cirrhosis in the absence of intrinsic renal disease, occurs in patients with cirrhosis as a result of intense vasoconstriction within the renal cortical vasculature. It is common and develops in approximately 40% of patients with cirrhosis and ascites within 5 years.⁸¹ The resultant reduction in blood supply to the kidneys causes avid sodium retention and oliguria. The pathophysiologic mechanism responsible for these effects is unknown, but is linked to both the increased vasoconstrictor and decreased vasodilator factors acting on the renal circulation. The three predominant factors involved in this process include the hemodynamic changes that decrease renal perfusion pressure, a stimulated renal sympathetic nervous system, and an increased synthesis of humoral and renal vasoactive mediators.⁸¹

Management of hepatorenal syndrome consists of excluding all other potential nephrotoxins, such as nonsteroidal antiinflammatory agents and aminoglycosides, and assessment for prerenal azotemia secondary to overaggressive diuretic use. Withholding diuretic therapy and administering a fluid challenge of up to 1.5 L is recommended for early diagnosis and therapy.⁸¹ Other therapies studied in the management of hepatorenal syndrome include low (subpressor)-dose dopamine, ornipressin, terlipressin, and midodrine in combination with octreotide, misoprostol, *n*-acetylcysteine, and dialysis.⁸¹ Liver transplantation, which if successful results in full recovery of renal function, remains the treatment of choice for refractory hepatorenal syndrome.

Hepatopulmonary syndrome affects somewhere between 10% and 70% of patients with cirrhosis.⁸² This abnormality is caused by alterations in lung mechanics caused by edema and tense ascites, an

abnormal ventilation-to-perfusion ratio, the presence of arterial venous shunts, and changes in the alveolar–arterial membrane.⁸² These patients present with dyspnea, and arterial oxygenation is often impaired. In the absence of intrinsic cardiopulmonary disease, cirrhotic patients with these findings should be evaluated for hepatopulmonary syndrome which is diagnosed based upon the presence of arterial hypoxemia, an increased alveolar–arterial oxygen gradient, and intrapulmonary vasodilation.⁸² Long-term management requires control of ascites (see Management of Ascites and Spontaneous Bacterial Peritonitis above), supportive therapy with supplemental oxygen, and optimizing fluid status. The prognosis for these patients is poor. Ultimately, liver transplantation offers the best chance for long-term recovery.

Coagulation disorders are common in patients with chronic liver disease. These disorders increase the risk of bleeding and tend to become more profound as the liver failure becomes more severe. Correction of the coagulopathy is essential for patients actively bleeding (see Management of Acute Variceal Hemorrhage above), but is not required for patients who present with only minor symptoms such as bruising or nose bleeds and who are not actively bleeding. The pathophysiology of the coagulopathy is complex and involves impaired synthesis of clotting factors, excessive fibrinolysis, disseminated intravascular coagulation, thrombocytopenia, and platelet dysfunction.¹⁴ Acute therapy involves platelet transfusions for thrombocytopenia, and fresh-frozen plasma for prolongation of the prothrombin time because of clotting factor deficiencies. Long-term management of cirrhotic patients with identified coagulopathies is supportive for the management of the underlying cause of cirrhosis; for example, encouraging abstinence from alcohol.

The presence of cirrhosis can produce abnormal regulation and function of multiple endocrine systems.⁸³ Most common are feminization and hypogonadism, and hypothyroidism. Cirrhosis perturbs the hypothalamic–pituitary axis, which is required for normal regulation of sex and thyroid hormones. In men with cirrhosis, testosterone levels are depressed, while estrogen levels are increased. The clinical manifestations of these changes include loss of libido, muscle wasting, and gynecomastia. These clinical findings are commonly seen and have been reported to occur in up to 60% of cirrhotic patients.⁸³ In women, feminization changes are less well studied. Alcohol use complicates and can worsen sex hormone abnormalities.

Both central and peripheral defects in thyroid secretion are noted in patients with cirrhosis. Alcohol plays a major role with direct toxic effects on the thyroid gland. Management includes thyroid hormone replacement for hypothyroidism with the usual doses (levothyroxine 50 to 100 mcg/day) and oral testosterone replacement (testosterone 200 mg three times daily) may be attempted to decrease prevalence of gynecomastia. Routine hormone replacement has not been shown to impact survival or disease progression.⁸³

■ LIVER TRANSPLANTATION

The complications seen in patients with chronic liver disease are essentially functional as a secondary effect of the circulatory and metabolic changes that accompany liver failure. Consequently, liver transplantation is the only treatment that can offer a cure for complications of end-stage cirrhosis. However, patient selection, evaluation, and pre- and postsurgical management are beyond the scope of this review.

PHARMACOKINETIC AND PHARMACODYNAMIC CHANGES IN LIVER FAILURE

Cirrhosis modulates the behavior of drugs in the body by inducing kinetic alterations in drug absorption, distribution, and clearance. Additionally, patients with cirrhosis may exhibit pharmacodynamic changes with increased sensitivity to the effects of certain drugs,

namely opiates, benzodiazepines, and nonsteroidal antiinflammatory drugs (NSAIDs). These pharmacodynamic changes are separate and distinct from the enhancement of drug effects seen in cirrhosis patients as a result of pharmacokinetic changes.⁸⁴ Hepatic drug clearance is primarily dependent upon protein binding, hepatic blood flow, and metabolic enzyme activity.⁸⁵ The pathophysiologic changes that occur in patients with cirrhosis, including reduced liver blood flow, altered microcirculatory distribution of blood flow within the liver, diminished metabolic and synthetic function, and changes in the endothelial lining of the sinusoids, can have a significant impact on each of these factors. The consequence of these changes is a reduction in intrinsic metabolic activity, a reduction in the delivery of blood to the liver that decreases clearance and prolongs half-life, and a reduction in the degree of protein binding that increases the fraction of unbound drug in the serum. Finally, patients with cirrhosis frequently accumulate large amounts of interstitial fluid resulting in substantial changes in the volume of distribution, which also prolongs drug half-life. These changes occur most commonly in combination in patients with cirrhosis and are dynamic throughout the disease course. The effect that these changes will have depends on the drug and the type of biotransformation that the drug undergoes.

Drugs with a high extraction ratio (high-extraction drugs) are dependent on blood flow for metabolism and the rate of metabolism is sensitive to changes in blood flow. Drugs with a low extraction ratio (low-extraction drugs) are dependent on intrinsic metabolic activity for metabolism and the rate of metabolism reflects changes in intrinsic clearance and protein binding.^{84,85} Furthermore, hepatic biotransformation involves two types of metabolic processes: phase I reactions and phase II reactions. Phase I reactions involve the cytochrome P450 system and include hydrolysis, oxidation, dealkylation, and reduction reactions. Phase II reactions involve conjugation of the drug with an endogenous molecule such as sulfate or an amino acid, rendering it more water soluble and enhancing its elimination. Drugs metabolized by phase I reactions, especially oxidation, tend to be significantly impaired in patients with cirrhosis, whereas drugs eliminated by conjugation are relatively unaffected.⁸⁶

The variability and complexity of the interaction between the extent and severity of liver disease and individual characteristics of the drug makes it very difficult to predict the degree of pharmacokinetic perturbation in an individual patient. Unfortunately, there are no sensitive and specific clinical or biochemical markers that allow us to quantify the extent of liver insufficiency or the degree of metabolic

activity. In addition, renal insufficiency and alterations that commonly accompany cirrhosis further complicate empiric dosing recommendations in these patients.⁸⁴ Dosing recommendations are most commonly nonspecific, with recommendations labeled for patients with mild to moderate liver impairment. Dosing information for patients with more severe liver impairment is not available. As a result, when patients with cirrhosis require therapy with drugs that undergo hepatic metabolism (e.g., benzodiazepines), monitoring response to therapy and anticipating drug accumulation and enhanced effects is essential. In the case of benzodiazepines, selection of an agent such as lorazepam, an intermediate-acting agent that is metabolized via conjugation and has no active metabolites, is easier to monitor than a drug such as diazepam, a long-acting benzodiazepine that is oxidized in the liver and has an active metabolite with a long half-life of its own. Up-to-date drug dosing recommendation information for patients with liver disease has been published.⁸⁷

PHARMACOECONOMIC CONSIDERATIONS

A number of issues related to the drug therapy and monitoring of cirrhosis have been studied over the years. Two such studies, both related to the prevention of variceal bleeding and published recently, are mentioned here. A recent analysis provides evidence that HVPG monitoring is not cost-effective for use in patients with varices and no history of variceal bleeding as compared to treatment with standard β -blocker therapy without invasive monitoring.⁸⁸ A cost-utility evaluation of secondary prophylaxis therapies concluded that patients are best served by treatment with either EBL or EBL plus medical management as compared to TIPS placement.⁸⁹ Because treatment approaches for patients with cirrhosis can range from supportive medical therapy, to repeated endoscopic procedures with serious complications, to liver transplantation, the need for application of economic analysis is obvious. Of critical importance is the question of when, in the course of chronic liver disease, are the various treatment interventions employed and should liver transplantation be attempted earlier, thereby avoiding most of the complications associated with chronic liver disease.

EVALUATION OF THERAPEUTIC OUTCOMES

Table 39–10 summarizes the management approach for patients with cirrhosis, including monitoring parameters and therapeutic out-

TABLE 39-10 Management Approach and Outcome Assessments

Complication	Treatment Approach	Monitoring Parameter	Outcome Assessment
Ascites	Diet, diuretics, paracentesis, TIPS	Daily assessment of weight	Prevent or eliminate ascites and its secondary complications
Spontaneous bacterial peritonitis	Antibiotic therapy, prophylaxis if undergoing paracentesis	Evidence of clinical deterioration (e.g., abdominal pain, fever, anorexia, malaise, fatigue)	Prevent/treat infection to decrease mortality
Variceal bleeding	Pharmacologic prophylaxis	Child-Pugh score, endoscopy, CBC	Appropriate reduction in heart rate and portal pressure
	Endoscopy, vasoactive drug therapy (octreotide), ligation or sclerotherapy, volume resuscitation, pharmacologic prophylaxis	CBC, evidence of overt bleeding	Acute: control acute bleed Chronic: variceal obliteration, reduce portal pressures
Coagulation disorders	Blood products (PPF, platelets), vitamin K	CBC, prothrombin time, platelet count	Normalize PT time, maintain/improve hemostasis
Hepatic encephalopathy	Ammonia reduction (lactulose, cathartics), elimination of drugs causing CNS depression, limit excess protein in diet	Grade of encephalopathy, EEG, psychological testing, mental status changes, concurrent drug therapy	Maintain functional capacity, prevent hospitalization for encephalopathy, decrease ammonia levels, provide adequate nutrition
Hepatorenal syndrome	Eliminate concurrent nephrotoxins (NSAIDs), decrease or discontinue diuretics, volume resuscitation, liver transplantation	Serum and urine electrolytes, concurrent drug therapy	Prevent progressive renal injury by preventing dehydration and avoiding other nephrotoxins Liver transplantation for refractory hepatorenal syndrome
Hepatopulmonary syndrome	Paracentesis, O ₂ therapy	Dyspnea, presence of ascites	Acute: relief of dyspnea and hypoxia Chronic: manage ascites as above

CBC, complete blood cell count; CNS, central nervous system; EEG, electroencephalogram; PT, prothrombin time; NSAID, nonsteroidal antiinflammatory drug; PPF, plasma protein fraction; TIPS, transjugular intrahepatic portosystemic shunt.

comes. Cirrhosis is generally a chronic progressive disease that requires aggressive medical management to prevent or delay common complications. Table 39–10 also lists monitoring criteria that need to be carefully followed in order to achieve the maximum benefit from the medical therapies employed and prevent adverse effects. A therapeutic plan including therapeutic end points for each medical and diet therapy needs to be developed and discussed with the patient.

ABBREVIATIONS

AASLD: American Association for the Study of Liver Diseases

ALT: alanine transaminase

AST: aspartate transaminase

EBL: endoscopic band ligation

EGD: esophagogastroduodenoscopy

EIS: endoscopic injection sclerotherapy

ERCP: endoscopic retrograde cholangiopancreatography

GABA: γ -aminobutyric acid

GGT: γ -glutamyl transpeptidase

HE: hepatic encephalopathy

HVPG: hepatic venous pressure gradient

MELD: Mayo End-Stage Liver Disease

NSAIDs: nonsteroidal antiinflammatory drugs

PMN: polymorphonuclear

SAG: serum-ascites albumin gradient

SBP: spontaneous bacterial peritonitis

TIPS: transjugular intrahepatic portosystemic shunt

UNOS: United Network for Organ Sharing

WILLIAM R. KIRCHAIN AND RONDALL E. ALLEN

KEY CONCEPTS

- 1 Drug-induced liver disease occurs as several different clinical presentations: idiosyncratic reactions, allergic hepatitis, toxic hepatitis, chronic active toxic hepatitis, toxic cirrhosis, and liver vascular disorders.
- 2 The mechanisms of drug-induced liver disease are diverse, representing many phases of biotransformation, and are susceptible to genetic polymorphism.
- 3 The assessment of a possible liver injury caused by drugs should include what is known in the literature, the timing involved, the clinical course, and, always, an exploration for preexisting conditions that may have encouraged the lesion's development.
- 4 Liver enzyme assays can help to determine if a particular type of liver damage is present.
- 5 Monitoring for drug-induced liver disease must be tailored to the drug and the patient's potential risk factors.

The number of drugs associated with adverse reactions involving the liver is extensive.¹ One of the more common reasons for the withdrawal of a drug from the marketplace is an elevation of serum concentrations of liver enzymes.² Its impact on the pharmaceutical industry has led regulatory agencies to withdraw drugs from the market, restrict the use of certain medications, and issue black box warnings.³ Alcohol-induced liver disease is the most common type of drug-induced liver disease. All other drugs together account for less than 10% of patients hospitalized for elevated liver enzymes.⁴ Overall, the reported incidence of drug-induced liver disease is around 1 in 10,000 to 1 in 100,000 patients.¹

In approximately 75% of these cases liver transplantation is ultimately required for patient survival.² The liver's function affects almost every other organ system in the body, but there are no specific diagnostic tests for drug-induced liver disease or a means to single out an implicated drug. Therefore it is important to know the patterns of drug-related pathology in order to assess adverse reactions when they occur. It is also important to understand how and when to monitor for these reactions.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

PATTERNS OF DRUG-INDUCED LIVER DISEASE

HEPATOCELLULAR INJURY

Hepatocellular injury is characterized by significant elevations in the aminotransferases in serum which usually precede elevations in total bilirubin levels and alkaline phosphatase levels.⁵ Most injuries occur within 1 year of initiating the offending agent. Hepatocellular injury can lead to fulminant hepatitis with a corresponding 20% survival rate with supportive care.⁶ For those patients who present with the combination of hepatocellular injury and jaundice, there is a 10% mortality rate.⁷ Acarbose, allopurinol, fluoxetine, and losartan are capable of causing hepatocellular injury.⁵

Hepatocellular injuries can be further subdivided by specific histologic patterns and clinical presentations. Centrolobular necrosis, steatohepatitis (steatonecrosis), phospholipidosis, and generalized hepatocellular necrosis are each identifiable by particular biopsy results and subtle differences in clinical presentation.

CENTROLOBULAR NECROSIS

Centrolobular necrosis is often a dose-related, predictable reaction secondary to drugs such as acetaminophen; however, it also can be associated with idiosyncratic reactions, such as those caused by the anesthetic halothane. Also called direct or metabolite-related hepatotoxicity, centrolobular necrosis is usually the result of the production of a toxic metabolite (Fig. 40-1). The damage spreads outward from the middle of a lobe of the liver.

Patients suffering from centrolobular necrosis tend to present in one of two ways, depending on the extent of necrosis. Mild drug reactions, involving only small amounts of parenchymal liver tissue, may be detected as asymptomatic elevations in the serum aminotransferases. If the reaction is diagnosed at this stage, most of these patients will recover with minimal cirrhosis and thus minimal chronic liver impairment. More severe forms of centrolobular necrosis are accompanied by nausea, vomiting, upper abdominal pain, and jaundice.^{8,9}

These reactions are predictable, often dose-related effects in the liver caused by specific agents. When taken in overdose, acetaminophen becomes bioactivated to a toxic intermediate known as *N*-acetyl-*p*-benzoquinone imine (NAPQI). NAPQI is very reactive, with a high affinity for sulfhydryl groups. The amino acid glutathione provides a ready source of available sulfhydryl groups within the hepatocyte. When the liver's glutathione stores are depleted and there are no longer sulfhydryl groups available to detoxify this metabolite, it begins to react directly with the hepatocyte (see Fig. 40-1). Replenishing the liver's sulfhydryl capacity through the administration of *N*-acetylcysteine early after ingestion of the overdose halts this pro-

FIGURE 40-1. A general diagram of biotransformation. (1) The drug is actively transported into the hepatocyte by the organic anion transport pump, a transmembrane protein. (2) The metabolite (drug) interacts with one of a number of enzymes, the most common being CYP2C9, 2C19, 2D6, and 3A4. This family of enzymes is regulated by the complementary DNA xenobiotic receptor. The xenobiotic receptor is in turn upregulated by other drugs, changes in cholesterol catabolism, and bile acids. (3) The immediate result of the action of these phase I enzymes is the production of an unstable metabolite. (4) The unstable metabolite then reacts with glucuronidase, various transferases, or hydroxylases to form a conjugated metabolite. The efficacy of these enzymes is affected by the patient's nutritional state and genetic polymorphism, leading to variations in individual risk for toxicity. (5) The conjugated metabolite is removed from the hepatocyte by the canaliculus membrane export pump, one of a large family of membrane proteins (other members of this family pump conjugated metabolites back into the blood for excretion by the kidney). These proteins are subject to genetic polymorphism as well, again leading to some patients having an increased risk for toxicity. (6) If unable to form a conjugate, the unstable metabolite can participate in oxidative reactions that damage lipids, proteins, or even DNA. (7) Alternatively the unstable metabolite may form damaging covalent bonds with available anions or cations. (SNP, indicates points in this process that are influenced by an individual's single nucleotide polymorphisms.)

cess.^{10,11} During the first hours after ingestion, some patients report mild symptoms of nausea and vomiting, but no elevations of the commonly measured liver enzymes are seen. Not for 40 to 50 hours after ingestion do serum elevations in the liver enzymes begin.¹¹

Reye's syndrome is an aggressive form of toxic hepatitis often associated with aspirin use in children. Valproate toxicity can also present in this pattern. Early in the process of Reye's syndrome, mitochondrial dysfunction leads to the depletion of acyl-coenzyme A and carnitine. Fatty acids accumulate and gluconeogenesis is impaired, resulting in hypoglycemia. A concurrent disruption of the urea cycle occurs, leading to a decrease in the removal of ammonia and a slowing of protein use. A threefold rise in the blood ammonia level and an increase in the prothrombin time are common findings. In advanced stages of Reye's syndrome, many patients develop intracranial hypertension that can be life-threatening and refractory to therapy.^{12,13}

STEATOHEPATITIS

Steatohepatitis (also known as steatonecrosis) is a specialized type of acute necrosis resulting from the accumulation of fatty acids in the hepatocyte. Drugs or their metabolites that cause steatonecrosis do so by affecting fatty-acid oxidation within the mitochondria of the hepatocyte (see Fig. 40-1). Hepatic vesicles become engorged with

fatty acids, eventually disrupting the homeostasis of the hepatocyte. The liver biopsy is marked by a massive infiltration by polymorphonuclear leukocytes, degeneration of the hepatocytes, and the presence of Mallory bodies.⁴

Alcohol is the drug that most commonly produces steatonecrotic changes in the liver. When alcohol is converted into acetaldehyde, the synthesis of fatty acids is increased.^{14,15} When the hepatocyte has become completely engorged with microvesicular fat, it often breaks open, spilling into the blood. If enough hepatocytes break open, an inflammatory response begins. If the offending agent is withdrawn before significant numbers of hepatocytes become necrotic, the process is completely reversible without long-term sequelae. In nonalcoholic steatohepatitis, the same end point is often achieved through oxidation of lipid peroxidases.¹⁶

Tetracycline produces steatohepatitis and steatosis.¹⁷ The lesions are characterized by large vesicles of fat found diffused throughout the liver. The development of this reaction is related to the high concentrations achieved when tetracycline is given intravenously and in doses greater than 1.5 g/day. The mortality of tetracycline steatohepatitis is high (70% to 80%), and those who do survive often develop cirrhosis. Sodium valproate also can produce steatonecrosis through the process of bioactivation. Cytochrome P450 converts valproate to *delta*-4-valproic acid, a potent inducer of microvesicular fat accumulation.¹⁸

Patients experiencing steatohepatitis may present with abdominal fullness or pain as their only complaint. Patients with more severe steatonecrosis will present with all the symptoms characteristic of alcoholic hepatitis such as nausea, vomiting, steatorrhea, abdominal pain, pruritus, and fatigue.

PHOSPHOLIPIDOSIS

Phospholipidosis is the accumulation of phospholipids instead of fatty acids. The phospholipids usually engorge the lysosomal bodies of the hepatocyte.¹⁹ Amiodarone is associated with this reaction. Patients treated with amiodarone who develop overt hepatic disease tend to have received higher doses of the drug. These patients also have higher amiodarone-to-N-desethyl-amiodarone ratios, indicating a greater accumulation of the parent compound. Amiodarone and its major metabolite N-desethyl-amiodarone remain in the liver of all patients for several months after therapy is stopped. Usually the phospholipidosis develops in patients treated for more than 1 year. The patient can present with either elevated aminotransferases or hepatomegaly; jaundice is rare.^{4,20}

GENERALIZED HEPATOCELLULAR NECROSIS

Generalized hepatocellular necrosis mimics the changes associated with the more common viral hepatitis. The onset of symptoms is usually delayed as much as a week or more after exposure to toxin. Bioactivation is often important for toxic hepatitis to develop, but may not be the immediate cause of damage. Many drugs that are associated with toxic hepatitis produce metabolites that are not inherently toxic to the liver. Instead, they act as haptens, binding to specific cell proteins and inducing an autoimmune reaction (see Fig. 40-1).²¹

The rate of bioactivation can vary between males and females and between individuals of the same sex.^{22,23} The cytochrome P450 (CYP450) system tends to metabolize lipophilic substrates that are actively pumped into the hepatocyte by an organic anion (or cation) transporting protein. The CYP450 subspecies 2C, 2D, 3A, and 4A are regulated by the highly inducible xenobiotic receptor on complementary DNA. The receptor is found in the liver, and to a lesser extent in the cells lining the intestinal tract, and is responsible for cholesterol catabolism and bile acid homeostasis. The activity of this receptor is subject to genetic polymorphism as well. This results in a wide variation in the sensitivity of the population to generalized hepatocellular necrosis and other forms of hepatic damage.^{16,24}

The long-term administration of isoniazid can lead to hepatic dysfunction in 10% to 20% of those receiving the drug. Yet severe toxic hepatitis develops in only 1% or less of this population.²⁵ The N-acetyltransferase 2 (NAT2) genotype appears to play a role in determining a patient's relative risk. In one study, patients with the slow-type NAT2 genotype had a 28-fold greater risk of developing serum aminotransferase elevations than did patients with the fast-type NAT2 genotype.²⁶ Isoniazid is metabolized by several pathways, acetylation being the major pathway. It is acetylated to acetylisoniazid, which, in turn, is hydrolyzed to acetylhydrazine.²⁷ The acetylhydrazine, and to a lesser extent the acetylisoniazid, are directly toxic to the cellular proteins in the hepatocyte, but rapid acetylators also detoxify acetylhydrazine very rapidly, converting it to diacetylhydrazine (a nontoxic metabolite).

Isoniazid simultaneously is an example of the potential predictability of drug-induced liver disease based on single nucleotide polymorphism and a lesson in the limitations of our current understanding. There are definite links to NAT2 genotype and toxicity.²⁸ The risk for this reaction is also influenced heavily by the age of the patient, with older patients having a much higher risk than younger patients. In fact, age may be more important than genotype.^{25,26,28}

Ketoconazole produces generalized hepatocellular necrosis or milder forms of hepatic dysfunction in 1% to 2% of patients treated for fungal infections. This reaction is fatal in high numbers of patients who are infected with the human immunodeficiency virus. The onset is usually early in therapy, although it can be delayed until several months into therapy. In immune-compromised patients in whom ketoconazole is used for long periods of time, special care should be taken to watch for changes in liver function.²⁹

TOXIC CIRRHOSIS

The scarring effect of hepatitis in the liver leads to the development of cirrhosis. Some drugs tend to cause such a mild case of hepatitis that it may not be detected. Mild hepatitis can be easily mistaken for a more routine generalized viral infection. If the offending drug or agent is not discontinued, this damage will continue to progress. The patient eventually presents not with hepatitis, but with cirrhosis. Methotrexate causes periportal fibrosis in most patients who experience hepatotoxicity.

The lesion results from the action of a bioactivated metabolite produced by CYP450.³⁰ This process occurs most commonly in patients treated for psoriasis and arthritis. The extent of damage can be reduced or controlled by increasing the dosage interval to once weekly or by routine use of folic acid supplements.³¹ Vitamin A is normally stored in liver cells, and causes significant hypertrophy and fibrosis when taken for long periods in high doses. Hepatomegaly is a common finding, along with ascites and portal hypertension. In patients with vitamin A toxicity, gingivitis and dry skin are also very common. This is accelerated by ethanol, which competes with retinol for aldehyde dehydrogenase.¹⁴

CHOLESTATIC INJURY

A second pattern of hepatic damage is an injury that primarily involves the bile canalicular system and is known as cholestatic injury. In cholestatic disease, disturbance of the subcellular actin filaments around the canaliculi prevents the movement of bile through the canalicular system.³¹ The inability of the liver to remove bile causes intrahepatic accumulation of toxic bile acids and excretion products.³² Although rare, some patients develop progressive destruction of the cholangiocytes leading to the vanishing bile duct syndrome.

Drug-induced cholestasis can occur as an acute disorder (e.g., cholestasis with or without hepatitis and cholestasis with bile duct injury) or as a chronic disorder (e.g., vanishing bile duct syndrome, sclerosing cholangitis, and cholelithiasis).³³ However, the most common form of drug-induced cholestasis is cholestasis with hepatitis. Most patients with this acute disorder present with nausea, malaise, jaundice, and pruritus.⁵ Elevations in serum alkaline phosphatase levels are more prominent and usually precede the elevations of other liver enzymes in serum.⁵ On histologic examination, portal inflammation and hepatocyte necrosis are noted.³⁴ Although the antipsychotic drug chlorpromazine appears to be the prototype drug for this disorder, other medications are associated with other forms of cholestatic injury, such as erythromycin estolate, amoxicillin-clavulanic acid, and carbamazepine.⁶

Cholestatic injury, also known as cholestatic jaundice or cholestasis, can be classified by the area of the bile canalicular or ductal system that is impaired. Canalicular cholestasis is often associated with long-term high-dose estrogen therapy. Clinically, these patients are often asymptomatic and present with mild to moderate elevations of serum bilirubin.³⁵ An intravenous form of vitamin E, α -tocopherol acetate, causes cholestatic jaundice, primarily involving the canalicular duct in premature infants. The incidence of this reaction in those receiving this formulation was high (>10%) and the mortality even higher (>50%).³⁶

The administration of total parenteral nutrition for periods greater than 1 week induces cholestatic changes and nonspecific enzyme elevations in some patients. Patients with low serum albumin concentrations may be at greater risk than patients with normal serum albumin concentrations.⁴ This reaction also has been reported to occur rarely with sulfonamides, sulfonyleureas, erythromycin estolate and ethylsuccinate, captopril, lisinopril, and other phenothiazines.³⁷

MIXED HEPATOCELLULAR AND CHOLESTATIC INJURY

The final pattern of hepatic damage is a combining of the previous two patterns. This presentation can be the result of three different processes. In some patients, an injury may begin as hepatocellular (or cholestatic) and simply spread so rapidly that by the time the patient presents for diagnosis and treatment, all areas of the liver are affected. In other patients, the underlying mechanism of damage is such that cells are injured regardless of their anatomical location or primary metabolic role.

LIVER VASCULAR DISORDERS

Focal lesions in hepatic venules, sinusoids, and portal veins occur with various drugs. The most commonly associated drugs are the cytotoxic agents used to treat cancer, the pyrrolizidine alkaloids, and the sex hormones. A centralized necrosis often follows and can result in cirrhosis. Azathioprine and herbal teas that contain comfrey (a source of pyrrolizidine alkaloids) are associated with the development of venoocclusive disease. The exact incidence is rare and may be dose related.⁴ Peliosis hepatitis is a rare type of hepatic vascular lesion that can be seen as both an acute and a chronic disease. The liver develops large, blood-filled lacunae (space or cavity) within the parenchyma. Rupture of the lacunae can lead to severe peritoneal hemorrhage. Peliosis hepatitis is associated with exposure of the liver to androgens, estrogens, tamoxifen, azathioprine, and danazol. Androgens with a methyl alkylation at the 17-carbon position of the testosterone structure are the most frequently reported agents that cause peliosis hepatitis, usually after at least 6 months of therapy.³⁸

MECHANISMS OF DRUG-INDUCED LIVER DISEASE

STIMULATION OF AUTOIMMUNITY

Autoimmune injuries involve antibody mediated cytotoxicity or direct cellular toxicity.^{34,39} This type of injury occurs when enzyme-drug adducts migrate to the cell surface and form neoantigens. The neoantigens serve as targets for cytolytic attack by T cells.⁵ The injury may be exacerbated by the recruitment of inflammatory cells. Halothane, sulfamethoxazole, carbamazepine, and nevirapine are associated with autoimmune injuries.³² Stimulation of autoimmunity is often associated with some stage of all fulminant presentations. It is the primary cause of injury in idiosyncratic reactions.

Dantrolene, isoniazid, phenytoin, nitrofurantoin, and trazodone are associated with a type of autoimmune-mediated disease in the liver called *chronic active hepatitis*.^{8,40} Patients experience periods of symptomatic hepatitis followed by periods of convalescence, only to repeat the experience months later. It is a progressive disease with a high mortality rate and is more common in females than males. Antinuclear antibodies appear in most patients. These drugs appear to form antiorganellar antibodies.²¹ The exact identification of a causative agent is sometimes difficult as diagnosis requires multiple episodes occurring long after exposure to the offending drug.

IDIOSYNCRATIC REACTIONS

Idiosyncratic drug-related hepatotoxicity is rare and usually occurs in a small proportion of individuals. These adverse reactions are often categorized into allergic and nonallergic reactions. The allergic reactions are characterized by fever, rash, and eosinophilia. They are usually dose-related and have a short latency period (<1 month). Upon reexposure to the offending agent, the patient will experience rapid recurrence of hepatotoxicity. Studies show that minocycline, nitrofurantoin, and phenytoin can cause allergic reactions.³

Unlike the allergic reactions, the nonallergic idiosyncratic reactions are devoid of the hypersensitivity features and usually have a long latency period (several months). These patients often have normal liver function tests for 6 months or longer and then suddenly develop hepatotoxicity. Dependent on the medication, the incident can be independent of dose or dose-related. Amiodarone, isoniazid, and ketoconazole are associated with nonallergic drug-related hepatotoxicity.³

DISRUPTION OF CALCIUM HOMEOSTASIS AND CELL MEMBRANE INJURY

Drug-induced damage to the cellular proteins that are involved with calcium homeostasis can lead to an influx of intracellular calcium that causes a decline in adenosine triphosphate levels and disruption of the actin fibril assembly. The resulting impact on the cell is blebbing of the cell membrane, rupture, and cell lysis.³² Lovastatin, venlafaxine, and phalloidin, which is the active component of mushrooms, impair calcium homeostasis.^{32,39}

METABOLIC ACTIVATION OF THE CYTOCHROME P450 ENZYMES

Most hepatocellular injuries involve the production of high-energy reactive metabolites by the CYP450 system. **2** These reactive metabolites are capable of forming covalent bonds with cellular proteins (enzymes) and nucleic acids that lead to adduct formation. In the case of acute toxicity, the enzyme-drug adduct can cause cell injury or cell lysis. Adducts that form with DNA can cause long-term consequences such as neoplasia. Acetaminophen, furosemide, and diclofenac are examples of this mechanism of liver injury.⁴¹ Individual genetic differences can play a role in the significance of this process. Patients with a single nucleotide polymorphism (SNP) that codes for slow-reacting variants of CYP450 will react differently from those with a SNP that codes for very-fast-reacting variants.

STIMULATION OF APOPTOSIS

Apoptosis represents a distinct pattern of cell lysis that is characterized by cell shrinkage and fragmentation of nuclear chromatin. Apoptotic pathways are triggered by interactions between death ligands (tumor necrosis factor and Fas ligand) and death receptors (tumor necrosis factor receptor-1 and Fas). These interactions activate caspases which cleave cellular proteins and eventually lead to cell death.⁴² Cumulative doses of acetaminophen cause apoptosis.³⁹

MITOCHONDRIAL INJURY

Drugs that impair mitochondrial structure, function, or DNA synthesis can disrupt β -oxidation of lipids and oxidative energy production within the hepatocyte.³¹ In acute disease, prolonged interruption of β -oxidation leads to microvesicular steatosis, whereas, in chronic disease, macrovesicular disease is present.⁶ Severe damage to the mitochondria eventually leads to hepatic failure and death. Aspirin, valproic acid,

and tetracycline cause mitochondrial injury by inhibiting β -oxidation and amiodarone via disruption of oxidative phosphorylation.³²

LIVER NEOPLASTIC DISEASE

A large body of the current literature on adverse reactions and the liver addresses the development of neoplasms following drug therapy. Both carcinoma- and sarcoma-like lesions have been identified. Fortunately, hepatic tumors associated with drug therapy are usually benign and remit when drug therapy is discontinued. Except in rare instances, these lesions are associated with long-term exposure to the offending agent.⁴³ Androgens, estrogens, and other hormonal-related agents are the most frequently associated causes of neoplastic disease. The model for drug-induced hepatic cancer is polyvinyl chloride exposure. Used in the production of many types of plastic products, polyvinyl chloride induces angiosarcoma in exposed workers after as few as 3 years of exposure.⁴⁴

ASSESSMENT

The best and most important technique for assessing and monitoring drug-induced liver disease is the patient's history. **3** Questions addressing the patient's drug use along with a thorough review of systems are essential. The use of a protocol, such as that proposed by Danan and Benichou, can significantly improve the accuracy of the assessment (Table 40-1).⁴⁵ The use of drugs for recreational purposes must not be overlooked. Cocaine has been directly linked to liver disease.⁴⁶ Ecstasy, the street name of methylenedioxymethamphetamine, has induced fulminant hepatitis, which has led to death in some cases.⁴⁷ The more pervasive impact of street drugs on the incidence of hepatic disease is the concomitant injection or ingestion of adulterants. Many of these adulterants are either directly toxic or serve to enhance the toxicity of the drug.

It is also important to determine nondrug hepatic disease risk. Arsenic, for example, is known to induce both acute and chronic hepatic reactions. Arsenic in low concentrations is found in insect-resistant lumber.⁴⁷ Following Occupational Safety and Health Administration guidelines should decrease the danger of using these products, but will not eliminate it. Even if exposure to an environmental toxin in and of itself does not produce a hepatic reaction, it may predispose a patient to a hepatic reaction when a drug is added. Table 40-2 lists some of the more common hepatic toxins found in occupational or environmental exposures that can add to a patient's risk for developing a hepatic lesion.⁴⁸

A person's use of alternative medicine must be solicited. Many herbal remedies were once wisely abandoned because of their common adverse reactions. Comfrey tea is a common cause of hepatocellular damage. As in the case of the Chinese remedy *jin bu huan*, or as in the case of the more elegantly presented chaparral capsules containing grease wood leaves, the end of therapy with these types of agents is occasionally severe disability or death from fulminant hepatic failure.⁴⁹ Pennyroyal oil, margosa oil, and clove oil cause a dose-related hepatotoxicity.⁴⁹

The nutritional status of a patient can be as important to the development of a drug-induced liver disease as the hepatotoxin itself.⁴⁷ Patients who are malnourished because of illness or long-term alcohol abuse make up the most troublesome group.⁵⁰ Low serum levels of vitamins E and C, along with lutein and the α - and β -carotenes are associated with asymptomatic elevations in transaminases. Conversely, high serum iron, transferrin, and selenium levels are also associated with asymptomatic elevations of transaminases.⁵¹

All potential drug reactions should be judged as to the timing of the reaction versus drug administration, pharmacokinetic considerations, the information in the literature records about previous reactions, the inclusion of alternative nondrug causes, and close clinical observation when the drug in question is stopped. It is also

TABLE 40-1 An Approach to Evaluating a Suspected Hepatotoxic Reaction Using a Clinical Diagnostic Scale

Patient Presents with Elevated Liver Enzymes	Score	Component Subscore
<i>Literature</i>		
Literature supports this drug (drug combination) and pattern of liver enzyme elevation	+2	
No literature supports this, but the drug has been on the market less than 5 years	+0	—
No literature supports this and the drug has been on the market for 5 years or more	−3	
<i>Alternative causes</i>		
Alternative causes (e.g., viral, alcohol) are completely ruled out	+3	
Alternative causes are partially ruled out	+0	—
Alternative causes cannot be ruled out and are possible or even probable	−1	
<i>Presentation</i>		
The presentation includes 4 or more extrahepatic (fever, malaise, etc.) symptoms	+3	
The presentation includes 2–3 extrahepatic symptoms	+2	—
The presentation includes only 1 identifiable extrahepatic symptom	+1	
The presentation is essentially a laboratory abnormality, with no extrahepatic symptoms	+0	
<i>Temporality</i>		
Initiation of drug therapy to onset is 4–56 days	+3	
Initiation of drug therapy to onset is <4 or >56 days	+1	
Discontinuance of therapy to onset is 0–7 days	+3	—
Discontinuance of therapy to onset is 8–15 days	+0	
Discontinuance of therapy to onset is >15 days	−1	
<i>Rechallenge</i>		
Rechallenge was positive	+3	—
Rechallenge was negative or not attempted	+0	
<i>Total Score</i>		—

The likelihood that this presentation is an adverse reaction in the liver increases linearly with an increasing score. The maximum score is 14, and scores below 7 are associated with an ever-decreasing likelihood that the drug or drug combination in question caused the problem. This approach is not designed for the assessment of hepatic cancers or cirrhotic conditions. Reprinted from *J Clin Epidemiol*, Vol 46, Danan G, Benichou C. *Causality assessment of adverse reactions to drugs—I. A novel method based on the conclusions of international consensus meetings: Application to drug-induced liver injuries*; pages 1323–1330, Copyright 1993, with permission from Elsevier.

important to keep in mind that most elevations in liver enzymes will not be associated with a drug. In a study of all patients admitted to a hospital in the United Kingdom with elevated liver aminotransferases, only 9% of cases involved a drug other than alcohol as the possible cause.³ In all cases, titers of serum antibodies to hepatitis A, B, and C should be drawn. Even in cases in which the drug is absolutely targeted as the cause, viral hepatitis may be a complication.

TABLE 40-2 Environmental Hepatotoxins and Associated Occupations at Risk for Exposure

Hepatotoxin	Associated Occupations at Risk for Exposure
Arsenic	Chemical plant, construction, agricultural workers
Carbon tetrachloride	Chemical plant workers, laboratory technicians
Copper	Plumbers, outdoor sculpture artists, copper foundry workers
Dimethylformamide	Chemical plant workers, laboratory technicians
2,4-Dichlorophenoxyacetic acid	Horticulturists
Fluorine	Chemical plant workers, laboratory technicians
Toluene	Chemical plant, agricultural workers, laboratory technicians
Trichloroethylene	Printers, dye workers, cleaners, laboratory technicians
Vinyl chloride	Plastics plant workers; also found as a river pollutant

TABLE 40-3 Relative Patterns of Hepatic Enzyme Elevation versus Type of Hepatic Lesion				
Enzyme	Abbreviations	Necrotic	Cholestatic	Chronic
Alkaline phosphatase	Alk Phos, AP	↑	↑↑↑	↑
5'-Nucleotidase	5-NC, 5NC	↑	↑↑↑	↑
γ-Glutamyltransferase	GGT, GGTP	↑	↑↑↑	↑↑
Aspartate aminotransferase	AST, SGOT	↑↑↑	↑	↑↑
Alanine aminotransferase	ALT, SGPT	↑↑↑	↑	↑↑
Lactate dehydrogenase	LDH	↑↑↑	↑	↑

↑, <100% of normal; ↑↑, >100% of normal; ↑↑↑, >200% of normal.

Often there is no good clinical test available to determine the exact type of hepatic lesion, short of liver biopsy. 4 There are certain patterns of enzyme elevation that have been identified and can be helpful (Table 40–3).^{52,53} The specificity of any serum enzyme depends on the distribution of that enzyme in the body. Alkaline phosphatase is found in the bile duct epithelium, bone, and intestinal and kidney cells. 5'-Nucleotidase is more specific for hepatic disease than alkaline phosphatase, because most of the body's store of 5'-nucleotidase is in the liver. Glutamate dehydrogenase is a good indicator of centrilobular necrosis because it is found primarily in centrilobular mitochondria. Most hepatic cells have extremely high concentrations of transaminases. Aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are commonly measured in serum. Because of their high concentrations and easy liberation from the hepatocyte cytoplasm, AST and ALT are sensitive indicators of necrotic lesions within the liver. After an acute hepatic lesion is established, it may take weeks for these concentrations to return to normal.⁵³

Serum bilirubin concentration is a sensitive indicator of most hepatic lesions and has significant prognostic value. High peak bilirubin concentrations are associated with poor survival. Other important findings that indicate poor survival are a peak prothrombin time greater than 40 seconds, elevated serum creatinine, and low arterial pH. The presence of encephalopathy or prolonged jaundice are not good signs for the survival of the patient and are strong indicators for transplantation.⁵⁴

Bilirubin concentrations and serum enzyme elevations give a static picture of the liver's condition and are not good indicators of hepatic function. Clinically available tests to predict hepatic function include measurement of serum proteins (albumin or transferrin). As a hepatic function decreases, serum protein concentrations in the body decrease at a rate determined by each protein's own elimination rate. Overhydration and starvation can also decrease serum protein concentrations. Changes in the prothrombin time often occur earlier than the changes in albumin or transferrin. The response of the prothrombin time to the administration of 10 mg of parenteral vitamin K is often used to differentiate between hepatic and extrahepatic disease.

MEASUREMENT OF LIVER FUNCTION

A good compound for a liver function test would theoretically be (a) nontoxic and lacking any pharmacologic effect; (b) either rapidly and completely absorbed orally or easily administered via a peripheral vein; (c) eliminated only by the liver; and (d) easily measured (drug and its metabolite) in blood, saliva, or urine.⁵⁵

Several tests are used in research settings and in liver transplant patients to indicate liver function. Tests such as sulfobromophthalein, indocyanine green, or sorbitol measure qualities of hepatic clearance. There are also a few drugs that have been used to test liver function. The advantage of sorbitol over indocyanine green is a much lower incidence of allergic reactions. It is partially cleared by the kidney, and urine levels must also be determined during the test.⁵⁶ A good estimate of hepatic clearance can be obtained by serial

blood levels of a variety of hepatically eliminated drugs if an assay is locally available. Ultrasound and computed tomographic imaging can be used on a periodic basis to monitor for the development of fibrosis or vascular lesions in the liver and for hepatocellular carcinomas.⁵⁷

If a liver biopsy has been performed, the injury should be classified by the histologic findings. In cases in which there is no biopsy, the pattern of liver enzyme elevation can estimate the type of injury. Hepatocellular injuries are marked by elevations in transaminase that are at least two times normal. If the alkaline phosphatase is also elevated, a hepatocellular lesion is still suspected when the elevation of ALT is notably higher than the elevation of alkaline phosphatase. If the magnitude of elevation is nearly equal between ALT and alkaline phosphatase, the lesion is likely cholestatic.

A liver injury is acute if it lasts less than 3 months; it is considered chronic after 3 months of consistent symptoms or enzyme elevation. A liver injury is severe if the patient has marked jaundice, if the prothrombin time does not improve by more than 50% after the

TABLE 40-4 An Approach to Determining a Drug-Monitoring Plan to Detect Hepatotoxicity

The patient is to be started on a drug that may cause a hepatotoxic reaction

↓

Is the patient pregnant?

Is the patient older than age 60 years?

Is the patient exposed to an environmental hepatotoxin at work or at home?

Is the patient drinking more than one alcoholic beverage per day or bingeing on weekends?

Is the patient using any injected recreational drug?

Is the patient using herbal remedies or tisanes that are associated with hepatic damage?

Is the patient's diet deficient in magnesium, vitamin E, vitamin C, or α- or β-carotenes?

Is the patient's diet excessive in vitamin A, iron, or selenium?

Does the patient have hypertriglyceridemia or type 2 diabetes mellitus?

Does the patient have juvenile arthritis or systemic lupus erythematosus?

Is the patient HIV-positive, have AIDS, or on reverse transcriptase inhibitors?

Does the patient have chronic or chronic remitting viral hepatitis (hepatitis B or C)?

↓

Draw a baseline set of blood samples for liver enzymes, bilirubin, albumin, and transferrin before beginning the drug

↓

Does the patient have more than two risk factors?

Is the drug identified as one that may cause a predictable hepatotoxic reaction?"

↓Yes

Redraw liver enzymes every 60–90 days depending on the drug, for the first year

↓No

Redraw liver enzymes if other signs or symptoms manifest

If no toxicity is manifested during the first year of therapy, then redraw liver enzymes every 6–12 months; assess liver for cirrhosis every 1–2 years by ultrasound and every 4–6 years by CT or MRI scan; biopsy as directed by other findings

AIDS, acquired immunodeficiency syndrome; CT, computer tomography; HIV, human immunodeficiency virus; MRI, magnetic resonance imaging.
A drug can become a predictable risk if it is administered concurrently with another drug or food that is known to induce or inhibit its metabolism.

administration of vitamin K, or if encephalopathy is detectable. If an acute liver injury progresses from normal to severe in a matter of a few days or weeks, it is considered fulminant.^{58,59}

MONITORING

The serum transaminases AST and ALT are the most commonly used transaminases in the clinical setting. There are often no set rules available for a particular drug. ⁵ The general guidelines found in Table 40–4 can help in determining a monitoring schedule for drugs where no prior recommendations are published. Concentrations of these enzymes should be obtained approximately every 4 weeks, depending on the reported characteristics of the reaction in question. Methotrexate should be monitored every 4 weeks, because toxicity usually develops over a period of several weeks to months.⁵⁷ In addition, some recommend that sulfobromophthalein or indocyanine-green excretion studies be performed on a regular basis and that patients treated for very long periods of time should have a liver biopsy performed every 12 months.⁶⁰

ABBREVIATIONS

ALT: alanine aminotransferase

AST: aspartate aminotransferase

CYP450: cytochrome P450 liver enzyme system

NAPQI: *N*-acetyl-*p*-benzoquinone imine

NAT2: *N*-acetyltransferase 2 genotype

SNP: single nucleotide polymorphism

ROSEMARY R. BERARDI AND PATRICIA A. MONTGOMERY

KEY CONCEPTS

ACUTE PANCREATITIS

- 1 Patients with severe acute pancreatitis require early and aggressive intravenous fluid resuscitation.
- 2 Treatment requires that if at all possible, medications that potentially cause pancreatitis be discontinued.
- 3 Use parenteral narcotic analgesics to control abdominal pain. Meperidine is not recommended as a first-line agent because of dosing limitations and the risk for seizures in patients with renal failure.
- 4 Octreotide may be used in severe acute pancreatitis, but its efficacy in decreasing complications and mortality remains uncertain.
- 5 Antibiotics should not be used in the absence of signs of infection except in patients with severe acute pancreatitis when pancreatic necrosis is present.

CHRONIC PANCREATITIS

- 6 Abstinence from alcohol is an important factor in preventing abdominal pain in the early stages of alcohol-induced chronic pancreatitis.
- 7 Initiate pain control with nonnarcotic analgesics such as acetaminophen or a nonsteroidal antiinflammatory agent. The dose and frequency of administration should be increased before the patient is switched to a narcotic. Parenteral narcotics should be reserved for patients with severe pain that is unresponsive to oral agents. Patients with frequent or constant pain should receive the lowest effective analgesic dose scheduled around the clock.
- 8 A trial of non-enteric-coated pancreatic enzymes with either an H₂-receptor antagonist or a proton pump inhibitor should be considered for pain control in patients with mild to moderate disease.
- 9 Pancreatic enzyme supplementation and a reduction of dietary fat are used to treat malabsorption and steatorrhea. An initial lipase dose of about 30,000 international units should be given with each meal.
- 10 Symptomatic patients whose steatorrhea is not corrected by pancreatic enzyme supplementation and a reduction in dietary

fat may benefit from the addition of an H₂-receptor antagonist or a proton pump inhibitor.

Pancreatitis is inflammation of the pancreas with variable involvement of regional tissues or remote organ systems.¹ Acute pancreatitis (AP) is characterized by severe pain in the upper abdomen and elevations of pancreatic enzymes in the blood.² In the majority of patients, AP is a mild, self-limiting disease that resolves spontaneously without complications. Approximately 20% of adults have a severe course, and 10% to 30% of those with severe AP die.^{3,4} Although exocrine and endocrine pancreatic function may remain impaired for variable periods after an attack, AP seldom progresses to chronic pancreatitis.²

Chronic pancreatitis (CP) is characterized by permanent damage to pancreatic structure and function because of progressive inflammation and long-standing pancreatic injury.^{1,5-7} In the early stages of the disease, recurrent, acute, symptomatic exacerbations resemble attacks of AP and may not be distinguishable from AP. Most patients have periods of intractable upper abdominal pain, which is the dominant feature. Progressive pancreatic exocrine and endocrine insufficiency leads to maldigestion and diabetes mellitus. CP patients are at an increased risk of developing pancreatic cancer.^{5,7} Patients with AP and CP suffer from many of the same complications.

EPIDEMIOLOGY

The prevalence of pancreatitis varies widely with geographic, etiologic (e.g., alcohol consumption), environmental, and genetic factors. The reported prevalence of AP among men and women in the United States is less than 1%, whereas the prevalence of CP is 0.05% in males and 0.01% in females, but the true spectrum of these diseases is probably underestimated.⁷ Hospitalizations for AP have increased in the United States, most likely related to an increase in gallstones in association with obesity.⁸ The incidence of gallstone-related AP is increased among white women older than age 60 years.³ Alcoholic CP is more common in men and has a peak incidence between 35 and 45 years of age.⁷ Blacks are more likely than whites to be hospitalized for CP than for alcoholic cirrhosis, but an underlying genetic factor remains elusive.⁷

PHYSIOLOGY OF EXOCRINE PANCREATIC SECRETION

The pancreas possesses both endocrine and exocrine functions. The islets of Langerhans, which contain the cells of the endocrine pancreas, secrete insulin, glucagon, somatostatin, and other polypeptide hormones. The exocrine pancreas is composed of acini that secrete about 1 to 2 L/day of isotonic fluid that contains water, electrolytes,

Learning objectives, review questions,

www.pharmacotherapyonline.com.

FIGURE 41-1. Anatomic structure of the pancreas and biliary tract.

and pancreatic enzymes necessary for digestion. Bicarbonate is secreted primarily by the centroacinar (ductular) cells and is the principal ion of physiologic importance. Pancreatic juice is delivered to the duodenum via the pancreatic ducts (Fig. 41-1) where the alkaline secretion (pH approximately 8.3) neutralizes gastric acid and provides an appropriate pH for maintaining the activity of pancreatic enzymes.⁹

The major pancreatic exocrine enzyme groups are:

- *Proteolytic:* trypsinogen, chymotrypsinogen, procarboxypeptidase, and proelastase
- *Amylolytic:* amylase
- *Lipolytic:* lipase, procolipase, prophospholipase A₂, and carboxylesterase lipase
- *Nucleolytic:* ribonuclease, deoxyribonuclease
- *Other:* trypsin inhibitor

The proteolytic enzymes are synthesized within the acinar cells and secreted as zymogens (inactive enzymes), which are activated in the lumen of the duodenum. Enterokinase secreted by the duodenal mucosa converts trypsinogen to trypsin, which then activates all other proteolytic zymogens. Two important mechanisms protect the pancreas from the potential degradative action of its own digestive enzymes. The synthesis of proteolytic enzymes as zymogens requires extrapancreatic trigger enzymes for activation. In addition, pancreatic juice contains a low concentration of trypsin inhibitor, which inactivates trypsin and partially inhibits chymotrypsin. Proteolytic activity in the intestinal lumen is not inhibited because the concentration is minimal. Lipase, amylase, ribonuclease, and deoxyribonuclease are secreted by the acinar cells in their active form. Colipase facilitates the action of lipase by binding to the bile salt-lipid surface and lowering the optimum pH of lipase from 8.5 to 6.5, the normal luminal pH in the duodenum.⁹

The regulation of exocrine pancreatic secretion is complex and depends on stimulatory and inhibitory factors exerted through hormonal and neuronal mechanisms. Two hormones, secretin (SC) and cholecystikinin (CCK), play an important role in mediating postprandial pancreatic secretion and have synergistic effects: SC stimulates ductular cells to increase water and bicarbonate; CCK stimulates acinar cells to secrete a juice that is low in volume and bicarbonate, but rich in enzyme content. The release of SC from the intestinal mucosa is pH dependent and occurs when the duodenal pH is approximately 4.5. Below this pH, titratable acid in the duodenum governs pancreatic bicarbonate output. Although the postprandial release of SC is small, nonacid factors such as products of fat digestion and bile can also stimulate SC release. The release of CCK from the small intestine depends on the presence of fatty acids and amino acids

in the duodenum. Vasoactive intestinal polypeptide is structurally similar to SC and exhibits weak secretin-like effects on exocrine pancreatic secretion. Gastrointestinal peptides such as somatostatin inhibit enzyme secretion by modulating cholinergic transmission. Intestinal serotonin (5-hydroxytryptamine) is released in response to a number of stimuli, including duodenal acidification, and may play a role in postprandial pancreatic secretion.⁹

There are three phases of pancreatic exocrine secretion: cephalic, gastric, and intestinal. In the fasted state, basal secretion occurs at a low rate; output fluctuates in cycles with the interdigestive migrating motor complex (IMMC), so that peak secretions occur during phase III of the IMMC.⁹ The cephalic phase is stimulated by the sight and smell of food and is mediated by vagal pathways. Gastric distension and the rate of gastric emptying stimulate an increase in enzyme-rich pancreatic fluid. In the intestinal phase, chyme and acid stimulate pancreatic secretion through the release of SC and CCK. A more in-depth discussion of pancreatic physiology is found elsewhere.⁹

ACUTE PANCREATITIS

AP varies from mild to severe disease, in which the severity of the attack correlates with the degree of pancreatic involvement and complications. The morphologic appearance of the pancreas and surrounding tissue ranges from interstitial edema and inflammatory cells (interstitial pancreatitis) to pancreatic and extrapancreatic necrosis (necrotizing pancreatitis), which has a higher risk of infection, organ failure, and mortality.² The rupture of blood vessels within or around the pancreas may lead to a collection of blood in the retroperitoneal spaces.

ETIOLOGY

Table 41-1 lists the etiologic risk factors associated with AP. Gallstones and alcohol abuse together account for 70% to 80% of all cases of AP.⁸ Approximately 20% of adult cases are idiopathic (a cause cannot be determined).^{3,10} AP occurs in 5% to 15% of all patients who have undergone endoscopic retrograde cholangiopancreatography (ERCP), and in 30% to 40% of high-risk patients.^{8,11} End-stage renal disease increases the risk of AP, with patients who are receiving chronic peritoneal dialysis being at higher risk than those receiving hemodialysis.¹² Cigarette smoking appears to increase the risk of pancreatitis, especially in alcohol-related disease.¹³ Pregnancy is not

TABLE 41-1 Etiologic Risk Factors Associated with Acute Pancreatitis	
Structural	Gallstone disease, sphincter of Oddi dysfunction, pancreas divisum, pancreatic tumors
Toxins	Alcohol (ethanol) consumption, scorpion bite, organophosphate insecticides
Infectious	Bacterial, viral (including AIDS), parasitic
Metabolic	Genetic hypertriglyceridemia, chronic hypercalcemia
Genetic	Cystic fibrosis, α_1 -antitrypsin deficiency, hereditary (trypsinogen gene mutations)
Medications	See Table 41-2 for specific drugs
Iatrogenic	Abdominal surgery, ERCP
Renal disease	Chronic renal failure, dialysis related
Trauma	Blunt trauma to the abdomen
Vascular	Vasculitis, atherosclerosis, cholesterol emboli, coronary bypass surgery
Other etiologies	Congenital, Crohn's disease, autoimmune, tropical, solid-organ transplantation (liver, kidney, heart), refeeding
Idiopathic	Undetermined cause

AIDS, acquired immune deficiency syndrome; ERCP, endoscopic retrograde cholangiopancreatography. From references 1, 2, 8, 10, 12.

TABLE 41-2 Medications Associated with Acute Pancreatitis

Class I Definite Association	Class II Probable Association	Class III Possible Association
5-Aminosalicylic acid	Acetaminophen	Aldesleukin
Asparaginase	Carbamazepine	Amiodarone
Azathioprine	Cisplatin	Asparaginase
Corticosteroids	Enalapril	Calcium
Cytarabine	Erythromycin	Celecoxib
Didanosine	Hydrochlorothiazide	Clozapine
Estrogens	Interferon α_{2b}	Cholestyramine
Furosemide	Lamivudine	Cimetidine
Mercaptopurine	Octreotide	Ciprofloxacin
Opiates		Clarithromycin
Pentamidine		Clonidine
Pentavalent antimonials		Cyclosporine
Sulfasalazine		Danazol
Sulfamethoxazole and trimethoprim		Diazoxide

considered a cause of AP as pregnant women develop pancreatitis as a result of a coincident process, most commonly cholelithiasis.

Medications

The incidence of drug-induced AP ranges from 2% in the general population to as high as 40% in human immunodeficiency virus (HIV)-positive patients.¹⁴ It is not clear how drugs cause AP, but once the process is initiated, disease severity is determined by the propagation of proinflammatory mediators. Numerous drugs are believed to cause AP, but ethical and practical considerations prevent rechallenge with the suspected agent.^{14,15} In the past, drugs were divided based on a definite, probable, or possible association with AP.¹⁵ Recently, a new, updated classification was devised that improves the strength of evidence implicating a drug as a cause of AP (Table 41–2).¹⁴ Class I (definite association) implies a temporal relationship of drug administration to abdominal pain and hyperamylasemia in at least 20 reported cases with at least 1 positive response to rechallenge with the offending agent. Class II medications are implicated in more than 10 (but less than 20) reported cases of AP and suggest a probable association. Class III medications include all drugs implicated in AP (including classes I and II), as well as numerous others with a possible association (10 or fewer reported cases or unpublished reports in pharmaceutical or U.S. Food and Drug Administration files). Table 41–2 lists medications according to this updated classification but only includes selected class III medications. A comprehensive list of class III drugs (including references) is found elsewhere.¹⁴

Most information on drug-induced AP is obtained from case reports.^{16–24} Proton pump inhibitors and histamine₂-receptor antagonists may be initiated in response to early symptoms of unrecognized pancreatitis and may confound the association between the drug and the disease. A retrospective cohort study, however, does not support an association between AP and proton pump inhibitors or histamine₂-receptor antagonists.¹⁶ Medications such as propofol and tamoxifen are associated with hyperlipidemia and pancreatitis.^{17,18} Metformin is associated with AP in toxic levels.¹⁹ The clinician should be especially suspicious of drug-induced AP in high-risk patients, such as those receiving multiple medications or immunomodulating drugs, and in geriatric, HIV-positive, and cancer patients.¹⁴ AP is an infrequent complication of drug therapy, but it is prudent to with-

draw medication when an association is suspected. Allergic reactions (e.g., urticaria) usually do not accompany drug-induced AP.

PATHOPHYSIOLOGY

The pathophysiology of AP is based on events that initiate the injury and secondary events that establish and perpetuate the injury (Fig. 41–2). The premature activation of trypsinogen to trypsin leads to activation of other digestive enzymes and autodigestion of the gland.^{1,2} Genetic abnormalities in pathways that protect the pancreas from autodigestion also play a pathophysiologic role.¹ The release of activated pancreatic enzymes into the pancreas and surrounding tissues produces tissue damage and necrosis to the pancreas, the surrounding fat, and adjacent structures. Lipase damages the fat cells, producing noxious substances that cause further pancreatic and peripancreatic injury. The release of cytokines by the acinar cell directly injures the acinar cell and enhances the inflammatory response.^{25–27} Injured acinar cells liberate chemoattractants that attract neutrophils, macrophages, and other cells to the area of inflammation. Vascular damage and ischemia causes the release of kinins, which makes capillary walls

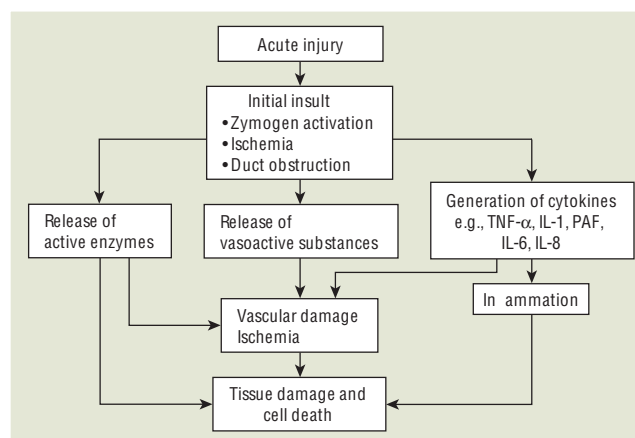

FIGURE 41-2. Pathophysiology of acute pancreatitis: initiating and secondary events. (IL-1 β , interleukin-1 β ; IL-6, interleukin-6; IL-8, interleukin-8; PAF, platelet-activating factor; TNF- α , tumor necrosis factor- α .)

permeable and promotes tissue edema. The release of damaging oxygen-free radicals appears to correlate with the severity of pancreatic injury.² Pancreatic infection may result from increased intestinal permeability and translocation of colonic bacteria. The release of activated pancreatic enzymes into the systemic circulation may progress to distant organ damage, multiorgan failure, and death.²⁻⁴

COMPLICATIONS

Local complications—including acute fluid collection, pancreatic necrosis, infection, abscess (collection of pus in or adjacent to the pancreas), and pseudocyst (collection of pancreatic juice and tissue debris enclosed by a wall of fibrous or granulation tissue)—develop approximately 3 to 4 weeks after the initial attack. Pancreatic infections occur in 15% to 30% of those with pancreatic necrosis and are usually secondary infections of necrotic tissue.⁸ Most deaths result from infected necrosis, pancreatic abscess, and sepsis.² Pancreatic ascites occurs when pancreatic secretions spread throughout the peritoneal cavity. Systemic complications include cardiovascular, renal, pulmonary, metabolic, hemorrhagic, and central nervous system abnormalities.² Of the early complications, shock is the main cause of death. Hypotension results from hypovolemia, hypoalbuminemia, the release of kinins, and sepsis. Renal complications are usually caused by hypovolemia. Pulmonary complications develop when fluid accumulates within the pleural space and compresses the lung and the acute respiratory distress syndrome (ARDS) restricts gas exchange. The most common cause of hypoxemia in patients with AP is ARDS. Pleural effusions occur in 4% to 17% of patients, and occur more frequently on the left.² Gastrointestinal bleeding occurs secondary to numerous causes including rupture of a pseudocyst. Severe AP is associated with confusion and coma.

CLINICAL PRESENTATION

Signs and Symptoms

The clinical presentation of AP varies depending on the severity of the inflammatory process and whether damage is confined to the pancreas or involves local and systemic complications (Table 41-3).^{2,3,8}

Diagnosis

The definitive diagnosis of AP is surgical examination of the pancreas or pancreatic histology. In the absence of these procedures, the diagnosis depends on the recognition of an etiologic factor, the clinical signs and symptoms, abnormal laboratory tests, and imaging techniques that predict the severity of the disease (see Table 41-3). ERCP is usually reserved for abnormalities found by less-invasive imaging techniques.²⁸ In most patients, the diagnosis is based on the clinical presentation, an elevated serum amylase or lipase, and either computed tomography (CT) or an ultrasonogram of the pancreas.^{1,2} Evaluation of the patient with recurrent AP requires systematic identification and elimination of correctable inciting factors.²⁹

Prediction of Disease Severity The risk for severe AP is assessed within the first 24 to 48 hours of hospitalization and is predicted by the presence of local complications and organ failure.^{2,4,30} Several recognized scoring systems have been developed to assess the likelihood of severe disease (Table 41-4). The Ranson criteria assesses 11 variables that must be monitored at the time of admission and during the initial 48 hours of hospitalization.^{2,3} Severe AP is characterized by three or more criteria. Patients with fewer than three Ranson criteria have a mortality rate of less than 1%, whereas those with six or more have a 100% mortality rate.² Some modifications of the Ranson criteria have dropped the base deficit and fluid requirements, whereas others have added obesity as an independent risk factor.² The Acute Physiology and Chronic Health Evaluation

TABLE 41-3 Presentation of Acute Pancreatitis

General

- The patient may have acute mild symptoms or present with a severe acute attack with life-threatening complications.

Symptoms

- The patient may present initially with moderate abdominal discomfort to excruciating pain, nausea, shock, and respiratory distress.
- Abdominal pain occurs in 95% of patients. The pain is usually epigastric and radiates to either of the upper quadrants or the back in two-thirds of patients. In gallstone pancreatitis, the pain is typically sudden and quite severe and the intensity is often described as “knife-like” or “boring.” The pain usually reaches its maximum intensity within 30 minutes and may persist for hours or days. Repositioning the patient relieves very little of the pain. In alcohol abuse and other cases, the onset of pain may be less abrupt and poorly localized. Pain may not be the dominant symptom if it is masked by multiorgan failure.
- Nausea and vomiting occur in 85% of patients and usually follows the onset of abdominal pain. Vomiting does not provide relief of the abdominal pain.

Signs

- Marked epigastric or diffuse tenderness on palpation with rebound tenderness and guarding in severe cases. The abdomen is often distended and tympanic, with bowel sounds decreased or absent in severe disease.
- Vital signs may be normal, but hypotension, tachycardia, and low-grade fever are observed, especially with widespread pancreatic inflammation and necrosis.
- Dyspnea and tachypnea are often signs of acute respiratory complications. Jaundice and altered mental status may be present and have multiple causes. Other signs of alcoholic liver disease may be present in patients with alcoholic pancreatitis.

Laboratory tests

- Leukocytosis is frequently present; hyperglycemia or hypoalbuminemia may be present. Liver transaminases, alkaline phosphatase, and bilirubin are usually elevated in gallstone pancreatitis and in patients with intrinsic liver disease.
- The hematocrit may be normal, but hemoconcentration results from multiple factors, e.g., vomiting. In patients with third-space fluid loss, hemoconcentration is present and a reasonably accurate marker of severe disease.
- The total serum calcium is usually normal initially, but hypocalcemia disproportionate to the hypoalbuminemia may develop. Marked hypocalcemia is an indication of severe necrosis and a poor prognostic sign.
- The serum amylase concentration usually rises within 4 to 8 hours of the initial attack, peaks at 24 hours, and returns to normal over the next 8 to 14 days. Serum amylase concentrations greater than three times the upper limit of normal are highly suggestive of acute pancreatitis. Persistent elevations suggest extensive pancreatic necrosis and related complications. Normal concentrations may be observed if testing is delayed (amylase may have returned to normal) or in patients with hyperlipidemic pancreatitis (marked triglyceride elevations may interfere with amylase assay).
- Serum lipase is specific to the pancreas and concentrations are elevated and parallel the elevations in serum amylase. Levels remain elevated with pancreatic inflammation and return to normal when the inflammatory process resolves. Because of its longer half-life, elevations of serum lipase can be detected after the serum amylase has returned to normal.
- C-reactive protein is elevated by 48 hours after the onset of symptoms and may be useful in differentiating between mild and severe pancreatitis.
- Thrombocytopenia and an increase in the international normalized ratio are seen in some patients with severe acute pancreatitis.

Abdominal imaging

- Contrast-enhanced computed tomography (CT) is used to identify the cause of pancreatitis and confirm the diagnosis. It is less accurate for evaluating the gallbladder and biliary ducts. The test distinguishes interstitial from necrotizing pancreatitis, but does not distinguish between fat necrosis and acute fluid collection.
- Magnetic resonance imaging is used to grade the severity of acute pancreatitis, identify biliary duct problems that are not seen on CT, or if there are contraindications to contrast-enhanced CT.
- Ultrasonography of the abdomen is useful to determine pancreatic enlargement and peripancreatic fluid collections. It is also sensitive for detecting dilated biliary ducts and stones in the gallbladder.

consolidates clinical indicators, organ failure, and local complications and provides an ongoing assessment of disease severity.^{3,8,31}

Laboratory Tests Laboratory test results vary depending on the severity of the inflammatory process, whether damage is confined to the pancreas or involves contiguous organs, and the time course from the onset of the acute attack (see Table 41–3).^{8,32} C-reactive protein greater than 150 mg/L can be used to identify severe pancreatitis. Serum amylase and lipase are the most widely used for detecting elevations of pancreatic enzymes in AP, but elevations do not necessarily correlate with either the etiology or severity of the disease. In addition, many nonpancreatic diseases may be associated with hyperamylasemia, including salivary, renal, hepatobiliary, metabolic, female reproductive tract, and neoplastic diseases.^{2,8,32} Pancreatic isoamylase studies assist in determining the origin of elevated serum amylase concentrations, but are not useful for the diagnosis of AP because the diseases that simulate pancreatitis cause pancreatic rather than nonpancreatic amylase levels to rise. Serum concentrations of proinflammatory cytokines such as tumor necrosis factor- α and interleukin-6 are markers of disease severity, but elevations are not specific for pancreatitis and the tests are not widely available.^{25,26,32} Newer markers (e.g., urinary trypsinogen activation peptide) provide both diagnostic and prognostic information, but are not routinely used in practice. Other tests have been used to detect pancreatic enzymes in the serum (e.g., elastase) and urine (e.g., amylase), but most are not useful in the diagnosis of AP.^{1,2,32}

Abdominal Imaging A number of radiologic imaging techniques reveal pancreatic abnormalities during the disease course (see Table 41–3). Although no single imaging technique provides a positive diagnosis for AP, CT is usually considered the gold standard.

CLINICAL COURSE AND PROGNOSIS

The clinical course of AP varies from a mild transitory disorder to a severe necrotizing disease. Mild AP is self-limiting and subsides spontaneously within 3 to 5 days. Mortality increases with unfavorable early prognostic signs, local complications, and organ failure. The mortality of pancreatic necrosis is 10%, but increases to 30% to 40% in infected pancreatic necrosis.² Mortality is influenced by etiology, as idiopathic or postoperative AP have higher rates than gallstone- or alcoholic-induced disease. Mortality is higher during the first or second attacks than during recurrent acute episodes. Death during the first few days results from systemic complications. When death occurs after this period, it is associated with local complications.

TREATMENT

Acute Pancreatitis

■ DESIRED OUTCOME

Treatment of AP is aimed at relieving abdominal pain and nausea, replacing fluids, minimizing systemic complications, and preventing pancreatic necrosis and infection. Management varies depending on the severity of the attack (Fig. 41–3). Patients with mild AP respond very well to the initiation of supportive care and the reduction of pancreatic secretions. Patients with severe AP follow a more fulminant course and should be treated aggressively and monitored closely.

■ GENERAL APPROACH TO TREATMENT

All patients with AP should receive supportive care, including intravenous fluid resuscitation, adequate nutrition, and effective relief of pain and nausea. The use of nasogastric aspiration offers no clear advantage in patients with mild AP, but is beneficial in patients with profound pain, severe disease, paralytic ileus, and intractable vomiting.² Patients predicted to follow a severe course will require treatment of cardiovascular, respiratory, renal, and metabolic complications. ① Aggressive fluid resuscitation is essential to correct intravascular volume. The prognosis of the patient often depends on the rapidity and adequacy of volume restoration, as large quantities of fluid are sequestered within the peritoneal and retroperitoneal spaces. Vasodilation from the antiinflammatory response, vomiting, and nasogastric suction contribute to hypovolemia and fluid and electrolyte losses. Intravenous colloids may be required to maintain intravascular volume and blood pressure because fluid losses are rich in protein. Patients with pancreatitis and systemic inflammatory response syndrome may benefit from treatment with drotrecogin alfa. Intravenous potassium, calcium, and magnesium are used to correct deficiency states. Insulin is used to treat hyperglycemia. Local complications resolve as the inflammatory process subsides; however, patients with necrotizing pancreatitis may require antibiotics and surgical intervention. ② Medications listed in Table 41–2 should be discontinued, if possible.

■ NONPHARMACOLOGIC THERAPY

Nonpharmacologic therapy includes ERCP for removal of an underlying biliary tract gallstone, surgery, and nutritional support. Surgery is indicated in patients with pseudocyst, pancreatic abscess, or to drain the pancreatic bed if hemorrhagic or necrotic material is present.

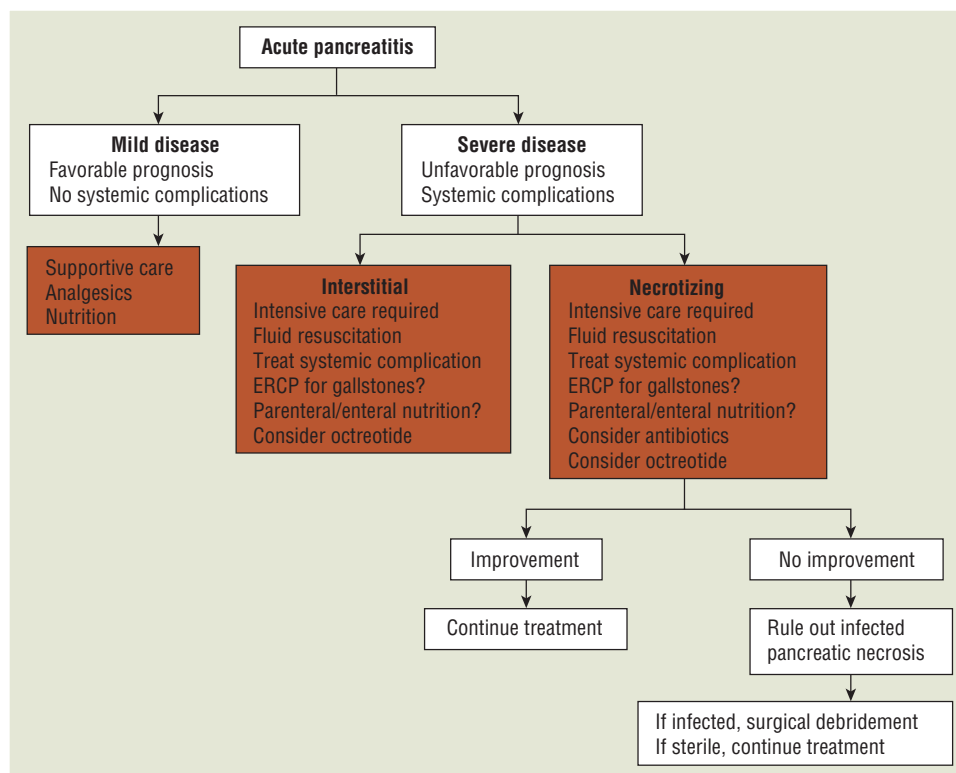

FIGURE 41-3. Algorithm of guidelines for evaluation and treatment of acute pancreatitis. (ERCP, endoscopic retrograde cholangiopancreatography.)

Nutrition and Probiotics

Nutritional support plays an important role in the management of patients with mild or severe disease as AP creates a catabolic state that promotes nutritional depletion, which can impair recovery, increase the risk of complications, and prolong hospitalization.^{33–35} Patients with mild AP can begin oral feeding when bowel sounds have returned and pain has resolved.⁸ In severe or complicated disease, nutritional deficits develop rapidly and are complicated by tissue necrosis, organ failure, and surgery. Enteral or parenteral nutrition should be initiated if it is anticipated that oral nutrition will be withheld for more than 1 week, but the optimal means of providing nutrition is controversial.^{35–37} In the past, there was concern that enteral feeding stimulated pancreatic enzyme secretion and exacerbated the underlying disease. Today, there is consensus among studies in patients with severe AP that enteral feeding is the preferred route of administration because it is as safe and as effective as parenteral nutrition, attenuates the acute inflammatory response, and improves disease severity.^{34–37} Although nasojejunal administration has been used, the nasogastric route also appears to be safe and effective.^{33,38} If enteral feeding is not possible or if the patient is unable to obtain sufficient nutrients, total parenteral nutrition should be implemented before protein and calorie depletion becomes advanced. Intravenous lipids should not be withheld unless the serum triglyceride concentration is greater than 500 mg/dL.² Preliminary data suggest that the early nasojejunal administration of probiotics (such as lactobacillus) to enteral nutrition may reduce bacterial translocation and possibly decrease pancreatic necrosis and abscess.^{39–42}

■ PHARMACOLOGIC THERAPY

Recommendations

Patients with mild AP respond well to supportive care, intravenous fluid resuscitation, nutrition, and relief of pain and nausea. Pain and nausea can be treated with moderate dosages of intravenous analgesics and antiemetics. Antibiotics are not indicated in mild disease. Patients with severe AP require intensive care, vigorous fluid resuscitation, nutritional support, and analgesia. Antisecretory drugs may be

used to prevent stress-related mucosal bleeding. Octreotide may be tried in severe AP, but its efficacy remains uncertain (see Fig. 41–3). The use of prophylactic antibiotics is controversial in the absence of signs of infection except in patients with biliary tract gallstones, or in severe AP when pancreatic necrosis or abscess is likely.

Relief of Abdominal Pain

Analgesics are administered to reduce the severity of abdominal pain. The most important factors to consider in selecting an analgesic are efficacy and safety. Although the administration of some narcotics is associated with mild and transient increases in serum amylase and lipase, these effects are not deleterious to the patient. Traditionally, treatment was usually initiated with parenteral meperidine (50 to 100 mg every 3 to 4 hours) because it did not cause pancreatitis or significantly alter the function of the sphincter of Oddi, thereby worsening the pancreatitis.^{43,44} 3 Today many hospitals have either restricted or eliminated the use of meperidine because, unlike other narcotics, there is a ceiling on the dose and it is contraindicated in patients with renal failure. Active metabolites of meperidine accumulate in renal impairment and may cause seizures or psychosis. The maximum recommended parenteral dose of meperidine is 600 mg/day in patients with normal renal function, but it should not be used in patients with renal failure.

Parenteral morphine is often recommended for pain control because it provides a longer duration of pain relief than meperidine with less risk of seizures. However, its use in AP is sometimes avoided because it is thought to cause spasm of the sphincter of Oddi, increases in serum amylase, and, rarely, pancreatitis.² Although morphine increases biliary pressure, there is no evidence to indicate that it is contraindicated for use in AP as no studies have compared clinical outcomes of AP using various analgesics.⁴⁴ Hydromorphone may be used because it also has a longer half-life than meperidine. Patient-controlled analgesia should be considered in patients who require frequent narcotic dosing (e.g., every 2 to 3 hours) and usually achieves adequate pain control. Dosing should be monitored carefully and adjusted daily. There is no evidence that antisecretory drugs (such as H₂-receptor antagonists or proton pump inhibitors) prevent an exacerbation of abdominal pain.⁴⁵

Limitation of Systemic Complications and Prevention of Pancreatic Necrosis

Aggressive fluid resuscitation and support of respiratory, renal, cardiovascular, and hepatobiliary function may limit systemic complications.^{2,30,46,47} However, there is no proven method to prevent these complications.⁴⁵ Although hemoconcentration (decreased intravascular volume) is strongly associated with pancreatic necrosis, it is not clear whether vigorous fluid resuscitation alone during the first 24 hours can prevent pancreatic necrosis.⁴⁸ Procedures such as ERCP, hypothermia, nasogastric suction, pancreatic irradiation, peritoneal lavage, and thoracic duct drainage remain unproven.^{2,45}

A number of agents have been investigated to limit disease progression by either directly or indirectly reducing pancreatic secretion, inhibiting the action of circulating inflammatory mediators, or increasing pancreatic microcirculation.^{30,46,47,49–51} The use of parenteral H₂-receptor antagonists or proton pump inhibitors does not improve the overall outcome of patients with AP.⁸ Corticosteroids are not helpful in limiting systemic complications and altering the course of the disease.⁴⁷ Clinical studies with protease inhibitors such as aprotinin and gabexate fail to reduce mortality in AP.^{8,46–48,50} Conflicting or inconclusive data exists regarding the efficacy of atropine, lexipafant, low-molecular weight dextran, antioxidants such as N-acetylcysteine, indomethacin, interleukin-10, and infliximab.^{47,49,51}

Somatostatin and its synthetic analog octreotide are potent inhibitors of pancreatic enzyme secretion and have been used to interrupt the inflammatory process. Several studies and a meta-analysis that evaluated the efficacy of somatostatin and octreotide suggest a slight trend toward benefit.^{52–54} A randomized, open-label trial in severe AP indicates that octreotide 0.1 mg subcutaneously every 8 hours

decreased mortality, sepsis, and length of hospital stay.⁵³ In a study using higher dosages (0.5 mcg/kg per hour given by continuous intravenous infusion), octreotide provided a decrease in serum amylase, greater improvement in pancreatic edema, and earlier return to oral intake than controls.⁵⁴ These studies are confounded by the lack of a reliable scoring system for severe AP, had small numbers of patients, were not placebo-controlled, and included patients with mild disease.⁴⁶

4 There is insufficient data to support the routine use of somatostatin or octreotide in the treatment of AP.

CLINICAL CONTROVERSY

Some clinicians believe that octreotide should be used routinely to decrease pancreatic secretions in patients with AP, whereas others believe it is unnecessary. Octreotide can be used in selected patients with severe AP, but its efficacy in decreasing mortality remains uncertain.

Prevention of Infection

5 Patients with severe AP complicated by necrosis should receive antibiotic prophylaxis with a broad-spectrum antibiotic (Fig. 41–4).^{1–3,45,55} The use of antibiotic prophylaxis in those without CT-proven necrosis is controversial.^{3,8,55} Prophylactic antibiotics do not offer any benefit in cases of mild AP or when there is no necrosis.

Antibiotic prophylaxis in early clinical trials showed no benefit, but the studies were flawed, as they included all degrees of disease severity and did not have a sufficient number of patients with severe necrotiz-

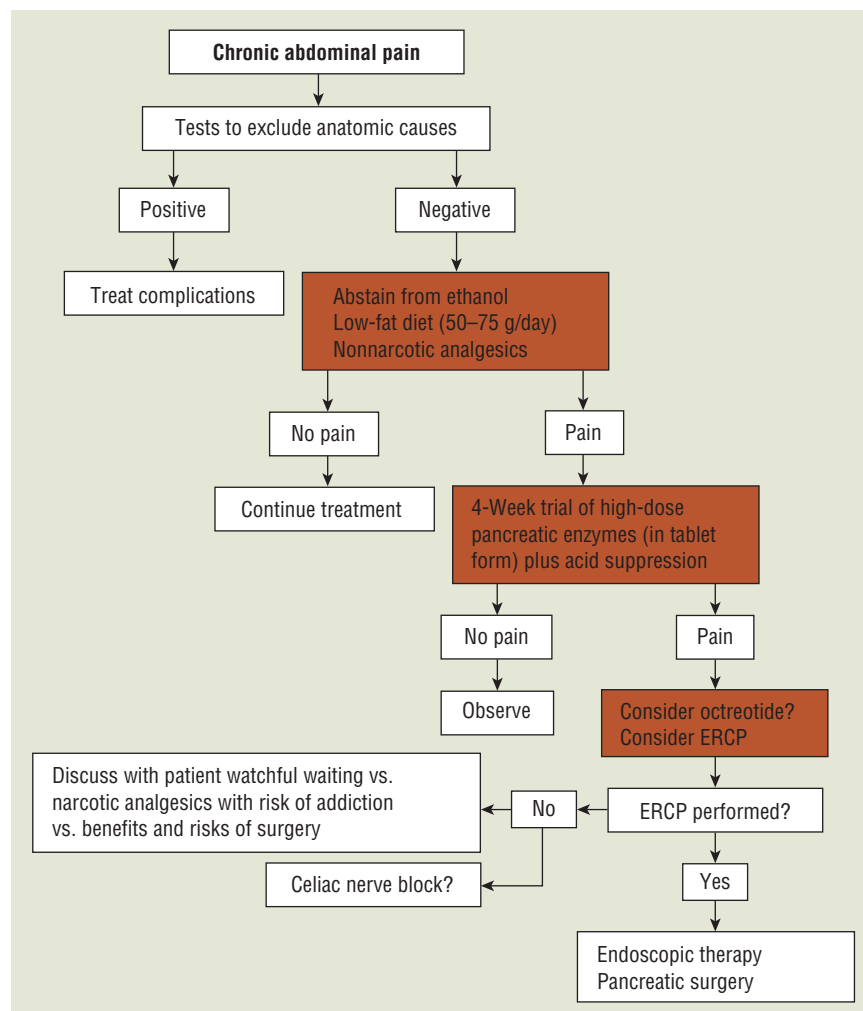

FIGURE 41-4. Algorithm of guidelines for the treatment of chronic abdominal pain in chronic pancreatitis. (ERCP, endoscopic retrograde cholangiopancreatography.)

ing AP.^{1,47} In addition, the studies used ampicillin, which does not penetrate well into pancreatic tissue.⁴⁷ Imipenem-cilastatin, metronidazole, cefotaxime, piperacillin, mezlocillin, ofloxacin, and ciprofloxacin all achieve satisfactory bactericidal tissue concentrations, whereas aminoglycosides have poor penetration.^{46,47,55} However, the importance of antibiotic penetration into pancreatic tissue has been debated, as it is the peripancreatic retroperitoneal necrotic fat and debris, not the pancreas itself, that becomes infected.

At present, there is sufficient evidence to recommend that patients with severe acute necrotizing pancreatitis receive antibiotic prophylaxis as soon as possible after diagnosis. Several randomized clinical trials have compared antibiotic prophylaxis with no antibiotics in patients with acute necrotizing pancreatitis, with varying results (Table 41–5).^{56–61} In one study, prophylaxis with cefuroxime 4 to 5 g/day lowered mortality, length of hospital stay, and the overall infection rate, but a decrease in the total number of infections was attributed to fewer urinary tract infections in the antibiotic group.⁵⁶ In contrast, other antibiotic regimens decreased the incidence of sepsis, but had no effect on mortality.^{57–59} Another study with imipenem-cilastatin found a reduction in the need for surgery, but no effect on mortality or sepsis.⁶⁰ Studies that included severe AP without CT demonstration of necrosis failed to show a beneficial effect on mortality.^{58,61} Despite differences among the studies, two meta-analyses and a Cochrane review concluded that prophylaxis with broad-spectrum antibiotics decreases sepsis and mortality in patients with severe AP and necrosis.^{62–64} Generally, treatment is initiated with imipenem-cilastatin or a fluoroquinolone plus metronidazole and continued for 10 to 14 days.^{8,55} Early antibiotic treatment may improve the prognosis of necrotizing AP,⁶⁵ but benefits must be weighed against inappropriate antibiotic prophylaxis and increasing microbial resistance.

Selective gut decontamination with oral nonabsorbable antibiotics is aimed at eradicating bacteria in the intestinal flora and reducing translocation.^{55,66} This alternative may be of benefit in reducing the risk of pancreatic infection, but randomized controlled trials in patients with AP are needed to confirm its effectiveness when compared to parenteral antibiotic prophylaxis.^{1,2,47,55} Because the source of bacterial contamination is most likely the colon, the choice of antibiotic should be broad-spectrum, covering the range of enteric aerobic gram-negative bacilli and anaerobic microorganisms. Treatment should be initiated within the first 48 hours and continued for 2 to 3 weeks. Imipenem-cilastatin (500 mg orally every 8 hours) is probably the most effective agent, but a fluoroquinolone (such as ciprofloxacin or levofloxacin) with metronidazole should be considered for the penicillin-allergic patient.^{1,47}

Antibiotic prophylaxis is not always effective in eliminating the risk of infected pancreatic necrosis. Patients receiving broad-spectrum antibiotics are at increased risk for resistant bacterial and fungal infections leading to a worsening of the disease course. There appears to be a shift toward gram-positive infections (primarily enterococci and staphylococci) in AP patients who receive antibiotic prophylaxis as compared to

earlier studies when patients did not receive antibiotic prophylaxis.⁶⁷ The use of prophylactic antibiotics may also alter the bacteriology of infected necrosis and is associated with an increase in the incidence of fungal and β -lactam-resistant gram-positive organisms.⁶⁸ The rise in fungal infections has led some clinicians to consider the addition of an antifungal agent to the prophylactic regimen.⁶⁹ Although agents such as fluconazole penetrate pancreatic tissue,⁷⁰ the effectiveness of prophylactic antifungal agents remains unproven and there are no definitive recommendations for use. Once infection develops in the patient with necrotic AP, surgical debridement is required.

CLINICAL CONTROVERSY

Some clinicians believe that antibiotic prophylaxis is necessary in patients with severe AP so as to prevent pancreatic infection, whereas others believe that this practice is unnecessary. Antibiotic use in AP remains controversial especially in patients without definite proof of pancreatic necrosis. Patients with severe AP complicated by necrosis should receive prophylactic treatment with a broad-spectrum antibiotic.

POST-ERCP PANCREATITIS

The clinical characteristics of post-ERCP pancreatitis are similar to those of AP from other causes. In most cases, the pancreatitis is mild and resolves in several days. Pretreatment with octreotide, corticosteroids, calcium channel blockers, natural β -carotene, and aprotinin has been disappointing,^{1,11,71,72} but somatostatin, diclofenac suppositories, and gabexate have shown some benefit.^{1,73–75} To date, there have not been any studies to evaluate the cost-effectiveness of prophylactic therapy.

CHRONIC PANCREATITIS

CP is an inflammatory condition that usually results in functional and structural damage to the pancreas. In most patients CP is progressive, and loss of pancreatic function is irreversible. Permanent destruction of pancreatic tissue usually leads to exocrine and endocrine insufficiency.^{5–8} Cystic fibrosis may be associated with pancreatic exocrine insufficiency in children and is discussed in Chap. 32.

ETIOLOGY

Table 41–6 identifies the etiologic risk factors associated with CP. Prolonged alcohol consumption accounts for 70% of all cases in the United States, approximately 20% are idiopathic, and the remaining 10% constitute other, less-frequent causes.^{5–8} Recent evidence sug-

gests that there is a strong association between cigarette smoking and CP.^{5,6} Autoimmune pancreatitis may be isolated or occur in association with immune-mediated disorders.⁷⁶ Although cholelithiasis may coexist with CP, gallstones rarely lead to chronic disease.

PATHOPHYSIOLOGY

The exact mechanism by which alcohol causes CP is uncertain. One major theory is that alcohol-induced pancreatitis progresses from inflammation to cellular necrosis, and that fibrosis occurs over time. Chronic alcoholism results in a number of changes in pancreatic fluid that creates an environment for the formation of intraductal protein plugs that block small ductules.⁵ Blockage of the ductules produces progressive structural damage in the ducts and the acinar tissue. Calcium complexes to the protein plugs, first in the small ductules and then in the main pancreatic duct (see Fig. 41–1), eventually resulting in injury and destruction of pancreatic tissue. Newer theories have been hypothesized, all of which lead to pancreatic destruction and insufficiency.^{6,77}

The pathogenesis of the abdominal pain associated with CP is multifactorial and related in part to increased intraductal pressure secondary to continued pancreatic secretion, pancreatic inflammation, and abnormalities involving pancreatic nerves. Malabsorption of protein and fat occurs when the capacity for enzyme secretion is reduced by 90%.⁵ Lipase secretion decreases more rapidly than the proteolytic enzymes. Bicarbonate secretion may be decreased, leading to a duodenal pH of less than 4.⁵ A minority of patients develop complications, including pancreatic pseudocyst, abscess, and ascites or common bile duct obstruction, leading to cholangitis or secondary biliary cirrhosis. Bleeding is associated with a variety of causes.

CLINICAL PRESENTATION

Signs and Symptoms

The clinical presentation of CP varies depending on the etiology of the disease, the severity of the inflammatory process, and the extent of irreversible damage to the pancreas (Table 41–7).^{5–8} The classic features are abdominal pain, malabsorption, weight loss, and diabetes. Most alcoholic patients have chronic pain; others have intermittent attacks or painless pancreatitis. Abstinence from ethanol may relieve pain, but does not prevent exocrine dysfunction.⁵ The course of pain is unpredictable, but may lessen as pancreatic insufficiency progresses.⁷⁸

DIAGNOSIS

Most patients with CP have a history of heavy alcohol use and attacks of recurrent upper abdominal pain. The diagnosis is suspected in those with suggestive signs and symptoms and confirmed by the classic triad of calcification of the pancreas, steatorrhea, and diabetes, but surgical biopsy of the pancreas through laparoscopy or laparotomy is the gold standard.⁵ In the absence of histologic samples, imaging techniques (see Table 41–7) are helpful in detecting pancreatic calcification, other causes of pain (ductal obstruction secondary to stones, strictures, or pseudocysts), and in differentiating CP from pancreatic cancer. Direct tests of pancreatic exocrine function involve the collection of pancreatic fluid after stimulation with exogenous hormones such as secretin or cholecystokinin. The functional tests are not diagnostic, but serve as a sign of CP and a measure of the severity of injury.⁷⁹ Because these tests are complicated and require intubation and special collection techniques, they are not routinely performed.

CLINICAL COURSE AND PROGNOSIS

Patients with alcoholic CP usually present with an initial acute attack followed by successive attacks that are slower to resolve. Continued

TABLE 41-7 Presentation of Chronic Pancreatitis

General

- The patient may appear well-nourished or have coexistent signs of malnutrition and chronic alcoholic liver disease. During the acute attack, the patient may be thought to have acute pancreatitis until the diagnosis of chronic pancreatitis is established.

Symptoms

- Dull epigastric or abdominal pain that radiates to the back is seen. Pain is the most prominent clinical feature and tends to be episodic initially, but becomes more consistent as the disease progresses. A minority of patients will have no pain.
- Characteristically the pain is deep-seated, positional, frequently nocturnal, and unresponsive to medication. The intensity of the pain varies from mild to severe, and does not usually correlate directly with the inflammatory process or other physical findings. Severe attacks last from several days to several weeks and may be aggravated by eating.
- Nausea and vomiting often accompany the pain.

Signs

- Steatorrhea (excessive loss of fat in the feces) and azotorrhea (excessive loss of protein in the feces) are seen in most patients. Steatorrhea is often associated with diarrhea and bloating.
- Weight loss may be seen.
- Approximately 50% of patients with advanced pancreatic insufficiency present with vitamin B₁₂ malabsorption.
- Jaundice occurs in approximately 10% of patients.
- Pancreatic diabetes is usually a late manifestation that is commonly associated with pancreatic calcification. Ketoacidosis, vascular complications, and nephropathy are uncommon with this form of diabetes.
- Neuropathy is sometimes seen.
- Complications, including pancreatic pseudocysts, pleural effusions, and ascites, may be detected on physical examination.

Laboratory tests

- The white blood cell count, fluids, and electrolytes usually remain normal unless fluids and electrolytes are lost as a result of vomiting and diarrhea.
- Serum amylase and lipase concentrations usually remain normal unless the pancreatic duct is blocked or a pseudocyst is present.

Other diagnostic tests

- Malabsorption of fat can be detected by Sudan staining of the feces or by a 72-hour quantitative measurement of fecal fat.
- Ultrasonography is the simplest and least expensive of the imaging techniques. Abdominal computed tomography is often used in patients who have a negative or unsatisfactory ultrasonogram examination.
- Endoscopic retrograde cholangiopancreatography is the most sensitive and specific test for the diagnosis of chronic pancreatitis. However, because it is associated with complications, it is reserved for patients for whom the diagnosis cannot be established by imaging techniques.

From Owyang,⁵ Etemad and Whitcomb,⁷ and Draganov and Forsmark.⁸

alcohol use leads to chronic abdominal pain and progressive exocrine and endocrine insufficiency.⁸ In approximately 50% of patients, the pain diminishes 5 to 10 years after the onset of symptoms.⁸⁰ Steatorrhea, calcification, and diabetes usually develop after 10 to 20 years of heavy ethanol ingestion. Most patients present with varying degrees of pain, malnutrition, and glucose intolerance. The 10-year survival rate is approximately 70%, whereas the 20-year survival rate is 45%.⁸ Approximately 15% to 20% of patients with alcohol-related CP die of complications associated with acute attacks. Most deaths occur as a consequence of malnutrition, infection, or ethanol, narcotic, and tobacco use. CP is a risk factor for pancreatic adenocarcinoma, which contributes to the high mortality.^{5,7} The clinical course of idiopathic CP is more favorable than that of alcoholic pancreatitis.^{5,10}

TREATMENT

Chronic Pancreatitis

■ DESIRED OUTCOME

The treatment of uncomplicated CP is aimed primarily at the control of chronic abdominal pain (see Fig. 41–4) and the correc-

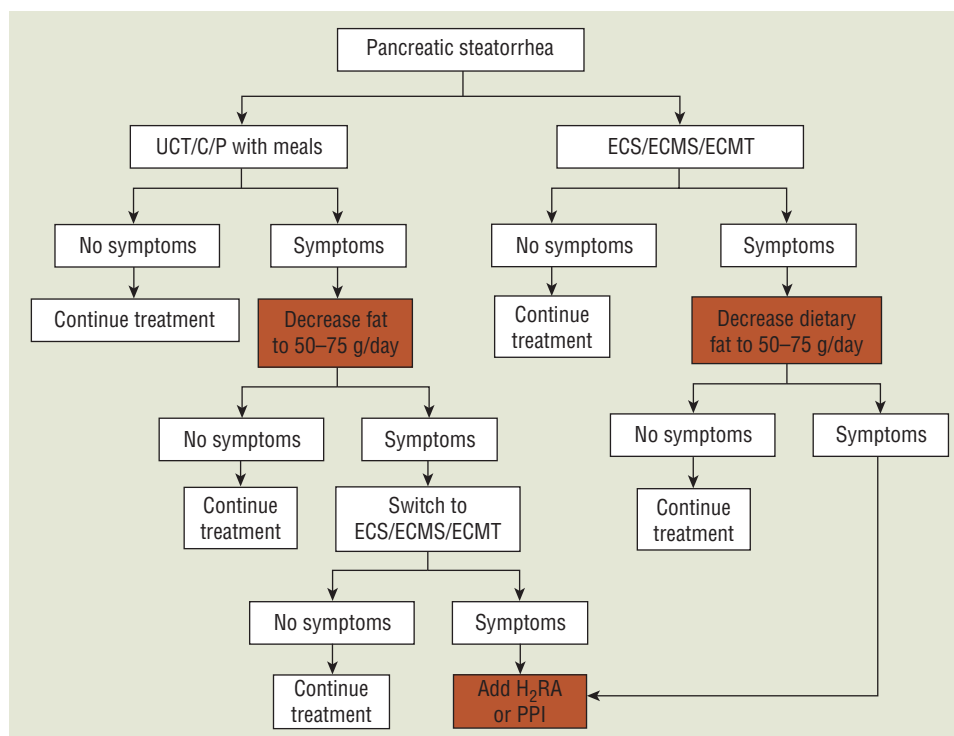

FIGURE 41-5. Algorithm of guidelines for the treatment of pancreatic steatorrhea in chronic pancreatitis. (C, capsule; ECMS, enteric-coated microsphere; ECS, enteric-coated sphere; ECMT, enteric-coated microtablet; H₂RA, H₂-receptor antagonist; P, powder; PPI, proton pump inhibitor; UCT, uncoated tablet.)

tion of malabsorption with pancreatic enzymes (Fig. 41-5). Diabetes associated with CP may require exogenous insulin.

■ GENERAL APPROACH TO TREATMENT

The majority of patients with alcohol-related CP require pain control and pancreatic enzyme supplementation.^{5,8,80-83} Avoidance of alcohol usually decreases pain, but oral analgesics remain the cornerstone of therapy. Nonnarcotic analgesics such as acetaminophen, nonsteroidal antiinflammatory drugs (NSAIDs), or tramadol should be tried initially. The dose and frequency of administration is usually increased before the patient is switched to a narcotic. Patients unresponsive to nonnarcotic analgesics should be given a trial of non-enteric-coated pancreatic enzymes prior to using narcotics. Narcotics are required for patients with severe pain. Specific endoscopic or surgical procedures may be necessary in patients refractory to drug therapy. Patients with malabsorption require pancreatic enzymes to reduce steatorrhea and azotorrhea. Most patients achieve satisfactory results with standard-dosage regimens of either the non-enteric-coated or microencapsulated enteric-coated dosage forms. In patients who remain symptomatic, dietary fat should be reduced. An antisecretory drug should be added to the regimen when enzymes alone provide an inadequate reduction in steatorrhea or when low duodenal pH is documented.

■ NONPHARMACOLOGIC THERAPY

6 Abstinence from alcohol is the most important factor in preventing abdominal pain in the early stages of alcoholic CP, although reports of the effect of abstinence from alcohol have varied.^{5,80} Small and frequent meals (6 meals per day) and a diet restricted in fat (50 to 75 g/day) are recommended to minimize postprandial pancreatic secretion and resulting pain.⁸³ Enteral nutrition (elemental diets) may be necessary if oral calorie intake is insufficient or if the patient is chronically debilitated.³³ Parenteral nutrition should be instituted when an enteral tube cannot be placed, gastric decompression is required, or a complicated fistula is present.³³

In some patients, pain may be associated with pseudocysts, peptic ulcer, cholelithiasis, biliary or duodenal obstruction, or pancreatic cancer, and if detected may be amenable to other forms of treatment

(see Fig. 41-4), including endoscopic procedures such as sphincterotomy, pancreatic duct stenting, and lithotriptic destruction of pancreatic calculi.^{5,8,80,84} The most common indication for surgery is abdominal pain that is refractory to medical therapy. Surgical procedures that alleviate pain include a subtotal pancreatectomy, decompression of the main pancreatic duct, or interruption of the splanchnic nerves.^{5,8,80,84} Although the pain may diminish as the gland deteriorates, it is unreasonable to wait years for spontaneous relief. A percutaneous injection of a corticosteroid or endoscopic ultrasonography-guided injection of a local anesthetic into the celiac ganglion (celiac plexus block) may be attempted. Pain relief obtained by these procedures lasts only a few months and repeated treatments are not as effective.^{80,84,85}

■ PHARMACOLOGIC THERAPY

Recommendations

Pain management should begin with nonnarcotic analgesics such as acetaminophen or NSAIDs (see Fig. 41-4). If pain persists, the response to exogenous non-enteric-coated pancreatic enzymes should be evaluated in patients with mild to moderate CP. If these measures fail, an oral narcotic should be added to the drug regimen. Parenteral narcotics should be reserved for patients with severe pain that is unresponsive to oral analgesics. Nonnarcotic modulators of chronic pain should be considered in patients with difficult-to-manage pain.

Most patients with malabsorption will require pancreatic enzyme supplementation and a reduction in dietary fat so as to achieve satisfactory nutritional status and become relatively asymptomatic. An initial prandial dose of 30,000 international units of lipase (uncoated tablet, capsule, or powder) is recommended to be given with each meal (see Fig. 41-5). Unlike the treatment of pain, the use of the microencapsulated enteric-coated pancreatic enzyme dosage forms are often selected to treat steatorrhea because of their higher potency and the need to take fewer tablets or capsules. The total daily lipase dose should be titrated to reduce steatorrhea. In some patients, a reduction in dietary fat may be necessary. An antisecretory drug should be added to the regimen when there is an inadequate response to enzyme therapy alone (see Fig. 41-5). If these measures are

ineffective, documentation of the diagnosis and exclusion of other diseases should be undertaken.

Relief of Chronic Abdominal Pain

Analgesics **7** Nonnarcotic analgesics such as acetaminophen or NSAIDs should be given before meals to prevent postprandial exacerbation of pain (Table 41–8).^{5,80–84} Treatment should be individualized and should begin with the lowest effective dose. The dosage regimen should usually be maximized before switching to narcotic alternatives. Analgesics should be scheduled around the clock, because they may be more effective and the total amount of medication required over 24 hours may be less. If the nonnarcotic analgesic is ineffective, consideration should be given to using tramadol or adding a low-dose narcotic to the regimen (e.g., acetaminophen plus codeine). Severe pain relief necessitates the use of opiate analgesics. Narcotics should not be withheld because of the risk of inducing addiction. Oral agents should be used before parenteral narcotics are administered. Nonnarcotic modulators of chronic pain such as selective serotonin reuptake inhibitors (e.g., paroxetine) or tricyclic antidepressants should be considered in difficult-to-manage patients.^{1,81,84} Tricyclic antidepressants are useful adjuncts, as they not only treat depression, but have a direct effect on pain and potentiate the effect of opioid narcotics.⁸⁴ Referral to a dedicated pain clinic should be considered when available.

Pancreatic Enzymes **8** The use of orally administered pancreatic enzymes to relieve abdominal pain remains controversial, although a consensus review has advocated their use (see Table 41–8).⁸⁰ Results from clinical trials are conflicting, especially when non–enteric-coated preparations were compared to enteric-coated enzyme products.^{5,81–84,86,87} Only those studies that used a non–enteric-coated dosage form plus a gastric acid suppressant demonstrated a reduction in pain.⁸ The administration of non–enteric-coated pancreatic enzymes may afford pain relief by suppressing pancreatic enzyme secretion through a negative feedback mechanism involving proteases present in the duodenum.⁸⁸ Effective enzyme therapy reduces pancreatic stimulation, diminishes intraductal pressure, and should decrease pain. Enteric-coated enzyme preparations deliver proteases too far distally to achieve a negative-feedback effect. Possible reasons for failure of enzymes to relieve abdominal pain include insufficient concentrations of trypsin in the pancreatic enzyme preparation and gastric acid inactivation or proteolytic destruction of trypsin.^{5,84,86,87} The addition of an antisecretory drug to the non–enteric-coated enzyme preparation is recommended, as it reduces the degradation of proteases in the stomach.^{5,81} A trial of non–enteric-coated enzymes may be beneficial in a subset of individuals, primarily those with mild to moderate disease and in patients with a nonalcoholic etiology.^{5,80,84}

CLINICAL CONTROVERSY

Some clinicians believe that pancreatic enzyme supplementation should be used to relieve mild to moderate abdominal pain, whereas others believe that these agents are ineffective. A trial of non–enteric-coated pancreatic enzyme supplementation and an antisecretory drug should be given to patients with mild to moderate disease when nonnarcotic medications have failed and before initiating treatment with narcotics.

Other Agents A number of other agents, including octreotide, allopurinol, and antioxidant therapy (e.g., organic selenium, vitamin E, vitamin C, or β -carotene), have been investigated for the purposes of relieving pain in chronic pancreatitis.^{5,80} There is insufficient evidence to support the use of these agents.

TABLE 41-8 Guidelines for the Pharmacologic Treatment of Chronic Pancreatitis

Treatment of chronic pain (oral drug regimens)

Nonnarcotic

- Acetaminophen: Dosage should be limited to 500 mg four times a day if patient drinks more than two alcoholic beverages per day; increased risk of hepatotoxicity, especially in chronic heavy alcohol use
- Nonsteroidal antiinflammatory drugs (NSAIDs): Standard dosage regimens of aspirin or traditional NSAIDs (e.g., ibuprofen). Use with caution in patients at risk for upper GI bleeding and in renal insufficiency
- Tramadol: 50–100 mg every 4–6 h not to exceed 400 mg/day; has narcotic-like effect; contraindicated in alcohol or hypnotic intoxication; drug interactions; expensive
- Consider use of selective serotonin reuptake inhibitors (e.g., paroxetine) or tricyclic antidepressants in difficult-to-manage patients

Narcotics

- Codeine 30–60 mg every 6 h; hydrocodone 5–10 mg every 4–6 h; oxycodone 5–10 mg every 6 h; fentanyl patch 25–100 mcg/h; pentazocine 25–50 mg every 4–6 h; propoxyphene 65 mg every 4–6 h not to exceed 390 mg/day; methadone 2.5–10 mg every 4–6 h; morphine sulfate (extended-release) 30–60 mg every 8–12 h; hydromorphone 2–4 mg every 4–6 h
- Risk of potentiation with alcohol; impaired respiration; constipation; hypotension
- Dosing is usually based on providing continuous pain relief; consider combining narcotic with acetaminophen or NSAIDs; narcotic dependence is common; narcotic abuse is a concern in alcoholics; tolerance to narcotics may develop

Pancreatic enzymes

- Requires that high doses of proteases be delivered to the duodenum for relief of pain; non–enteric-coated pancreatic enzymes are recommended and should be taken with each meal and at night if needed; recommend name brands with proven efficacy and safety, as generic products have been associated with treatment failure; add H_2 -receptor antagonist or proton pump inhibitor
- Viokase-8 tablets or Ku-Zyme HP capsules: 6–8 with each meal (see Table 41–9) plus either an H_2 -receptor antagonist or proton pump inhibitor
- May cause nausea, cramping, hyperuricemia; hypersensitivity to pork protein

Treatment of maldigestion and steatorrhea

Non–enteric-coated pancreatic enzymes

- Viokase-8 tablets or Ku-Zyme HP capsules, 6–8 with each meal and at bedtime if needed (see Table 41–9)
- Addition of antisecretory drug (H_2 -receptor antagonist or proton pump inhibitor) may increase efficacy, but also increases cost
- May cause nausea, cramping, hyperuricemia; hypersensitivity to pork protein

Enteric-coated pancreatic enzymes

- Enteric-coated spheres, microspheres, and microtablets are available (see Table 41–9)
- Usually requires fewer capsules or tablets per meal than non–enteric-coated enzymes; may enhance compliance
- Does not usually require additional antisecretory agents; may be less expensive than non–enteric-coated plus H_2 -receptor antagonist or proton pump inhibitor
- May cause nausea, cramping, hyperuricemia; hypersensitivity to pork protein
- Fibrosing colonopathy has occurred in children using preparations that contain the methacrylic acid copolymer coating

Antisecretory drugs

- May improve enzyme treatment of steatorrhea

From references 5, 81–84, 86, 87, 89–91.

Treatment of Malabsorption

Malabsorption requires treatment when steatorrhea is documented (>7 g of fat in the feces per 24 hours while on a diet of 100 g/day of fat) and persistent weight loss occurs despite efforts to correct it. The combination of pancreatic enzymes (lipase, amylase, and protease) and a reduction in dietary fat (to <25 g/meal) enhances the patient's nutritional status and reduces (but does not totally correct) steatorrhea. **9** The success of a pancreatic enzyme preparation requires that it contain a high concentration of lipase and proteases, be enteric-coated to avoid destruction by gastric acid, and be the appropriate size to permit efficient delivery of the enzymes to the small intestine.^{5,89–92} A critical amount of enzymes must be delivered to the duodenum in sufficient concentrations for digestion to occur. The maximal delivery of endogenous pancreatic lipase following a meal is approximately 140,000 international units per hour for 4 hours.⁵ Malabsorption is

minimized if the concentration of enzymes delivered to the duodenum is at least 5% of normal maximal enzyme output. This requires that approximately 30,000 international units of lipase and 10,000 international units of trypsin be delivered during the 4-hour postprandial period.^{5,89} In many cases, the lipase dose will need to be increased (up to a maximum of 75,000 international units) because of insufficient lipolytic activity.⁹⁰ Most exogenous lipase is rapidly and irreversibly destroyed at an intragastric pH below 4.^{5,89–92} Enteric coating is an effective way to protect the acid-labile enzymes, but the enzymes must be emptied from the stomach at the same rate as the ingested food and released in the duodenum. The polymer used to coat the enzyme is pH-dependent and dissolves in the duodenum at a pH of >5, where the enzymes are released.^{5,89} If an intragastric pH of <4 prevails, the enteric coating will remain intact and the enzymes will be released in the upper portion of the small intestine. A duodenal pH of <4 may prolong dissolution of the enteric coating and release of the enzymes. The size of the enteric-coated enzyme preparation influences the timing of enzyme delivery to the duodenum.^{5,89,93,94} Microencapsulated enteric-coated preparations with a microcapsular diameter of about 1.4 mm empty from the stomach in synchrony with food and mix effectively with intestinal chyme.^{5,89} Large enteric-coated tablets and some microspheres (microcapsular diameter >2 mm) do not empty at the same rate as stomach contents, and thus are not as effective in treating steatorrhea.

Pancreatic Enzyme Supplements Oral pancreatic enzyme supplements are available as a powder, uncoated or coated tablet, capsule, enteric-coated sphere (ECS) and microsphere (ECMS), or enteric-coated microtablet (ECMT) encased in a cellulose or gelatin capsule (Table 41–9). Recommended dosages of microencapsulated enteric-coated products are not necessarily more effective than recommended dosages of the non–enteric-coated enzyme preparations.^{5,89} This is because a lesser quantity of lipase is usually administered at

each meal with the enteric-coated preparations. Thus the most important determinant in reducing steatorrhea is the total amount of active lipase that reaches the duodenum and empties with the meal. Generic pancreatic enzyme preparations have been associated with treatment failures when substituted for brand-name products.⁹⁵

Pancreatic enzyme supplements differ in enzyme content and activity, bioavailability, clinical efficacy, patient acceptance, and cost. Compliance is often a problem because of the number of tablets or capsules required per dose, the need to take them with each meal or snack, and the cost of pancreatic enzyme therapy. The efficacy of enzyme supplements may be optimized by administration during or after meals.⁹⁶ Consideration should be given to selecting a product that contains higher lipase activity (see Table 41–9) so that fewer tablets or capsules are required. However, reports of colonic strictures and intestinal obstruction in cystic fibrosis patients taking high-dose pancreatic enzymes (>20,000 international units lipase per capsule) have led to their withdrawal from the market in the United States.^{5,97} Pancreatic enzymes contain nucleic acids, and when given in high therapeutic doses, they have been associated with hyperuricosuria, hyperuricemia, and kidney stones.^{5,82} Impaired folic acid absorption by oral pancreatic enzymes may lead to folic acid deficiency. Gastrointestinal side effects appear to be dose-related, but occur less frequently with the enteric-coated products. Sensitization and allergic reactions are uncommon but may occur in patients taking the powder.

Adjuncts to Enzyme Therapy The use of antisecretory drugs as adjuncts to enzyme therapy may improve the efficacy of pancreatic enzyme supplementation.^{5,89,98} The beneficial effects of an H₂-receptor antagonist or proton pump inhibitor result from both an increase in pH and a decrease in intragastric volume.^{5,98} These agents should maintain luminal gastric and duodenal pH above 4 and enhance lipase activity. Increased duodenal pH also prevents bile acid precipitation, increasing fatty acid solubility. Antacids appear to have little or no added effect in reducing steatorrhea.⁵

10 Symptomatic patients whose steatorrhea is not corrected by enzyme replacement therapy and a reduction in dietary fat may benefit from the addition of an H₂-receptor antagonist. A proton pump inhibitor should be considered in patients who fail to benefit from the addition of an H₂-receptor antagonist. The additional cost of antisecretory therapy and the potential for adverse effects and drug interactions should be considered.

■ PHARMACOECONOMIC CONSIDERATIONS

The pharmacoeconomic issues associated with the medical treatment of AP and CP have not been extensively examined. Aggressive medical and surgical care decreases mortality in AP, but the overall cost-effectiveness of a specific treatment is unknown. The relief of abdominal pain in AP and CP, as well as pancreatic enzyme supplementation in patients with CP, improves quality of life and nutritional status.⁹⁹ Although the efficacy of octreotide in AP remains uncertain, its use in severe AP is reasonable and potentially cost-effective. Antibiotic prophylaxis of targeted patients may reduce mortality and length of hospital stay, but pharmacoeconomic studies have not confirmed this suspicion. However, a reduction in the length of stay could offset the cost of antibiotic therapy.

In some cases, medications that cost more may be more cost-effective. This is particularly true with pancreatic enzymes and the microencapsulated enteric-coated dosage forms. These latter products may cost more per unit, but they offer greater patient acceptance and compliance when compared to uncoated tablets. In addition, when cost is based on the total number of tablets or capsules per day, rather than the cost of a single tablet or capsule, the high-potency preparations are usually similar in price to the uncoated products. The addition of an H₂-receptor antagonist or proton pump inhibitor

TABLE 41-9 Frequently Used Pancreatic Enzyme Preparations				
Product	Dosage Form	Enzyme Content (Units) ^a		
		Lipase	Amylase	Protease
Creon-10	ECMS	10,000	33,200	37,500
Creon-20	ECMS	20,000	66,400	75,000
Ku-Zyme HP	C	8,000	30,000	30,000
Lipram-CR10	ECMS	10,000	33,200	37,500
Lipram-PN16	ECMS	16,000	48,000	48,000
Lipram-CR20	ECMS	20,000	66,400	75,000
Lipram-PN20	ECMS	20,000	56,000	44,000
Lipram-UL12	ECMS	12,000	39,000	39,000
Lipram-PN10	ECMS	10,000	30,000	30,000
Lipram-UL18	ECMS	18,000	58,500	58,500
Lipram-UL20	ECMS	20,000	65,000	65,000
Pancrease	ECMS	4,500	20,000	25,000
Pancrease MT-4	ECMT	4,000	12,000	12,000
Pancrease MT-10	ECMT	10,000	30,000	30,000
Pancrease MT-16	ECMT	16,000	48,000	48,000
Pancrease MT-20	ECMT	20,000	56,000	44,000
Ultrase MT 12	ECMT	12,000	39,000	39,000
Ultrase MT 18	ECMT	18,000	58,500	58,500
Ultrase MT 20	ECMT	20,000	65,000	65,000
Viokase ^b	P	16,800	70,000	70,000
Viokase 8	UCT	8,000	30,000	30,000
Viokase 16	UCT	16,000	60,000	60,000

C, powder encased in a cellulose capsule; ECS, enteric-coated sphere encased in a cellulose capsule; ECMS, enteric-coated microspheres encased in a cellulose or gelatin capsule; ECMT, enteric-coated microtablets encased in a cellulose capsule; P, powder; UCT, uncoated tablet.
^aAll listed products contain pancrelipase. Pancrelipase contains not less than 24 USP units of lipase activity, not less than 100 USP units of amylase activity, and not less than 100 USP units of protease activity per milligram.
^bUnits of 0.7 g of powder.

may actually be cost-effective for patients who are inadequately controlled on maximal enzyme therapy.

EVALUATION OF THERAPEUTIC OUTCOMES

ACUTE PANCREATITIS

Pain control, fluid and electrolyte status, and nutrition should be assessed periodically in patients with mild AP, depending on the degree of abdominal pain and fluid loss. Patients with severe AP should receive intensive care and close monitoring of vital signs, fluid and electrolyte status, white blood cell count, blood glucose, lactic dehydrogenase, aspartate aminotransferase, serum albumin, hematocrit, blood urea nitrogen, serum creatinine, and international normalized ratio. Continuous hemodynamic and arterial blood gas monitoring is essential. Serum lipase, amylase, and bilirubin require less-frequent monitoring. The patient should be monitored for signs of infection, relief of abdominal pain, and adequate nutritional status. Therapeutic outcome depends on the severity of the acute attack, medical management (which is primarily supportive), and prevention or treatment of infection. Despite appropriate supportive therapy, deterioration of respiratory, renal, and cardiovascular function may lead to death.

CHRONIC PANCREATITIS

The severity and frequency of abdominal pain should be assessed periodically so as to determine the efficacy of the patient's pain control regimen. Most patients with abdominal pain can be adequately controlled with acetaminophen or NSAIDs. A trial of non-enteric-coated pancreatic enzymes and either an H₂-receptor antagonist or proton pump inhibitor may relieve pain in patients with mild to moderate disease. Patients with severe pain will require narcotics. In these patients, pain should be monitored daily and medications adjusted accordingly. Some patients will require endoscopic therapy or pancreatic surgery.

The effectiveness of pancreatic enzyme supplementation in treating malabsorption is measured by improvement in body weight and stool consistency or frequency. The 72-hour stool test for fecal fat may be used when there is concern regarding the adequacy of treatment. Serum uric acid and folic acid concentrations should be monitored yearly in patients prone to hyperuricemia or folic acid deficiency. Blood glucose must be closely monitored in the diabetic patient. Therapeutic outcome depends in part on the ability of the patient to discontinue alcohol and tobacco use and to maintain adequate nutrition. Pain control and pancreatic enzyme supplementation are important therapeutic measures that contribute to the patient's quality of life. A small number of patients die from complications associated with an acute attack.

CONCLUSIONS

Important advances have been made regarding our understanding of acute and chronic pancreatitis, especially as it relates to genetics, pathogenesis, and the natural history of the diseases. Although there has been a reduction in the mortality of patients with severe AP, controversy remains regarding the use of antibiotic prophylaxis. Patients with CP benefit from improved strategies for managing pain and malabsorption. New and improved diagnostic techniques and medical treatments will replace many of the procedures and drugs we use today.

ABBREVIATIONS

AP: acute pancreatitis

ARDS: acute respiratory distress syndrome

CT: computed tomography

CCK: cholecystokinin

CP: chronic pancreatitis

ERCP: endoscopic retrograde cholangiopancreatography

IMMC: interdigestive migrating motor complex

NSAID: nonsteroidal antiinflammatory drug

SC: secretin

PAULINA DEMING, RENEE-CLAUDE MERCIER, AND MANJUNATH P. PAI

KEY CONCEPTS

- 1 Hepatitis A is transmitted via the fecal–oral route. Transmission is most likely to occur through travel to countries with high rates of hepatitis A, poor sanitation and hygiene, and overcrowded areas.
- 2 Hepatitis A causes an acute, self-limiting illness and does not lead to chronic infection. There are three stages of infection: incubation, acute hepatitis, and convalescence. Rarely the infection progresses to liver failure.
- 3 Treatment of hepatitis A consists of supportive care. There is no role for antiviral agents in treatment.
- 4 Hepatitis B causes both acute and chronic infection. Infants and children are at high risk for chronic infection.
- 5 Several therapies are available for hepatitis B, including lamivudine, interferon α_{2b} , pegylated interferon α_{2a} , entecavir, adefovir, and telbivudine. Patient status, extent of disease, viral load, and viral resistance are all considered when deciding on treatment.
- 6 Chronic hepatitis B patients may require long-term therapy. Long-term therapy poses a challenge because of the potential for developing resistance. Resistance to lamivudine is most common, although resistance mutations to telbivudine, adefovir, and entecavir have also been seen. Optimal treatment of resistant strains is unknown.
- 7 Prevention of hepatitis B infections focuses on immunization of all children and at-risk adults.
- 8 Hepatitis C is an insidious, blood-borne infection. Injection drug use is the major mode of transmission in the United States.
- 9 Combination pegylated interferon and ribavirin therapy is the treatment of choice for hepatitis C. Treatment duration for hepatitis C infections is 48 weeks for viral genotype 1, and 24 weeks for genotypes 2 and 3. However, therapy may be optimized based on infecting genotype and virologic response. Viral genotype 1 is most difficult to treat.
- 10 Side effects of hepatitis C therapy pose a significant obstacle to completion of therapy and chance for cure. Adjunct pharmacologic therapy and dose reductions may be necessary to prevent premature cessation of treatment.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

The major hepatotropic viruses responsible for viral hepatitis are hepatitis A, hepatitis B, hepatitis C, delta hepatitis, and hepatitis E. All share clinical, biochemical, immunoserologic, and histologic findings. Both hepatitides A and E are spread through fecal–oral contamination; whereas hepatitides B, C, and delta are transmitted parenterally. Infection with delta hepatitis requires coinfection with hepatitis B. Although the rates of acute infection have declined, viral hepatitis remains a major cause of morbidity and mortality with a significant impact on healthcare costs in the United States. Significant therapeutic advances have occurred with hepatitis B with the approval of new agents and updated guidelines for care. For hepatitis C, the challenge remains of increasing successful outcomes while minimizing side effects of therapy. This chapter focuses on hepatitides A, B, and C.

HEPATITIS A

Hepatitis A virus (HAV), or infectious hepatitis, is often a self-limiting and acute viral infection of the liver posing a health risk worldwide. The infection is rarely fatal. According to the Centers for Disease Control and Prevention (CDC), the 4,488 reported cases of acute clinical hepatitis A infection in the United States in 2005 were the lowest in recorded history.¹ Although vaccine preventable, HAV continues to be one of the most commonly reported infections.

EPIDEMIOLOGY

Various patient groups are at increased risk for infection with HAV. Children pose a particular problem with the spread of the disease because they often remain clinically asymptomatic and are infectious for longer periods of time than adults. Traditionally, the most likely patient group to be affected is household or close personal contacts of an infected person. 1 Infection primarily occurs through the fecal–oral route, by person-to-person, or by ingestion of contaminated food or water. Incidentally, HAV's prevalence is linked to regions with low socioeconomic status and specifically to those with poor sanitary conditions and overcrowding. Rarely, the virus can be spread through blood or blood products. Despite being detectable in saliva, there are no data to suggest transmission through this mode of contact.² International travel and immigration also mitigate potential exposure to the virus.

Analysis of the 5,683 cases reported in the United States in 2004 revealed a change in risk factors for infectivity.³ Although rates have declined as a result of successful vaccination programs to a record low of 1.9 cases per 100,000 people in 2004, HAV rates have increased among international travelers, injection-drug users (IDUs), and men who have sex with men (MSM).³ Travel to HAV endemic areas now represents the largest proportion of acute HAV cases.^{1,3} Additional patient groups that are at risk include patients with chronic liver disease and persons working with nonhuman

primates. In pregnant women, acute HAV infection may be associated with maternal complications and preterm labor.⁴ Food-borne outbreaks also occur; a 2003 outbreak in Pennsylvania was associated with more than 500 persons infected and 3 deaths, and was linked to green onions imported from Mexico.⁵

HAV infections acquired through international travel create significant HAV-associated costs in terms of loss of work time and healthcare costs. Despite low endemic rates and successful vaccinations of at-risk populations in the United States, unvaccinated children acquiring HAV infections abroad can serve as reservoirs of the virus upon return to the United States, even while remaining clinically asymptomatic themselves. Nearly 40% of children younger than age 15 years with HAV had international travel as a risk factor in 2004.³ According to the CDC, the majority of travel-related cases correspond to travel to Central and South America and Mexico.³ Most Americans traveling to Mexico do not consider that country to be a risk in part because of Mexico's proximity to the United States. Moreover, most tourists falsely believe that higher-end resorts imply safety and that short visits to foreign countries are not associated with a risk for infection. In fact, frequent, short visits will have a cumulative risk for infection that should not be ignored.⁶

ETIOLOGY

Hepatitis A is a RNA virus belonging to the genus *Hepatovirus* of the Picornaviridae family. Humans are the only known reservoir for the virus and transmission occurs primarily through the fecal-oral route.⁷ The virus is stable in the environment for at least a month and requires heating foods to a minimum of 85°C (185°F) for 1 minute or disinfecting with a 1:100 dilution of sodium hypochlorite (bleach) in tap water for inactivation.^{2,8}

Multiple genotypes of the virus exist and although the clinical implications of infection by particular type are unknown, types I and III are the most commonly identified in human outbreaks.⁷

PATHOPHYSIOLOGY

HAV infection is usually acute, self-limiting, and confers lifelong immunity. HAV's life cycle in the human host classically begins with ingestion of the virus. Absorption in the stomach or small intestine allows entry into the circulation and uptake by the liver. Replication of the virus occurs within hepatocytes and gastrointestinal epithelial cells. New virus particles are released into the blood and secreted into bile by the liver. The virus is then either reabsorbed to continue its cycle or excreted in the stool. The enterohepatic cycle will continue until interrupted by antibody neutralization.⁷ The exact mechanism of replication and secretion is unknown; however, the initial viral expansion does not seem to be associated with hepatic injury as peak viral fecal excretion precedes clinical signs and symptoms of infection.²

On biopsy, acute hepatitis is marked by hepatocellular degeneration, inflammatory infiltrate, and hepatocyte regeneration. Hepatocellular degeneration occurs as a result of immune-mediated injury and not as a direct cytopathic effect of the virus.⁹ Clinical symptoms of HAV typically identify the onset of the immune response. Cytolytic T cells mediate hepatocyte lysis to eradicate the virus and mark the cellular immune response with rising hepatic enzyme levels.⁷

CLINICAL PRESENTATION

2 The incubation period of HAV is approximately 28 days, with a range of 15 to 50 days. Viremia occurs within 1 to 2 weeks of exposure as patients begin to shed the virus.² Table 42-1 summarizes the clinical features of acute hepatitis A. Peak fecal shedding of the virus precedes the onset of clinical symptoms and elevated liver enzymes. Acute hepatitis follows, beginning with the preicteric or

TABLE 42-1 Clinical Presentation of Acute Hepatitis A

Signs and symptoms

- The preicteric phase brings nonspecific influenza-like symptoms consisting of anorexia, nausea, fatigue, and malaise
- Abrupt onset of anorexia, nausea, vomiting, malaise, fever, headache, and right upper quadrant abdominal pain with acute illness
- Icteric hepatitis is generally accompanied by dark urine, acholic (light-colored) stools, and worsening of systemic symptoms
- Pruritus is often a major complaint of icteric patients

Physical examination

- Icteric sclera, skin, and secretions
- Mild weight loss of 2 to 5 kg
- Hepatomegaly

Laboratory tests

- Positive serum immunoglobulin M anti-hepatitis A virus
- Mild elevations of serum bilirubin, γ -globulin, and hepatic transaminase (alanine transaminase and aspartate transaminase) values to about twice normal in acute anicteric disease
- Elevations of alkaline phosphatase, γ -glutamyl transferase, and total bilirubin in patients with cholestatic illness

prodromal period. The phase is marked by an abrupt onset of nonspecific symptoms, some very mild.² Other, more unusual symptoms include chills, myalgia, arthralgia, cough, constipation, diarrhea, pruritus, and urticaria. The phase generally lasts 2 months. There are no specific symptoms unique to HAV. Liver enzyme levels rise within the first weeks of infection, peaking approximately in the fourth week and normalizing by the eighth week. Conjugated bilirubinemia, or dark urine, precedes the onset of the icteric period. The concentration of virus declines at this point and patients are generally considered noninfectious approximately 1 week after the onset of jaundice.¹⁰ Gastrointestinal (GI) symptoms may persist or subside during this time and some patients may have hepatomegaly. Duration of the icteric period varies and corresponds to disease duration. It averages between 7 and 30 days.⁷

Symptoms and severity of HAV vary according to age. Children younger than 6 years of age typically are asymptomatic. Symptoms, if they do occur, do not include jaundice. In older children and adults, the majority of patients present with symptoms that last less than 2 months and 70% of adults experience jaundice. Peak viral shedding precedes the onset of GI symptoms in adults. In young children, shedding can occur for months following diagnosis.² Because children are often asymptomatic and will shed the virus for long periods of time they can serve as a reservoir for the spread of HAV.

HAV RNA is detectable in the serum for an average of 17 days before peak alanine aminotransferase (ALT) levels and can persist for an average of 79 days after the onset of symptoms. In some patients, serum HAV is detectable for more than a year.¹¹ Immunoglobulin (Ig) M antibody to HAV (anti-HAV) is required for a diagnosis of acute infection. It becomes detectable 5 to 10 days before the onset of symptoms and can persist for months after. IgG anti-HAV replaces IgM and indicates host immunity following the acute phase of the infection. Serologic tests exist but should be interpreted with caution.⁸ FDA-approved assays for serologic testing detect IgM and total anti-HAV (IgG and IgM). Patients who have detectable total anti-HAV and a negative IgM have resolved their infection. Although patients who are successfully immunized will have IgG, assays are not sensitive enough to detect anti-HAV in most patients. Similarly, patients who receive intramuscular (IM) Ig will also have anti-HAV but concentrations are below the level of detection of most assays.^{2,8} Concentrations of antibody often fall to 10 to 100 times lower than what would be expected after a natural course of infection. Although a positive anti-HAV result confirms protection, undetectable concentration of anti-HAV may not necessarily imply that protective levels were not achieved.⁸

HAV does not lead to chronic infections. Some patients may experience symptoms for up to 9 months. Rarely, patients experience complications from HAV including relapsing hepatitis, cholestatic hepatitis, and fulminant hepatitis. Fatalities from HAV are generally rare though more likely in patients older than age 50 years and in persons with preexisting liver disease.⁸ Fulminant hepatitis occurs mostly in young children and adults with chronic liver disease. Although occurring in 0.01% of clinical infections, fulminant hepatitis has a high fatality rate and therapy consists of supportive care.⁹

Diagnosis

A diagnosis of HAV is based on clinical criteria of an acute onset of fatigue, abdominal pain, loss of appetite, intermittent nausea and vomiting, jaundice or elevated serum aminotransferase levels, and serologic testing for IgM anti-HAV. Serologic testing is necessary to differentiate the diagnosis from other types of hepatitis.

TREATMENT

Hepatitis A Virus

■ DESIRED OUTCOME

③ The majority of people infected with HAV can be expected to fully recover without clinical sequelae.⁷ Nearly all individuals will have clinical resolution within 6 months of the infection, and a majority will have done so by 2 months. Rarely, symptoms persist for longer or patients relapse. The ultimate goal of therapy is complete clinical resolution. Other goals include reducing complications from the infection, normalization of liver function, and reducing infectivity and transmission.

■ GENERAL APPROACH TO TREATMENT

No specific treatment options exist for HAV infections. Instead, patients should receive general supportive care. In patients who develop liver failure, transplant is the only option. Although hepatocellular damage occurs through immune-mediated responses, steroid use is not recommended.¹² Prevention and prophylaxis are key to managing the virus. The importance of good hand hygiene cannot be overemphasized in preventing disease transmission. Immunoglobulin is used for pre- and postexposure prophylaxis, and offers passive immunity. Active immunity is achieved through vaccination. Vaccines were approved for use in 1995 and implemented in the routine vaccination of children, as well as at-risk adults, to reduce the overall incidence of HAV.⁸

Prevaccination serologic testing to determine susceptibility is generally not recommended. In some cases, testing may be cost-effective if the cost of the test is less than that of the vaccine and if the person is from a moderate to high endemic area and likely to have prior immunity. Prevaccination serologic testing of children is not recommended. Similarly, because of high vaccine response, postvaccine serologic testing is not recommended.⁸

PREVENTION OF HEPATITIS A

HAV is easily preventable with vaccination. Because children often serve as reservoirs of the disease, vaccine programs have targeted children as the most effective means to control HAV. Two vaccines for HAV are available and are incorporated into the routine childhood vaccination schedule. In October 2005, the FDA reduced the minimum age for the vaccines to 12 months of age. In response, the Advisory Committee on Immunization Practices recommended expanding vaccine coverage to all children, including catch-up programs for children living in areas without existing vaccination

TABLE 42-2 Recommendations for Hepatitis A Virus (HAV) Vaccination

All children at 1 year of age
In areas without existing hepatitis A vaccination programs, catch-up vaccination of children ages 2–18 years can be considered
Persons traveling to or working in countries that have high or intermediate endemicity of infection ^a
Men who have sex with men
Illegal-drug users
Persons with occupational risk for infection (e.g., persons who work with HAV-infected primates or with HAV in a research laboratory)
Persons who have clotting factor disorders
Persons with chronic liver disease

^aTravelers to Canada, Western Europe, Japan, Australia, or New Zealand are at no greater risk for infection than they are in the United States. All other travelers should be assessed for HAV risk. From Centers for Disease Control and Prevention.^{8,13}

programs. The new recommendations were enacted in the attempt to further reduce HAV incidence rates and possibly to eradicate the virus.¹³ Adult vaccination recommendations also exist (Table 42–2).

Routine prevention of HAV transmission includes regular hand washing with soap and water after using the bathroom, changing a diaper, and before food preparation. For travelers to countries with high endemic rates of HAV, even short-term stays in urban and upscale resorts are not risk-free.⁸ In particular, contaminated water and ice, fresh produce, and any uncooked foods pose a risk.⁷

Vaccines to Prevent Hepatitis A

Two inactivated virus vaccines are currently licensed in the United States: Havrix and Vaqta. Both vaccines are inactivated virus and are available for pediatric and adult use. The differences in the two vaccines are in the use of a preservative and in expression of antigen content. Vaqta is formulated without a preservative and uses units of HAV antigen to express potency. Havrix uses 2-phenoxyphenol as a preservative and antigen content is expressed as enzyme-linked immunosorbent assay units. Pediatric dosing is indicated for children 12 months of age through 18 years of age, and adult dosing is for patients ages 19 years and older (Table 42–3).⁸ Although high seroconversion rates of ≥94% are achieved with the first dose, both vaccines recommend a booster shot to achieve the highest possible antibody titers. There are insufficient data to suggest the vaccines offer sufficient postexposure protection in outbreak settings. Both vaccines may be given concomitantly with immunoglobulin and the two brands are interchangeable for booster shots.⁸

Vaccine efficacy may be reduced in certain patient populations. In HIV (human immunodeficiency virus)-infected patients, greater immunogenic response may correlate with higher baseline CD4 cell counts. Response to the HAV vaccine as determined by detection of anti-HAV after vaccination found that among HIV patients, females and patients with CD4 counts >200 cells/mm³ at vaccination had a higher response rate.¹⁵

The most common side effects of the vaccines include soreness and warmth at the injection site, headache, malaise, and pain.

TABLE 42-3 Recommended Dosing of Havrix and Vaqta

Vaccine	Age (y)	Dose	No. of Doses	Schedule (mo)
Havrix	1–18	720 ELISA units	2	0, 6–12
	≥19	1,440 ELISA units	2	0, 6–12
Vaqta	1–18	25 units	2	0, 6–18
	≥19	50 units	2	0, 6–18

ELISA, enzyme-linked immunoabsorbent assay.

From Centers for Disease Control and Prevention.¹³

Reported serious adverse events include anaphylaxis, Guillain-Barré syndrome, brachial plexus neuropathy, transverse myelitis, multiple sclerosis, encephalopathy, and erythema multiforme. However, causality of these reported events has not been established. Furthermore, incidence of serious adverse events in the vaccinated population did not differ from the incidence in nonvaccinated populations. It is important to note that more than 65 million doses of the vaccine have been administered and despite routine monitoring for adverse events, there are no data to suggest a greater incidence of serious adverse events among vaccinated people compared to nonvaccinated. The vaccine is considered safe.⁸

Twinrix is a bivalent vaccine for hepatitis A and B that was approved by the FDA in 2001. The vaccine is approved for people ages 18 and older and is given at 0, 1, and 6 months. Although seroconversion exceeds 90% for HAV after the first dose, the full three-dose series is required for maximal hepatitis B virus (HBV) seroconversion. The combined vaccine offers the advantage of immunization against both types of hepatitis in a single vaccine.

Immunoglobulin

Ig is used when pre- or postexposure prophylaxis against HAV infection is needed. A sterile preparation of concentrated antibodies against HAV, Ig provides protection by passive transfer of antibody. Ig is most effective if given in the incubation period of the infection. Receipt of Ig within the first 2 weeks of infection will reduce infectivity and moderate the infection in 85% of patients. Patients who received at least 1 dose of the HAV vaccine at least 1 month earlier do not need pre- or postexposure prophylaxis with Ig.⁸ Ig is available both as an intravenous (IV) and IM injection but for HAV exposure, only the IM is used. If given to infants or pregnant women, the thimerosal-free formulation should be used.

International travelers are the major patient population receiving preexposure prophylaxis with Ig. HAV vaccination or prophylaxis with Ig is recommended for travelers to countries with high endemic rates of HAV. Serious adverse events are rare. Anaphylaxis has been reported in patients with Ig A deficiency. Patients who had an anaphylaxis reaction to Ig should not receive it. There is no contraindication for use in pregnancy or lactation.

Dosing of Ig is the same for adults and children. For postexposure prophylaxis and for short-term preexposure coverage of <3 months, a single dose of 0.02 mL/kg is given intramuscularly. For long-term preexposure prophylaxis of ≤5 months, a single dose of 0.06 mL/kg is used. Either the deltoid or gluteal muscle may be used. In children younger than 24 months of age, Ig can be given in the anterolateral thigh muscle.⁸

For people who were recently exposed to HAV and who had not been previously vaccinated, Ig is indicated in the following situations: (a) when in close personal contact with an HAV-infected person; (b) all staff and attendees of daycare centers when HAV is documented; (c) if they were involved in a common source exposure; for example, in a food-borne outbreak with an HAV-infected food handler, other food handlers at the location should receive Ig; if the case person handled food and had poor hygiene or diarrhea, patrons of the location should also receive Ig if they can be identified and located within the 2 weeks of the exposure; (d) classroom contacts of an index case patient; and (e) schools, hospitals, and work settings where close personal contact occurred with the case patient.⁸

Ig can be given concomitantly with the HAV vaccine. Although the antibody titer will be lower than if the vaccine were administered alone, the response is still protective. However, Ig can interfere with the response of other vaccines and should be delayed. The measles, mumps, and rubella (MMR) vaccine should be delayed for a minimum of 3 months after receipt of Ig. The varicella vaccine must be delayed for 5 months. Conversely, Ig should not be given to patients who received the MMR within 2 weeks or the varicella

vaccine within 3 weeks. In situations where the benefits of Ig outweigh the benefits of the other vaccines, revaccination can be performed after Ig administration. For the MMR, revaccination should be at least 3 months later, and for the varicella vaccine, at least 5 months later.⁸ In general, Ig does not interfere with inactivated vaccines and may be administered safely with other vaccines traditionally given to travelers to some developing countries, such as the oral poliovirus or yellow fever vaccine.⁸

PHARMACOECONOMIC CONSIDERATIONS

Although the costs of an HAV outbreak are significant, routine vaccination of all individuals is not cost-effective. Rather, by targeting at-risk populations, the majority of cases can be prevented. Children play a pivotal role in disease persistence. The use of the HAV vaccine is cost-effective in children and offers the most benefit to the personal contacts of children, reflecting the role of children as a reservoir for the disease.¹⁵ The use of the combined HAV-HBV vaccine is effective in reducing costs associated with HAV among persons who are at increased risk for infection. Among 100,000 healthcare workers in high endemic states, the vaccine was anticipated to reduce the number of related work loss days from 34,463 to 4,667 days, an estimated savings of \$6.1 million.¹⁵ Nearly \$2 million in savings could be seen in costs associated with HAV treatment. In a sexually transmitted diseases clinic serving 1 million patients, the combined vaccine was expected to prevent 2,263 occult infections and cost \$13,397 per quality-adjusted life-year (QALY).¹⁶ Both studies predicted between \$2 and \$2.5 million in savings associated with HAV treatment, realized mostly in reduced hospitalizations. The risk of HAV from food transmission in the United States is low and can be avoided in many cases by adherence to basic hygiene practices.

HEPATITIS B

Although a vaccine was made available in 1981, HBV has acutely infected more than 2 billion people globally, leading to chronic infection in more than 350 million people.¹⁷ Chronic infection with HBV is a major public health issue as it serves as a reservoir for continued HBV transmission and poses a significant risk of death resulting from liver disease. More than 1 million people per year die as a result of liver cirrhosis and hepatocellular carcinoma (HCC).

EPIDEMIOLOGY

According to the CDC, only 12% of the global population lives in an area of low prevalence for hepatitis B, defined as an area where <2% of the population is HB_sAg (hepatitis B surface antigen)-positive.¹⁷ Prevalence can vary regionally; however, areas commonly associated with high infectivity rates include sub-Saharan Africa, most of Asia, as well as the Amazon and southern parts of Eastern and Central Europe.¹⁷ Areas of high prevalence, approximately 45% of the global population, are of special concern because most infections are of infants and children and >90% of cases lead to a chronic carrier state. Although less than 1% of people have chronic infection in both Western Europe and North America,¹⁷ in the United States, HBV is the second most common type of acute viral hepatitis and the third most reported preventable disease, second only to HAV.¹⁸ There are approximately 1.25 million chronically infected HBV people in the United States. In 2005, an estimated 51,000 people developed new infections. Annually, an estimated 3,000 to 5,000 people die from chronic liver disease attributable to HBV.¹

HBV is transmitted sexually, parenterally, and perinatally. In areas of high HBV prevalence, perinatal transmission from mother to infant is most common, whereas in areas of intermediate prevalence, horizontal transmission from child to child is most common. Sexual

contact, both homosexual and heterosexual, and injection-drug use are the predominant forms of transmission in low-endemic countries such as the United States.¹⁹ Concentration of HBV is high in blood, serum, and wound exudates of infected persons. The virus is detectable in moderate quantities in semen, vaginal fluid, and saliva, and is present in low concentrations in urine, feces, sweat, tears, and breast milk.^{18,20} Transmission can occur through contact with infected body fluids in the absence of blood, as the virus may be stable in the environment for a number of days.^{20,21} In the United States in 2004, no risk factor could be identified for the majority of acute infections with HBV. International travel was the most prevalent identifiable risk factor, followed by injection drug use and sexual or household contact with a hepatitis B-infected person. Among children younger than 15 years of age, the largest overall risk factor in 2004 was international travel.³ No cases were documented for patients receiving transfusions or on hemodialysis.¹⁷ Among racial and ethnic groups, HBV is highest among non-Hispanic blacks. Asians/Pacific Islanders and non-Hispanic whites have similar rates, while Hispanics have the lowest HBV rates.³

The mode of transmission has clinical implications because chronic infections are associated with infection acquired in younger patients, especially those infected perinatally and in early childhood.²⁰

ETIOLOGY

The HBV is a DNA virus of the family Hepadnaviridae. It is a partially double-stranded, circular DNA with 3,200 base pairs that typically infects liver cells, although it has been found in kidney, pancreas, and mononuclear cells.^{22,23} Seven HBV genotypes exist (A to H) with distinct geographic distribution (Table 42–4). It is possible that genotype prevalence may be dependent on mode of transmission as types B and C are found in areas where vertical transmission is the primary mode of infection.²⁴ Correlations between clinical outcomes and HBV genotypes have been suggested, with genotype C associated with more severe liver injury, including liver cirrhosis and progression to HCC.²⁴ A noted limitation of studies is frequently small sample sizes and a predominance of research from Asia, primarily comparing genotypes B and C.²⁴ Nonetheless, a study of a diverse patient immigrant population infected with genotypes A, B, C, D, and E, confirmed that more severe liver fibrosis was significantly higher in HBV genotypes A, C, and D-infected patients. Genotype B may be more benign because it is associated with faster seroconversion.²⁵ Resistance mutations may contribute to genotype virulence and hence impact severity of liver disease in infection.²⁶

PATHOPHYSIOLOGY

Upon infection, replication of the virus begins by attachment of the virion to the hepatocyte cell surface receptors. The particles are transported to the nucleus where the DNA is converted into closed, circular DNA that serves as a template for pregenomic RNA. Viral

TABLE 42-5 Interpretation of Serologic Tests in Hepatitis B Virus

Tests	Result	Interpretation
HB _s Ag	(–)	Susceptible
Anti-HB _c	(–)	
Anti-HB _s	(–)	
HB _s Ag	(–)	Immune because of natural infection
Anti-HB _c	(+)	
Anti-HB _s	(+)	
HB _s Ag	(–)	Immune because of vaccination (valid only if test performed 1–2 months after third vaccine dose)
Anti-HB _c	(–)	
Anti-HB _s	(+)	
HB _s Ag	(+)	Acute infection
Anti-HB _c	(+)	
IgM anti-HB _c	(+)	
HB _s Ag	(+)	Chronic infection
Anti-HB _c	(+)	
IgM anti-HB _c	(–)	
Anti-HB _s	(–)	Four interpretations possible: 1. Recovery from acute infection 2. Distant immunity and test not sensitive enough to detect low level of HB _s in serum 3. Susceptible with false-positive anti-HB _c 4. May have undetectable level of HB _s Ag in serum and be chronically infected
HB _s A	(–)	
Anti-HB _c	(+)	
Anti-HB _s	(–)	
Anti-HB _s	(–)	

HB_c, hepatitis B core; HB_s, hepatitis B surface; HB_sA, hepatitis B surface associated; HB_sAg, hepatitis B surface antigen; IgM, immunoglobulin M.

RNA is then transcribed and transported back to the cytoplasm where it can alternatively serve as a reservoir for future viral templates or bud into the intracellular membrane with the viral envelope proteins and infect other cells.^{22,27} The viral genome has four reading frames coding for various proteins and enzymes required for viral replication and spread. Several of these proteins are used diagnostically (Table 42–5). The HB_sAg is the most abundant of the three surface antigens and is detectable at the onset of clinical symptoms. Its persistence past 6 months after initial detection corresponds to chronic infection and poses an increased risk for cirrhosis, hepatic decompensation, and HCC. Development of antibody to HB_sAg (anti-HB_sAg) confers immunity to the virus and clearance of HB_sAg is associated with favorable outcomes.^{23,28} The precore polypeptide encodes for the secretory protein hepatitis B_e antigen (HB_eAg) and the hepatitis B core antigen (HB_cAg) proteins. Although HB_cAg's role in infection is nebulous, it is present in an acute infection and is replaced by antibodies (anti-HB_cAg) once an infection is resolved. HB_cAg was assumed to be a marker of viral replication and infectivity; however, it is now known that some viral mutants exist that are unable to have or have downregulated expression of HB_cAg, although their ability to replicate is not affected.²⁹ HB_eAg-negative mutants pose a particular clinical challenge because they are refractory to treatment. The HB_cAg is a nucleocapsid protein that, when expressed on hepatocytes, promotes immune-mediated cell death. High levels of antibodies (IgM anti-HB_cAg) are detectable during acute infections. The detection of IgM anti-HB_cAg is also a reliable assay for diagnosing fulminant acute hepatitis where HB_sAg and HBV DNA are often undetectable.^{22,30} Patients who respond to vaccine will have anti-HB_sAg only.⁸

HBV itself does not seem to be pathogenic to cells; rather, it is thought that the immune response to the virus is cytotoxic to hepatocytes. Antigen nonspecific inflammatory responses triggered by T cells may be responsible for most hepatic injury, with progression to cirrhosis and HCC.^{20,22} The immune response includes major histocompatibility complex (MHC) class I CD8 cytotoxic T cells and MHC class II CD4 T-helper cells. In both an acute and chronic

H	Central America

Data from Ganne-Carrie N, Williams V, Kaddouri H, et al. Significance of hepatitis B virus genotypes A to E in a cohort of patients with chronic hepatitis B in the Seine Saint Denis district of Paris (France). *J Med Virol* 2006;78:335–340.

infection, the antibody response is strong. In an acute infection, however, the cytotoxic T-cell response is critical to viral clearance. If the response is weak, chronic infection is likely.²² Moreover, liver injury is likely caused by secondary, nonspecific inflammation activated by the initial cytotoxic lymphocyte response and as an attempt by the immune system to clear the virus by destroying HBV antigen presenting hepatocytes. Destruction of hepatocytes results in release of circulating, and hence increased, ALT levels.

Cirrhosis

Cirrhosis results as the liver attempts to regenerate while in an environment of persistent inflammation. Like in other viral hepatitis-induced cirrroses, continued alcohol consumption exacerbates hepatocellular damage. Most patients with compensated cirrhosis are either asymptomatic or have mild symptoms of epigastric pain and dyspepsia.²⁵ During cirrhosis, the liver enters a cycle of ongoing liver damage, fibrosis, and attempts at regeneration. The classical appearance of a small and knobby liver reflects the irreversible effect of nodules of regenerating cells integrated with infiltrates of inflammatory induced fibrous tissue. Both viral and clinical factors affect the outcome of cirrhosis (Table 42–6). The development of cirrhosis is mostly insidious and patients can remain stable for years before disease progression. An estimated 20% of all chronic hepatitis B patients develop complications of hepatic insufficiency and portal hypertension as their compensated cirrhosis progresses to decompensated cirrhosis within a 5-year period.²⁷ Typically, the initial clinical findings of decompensated cirrhosis are ascites, jaundice, variceal bleed, encephalopathy, or a combination of symptoms.²⁵ Damage is irreversible. Treatment is supportive care and patients are candidates for liver transplantation.

Hepatocellular Carcinoma

HBV is a known risk factor for the development of HCC and in areas of high HBV endemicity, a major complication of the infection.^{20,22} The development of HCC can be insidious, occurring in the absence of cirrhosis or in the presence of clinically silent, compensated cirrhosis. Many patients with HCC have no signs of decompensated cirrhosis.²⁵ The virus itself is not likely the causative agent of the cancer. In most cases, HCC develops after years of inflammatory processes provoked by ongoing HBV infection. Compared to hepatitis C virus (HCV), however, HBV does seem to provoke a more direct carcinogenic effect as evidenced by its presence in less-severe liver disease, and among patients with advanced HCC, HBV infection is associated with a worse survival rate.³¹ Several factors influence the development of HCC, as well as predict survival (see Table 42–6). HCC is more prevalent in males; in older patients; in patients coinfectd with HCV or delta hepatitis; and in patients with serologic markings of past or present HBV infection, preexisting cirrhosis, or continued alcohol ingestion. Risks for death and decompensation increase with underlying liver disease. Other host-specific or envi-

ronmental factors may impact the course of liver disease. In Asian patients, HCC tumors are commonly seen in otherwise healthy patients, whereas HCC is typically seen in white patients with chronic liver disease.³² Persistently elevated HBV DNA levels ($\geq 10,000$ copies/mL) predict HCC development, even after adjusting for sex, age, cigarette smoking, alcohol consumption, HB_eAg status, ALT level, and liver cirrhosis.³³ HB_eAg status is not a risk factor. In otherwise healthy patients without coinfection or who do not have HCC or decompensation at the time of seroclearance, HB_eAg seroclearance does predict a favorable long-term outcome.²⁸ Additional predictors of survival include younger age and maintenance of liver function as evidenced by laboratory findings.²⁵

CLINICAL PRESENTATION

4 The clinical symptoms and course of an HBV infection are indistinguishable from other types of viral hepatitis. Three phases of an HBV infection exist. During the initial or acute phase of a HBV infection in adults and older children, the HBV enters a 4- to 10-week incubation period, during which antibodies toward the HBV core are produced and the virus replicates profusely. Active viral replication results in high serum HBV DNA levels and HB_eAg secretion.²² ALT levels may rise slightly, but most patients will remain asymptomatic. Symptoms, if they do occur, include fever, anorexia, nausea, vomiting, jaundice, dark urine, clay-colored or pale stools, and abdominal pain. Most neonates and children are anicteric and have no clinical symptoms, whereas up to half of adult patients are icteric.²⁵ HB_sAg does not become detectable until after significant viremia. The initial phase is considered immunotolerant because no hepatic injury is sustained, as evidenced by generally normal ALT levels. Patients are highly infectious during this time.²⁴ In perinatally acquired infections, and in young children, the phase can last for decades—until adulthood.²³ Infected children pose a particular risk because they are often asymptomatic, undiagnosed, and highly infectious.

The immunoactive phase marks a decrease in HBV DNA levels with ongoing secretion of HB_eAg. Patients are symptomatic with intermittent flares of hepatitis and marked increases in ALT levels. More frequent flares are associated with disease progression.³⁴ The phase can last a few weeks in acute disease, and for years in patients with chronic disease. As the host immune system attempts to gain control of the infection by stopping active viral replication, serum HBV DNA levels drop to undetectable, ALT levels normalize, and liver necroinflammation resolves.²⁵

If the infection is self-limiting, HBV DNA quickly subsides, HB_eAg disappears within weeks, and HB_sAg usually resolves within 4 months. The final phase is seroconversion and is defined by the replacement of HB_eAg with anti-HB_eAg. Factors favoring seroconversion include female sex, older age, biochemical activity, and genotype. Flares of hepatitis with ALT levels >5 times the upper limits of normal, compared to <5 times the upper limits of normal, correspond to increased immune system activity and precede seroconversion. The B genotype is associated with earlier seroconversion than genotype C.²⁵

Chronic HBV

4 Patients who continue to have detectable HB_sAg and HB_eAg and a high serum titer of HBV DNA for more than 6 months have chronic HBV.²⁵ Table 42–7 lists the clinical features of chronic hepatitis B. The most predictive factor for developing a chronic infection is age. Perinatal infections almost always result in chronic infections because of immune tolerance to the virus.³⁵ Risks of chronicity declines to a rate of 30% in infants and to less than 5% of acute adult infections.²³

Chronic infections can be controlled in many cases, but cure is not possible because the HBV template is integrated into the host

TABLE 42-7 Clinical Presentation of Chronic Hepatitis B^a

Signs and symptoms
<ul style="list-style-type: none"> • Easy fatigability, anxiety, anorexia, and malaise • Ascites, jaundice, variceal bleeding, and hepatic encephalopathy can manifest with liver decompensation • Hepatic encephalopathy is associated with hyperexcitability, impaired mentation, confusion, obtundation, and eventually coma • Vomiting and seizures
Physical examination
<ul style="list-style-type: none"> • Icteric sclera, skin, and secretions • Decreased bowel sounds, increased abdominal girth, and detectable fluid wave • Asterix • Spider angiomas
Laboratory tests
<ul style="list-style-type: none"> • Presence of hepatitis B surface antigen for at least 6 months • Intermittent elevations of hepatic transaminase (alanine transaminase and aspartate transaminase) and hepatitis B virus DNA greater than 10⁵ copies/mL • Liver biopsies for pathologic classification as chronic persistent hepatitis, chronic active hepatitis, or cirrhosis

^aChronic hepatitis B can be present even without all the signs, symptoms, and physical examination findings listed being apparent.

genome. In patients with recurring cycles of viral expression and host immune response, progressive liver damage ensues.³⁵ Patients can be divided into two types of chronic hepatitis B: those who are HB_eAg-positive and those who are HB_eAg-negative. The ability to express HB_eAg by the virus differentiates the two types of chronic infection. Patients who are HB_eAg-negative can be further subdivided into the active or inactive carrier. HB_eAg-negative chronic HBV patients who are active carriers have high serum HBV DNA, elevated ALT levels, and liver necroinflammation.²⁵ The clinical course tends to be worse with a very low rate of spontaneous remission. Patients may have long periods of disease remission but recurring flares of hepatitis with increased frequency and severity can progress to cirrhosis and HCC. HB_eAg-negative chronic HBV patients who are inactive carriers have detectable HB_sAg and anti-HB_eAg and have normal ALTs. This patient population usually experiences a more benign course of disease, with the possibility of long-term remission, even seroconversion, although reactivation is possible with the progression to cirrhosis and HCC. Rarely, patients will resolve their infection. Patients with undetectable HB_sAg but with anti-HB_sAg and anti-HB_eAg represent a small portion of patients who are not likely to experience reinfection or reactivation unless immunosuppressed.²⁵

HBV MUTATIONS

5 Among the DNA viruses, HBV is notable for its significantly higher mutation rate.²⁹ One of the most common mutations consists of a nucleotide substitution either preventing or causing downregulation of the production of HB_eAg. This mutation results in a chronic infection that may have a poorer long-term prognosis. Typically the mutation emerges during the infection and not as an infection by a mutant form of the virus.²⁹ The selective pressures of the L-nucleoside analog antivirals, including lamivudine, cause the YMDD mutation. The mutation is associated with the active site of the DNA polymerase and causes an altered active site. The incidence of lamivudine resistance increases with each subsequent year of therapy and may be associated with a more severe disease progression.²⁹ Cross-resistance of lamivudine-resistant YMDD mutants to telbivudine has been demonstrated and patients treated with both lamivudine and telbivudine showed resistance mutations to both drugs. Telbivudine-specific resistance can also occur at rates lower than that seen in lamivudine.³⁶ Other mutations include resistance to adefovir and entecavir. The addition of lamivudine in adefovir resistance may overcome resistance although the optimal management of either adefovir or entecavir resistant strains is not clear.^{29,37}

TABLE 42-8 Recommendations for Hepatitis B Virus (HBV) Vaccination

Infants
Adolescents including all previously unvaccinated children <19 years old
All unvaccinated adults at risk for infection
All unvaccinated adults seeking vaccination (specific risk factor not required)
Men and women with a history of other sexually transmitted diseases and persons with a history of multiple sex partners (>1 partner/6 months)
Men who have sex with men
Injection-drug users
Household contacts and sex partners of persons with chronic hepatitis B infection and healthcare and public safety workers with exposure to blood in the workplace
Clients and staff of institutions for the developmentally disabled
International travelers who plan to spend >6 months in countries with high rates of HBV infection and who will have close contact with the local population
Recipients of clotting-factor concentrates
Sexually transmitted disease clinic patients
HIV patient/HIV-testing patients
Drug-abuse treatment and prevention clinic patients
Correctional facilities inmates
Chronic dialysis/ESRD patients

ESRD, end-stage renal disease; HIV, human immunodeficiency virus.

PREVENTION OF HEPATITIS B

Despite the introduction of the HBV vaccine in 1981 and recommendations on vaccination in 1982, rates of HBV did not decline in the early 1980s. Initial declines in incidence were likely attributable to behavioral changes among high risk groups as a result of the acquired immune deficiency syndrome (AIDS) epidemic. A 94% decline in rates between 1990 and 2004 was seen in children and adolescents, which began with the initiation of screening of pregnant women and subsequent immunizations of infants and recommendations set forth in the 1990s to immunize adolescents. Regulations enacted by Occupational Safety and Health Administration (OSHA) further reduced overall U.S. rates by 75%.^{18,21}

7 Prophylaxis against HBV can be achieved by vaccination or by passive immunity in postexposure cases with hepatitis B immunoglobulin. Vaccination is the most effective strategy to prevent infection and a comprehensive vaccination strategy has been implemented in the United States (Table 42-8). Vaccines use HB_sAg for the antigen via recombinant DNA technology using yeast to prompt active immunity. More than 60 million adolescents and more than 40 million infants and children have received a HBV vaccine in the United States since 1982. The vaccine is considered safe. Since 2000, vaccines licensed in the United States either contain none or trace amounts of thimerosal as a preservative. Available vaccines include two single-antigen products and three combination products. The two single-antigen products are Recombivax HB and Engerix-B. Twinrix is a combination vaccine for HAV and HBV in adults. Comvax and Pediarix are used for children and are used for HBV along with other scheduled vaccines.

Passive immunity in the form of anti-HB_sAg offers temporary protection against HBV and is used in conjunction with the hepatitis B vaccine for postexposure prophylaxis.²¹

TREATMENT

Hepatitis B Virus

■ DESIRED OUTCOME

HBV infections are not curable; rather, the goals of therapy are to increase the chances for seroclearance, prevent disease progression to cirrhosis and HCC, and to minimize further injury in patients with ongoing liver damage.

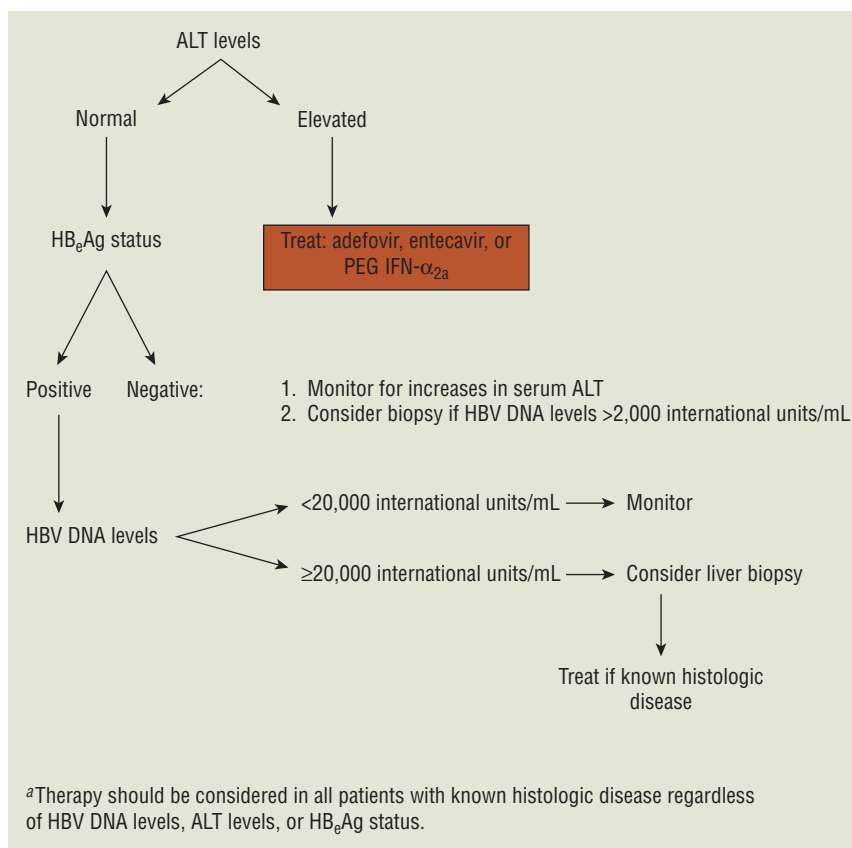

FIGURE 42-1. Suggested treatment algorithm for chronic hepatitis B virus infection based on the recommendations of the American Gastroenterological Association. (ALT, alanine transaminases; HB_sAg, hepatitis B e antigen; PEG IFN, pegylated interferon.) (Adapted from reference 29.)

■ GENERAL APPROACH TO TREATMENT

5 Response to therapy is monitored by biochemical (normalization of ALT levels), histologic examination of liver cells from biopsy (a minimum 2-point decrease in histology activity compared to baseline biopsy), and virologic response (undetectable serum HBV DNA levels and loss of HB_sAg in HB_sAg-positive patients).²⁷ Maintenance of viral suppression is defined as durability of response. In HB_sAg-positive patients, successful therapy includes loss of HB_sAg status and seroconversion to anti-HB_sAg. Other serologic markers are typically not evaluated in clinical trials. Recommendations for treatment consider the patient's age, serum HBV DNA and ALT levels, as well as histologic evidence and clinical progression of disease (Figs. 42-1 and 42-2). Not all chronic HBV patients are candidates for treatment. Some patients may be best managed with periodic monitoring for disease progression because the chances for therapeutic response are unlikely and do not outweigh the risks and costs associated with treatment. Various guidelines have been published and updates made as more drugs are indicated for use in HBV.^{27,29,38}

■ NONPHARMACOLOGIC THERAPY

All chronic HBV patients should be counseled on preventing disease transmission. Sexual and household contacts should be vaccinated. To minimize further liver damage, all chronic HBV patients should avoid alcohol and be immunized against HAV. No level of alcohol use has been established as safe.²⁹ Moreover, patients are encouraged to consult their medical provider before using any new medications, including herbals and nonprescription drugs.²¹

Herbal medicines are an intriguing option to many patients. Four common preparations include *Phyllanthus*, milk thistle, glycyrrhizin (licorice root extract), and a mixture of herbs known as Liv 52. Although some of the products may have some benefits, the methodologic qualities of the trials evaluating the herbs are poor. Randomized, placebo-controlled studies and long-term followup data are lacking. Meta-analysis of existing studies demonstrated that milk thistle and Liv 52 do not affect the course of liver disease. Herbal treatment is not recommended for patients with chronic hepatitis B.³⁹

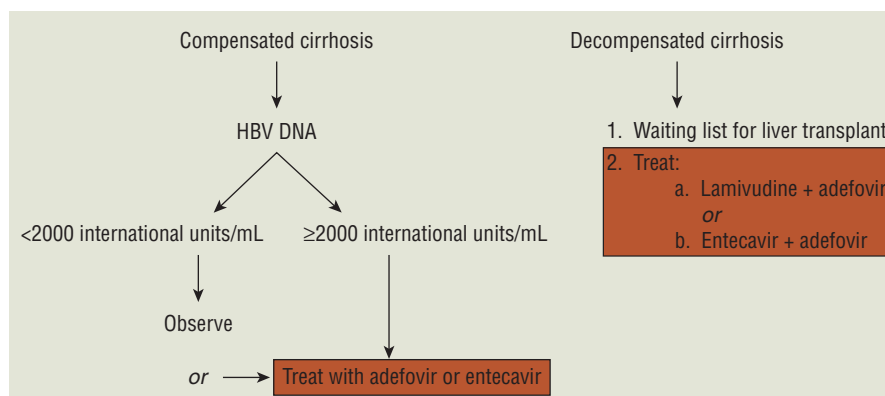

FIGURE 42-2. Suggested treatment algorithm based on the recommendations of the American Gastroenterological Association for chronic hepatitis B virus-infected patients with cirrhosis. (Adapted from reference 29.)

■ PHARMACOLOGIC THERAPY

5 Because hepatic damage is sustained by ongoing viral replication, drug therapy aims to suppress viral replication by either immune mediating or antiviral agents. In the United States, interferon (IFN)- α_{2b} , lamivudine, telbivudine, adefovir, entecavir, and pegylated IFN- α_{2a} are all approved as first-line therapy options for chronic HBV.²⁹

Interferon

IFN- α_{2b} therapy was the first approved therapy for treatment of HBV and improves long-term outcomes and survival.²⁰ Acting as a host cytokine, it has antiviral, antiproliferative, and immunomodulatory effects in chronic HBV.⁴⁰ Several factors correlate with improved response to IFN therapy, including increased ALT and HBV DNA levels, high histologic activity score at biopsy, and being non-Asian. Asian patients tend to have more normal ALT levels in chronic infection, confounding the actual impact of ethnicity on infection.⁴⁰

Patients who respond to IFN therapy tend to have a more durable response than that seen with lamivudine, likely as a consequence of IFN's stimulation of the immune response for seroconversion. Seroconversion rates range from 30% to 40% and are often permanent, although relapse is more likely in HB_eAg-negative patients.^{35,41} The duration of therapy is finite, although the optimal duration of treatment is unclear. Treatment for a minimum of 12 months is associated with greater sustained virologic response rates than treatment for 4 to 6 months. Seroconversion can occur during or after therapy is complete. An extended treatment duration of 24 months may benefit the difficult-to-treat HB_eAg-negative patient.³⁵ Conventional IFN therapy is plagued with numerous problems, including the inconvenience of thrice-weekly injections; however, standard interferon therapy has virtually been replaced by the use of pegylated IFN (PEG-IFN) because of the benefits in ease of administration, decreased side effect profile, and improvements in efficacy. Compared to conventional IFN, PEG-IFN has a longer half-life enabling once-weekly injections. For HBV treatment, the approved PEG-IFN formulation is PEG-IFN- α_{2a} . Studies comparing PEG-IFN- α_{2a} monotherapy with PEG-IFN- α_{2a} -lamivudine combination therapies suggest that combination therapy caused greater HBV DNA suppression than PEG-IFN- α_{2a} monotherapy, PEG-IFN- α_{2a} monotherapy better achieved HB_eAg seroconversion than lamivudine monotherapy with no difference in combination therapy, and combination therapy resulted in less lamivudine resistance than lamivudine monotherapy. Interferon-based therapies are still limited by multiple adverse effects (Table 42-9). The high risk of infection precludes use of IFN in decompensated cirrhotic patients.²⁹ In patients with compensated cirrhosis, IFN appears to be safe and effective, although it can provoke hepatic flares and precipitate hepatic decompensation.^{29,35}

Lamivudine

Lamivudine, a nucleoside analog, has antiviral activity against both HIV and HBV. It is dosed at 100 mg daily; the optimal duration of treatment is unknown. In both HB_eAg-positive and -negative patients, lamivudine demonstrates profound viral suppression. HBV

DNA serum levels are undetectable in 90% of lamivudine-treated patients after 4 weeks.³⁵ Normalization of ALT levels occurs gradually over 3 to 6 months in most patients. Additionally, fibrotic changes are reduced and may be reversed in some cases. Response to lamivudine is dependent on baseline ALT levels, with higher levels corresponding to greater likelihood of seroconversion. Seroconversion rates increase with duration of therapy and are at 50% by the fifth year of therapy.²⁹ The advantages of lamivudine-based therapy include its safety profile and patient tolerability and the convenience of an oral tablet. Moreover, lamivudine can safely be used in immunosuppressed and cirrhotic patients.⁴¹ However, lamivudine therapy is not without problems. There is no clear duration of treatment and HB_eAg-negative patients have a less than 20% viral suppression rate after 12 months of therapy. Serum HBV DNA levels return to baseline upon cessation of therapy.⁴² Seroconversion rates are less than 20% after 1 year of therapy and will relapse in up to 58% of patients. Relapse rates are highest among Asian patients.⁴¹ Resistance is inevitable and can undermine the value of treatment. The emergence of YMDD mutants increases with each subsequent year of therapy, with rates approaching 70% after 4 years of therapy, and is associated with returns of serum HBV DNA and elevated ALT levels.^{20,22} Although seroconversion can occur even after the appearance of resistant mutants,²² the prognosis is poor for most patients who develop resistance.³⁵ In HB_eAg-negative chronic hepatitis B, where therapy is long-term and the exact duration of therapy unknown, resistance is an especially daunting problem.⁴³

Adefovir

Adefovir dipivoxil is an acyclic nucleoside analog of adenosine monophosphate. The drug acts by inhibiting HBV DNA polymerase. It is dosed at 10 mg daily for 1 year, although the optimal duration of therapy is unknown.²⁹ A 48-week course of treatment is effective in improving histologic findings, reducing serum HBV DNA and ALT levels, and increasing HB_eAg seroconversion in both HB_eAg-negative and -positive patients.^{44,45} Further suppression of HBV DNA and ALT levels occurred in long-term therapy over 4 to 5 years with improved histologic findings.³⁷ In HB_eAg-negative patients treated for 48 weeks, the benefits of therapy were lost within 4 weeks of stopping adefovir. In contrast, patients treated for 144 weeks maintained benefits throughout the treatment duration and saw continued improvement in fibrosis as the therapy continued. However, rates of seroconversion were low.³⁷ Historically, increases in serum creatinine limited treatment to doses of 30 mg/day or less. In patients treated chronically at a dose of 10 mg daily, the incidence of nephrotoxicity was the same as placebo. In patients treated with 10 mg/day for a subsequent 48 weeks, the incidence of serum creatinine abnormalities did not change from the first year of therapy.³⁷ Resistance to adefovir has not been seen within the first year of therapy. Resistant mutants have been identified and do respond to lamivudine therapy, although the full impact on clinical outcomes is not known.²⁹ In patients with developing lamivudine resistance as demonstrated by rising HBV DNA levels, the addition of adefovir was more effective if done while ALT levels were still normal.⁴⁶

Entecavir

Entecavir is a guanosine nucleoside analog that acts by inhibiting HBV polymerase. An oral agent, it is more potent than lamivudine in suppressing serum HBV DNA levels and is effective in lamivudine-resistant HBV.^{29,47} The drug is dosed at 0.5 mg daily in treatment-naïve or non-lamivudine-resistant infections and at 1 mg daily in lamivudine-refractory patients. In a 48-week trial comparing it to lamivudine, entecavir resulted in significantly higher rates of histologic improvement, HBV DNA reduction and undetectabil-

TABLE 42-9 Common Side Effects Associated with Peginterferon Therapy (Experienced by >20% of Patients)

ity, and ALT normalization. No difference in HB_eAg loss or seroconversion was observed in HB_eAg-positive patients.⁴⁸ Among all patients, no differences in fibrosis improvement were seen and resistance to entecavir was not detected after 2 years of therapy.^{48,49} However, treatment response in lamivudine-resistant patients is lower overall and entecavir-resistant mutants can develop during the course of treatment.²⁹ Resistance is most likely to occur in patients with preexisting lamivudine resistance.⁴⁷ In terms of safety, entecavir is comparable to lamivudine. Patients switched from lamivudine to entecavir are at risk for hepatic flares, although severe flares are unlikely.⁴⁷

Telbivudine

The most recently approved drug for HBV treatment is telbivudine, a HBV-specific nucleoside analog. Telbivudine acts as a competitive inhibitor of viral reverse transcriptase and DNA polymerase. The drug inhibits HBV DNA synthesis with no activity against other viruses or human polymerases.³⁶ Compared to lamivudine, telbivudine is a more potent suppressor of HBV DNA with greater median HBV DNA log reductions and more patients achieving undetectable viral loads.^{36,47} More patients also experienced a normalization of ALT levels. Although more telbivudine-treated patients experienced seroconversion, the difference was not significant. Compared to adefovir, telbivudine significantly reduced HBV DNA levels, although no difference was seen for HB_eAg loss or ALT normalization.⁵⁰ Resistance may limit telbivudine's efficacy, although long-term data are needed.⁴⁷ During a 1-year study, 5% of patients developed resistance and data suggest telbivudine should not be used in patients with resistance to lamivudine.³⁶ Varying degrees of hepatic impairment do not alter the kinetics of the drug, nor does the coadministration of lamivudine or adefovir.^{51,52} Combination therapy of telbivudine and lamivudine did demonstrate greater seroconversion rates but the difference was not statistically different from monotherapy.⁵⁵ The most commonly associated adverse event with telbivudine is upper respiratory tract infection.⁵⁰

■ ALTERNATIVE DRUG TREATMENTS

Emtricitabine is a cytosine analog approved for use in HIV and with activity against HBV. It is currently not approved for HBV. In a comparative study with placebo, emtricitabine showed a significant decrease in viral load to undetectable in 54% of patients, normalization of ALT levels in 65% of patients, and improvement in necroinflammatory score. However, seroconversion to anti-HB_eAg and HB_eAg loss did not differ between placebo and emtricitabine. Emtricitabine safety was comparable to placebo. At the end of the 48-week treatment, 20 emtricitabine-treated patients had YMDD or YMDD-related resistance mutations.⁵³

Tenofovir is a nucleotide analog approved for use in HIV and with activity against HBV. Compared to adefovir in lamivudine-resistant chronic hepatitis B, it showed an earlier and greater suppression of HBV DNA. Toxicity is minimal compared to adefovir. Resistance has not been seen.⁴¹

Combination therapy has been proposed to counter the issues of resistance. YMDD mutants remain susceptible to adefovir.⁴⁶ Adding adefovir to patients on lamivudine when HBV DNA levels began to increase better maintained normal ALT levels and suppressed HBV DNA than waiting to add adefovir until after ALT levels increased.⁴⁶ Combination therapy with interferon and lamivudine creates less resistance than lamivudine monotherapy, but the combination did not change the posttherapy response in chronic HB_eAg-negative patients. The American Gastroenterology Association recommends combination therapy with lamivudine or entecavir plus adefovir for decompensated cirrhotic patients with chronic HBV regardless of HBV DNA levels or HB_eAg status.²⁹

■ SPECIAL POPULATIONS

The decision to treat cirrhotic patients depends on disease progression. Patients with decompensated cirrhosis require referral for liver transplant. Most recently updated guidelines suggest lamivudine, adefovir, and entecavir are possible agents for use in cirrhotic patients (see Fig. 42–2).²⁹ In patients coinfecting with HCV, the more dominant form of the virus is targeted for treatment. The current recommendation is to treat HCV according to published guidelines and consider the addition of entecavir or adefovir if HBV DNA levels remain stable or rise.²⁹

In HIV coinfecting patients, therapy should be tailored specifically to the patient. If the patient is being treated for HIV, certain regimens may be optimized to include drugs with efficacy against HBV, including tenofovir or lamivudine. If patients are on a stable regimen that does not include HBV-active drugs, adefovir may be added.²⁹

Although the majority of chronic HBV patients are adults, children may be treated. Lamivudine is indicated for children ages 2 years and older and interferon is approved for use in children ages 1 year and older. Entecavir is approved for adolescents ages 16 years and older, whereas pegylated interferon and adefovir do not have indications for pediatric dosing.

PHARMACOECONOMIC CONSIDERATIONS

Cost considerations in HBV include the cost-effectiveness of the HBV vaccine and available antiviral treatments. The use of a combined HAV/HBV vaccine is cost-effective.¹⁶ Routine use of the HBV vaccine in HIV counseling and testing sites, including sexually transmitted disease clinics, showed it to be an effective and cost-effective measure in preventing HBV among high-risk groups. The model, which considered four different strategies in vaccination, including no vaccination, found that routine vaccination would cost \$4,400 per QALY and per life-year saved. When costs of HBV treatment and transplants were included, the cost decreased to \$2,200 per QALY, further supporting routine vaccination as a cost-effective measure.⁵⁵

The cost-effectiveness of therapy for chronic HBV patients must address the approval of new agents for treatment. For noncirrhotic chronic HBV patients with elevated ALT levels, the most cost-effective therapy consisted of initiating treatment with lamivudine and switching to adefovir with the development of lamivudine resistance. The salvage strategy cost \$8,447 per QALY. Pegylated interferon was not compared.⁵⁶ In chronic HBV patients with cirrhosis, entecavir was the most effective, yet more expensive, option. Entecavir cost \$25,626 per QALY as compared to adefovir's \$19,731 per QALY. Salvage therapy was not found to be cost-effective in this patient population.⁵⁷ Pegylated interferon was not compared for initial treatment because of its relative novelty in HBV treatment; because interferon is not considered a treatment option for cirrhosis, it was not included in the analysis of cirrhotic patients.

CLINICAL CONTROVERSY

Although previously published guidelines do not support the use of IFN in cirrhosis because of the potential for an IFN-induced hepatic flare progressing to decompensation, some experts suggest PEG-IFN- α_{2a} may be an option for some patients with compensated cirrhosis. Moreover, some experts argue that lamivudine, although indicated for use in cirrhosis, may cause clinical decompensation because of the drug's high risk for resistance and hence, viral rebound triggering decompensation.

HEPATITIS C

HCV is approximately five times as common as HIV and is responsible for an estimated 10,000 chronic liver disease-associated deaths per year.¹ More than 190,000 deaths from HCV-related disease are expected between 2010 and 2019, with projected costs exceeding \$10 billion.⁵⁸ Most acute infections are asymptomatic and the course of the infection is insidious. As a result, many patients are not diagnosed until significant disease progression.

EPIDEMIOLOGY

8 HCV is the most common blood-borne pathogen. In the United States, approximately 3.2 million people are chronically infected with HCV.¹ An estimated 20,000 new HCV infections occurred in 2005; however, because of the clinically silent nature of acute infections and the 20- to 30-year disease progression to cirrhosis, it is the 200,000 patients infected per year in the late 1980s who contribute to today's HCV burden.⁵⁸ Considering that HCV infection is prevalent in high-risk populations such as prisoners, IDUs, and the homeless, and that this population is generally excluded from most surveys, it is estimated that the actual number of chronically infected people is significantly higher. Nearly 75% of infected people may not be identified.⁵⁸ The single largest risk factor for infection is injection drug use. Some experts also consider other illicit drug use, for example intranasal cocaine, as a risk factor because of the possible contamination of drug paraphernalia not limited to syringes and needles.³ Historically, blood transfusion posed a major risk for infection. Patients who received blood transfusions or transplants before 1992, clotting factors before 1987, or were ever on chronic hemodialysis represent a majority of chronic HCV infections.⁵⁹ Improved screening of blood in 1992 decreased the risk of transfusion-related HCV.⁶⁰ Currently hemodialysis and transfusions both represent less than 1% of risk factors in known HCV exposures.³ Although sexual transmission is an often-identified risk factor, the actual risk is very low and may be confounded by other behaviors. Studies of monogamous couples in long-term relationships do not support the use of barrier methods for preventing transmission. Testing of sexual partners in a monogamous relationship is mainly recommended for ease of mind.⁶¹ Although sexual contact is considered an inefficient means of HCV transmission, multiple sexual partners and coinfection with sexually transmitted diseases, including HIV, increase the risk for HCV sexual transmission.⁶²

Screening

Although acute HCV infections are often not recognized and many progress to chronic infections, routine screening for infection is not recommended. Various guidelines and position papers for the screening and treatment of chronic HCV infection exist.^{59,61} Screening is warranted in patients who are at high risk for infection (Table 42–10).

TABLE 42-10 Recommendations for Hepatitis C Virus (HCV) Screening

Current or past use of injection drug use
Coinfection with HIV
Received blood transfusions or organ transplantations before 1992
Received clotting factors before 1987
Ever on chronic hemodialysis
Patients with unexplained elevated ALT levels or evidence of liver disease
Healthcare and public safety workers after an occupational exposure
Children born to HCV-positive mothers
Immigrants from countries with a high prevalence of HCV infection

ALT, alanine transaminase; HIV, human immunodeficiency virus.
Data from Hoofnagle.⁶³

Although the risk of HCV in monogamous relationships is very low and barrier methods are not recommended, sexual partners may be tested for the sake of reassurance.⁵⁹ The risk of infection from other needle-borne exposures, such as acupuncture, tattooing, and body piercing, is unclear and at this time not an indication for routine screening for HCV.⁶¹

ETIOLOGY

HCV is a single-stranded RNA virus of the family Flaviviridae notable for lacking a proofreading polymerase and enabling frequent viral mutations.^{58,63} The virus replicates within hepatocytes and like hepatitis B, is not directly cytopathic. HCV replicates copiously with an estimated serum half-life of 2 to 3 hours. The result is a proliferate, persistently mutating virus posing an immense challenge for immune-mediated control.⁶³

HCV is differentiated into six major genotypes, numbered 1 to 6, and varying in nucleotide sequence by 30% to 50%. Genotypes are further classified into subtypes (a, b, c, etc.), which differ by 10% to 30% in nucleotide sequence. The most widely distributed genotypes are 1 and 2, with genotype 1 the most common (Table 42–11). In the United States, the majority of infections are caused by genotypes 1a and 1b, followed by genotypes 2 and 3. Although infection caused by any of the genotypes can lead to cirrhosis, end-stage liver disease (ESLD), or HCC, the significance of the infecting genotype is related to therapeutic response. Genotypes 2 and 3 are at least twice as likely to respond to therapy as genotype 1. Genotypes 4, 5, and 6 are not well understood but are expected to respond with rates similar to genotype 1.⁶³

PATHOPHYSIOLOGY

In the vast majority of cases, an acute HCV infection leads to chronic infection. The immune response in an acute HCV infection is mostly insufficient to eradicate the virus. During the early phases of infection, natural killer cells are activated as HCV RNA levels rapidly rise. A combined effort of HCV specific CD4 and CD8 T lymphocytes and interferon coexpression decrease viral replication. The eradication of HCV by cytotoxic T lymphocytes may occur either as a result of induced apoptosis by infected hepatocytes or by the release of interferon to stifle viral replication. The extent of hepatocyte apoptosis may correlate with the course of the disease. Liver damage and HCC are associated with high levels of hepatocyte apoptosis. Low levels of apoptosis are associated with viral persistence. Moreover, CD4 T-helper cells are unlikely to mediate liver injury, but rather may promote an environment conducive for other immune responses damaging to the liver. Bystander killing may also play a role in hepatic damage. Although HCV infects less than 10% of hepatocytes, up to 20% of cells are activated for apoptosis.⁶⁴

HCV poses a daunting challenge for immune control because of its rapid viral diversification. HCV genomic mutations are detectable within 1 year of infection. Resolved cases of HCV are defined by a vigorous T-cell response with highly active CD8 and persistent

TABLE 42-11 Worldwide Hepatitis C Virus Genotype Distribution

CD4 cell response. It is hypothesized that the CD8 activity mediates protective immunity but requires the aid of CD4 cells to maintain the response during viral mutations.⁶⁴

CLINICAL PRESENTATION

In an acute HCV infection, most patients are asymptomatic and undiagnosed. HCV RNA is detectable within 1 to 2 weeks of exposure and levels rise quickly during the initial weeks. The HCV RNA levels plateau at 10^5 to 10^7 international units/mL and precede a peak in ALT levels and the onset of symptoms. Rising ALT levels indicate hepatic injury and cell necrosis. It is not unusual for levels to exceed values 10 times the upper limits of normal.⁶³ Although HCV RNA serum levels can show interpatient variability, the levels tend to be stable for the individual patient.⁶⁵ Typically, symptoms occur 7 weeks after the infection, with a range of 3 to 12 weeks. Approximately one-third of adults will experience some mild and nonspecific symptoms, including fatigue, anorexia, weakness, jaundice, abdominal pain, or dark urine.^{58,63} Acute infections rarely progress to fulminant hepatitis, although the course can be severe and prolonged. If the infection is self-limiting, symptoms last several weeks as ALT and HCV RNA levels subside. Almost all patients, including immunosuppressed patients, will develop antibodies to HCV. Typically, antibodies are not detectable until either at the time of or shortly after the development of symptoms and are not used diagnostically in an acute infection because a third of infected patients may test negative at the onset of symptoms despite infection.⁶³

Up to 85% of acutely infected patients will go on to develop a chronic HCV infection, defined as persistently detectable HCV RNA for 6 months or more. HCV RNA levels and ALT levels can fluctuate and even have periods of undetectable HCV RNA and normal ALTs. Most patients will have few, if any symptoms. The most common symptom is persistent fatigue. Additional symptoms include right upper quadrant pain, nausea, or poor appetite. On physical examination, hepatomegaly is usually present. With advanced disease, stigmata of liver disease is evident, such as spider nevi, splenomegaly, palmar erythema, testicular atrophy, and caput medusae. However, almost all patients with chronic HCV will have some degree of necroinflammatory disease on liver biopsy. The extent of structural damage varies considerably.⁶³ Chronic inflammation of the liver from chronic HCV infection may result in fibrosis. Fibrosis is defined by altered hepatic perfusion creating a distorted structure and affecting normal function.⁶⁶ The speed of fibrosis progression can vary and is not necessarily predictive of cirrhosis development. An estimated 20% of chronic HCV patients will develop cirrhosis and half of those patients will progress to either decompensated cirrhosis or HCC. Historically, one-third of untreated patients may expect to develop cirrhosis within 20 years, while another third of patients may delay the onset of cirrhosis for 50 years or never develop it.

It is currently not possible to definitively identify patients at risk for disease progression.⁶⁶ Several factors may correlate with a decreased risk for chronicity. Being younger than 40 years old, female, nonblack, not immunosuppressed, and with a symptomatic acute HCV infection decreases the risk of developing a chronic infection. Being older than age 20 years at infection triples the risk for chronic HCV. Blacks, especially black men, are more likely to develop chronic infection and have lower treatment responses.⁶⁷ Becoming symptomatic and having jaundice is associated with a lower likelihood of chronic infection, perhaps correlating to a stronger immune response to the acute infection. Finally, immunosuppressed patients, such as those with HIV, are more prone to chronic infection although they are not inherently unable to clear the infection.⁶³ Similarly, disease progression is associated with increased age, male sex, continued alcohol intake, and HIV coinfection. Diabetes, as well as steatosis and obesity, may also potentiate fibrosis

progression. Viral load and genotypes other than genotype 3 are not factors. Genotype 3 may be associated with fibrosis progression.⁶⁶ The development of HCV cirrhosis poses a 30% risk over 10 years for the development of ESLD, as well as a 1% to 2% risk per year of developing HCC.⁶¹ Progression to cirrhosis is the primary concern in patients infected with HCV for 2 decades or longer. Unfortunately, because acute infections are typically not recognized, the diagnosis of HCV is often not made until disease progression.

HCV is also rarely associated with extrahepatic manifestations. The most common is cryoglobulinemia, a local deposition of immune complexes that cause vasculitis. Typical manifestations involve the skin and internal organ damage, predominantly affecting the kidneys. Symptoms of cryoglobulinemia include fatigue, skin rash, purpura, arthralgias, renal disease, and neuropathy.⁶³ Other, more rare symptoms include B-cell non-Hodgkin's lymphoma, Sjögren syndrome, glomerulonephritis, arthritis, corneal ulcers, thyroid disease, neuropathies, and porphyria cutanea tarda.⁶⁸

DIAGNOSIS

For many patients, a diagnosis of hepatitis C is incidental. Some patients are diagnosed after persistently abnormal transaminases. Unfortunately, those patients who present with symptoms typically have advanced disease. A diagnosis of chronic HCV is confirmed with a reactive enzyme immunoassay for anti-HCV. Testing for anti-HCV is not routinely recommended because of the low prevalence of HCV in the general population and the nonspecificity of the test. Although many professional associations advocate testing for both symptomatic and asymptomatic persons with risk factors for HCV, the U.S. Preventative Task Force does not recommend routine screening of high-risk individuals.⁶⁹

TREATMENT

Hepatitis C Virus

■ DESIRED OUTCOME

The primary goal of therapy is to eradicate HCV infection. Resolving the infection prevents the development of chronic HCV infection sequelae. Even patients who are unable to achieve cure may see histological improvements with therapy.⁵⁹

■ GENERAL APPROACH TO TREATMENT

Treatment for HCV is necessary because nearly 85% of acutely infected patients develop chronic infections and are at risk of developing cirrhosis, ESLD, and HCC. Moreover, HCV infection is the most common indication for liver transplant. Treatment is indicated for patients previously untreated who have chronic HCV, circulating HCV RNA, increased ALT levels, evidence on biopsy of moderate to severe hepatic grade and stage, and compensated liver disease.⁵⁹ According to the American Association for the Study of Liver Diseases, among chronic HCV patients, symptomatic cryoglobulinemia is an indication for HCV antiviral therapy irrespective of the stage of liver disease.⁶¹ Therapy is not without risk, and in some cases may not be recommended, such as in patients with decompensated liver disease, a history of severe uncontrolled psychiatric disorder, and in patients with severe hematologic cytopenias.⁵⁹ Table 42-12 lists the contraindications to therapy.

Before therapy is initiated, quantitative HCV testing, genotyping, and a liver biopsy are performed. Quantitative amplification assays for HCV RNA are performed in patients who are candidates for therapy to obtain baseline information on the viral load. A baseline HCV RNA level serves as a prognostic indicator for response and is

TABLE 42-12 Contraindications to Hepatitis C Virus Combination Therapy

Autoimmune hepatitis

Patients with creatinine clearance <50 mL/min
Patients on hemodialysis
Patients with ischemic cardiovascular or cerebrovascular disease

used to monitor virologic response once therapy is initiated. Genotyping is also necessary for treatment candidates because response to therapy and duration of therapy vary depending on the infecting genotype. Liver biopsy is used to determine histologic grade and stage and to guide therapy.⁶¹ Because most chronic HCV patients are not diagnosed for years, a biopsy can provide clinical information on the extent of hepatic damage incurred since infection and offer baseline data to assess disease progression.⁵⁹ In some patients, liver biopsy may support a decision to delay treatment.

Overall, the greatest predictor of treatment response is infection with nongenotype 1. Adherence to therapy is a crucial component in response, especially among genotype 1-infected patients. Patients who take at least 80% of their medications for at least 80% of the treatment time are more likely to successfully respond to therapy.⁷⁴ Treatment response is monitored according to the following terminology:

Early virologic response (EVR): patient who experiences at least a 2-log reduction in viral load by the 12th week of treatment

End-of-treatment response (ETR): patient with no detectable viral load at the end of treatment

Sustained virologic response (SVR): patient with no detectable viral load at the conclusion of therapy and 6 months later

Relapser: patient who responds to therapy but whose viral load becomes detectable at the conclusion of therapy

Nonresponder: patient with a stable viral load during the course of therapy

Partial responder: patient with at least a 2-log reduction in viral load but who never has undetectable viral levels

Patients who experience an EVR are more likely to also have an SVR. Less than 3% of patients who fail to have an EVR can be expected to achieve an SVR.^{59,61} If the goal of therapy is viral eradication and an EVR is not achieved, therapy may be discontinued. In some patients, however, histologic benefits can occur without an EVR and histologic improvements alone may warrant continuation of therapy.⁵⁹

■ NONPHARMACOLOGIC THERAPY

All chronic HCV patients should be vaccinated against hepatitis A and B. Lifestyle changes are an important factor in reducing health consequences in hepatitis C. Continued alcohol use is a known risk factor for disease progression and severity. There is no established lower limit of alcohol consumption at which disease progression is not seen. Obesity is also a factor and patients should be encouraged to eat a balanced diet and exercise regularly to maintain a normal weight. Smoking may contribute to disease progression. Patients should be encouraged to maintain good overall health, stop smoking, and avoid alcohol and illicit drugs.^{61,71} The use of herbal therapy is ineffective.³⁹

■ PHARMACOLOGIC THERAPY

9 The current standard of care for chronic HCV patients is a combination therapy of a once-weekly injection of PEG-IFN and a

TABLE 42-13 Recommended Hepatitis C Virus Treatment Dosing

Genotype	Peg-IFN Dose	Ribavirin Dose	Duration ^a
1	Peginterferon α_{2a} 180 mcg/wk or Peginterferon α_{2b} 1.5 mcg/wk	<75 kg ^b 1,000 mg ≥75 kg 1,200 mg	48 weeks
2, 3	Peginterferon α_{2a} 180 mcg/wk or Peginterferon α_{2b} 1.5 mcg/wk	800 mg	24 weeks

^bPatient weight.

daily oral dose of ribavirin. Overall response rates are greatest with combination therapy at an SVR rate of 54% to 56%.⁵⁹ Therapy is optimized based on genotype, patient weight, and response to therapy. Table 42-13 lists current therapeutic regimens. For genotype 1, evaluation for an EVR at 12 weeks is recommended as an indicator of the probability of achieving an SVR. Because therapy is not without a significant side-effect profile and because failure to achieve EVR is so strongly correlated with treatment failure, some clinicians will terminate therapy early in genotype 1 patients (Fig. 42-3). Conversely, because genotypes 2 and 3 respond so well to therapy, there are data to support early treatment termination in patients who show an EVR at 4 weeks (Fig. 42-3).⁷²

Interferon

Historically, treatment of HCV involved the use of IFN- α . Although IFN monotherapy resulted in an SVR in less than 10% of patients, the

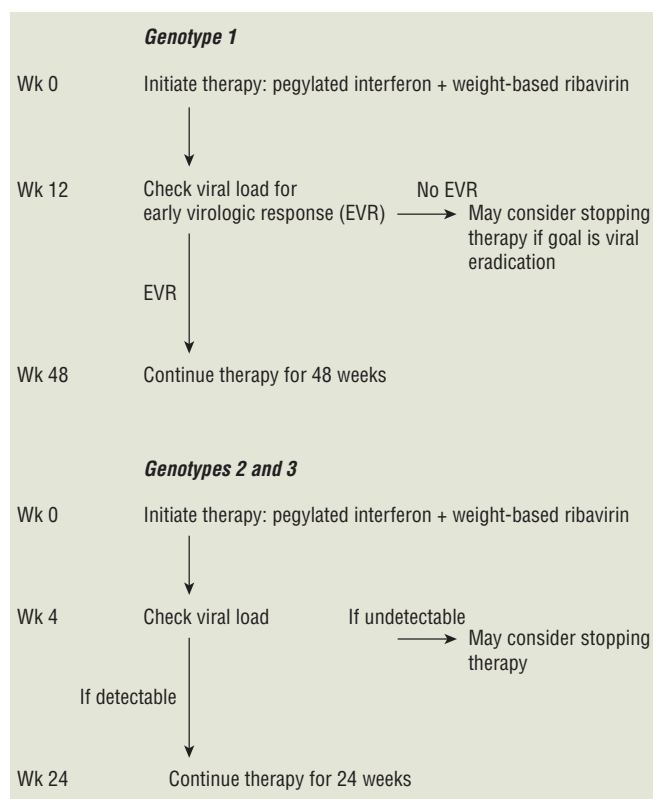

FIGURE 42-3. Suggested response-optimized chronic hepatitis C virus infection treatment regimens based on the recommendations of the American Gastroenterological Association. (Adapted from reference 59.)

response was durable. The addition of a pegylated moiety to IFN improved the pharmacokinetic profile of the drug to reduce injection frequency from three times to once a week, and doubled SVR rates. Even among cirrhotic patients, PEG-IFN was safe and effective.⁵⁹ Two PEG-IFNs are available, PEG-IFN- α_{2a} (Pegasys) and PEG-IFN- α_{2b} (PEG-Intron). Table 42–14 lists the differences between the two drugs. It is unclear which therapy is superior. A comparison trial on the antiviral effects of the two therapies found that PEG-IFN- α_{2b} had a greater decrease in HCV RNA during the first 4 weeks of monotherapy than PEG-IFN- α_{2a} .⁷³ Achievement of SVR may be more likely in patients with an early and intense viral suppression. Nonetheless, head-to-head trials are lacking and the true clinical difference between therapies remains unknown.

Ribavirin

Ribavirin, a synthetic guanosine analog, is ineffective as a monotherapy for HCV and its exact mechanism of action is unknown. When added to IFN, ribavirin significantly increases SVR rates, especially among genotypes 2 and 3. Ribavirin is dosed based on weight for optimal response. Although monotherapy with PEG-IFN is an option for patients with contraindications to ribavirin, ribavirin is ineffective as monotherapy and should not be used alone. However, SVR rates are highest among patients treated with a combination of PEG-IFN and ribavirin at >40% for genotype 1 patients and at approximately 80% for genotypes 2 and 3.⁵⁹

⑩ Side effects of therapy are extensive and a major obstacle to successful patient completion of therapy (see Table 42–9). Although many patients require dose reductions for laboratory abnormalities, very few result in withdrawal of therapy. In contrast, more patients prematurely stop therapy because of adverse events such as fatigue or flu-like symptoms.⁷⁴ The most common laboratory abnormalities are neutropenia, thrombocytopenia, and anemia. Ribavirin-induced hemolytic anemia is an inevitable effect of therapy, although varying in severity among patients. Anemia results from ribavirin uptake into erythrocytes, inducing membrane damage and resulting in hemolysis. Patients may complain of fatigue as hemoglobin levels decrease even though dose reductions are not recommended until hemoglobin levels fall to 10 g/dL. The mean decrease in hemoglobin is 3 g/dL in the initial weeks of therapy; thereafter levels stabilize until discontinuation of therapy. Hemoglobin levels normalize once ribavirin is stopped.⁷⁴ IFN can cause bone marrow suppression, resulting in neutropenia and thrombocytopenia. PEG-IFNs are more likely to cause neutropenia than non-PEG-IFN. Dose reductions are recommended for neutrophil counts <750 cells/mm³; discontinuation is recommended at <500 cells/mm³. However, patients are not at a greater risk for infection. Neither nadir neutrophil counts nor total neutrophil decrease from baseline are related to infection. One study examined the risk for total, viral, fungal, and bacterial infections and concluded that neither dose reductions of interferon nor the addition of granulocyte-stimulating factor in HCV-treatment-induced neutropenia is warranted.⁷⁵

Up to one-third of patients are expected to experience some degree of depression during treatment partly because of interferon's interference with the serotonin pathways.⁵⁴ Although many patients can be managed with selective serotonin reuptake inhibitors, various degrees of counseling and psychiatric consultations may be necessary. Severe depression and suicidal behaviors are rare but not undocumented. More common side effects include flu-like symptoms, which can be managed by acetaminophen or nonsteroidal inflammatory drugs.⁵⁹

Alternative Treatments

Currently investigated drug treatments for chronic HCV include VX-950 and valopicitabine (NM283). VX-950 is a reversible, selective, and specific inhibitor of HCV replication. It is an oral drug and current data suggest optimal dosing to be three times per day. Although VX-950 demonstrated great viral load reduction even among previous interferon nonresponders, when taken alone it demonstrated viral breakthrough within 2 weeks of initiation.⁷⁶ Valopicitabine, or NM283, is a ribonucleoside analog inhibiting viral replication. Studies in treatment-naïve and treatment-refractory patients are ongoing.

Special Populations

Clinical trials are conducted with a patient population that generally does not reflect the patient spectrum encountered in clinical practice. There are no contraindications to the treatment of intravenous-drug users, prisoners, persons with substance abuse issues, or persons with psychiatric disorders. However, barriers exist that can prevent access to care. A multidisciplinary approach to HCV treatment that includes mental health and substance abuse professionals should be considered in providing care to special populations.⁷⁷

Published recommendations for treatment in various special populations are as follows.^{59,61}

Patients with Normal ALTs The decision to treat patients with normal ALTs is somewhat controversial and made on individual patient basis. Clinicians should consider the risks and benefits of therapy, including histologic data, genotype, likelihood for response, and other factors, such as patient willingness to undergo therapy. Successful treatment significantly improves patient quality of life and reduce fatigue.⁷⁸

Patients with Decompensated Cirrhosis Patients with evidence of decompensation are candidates for liver transplantation. Therapy is not recommended.

Relapsed Patients The decision to re-treat should consider the previous therapeutic regimen. Patients with prior treatment with IFN monotherapy or IFN and ribavirin should be considered for retreatment with PEG-IFN and ribavirin. The likelihood for SVR is lower, but may be as high as 50%.

Nonresponders Retreatment with PEG-IFN and ribavirin can increase SVR rates in patients previously treated with IFN monotherapy or IFN and ribavirin. Previous adherence, treatment tolerance, severity of underlying liver disease, as well as factors affecting treatment response, such as genotype, should be considered before deciding to retreat.

Accidental Needle-Stick Exposures Prophylactic treatment immediately following an accidental needle-stick exposure is not recommended for multiple reasons. Risk of transmission is considered low and among those infected, a percentage will successfully seroconvert and not require treatment. Because an initial delay in therapy does not increase the risk for developing a chronic infection, most experts wait 2 to 3 months before initiating treatment. Treatment is continued for a minimum of 24 weeks.

Intravenous-Drug Users Injection drug use is a major factor in the cycle of HCV transmission. There are no recommendations against treatment for active IDUs although ongoing drug abuse can create many complications and expert opinion dictates that the decision to treat be made on a case-by-case basis. Treatment is recommended for recovering drug users, including those in drug treatment programs. Reinfection rates are low among intravenous drug users who achieve SVR.⁷⁹

Alcoholism Because continued alcohol use affects disease progression and severity and thus response to therapy, the cessation of alcohol use during therapy is recommended. Moreover, a period of abstinence before initiation of therapy is also recommended.

End-Stage Renal Disease The role of chronic HCV treatment is not defined for patients with end-stage renal disease. Hemodialysis is a contraindication for ribavirin use. Monotherapy with IFN is an option in patients with renal insufficiency or with end-stage renal disease. PEG-IFN can pose toxicity problems and requires careful monitoring.

HIV Coinfection A large portion of HIV-infected patients who acquired the virus via intravenous drug use will be coinfecting with HCV. Treatment poses additional problems because of hepatotoxicity issues associated with highly active antiretroviral treatment, hepatic complications from HIV-associated diseases, as well as flares in hepatitis as CD4 counts recover. The American Gastroenterological Association recommends a 48-week course of therapy regardless of genotype. The prognosis for an SVR is worse than in patients infected with HCV only. In general, treatment is recommended and both HIV and HCV therapies can be coadministered with the exception of ribavirin and didanosine. Other potential ribavirin drug interactions include zidovudine and stavudine.⁸⁰

Children Currently therapy is indicated for children ages 3 years and older and consists of IFN- α_{2b} monotherapy or in combination with ribavirin. PEG-IFN is not yet indicated for pediatric use. IFN is dosed at 3 million international units/m² (this is the dose used in the majority of pediatric studies) and ribavirin is available in a liquid formulation. Pediatric patients tend to better tolerate therapy than adults.

PREVENTION

No vaccine is available for HCV. It is unlikely that a vaccine will be developed in the near future because of the mutagenesis of the virus. Patients infected with HCV should be counseled on not being blood, organ, or semen donors. Although the likelihood of household transmission is small, patients should minimize risks by avoiding possible blood or mucus exposure, such as not sharing razors or toothbrushes and covering open wounds. Patients who continue to use illegal drugs should avoid sharing all drug paraphernalia, as risk of transmission is not limited to needles and syringes.

PHARMACOECONOMIC CONSIDERATIONS

The progression of HCV-induced liver disease is highly variable and identifying which patients will progress remains a clinical challenge. Because not all patients will develop clinical sequelae, therapy may not be necessary in all patients. Given the relative unreliability of treatment to achieve an SVR, the costs associated with therapy, and the side-effect profile of the drugs, the cost-effectiveness of therapy may be questioned. Several studies have assessed the economic values of treating chronically infected HCV patients.

Issues of cost-effectiveness must weigh the public health impact of HCV against the costs of therapy. Despite the decreased incidence of acute HCV infections, epidemiologic data suggest the greatest

disease burden will occur in 2015, reflecting the slow progression of disease in patients infected in the late 1970s and early 1980s. At the same time, HCV-related mortality is expected to triple.⁸¹ A projected 720,000 patient-years will be lost as a result of decompensated cirrhosis and HCC. Predicted costs exceed \$21 billion from the development of clinical sequelae. In patients who are younger than age 65 years, the costs associated with premature death are even higher—an expected \$54 billion.⁵⁸ Although not all patients will develop HCV-related liver disease, it is not currently possible to identify which patients will have disease progression. Moreover, HCV-infected patients are prone to high levels of fatigue and neuropsychiatric and cognitive impairment, further contributing to decreased patient quality of life.⁸¹

Treatment with PEG-IFN therapy compared to traditional IFN is a cost-effective approach among noncirrhotic patients who are infected with any of the genotypes, especially in patients who are infected with nongenotype 1.⁸² A review of studies published on the cost-effectiveness of therapies for HCV found that HCV therapy is cost-effective most of the time. Reduced cost-effectiveness was seen in patients treated with normal transaminases and healthy biopsies. However, most clinicians would opt not to treat such patients. Moreover, evaluating virologic response by week 12 and terminating therapy if no response is evident substantially lowers treatment costs by more than \$15,000. Overall, various studies found that HCV treatment falls within the accepted cost-effectiveness margin, defined as less than \$50,000 per QALY. The studies concluded that antiviral therapy costs offset costs associated with disease sequelae.⁸¹

CLINICAL CONTROVERSIES

In patients with advanced disease, a biopsy may be risky and offer no additional clinical information whether to treat or not. Some clinicians believe that if therapy is to be initiated regardless, the liver biopsy offers no additional information. In patients with genotype 2 or 3, because response to therapy is so high and most clinicians treat despite biopsy results, there may not be a reason for biopsy.

Histologic improvement is not limited to patients who experience an SVR. Some clinicians believe IFN-based antiviral therapies, regardless of response, can decrease the incidence of HCC development.

Drug Therapy Individualization in Patients with Hepatic Disease or Genetic Alterations in Drug Metabolizing Activity

Y. W. FRANCIS LAM

KEY CONCEPTS

- 1 Hepatic elimination of drugs is primarily dependent on three variables: activity of metabolizing enzymes, plasma protein binding, and liver blood flow, each of which could be altered significantly in patients with liver diseases.
- 2 Hepatic extraction ratio represents a conceptual measure of the efficiency of extraction of drug from the blood by the liver, and is not a measure of the metabolic capacity of the liver per se.
- 3 Increased systemic bioavailability is primarily a concern for orally administered drugs that have a high hepatic extraction ratio.
- 4 Evaluation of patient's liver function for assessment of need of dosage adjustment is difficult, with most clinicians opting to use the Child-Pugh classification system.
- 5 Genetic polymorphisms affecting the drug metabolizing enzymes represent an additional patient-specific factor to consider in optimization of drug therapy.
- 6 Both phase I and phase II enzymes are associated with altered drug exposure.
- 7 Currently, there are few examples of how metabolic genotypes or phenotypes can be used to determine dosage of individual drugs.
- 8 An increasing number of attempts have been made to incorporate pharmacogenetics in clinical studies during drug development and in regulatory review.

Although there are many patient-related variables that can change the pharmacokinetics of drugs and potentially necessitate dosage regimen modification, the most common dosing changes are due to alterations in elimination capacity of the two primary eliminating organs—the liver and the kidneys. This chapter focuses on the changes in drug pharmacokinetics and pharmacodynamics resulting from altered hepatic drug metabolism in patients with hepatic dysfunction, and the implications for dosing. In addition, genetic changes in metabolic capacity of individuals also affect drug elimination from the liver, and examples of how pharmacogenetic information can impact drug dosage regimen modification and labeling are discussed.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

DRUG ELIMINATION BY THE LIVER

1 Drugs are primarily eliminated from the body by metabolism and excretion. Of these two biologic processes, the liver plays a pivotal role in the metabolism of parent drugs and formation of metabolites prior to their excretion by the kidneys. The overall capacity of the liver to carry out its metabolic role is primarily dependent on three factors: activity of the metabolizing enzymes within the smooth endoplasmic reticulum and the cytosol of the hepatocyte; the degree of protein binding in the blood, which affects the amount of unbound drugs available for uptake into the hepatocyte; and liver blood flow, which delivers drugs to the hepatocyte via the portal vein for orally administered drugs and via the systemic circulation for all administered drugs. As such, any patient-specific factors that affect enzymatic activity, protein binding, or liver blood flow would potentially result in significant alteration in drug disposition and therapeutic response. An understanding of the pharmacokinetic basis of hepatic drug elimination is helpful to conceptualize and quantify altered drug disposition in patients with liver dysfunction, and is the focus of the next section.

PHARMACOKINETIC BASIS OF HEPATIC DRUG ELIMINATION

Within a healthy liver, only the unbound drugs can be transported from the vasculature to the hepatocyte, where biotransformation occurs via the activity of the metabolic enzymes. Consequently, blood flow to the liver, the degree of plasma protein binding, and the intrinsic metabolic activity all affect the efficiency of the liver to eliminate a specific drug. The intrinsic metabolic activity measures the ability of the hepatocyte to eliminate drug in the absence of drug supply limitations such as plasma protein binding and blood flow. Thus, in essence, it reflects the inherent activity of the drug metabolizing enzymes within the hepatocyte, and is quantified as intrinsic clearance (Cl_{int}) in the literature. The hepatic clearance (Cl_H), or elimination of a drug, is related to the three physiologic determinants by the following mathematical relationship:

$$Cl_H = \frac{Q_H \times f_{u_B} \times Cl_{int}}{Q_H + f_{u_B} \times Cl_{int}}$$

where Q_H is hepatic blood flow, f_{u_B} is unbound drug fraction in the blood, and Cl_{int} is intrinsic clearance.

Based on this mathematical relationship, when enzyme activity (Cl_{int}) and f_{u_B} are very low relative to hepatic blood flow, they will become the primary determinants and rate-limiting process for hepatic clearance, as Cl_H approximates $f_{u_B} \times Cl_{int}$. On the other hand, when enzyme activity and f_{u_B} are very high in relation to blood flow, Cl_H would approximate Q_H and blood flow carrying drug to the liver is the rate-limiting process for hepatic elimination. A more

detailed review of the complex mathematical relationship between hepatic clearance and the three physiologic determinants, as well as the different pharmacokinetic models used to explain the physiologic approaches to hepatic drug clearance, are provided by Wilkinson et al.^{1,2}

2 The hepatic clearance for any drug can also be conceptualized as the product of blood flow across the liver and the hepatic extraction ratio (ER_H) for that drug. The ER_H is a semiquantitative measure of the efficiency of extraction of drug from the blood by the liver, with a numerical value that ranges from zero to one. In general, the liver effectively “removes” high extraction ratio drugs (usually defined as $ER_H \geq 0.7$) from the blood as soon as they are presented via the blood supply. As such, the elimination of these drugs is more sensitive to changes in, and rate limited by, hepatic blood flow. Examples of drugs with this flow-dependent elimination characteristic are metoprolol, nitroglycerin, and verapamil (Table 43–1). Conversely, the liver does not exhibit a large metabolic capacity for drugs with a low extraction ratio (usually defined as $ER_H \leq 0.3$). The elimination of these drugs is more sensitive to changes in the degree of plasma protein binding and/or intrinsic metabolic activity, and rate limited by these two factors rather than by hepatic blood flow (flow-independent elimination). Warfarin, diazepam, erythromycin, phenytoin, theophylline, and valproic acid are representative examples of low-extraction ratio drugs.

Although it seems confusing that extensively metabolized drugs such as warfarin, phenytoin, and theophylline are classified as “low extraction” drugs, it is important to remember that the ER_H does not measure metabolic capacity per se; rather, it is a conceptual semiquantitative measure to help define the ease of extraction of a drug by the liver as the drug is delivered to the hepatocyte via the blood flow across the liver. Based on the degree of plasma protein binding, drugs with a low extraction ratio are sometimes further subgrouped as binding sensitive (e.g., phenytoin) and binding insensitive (e.g., theophylline). As such, the mathematical relationship discussed in the preceding paragraph would dictate that hepatic clearance of a highly protein-bound, low-extraction-ratio drug would depend on both intrinsic clearance and the degree of plasma protein binding, whereas the intrinsic clearance of unbound drug is the primary factor affecting hepatic clearance for a low-extraction-ratio drug with a low degree of plasma protein binding.

ALTERED HEPATIC DRUG ELIMINATION IN LIVER DISEASES

Patients with liver diseases can have altered drug elimination either at the level of hepatic blood flow, plasma protein binding, or intrinsic metabolic activity. Although there are different types of liver diseases that can result in reduced functional capacity, most disease states, such as hepatitis, liver cancer, and hepatosplenic schistosomiasis, are usually not associated with significant or prolonged alteration in drug metabolism unless cirrhosis is present, where there is irreversible

hepatic damage. Jorga et al.³ showed that there was no difference in the unbound clearance of tolcapone in patients with moderate chronic hepatitis compared to that in healthy volunteers. In contrast, patients with cirrhosis showed a significant decrease in unbound clearance of tolcapone. In fact, most literature studies that investigated the effect of liver diseases on drug disposition were primarily conducted in patients with cirrhosis.

CHANGES IN HEPATIC BLOOD FLOW

3 Perfusion of the liver is provided by blood supply from the hepatic artery, which carries oxygenated blood from the aorta, and the portal vein, which carries nutrient-rich blood from the gastrointestinal tract. The terminal branches of the hepatic artery and the portal vein merge into the hepatic sinusoids, the vascular capillaries of the hepatocyte. The hepatic vein allows blood to exit from the liver into the inferior vena cava and then the systemic circulation. The portal vein provides approximately 75% of the liver’s total blood supply of about 1.5 L/min in healthy adults. Consequently, the liver is the first site of elimination for orally administered drugs before they reach the systemic circulation (Fig. 43–1). This “first-pass effect” primarily affects high extraction ratio drugs and the extent of drug elimination can be significant, resulting in low systemic bioavailability (see Table 43–1). Simply put, under the assumptions of complete drug dissolution, absence of drug degradation in the gastrointestinal tract, and absence of gut wall metabolism, a drug with $ER_H \geq 70\%$, will have a bioavailability of $\leq 30\%$. Although the extent of drug loss can be circumvented by oral administration of a larger dose compared to that for intravenous administration, the oral bioavailability of some drugs could be very low and variable, necessitating administration by alternative routes such as sublingual for nitroglycerin.

In patients with chronic liver diseases such as cirrhosis, blood flow across the liver is usually decreased.⁴ In addition, cirrhosis also causes alteration of vasculature within the liver, resulting in intra- and extrahepatic portosystemic shunting. Shunt formation allows up to 80% of blood supply to bypass the hepatocytes.⁵ These changes in normal blood supply to the liver prevent a significant amount of drug from entering the site of metabolic inactivation. Furthermore, the permanent loss of hepatocyte function in patients with cirrhosis also results in reduced metabolic capacity. These two pathologic processes together decrease hepatic clearance significantly for orally administered, high extraction ratio drugs, and the reduced first-pass effect results in dramatic increase in systemic bioavailability (see Table 43–1).^{6–11} Pentikainen et al.¹² reported that in patients without cirrhosis, the oral bioavailability of clomethiazole, a sedative commonly used in Europe, is $10 \pm 7\%$. In patients with cirrhosis, the bioavailabil-

TABLE 43-1 Examples of High Extraction Drugs with Corresponding Reported Percent Increase in Bioavailability in the Presence of Cirrhosis	
High Extraction Ratio (≥ 0.7) Flow Dependent	Reported Increases in Bioavailability in Presence of Cirrhosis
Labetalol	91%
Midazolam	100%
Morphine	115%
Nifedipine	78%
Propranolol	67%
Verapamil	60%

FIGURE 43-1. Schematic representation of the liver integrating the concept of hepatic extraction and first-pass effect. (ER, extraction ratio.)

TABLE 43-2 Example of Drugs with Documented Changes in Phase 2 Metabolic Capacity in Patients with Liver Diseases

Drug	Types or Severity of Liver Disease	Changes in Pharmacokinetic Parameters	Recommended Dosing Modification	References
Diflunisal	Histologically proven cirrhosis	36% reduction in clearance of unbound diflunisal 38% reduction in formation of phenolic and acyl glucuronides	None	23
Oxazepam	Biopsy-proven cirrhosis	54% reduction in oral clearance	None	24
Tolcapone	Child-Pugh class B	44% reduction in unbound clearance	50% dose reduction	3
Zidovudine	Child-Pugh class B or C	73% reduction in oral clearance	50% dose reduction	26

Data from Kirchheiner J, Brosen K, Dahl M, et al. CYP2D6 and CYP2C19 genotype-based dose recommendations for antidepressants: a first step towards subpopulation-specific dosages. *Acta Psychiatr Scand Suppl* 2001;104:173–192.

ity is $116 \pm 25\%$, representing a greater than 10-fold increase. This can have significant impact on occurrence of adverse drug reaction and dosage adjustment for patients with liver diseases, and is discussed in subsequent sections. In contrast, low extraction ratio drugs have minimal first-pass effect and therefore exhibit high bioavailability after oral administration, as long as bioavailability is not reduced by additional biologic processes other than hepatic first-pass metabolism.

CHANGES IN METABOLIC CAPACITY

In addition to altering the liver vasculature, cirrhosis also causes irreversible hepatic damage and cell death. Although it is anticipated that extensive hepatic damage is associated with reduced drug metabolism with resultant decreased Cl_{int} and impaired hepatic drug elimination, the extent of impairment is variable among patients, as well as among different metabolic reactions.

In general, phase I oxidative metabolism mediated by the cytochrome P450 (CYP) enzyme system is more sensitive to the effect of cirrhosis than phase II conjugation reactions such as glucuronidation. For example, among the benzodiazepines, the clearances of diazepam¹³ and midazolam,⁷ but not of oxazepam¹⁴ and temazepam,¹⁵ are reduced in patients with cirrhosis. This differential effect between phase I oxidation and phase II conjugation reactions may be related to impaired uptake of oxygen caused by sinusoidal capillarization associated with cirrhosis,^{16,17} as hypoxia has an important role in suppressing CYP-mediated drug metabolism in both animal^{18–20} and human²¹ studies. Froome et al.²² showed that oxygen supplementation in cirrhotic patients resulted in normalization of clearance of the phase I substrate theophylline but not of acetaminophen, a phase II substrate. Despite the general belief of “sparing” of phase II conjugation reactions in patients with cirrhosis, it is important to note that more recent studies have shown conjugation reactions can be reduced in patients with liver dysfunction, especially those with severe liver cirrhosis (Table 43–2).^{3,23–26} The conflicting result between the study of Sonne et al.²⁴ and that of Shull et al.¹⁴ might be related to the difference in severity of liver diseases in the two study populations.

Given the presence of multiple isoforms of human CYP enzymes, different studies have investigated whether there are selective differences in expression and activity of individual isoenzymes. George et al.^{27,28} showed that compared to livers obtained from 20 healthy controls, the total CYP amount in the livers obtained from 50 patients with different types of end-stage chronic liver disease was reduced. Based on the Child-Pugh classification, 4 of the 50 patients have class A, 17 have class B, and 29 have class C cirrhosis. In addition, 18 patients also have cholestasis.

Selective alteration in amount, catalytic activities, and messenger ribonucleic acid (mRNA) level among CYP1A2, CYP2C8/10, CYP2E1, and CYP3A were reported in these 50 patients, and the presence or absence of cholestasis also have an effect on the observed changes. CYP1A2 amount and catalytic activity were significantly reduced with a corresponding decrease in mRNA level in patients with both cholestatic and noncholestatic cirrhosis. CYP3A4 amount, catalytic activity, and mRNA were significantly reduced only in

patients without cholestasis. The amount and catalytic activity of CYP2E1 were decreased only in cirrhotic patients with cholestasis, whereas the CYP2E1 mRNA level was lower in both types of cirrhosis. In contrast, CYP2C amount and catalytic activity were not reduced in either type of cirrhosis. Although the corresponding level of mRNA was shown to be decreased in both cirrhosis types, the use of a nonspecific polyclonal antibody to identify CYP2C8/10 might have recognized other 2C isoenzymes and produced erroneous results. In summary, although it is clear that based on *in vitro* studies at the protein level^{27,28} the extent of hepatic dysfunction-induced impairment in drug metabolism is dependent on both severity and type of disease, as well as the specific isoenzyme affected, the exact mechanism for this differential effect remains to be elucidated. In addition, the ability to extrapolate these results to the *in vivo* setting and possible dosage recommendation would likely require incorporation of the effect of additional patient-specific variables such as concurrent medications and disease states.

An additional complicating factor occurs for low-extraction, binding-sensitive drugs. In patients with cirrhosis, production of drug-binding proteins such as albumin and α_1 -acid glycoprotein decrease, resulting in an increase in the unbound concentration of acidic and basic drugs, respectively. This not only would lead to increased toxicity, but also increased hepatic elimination as the unbound fraction increases. The magnitude and duration of the elevated unbound concentration are difficult to predict.

ADDITIONAL EFFECTS OF LIVER DISEASES ON DRUG DISPOSITION AND EFFECTS

EFFECT ON DRUG ABSORPTION

Delayed gastric emptying possibly related to altered action of gastrointestinal hormones occurs in patients with cirrhosis.^{29,30} Although this will delay the rate of absorption, the extent of drug absorption is generally not reduced. Even though the liver has no functional role in affecting the absorption of drug from the gastrointestinal tract per se, its unique anatomical positioning within the circulating system makes it a primary site of loss for orally administered drug prior to its entry into the systemic circulation. As discussed in previous sections, drugs with a high extraction ratio will undergo significant “presystemic metabolism” or first-pass effect, resulting in low systemic bioavailability. In patients who have cirrhosis with associated portosystemic shunting and/or reduction in metabolic capacity, oral administration of these drugs could result in a significant increase in their systemic bioavailability and hence pharmacodynamic effect. In contrast, drugs with a low extraction ratio generally have a negligible first-pass effect and, hence, only minimal changes in systemic bioavailability is expected in the presence of cirrhosis.

EFFECT ON DRUG EXCRETION

Reduced glomerular filtration rate and renal plasma flow have been observed in patients with liver cirrhosis,^{31,32} potentially accounting

for reported decreased renal elimination of several drugs, including fluconazole,³³ lithium,³⁴ and ofloxacin.³⁵ In addition, in individual patients, advanced liver disease can be complicated by the presence of hepatorenal syndrome with renal failure. In these patients, dosage reduction would need to be considered even for drugs that are primarily excreted unchanged by the kidney.

EFFECT ON DRUG PHARMACODYNAMICS

Changes in therapeutic response to a drug can occur in patients with liver disease even in the absence of any changes in pharmacokinetics. The increased drug sensitivity can occur as a result of altered affinity of the drug to its target, altered binding to the target, alteration in the target itself, altered permeability of the blood-brain barrier, or increases in γ -aminobutyric acid (GABA) receptors or GABA-ergic activity. Altered pharmacodynamic responses have been reported in the literature with analgesics,³⁶ benzodiazepines,³⁷ loop diuretics, and β -blockers.

Bakti et al.³⁸ reported that with similar unbound triazolam concentration at 2.25 hours after drug administration, cirrhotic patients experienced on average a 30% greater impairment in psychometric performance tests, including the digit symbol substitution test, flicker sensitivity, and pursuit rotor, when compared to healthy control subjects. Test performance was similar in both groups prior to administration of triazolam. The study results suggest that the increased sensitivity is not a result of altered pharmacokinetic profile, and might explain why clinically some cirrhotic patients develop encephalopathy and other CNS effects even when administered standard doses of benzodiazepines, cimetidine,³⁹ and quinolones.⁴⁰

Conversely, resistance to the pharmacodynamic effect of loop diuretics in patients with cirrhosis has been reported for bumetamide,⁴¹ furosemide,^{42,43} torasemide,^{43,44} and triamterene.⁴⁵ For these drugs, the sigmoidal curve that describes the relationship between drug concentration and pharmacologic response is shifted to the right in patients with cirrhosis, indicating a reduced response compared to healthy individuals. Downregulation of β_2 -adrenoreceptors in patients with cirrhosis⁴⁶ has been suggested as a possible mechanism of lower therapeutic response observed with metipranolol⁴⁷ in patients with cirrhosis.

ADDITIONAL VARIABLES AFFECTING DRUG DISPOSITION

Drugs and metabolites that are excreted into the bile reach the small intestine via the biliary tract. Within the small intestine, these metabolites, especially the glucuronides, can be converted back to the parent compound, resulting in reabsorption of both parent and metabolites and thus complete the enterohepatic circulation. Consequently, interruption of this enterohepatic circulation could reduce systemic drug exposure. There is little information on the role of biliary excretion to the overall drug elimination and the effect of how biliary excretion of drugs could be affected by liver diseases.

Finally, it is important to note that it is only recently that the role of hepatic transport proteins, such as the organic anion transporting polypeptides and P-glycoprotein, was recognized. Research in elucidating the clinical significance of the different hepatic transport proteins in drug disposition will be forthcoming, but currently there is little information regarding how liver disease affects the function of these proteins and therefore drug uptake into the hepatocyte.

LIVER FUNCTION ASSESSMENT

In contrast to renal impairment, accurate quantification of liver function in patients with hepatic impairment is difficult to perform, especially for the purpose of dosage adjustment. The severity of liver

TABLE 43-3 Severity of Liver Disease Based on the Child-Pugh Classification

Clinical or Laboratory Parameters	1 Point	2 Points	3 Points
Ascites	absent	mild	moderate
Encephalopathy (grade)	absent	grade 1 or 2	grade 3 or 4
Serum albumin (g/dL)	>3.5	2.8–3.5	<2.8
Serum bilirubin (mg/dL)	1–2	2–3	>3
Prothrombin time (seconds >control)	1–4	4–10	>10

Note: A value of 5 suggests absence of liver impairment, whereas 15 would indicate severe liver failure. The original Child-Turcotte classification consisted of grades A, B, and C, with grade C being the most severe liver disease. Similar to the Pugh modification, the Child-Turcotte classification includes albumin, bilirubin, and ascites, plus assessment of nutrition and neurologic disorder.

function impairment is usually assessed clinically with the Pugh modification of the Child-Turcotte classification.⁴⁸ Based on the clinical evidence of ascites and encephalopathy and laboratory parameters that measure the liver’s synthetic and excretory functions, patients are assigned different scores in accordance to the level of impairment in these parameters (Table 43–3). The classification is easy to use and useful for following the clinical course of an individual patient or comparing groups of patient among studies. However, despite the expected correlation between decline in liver function such as synthesis of albumin or clotting factors and the corresponding changes in their respective laboratory parameters, the presence of patient-specific variables, such as nutritional status and vitamin K intake, would complicate the usefulness of these parameters. In addition, in contrast to renal impairment, none of the clinically used liver function tests, including those used in the Child-Pugh classification, correlate well with drug pharmacokinetic parameters. This not only is a result of their inability to quantify the primary physiologic determinants of hepatic clearance, including intrinsic clearance and hepatic blood flow, but also a reflection of the complex and multiple physiologic processes not being accurately accounted for by any individual laboratory test.

The inability of endogenous markers to provide a quantitative measurement of the liver capacity to metabolize drug has led to the administration of exogenous model substrates and calculation of their clearances as quantitative liver function measurements. Based on the physiologic determinants of hepatic clearance discussed previously, these exogenously administered model substrates can be generally categorized into flow-dependent, for example, indocyanine green,⁴⁹ lidocaine,⁵⁰ and sorbitol;⁵¹ and flow-independent, for example, aminopyrine,⁵² antipyrine,⁵³ caffeine,⁵⁴ and erythromycin.⁵⁵ However, none of these markers have been shown to be better than the Child-Pugh classification for assessing liver function in patients. The time and invasive procedure for performing these tests also limit their clinical usefulness. Indeed, to date, they have not gained widespread acceptance for predicting drug kinetics and aiding dosage adjustment in patients with liver dysfunction.

Furthermore, studies showed that administration of a flow-dependent and flow-independent model substrate in the same subjects did not result in an independent measure of the physiologic determinants of hepatic clearance. Rather, a correlation between the two test measures was unexpectedly obtained.^{56,57} Because cirrhosis causes both irreversible hepatic cell damage and altered vasculature via portosystemic shunting, the pharmacokinetic profile of a drug can be affected by changes in hepatic blood flow and drug-metabolizing enzyme activity. However, it is not known to what extent reduced hepatocyte function would impact elimination of flow-dependent drugs. Nevertheless, the “intact hepatocyte hypothesis,” which suggests the presence of intrahepatic shunts in chronic liver disease, has been proposed as a possible explanation for the reduced extraction of flow-dependent drugs, accounting for the observed positive correlation between the clearances of both flow-dependent and flow-independent drugs.^{56,57} In addition, given the complexity of the CYP

enzyme system, simultaneous administration of several model substrates for different metabolic enzymes as advocated by various cocktail approaches^{58–60} would be necessary to characterize the changes in metabolic capacities in patients with liver dysfunction.

DRUG DOSING IN PATIENTS WITH LIVER IMPAIRMENT

Similar to dosing considerations in patients with kidney dysfunction, dosing adjustment in patients with liver diseases can, in general, be accomplished by either a dose reduction or an extended dosing interval, or by a combination of both strategies. However, the lack of a clinical laboratory test that correlates well with the metabolic capacity of the liver hampers the development of dosing guidelines or algorithms similar to that for patients with kidney dysfunction.

Nevertheless, based on an understanding of the pharmacokinetic basis of hepatic drug metabolism, knowledge of the likely etiology of liver dysfunction (reduced liver blood flow, portosystemic shunting, or hepatic failure), and characteristics of the drug in question (flow-dependent or flow-independent, extent of plasma protein binding), a conceptual framework for rational dosing can be made. For drugs with a high ER_H and administered orally, the initial and maintenance doses in patients with cirrhosis need to be reduced because of the significant decrease in first-pass effect caused by portosystemic shunting and decreased hepatic blood flow across the liver. The challenge for adopting this conceptual framework to clinical practice is our ability to predict the magnitude of dose reduction needed. Given the data of Pentikainen¹² and the ranges of reported percent increase in bioavailability for some commonly used drugs (see Table 43–1), one prudent approach is to assume 100% bioavailability unless there is specific bioavailability data or specific dosage adjustment guidelines, and estimate the reduced maintenance dose proportionally by the following mathematical expression:

$$D_H/D_N = F/100$$

where F is the known bioavailability of the drug available from the literature or the manufacturer, and D_H and D_N are the doses used in patients with liver dysfunction and normal liver function, respectively. If drugs with a high ER_H were administered intravenously, then only the maintenance dose would need to be reduced as a result of reduced hepatic blood flow. For drugs with a low ER_H , change in bioavailability is minimal after oral administration and the initial dose for both oral and intravenous routes could be the same as patients with normal liver function. Conversely, the maintenance dose for both administration routes would need to be reduced in patients with cirrhosis according to the reduction in metabolic capacity.

Based on this concept, the oral dose of theophylline can be reduced by up to 50%, which would be in line with the clearance of 0.042 L/kg/h in patients with cirrhosis, as compared to 0.062 L/kg/h in patients with normal liver function.⁶¹ Similarly, the dosage of tolcapone could also be reduced by 50% given the difference in pharmacokinetic profiles in patients with Child-Pugh class B cirrhosis.³ Obviously, this dose modification serves only as a starting point, consideration of the therapeutic index of the drug in question and good clinical judgment with close monitoring of other factors that can further change the metabolic capacity (e.g., in the case of theophylline, viral illness, smoking, drug–drug interaction, congestive heart failure) would greatly enhance the ability of a clinician to optimize drug therapy in patients with liver dysfunction.

4 Since there is no equivalent of serum creatinine or creatinine clearance for assisting dosage adjustment in patients with liver dysfunction, the Child-Pugh classification, despite its limitation, is still used primarily by clinicians to assess the extent of liver dysfunction

and dose adjustment if needed.⁶² As a total Child-Pugh score of 5 and 15 represent, respectively, normal liver function and severe hepatic impairment, it is reasonable to reduce the maintenance dose by 25% for a drug that is primarily dependent on the liver for elimination ($\geq 65\%$ to 70%) in a patient with a score of 8 to 9. A dose reduction of 50% would be prudent for a patient with a score of ≥ 10 . Likewise, Child-Turcotte grades B and C classifications⁶³ could result in similar 50% and 75% reduction, respectively, of the daily maintenance dose. For both classification systems, depending on the severity of the liver dysfunction and clinical judgment, extension of the dosing interval should also be considered.

In addition, the Food and Drug Administration, through official guidance, also recommend the use of the Child-Pugh classification to categorize the extent of hepatic impairment in patients.⁶⁴ As a result, even though the recommendation is not binding, the classification has been employed during drug development in most studies designed to provide dosage recommendation for patients with liver diseases. As an example, a two- to four-fold increases, respectively, in the area under the curve of atomoxetine in patients with Child-Pugh B and C classifications, has led to the labeling recommendations of 50% and 75% reduction of the normal dose used in patients with normal liver function.⁶⁵ A summary of such dosage recommendations for 23 recently approved drugs was recently published and is the most quantitative resource currently available.⁶⁶

PHARMACOGENETIC ALTERATION IN DRUG METABOLIZING ENZYME ACTIVITIES

5 Although many factors, including age, gender, smoking, and diet, can influence drug disposition and therapeutic response in individual patients, recent research emphasis has focused on the effect of pharmacogenetics on drug pharmacokinetics and pharmacodynamics. Chapter 6 provides a more in-depth discussion of the concept of pharmacogenetics and how drug disposition and response are related to specific genotypes and/or phenotypes. The focus of the subsequent sections is to provide information on how pharmacogenetic testing has been reported in the literature for dosing individualization or labeling changes for specific drugs that rely on polymorphic enzymes for their metabolism.

Pharmacogenetic testing for presence of altered metabolic activity can be achieved by phenotyping, genotyping, or both methods. In general, a genotype is a trait marker of an individual's metabolic activity for a specific polymorphic enzyme, and is independent of time and external factors such as concurrent medications, smoking status, or diet. Currently, most laboratory genotyping tests only analyze the more common alleles of a specific polymorphic gene, for example, *2 and *3 for *CYP2C9* and *CYP2C19*, *3, *4, *5, *6, *2xN for *CYP2D6*, *28 for *UGT1A1*. Consequently, ethnicity would be important patient-specific information for CYP genotyping if ethnic-specific alleles, such as *5 and *6 for *CYP2C9*, *10, *17, and *21 for *CYP2D6*, are to be determined.

Phenotype, on the other hand, represents the metabolic activity at a specific time, which could be susceptible to changes in the presence of concurrent drug therapy. However, in patients receiving concurrent therapy, this usually conceived disadvantage of phenotype might be more useful than genotype in assessing metabolic capacity and hence dosing consideration. For example, in the presence of a potent *CYP2D6* inhibitor, the *CYP2D6* metabolic capacity of a genotypic extensive metabolizer could be significantly decreased to a level similar to that of a poor metabolizer.⁶⁷ In such a scenario, the metabolic capacity would be more reflected by the phenotype, and the dose of a *CYP2D6* substrate in a genotypic extensive metabolizer might need to be adjusted lower, so long as the patient is receiving the *CYP2D6* inhibitor concurrently.

DOSING IN PATIENTS WITH GENETICALLY ALTERED METABOLIC CAPACITIES

6 ALTERATION IN PHASE 1 ENZYMES

CYP2C9

Metabolism of the pharmacologically active S-warfarin is mediated by the polymorphic CYP2C9, with the *3 allele having a greater influence on its disposition than the *2 allele. The racemic warfarin doses in patients carrying either of these two allelic variants were in general 15% to 30% lower than those with the wild-type *1 allele.⁶⁸ Japanese patients with the CYP2C9*1/*3 and CYP2C9*3/*3 genotypes had median dosage requirements that were 48% (0.031 mg/kg/day) and 88% (0.007 mg/kg/day) lower, respectively, than the maintenance dose of 0.06 mg/kg/day in patients with the CYP2C9*1/*1 genotype.⁶⁹ Aithal et al.⁶⁸ and Margaglione et al.⁷⁰ both reported higher incidence of bleeding complications in patients with the *2 or the *3 allele compared to patients with the *1 allele. Although these and other results^{71–74} demonstrate a role for the CYP2C9 polymorphism in determining warfarin dose requirement and minimizing toxicity, the presence of polymorphisms in other target genes, including those affecting the activities of vitamin K 2,3-epoxide reductase complex, subunit 1,^{75–78} γ -glutamyl carboxylase,^{77,79} epoxide hydrolase,⁸⁰ and calumenin,⁸¹ as well as the uptake of vitamin K,^{82–84} suggest that we still need to develop a better dosing algorithm or model for widespread genotype-based warfarin dosing in clinical practice.⁸⁵ The FDA recently accepted the recommendation of its advisory committee to test for genetic variations in patients receiving warfarin therapy and thus the labeling of warfarin has been updated. Even though it might be difficult and expensive to conduct a randomized genotype-guided warfarin dosing trial, in April 2007 the National Institute of Health issued a Request for Proposal for a Clinical Trial Coordinating Center to conduct a large, multicenter, double-blind randomized trial to compare different approaches to guiding warfarin therapy initiation. The clinical trial primarily aims to evaluate whether using a genotype-enhanced dosing algorithm based on clinical information and knowledge of genetic variants known to affect warfarin metabolism to initiate warfarin treatment will improve anticoagulation status when compared to dosing algorithm using only clinical information.

CYP2C19

The polymorphic CYP2C19 is the primary isoenzyme responsible for the metabolism for proton pump inhibitors. Although there are up to 10-fold differences in systemic exposure between carriers of the CYP2C19*1 allele versus *2 and *3 alleles, patients possessing one or two of these variant alleles did not experience higher incidence of concentration-related toxicity, likely a reflection of the wide margin of safety for this group of drugs. Rather, the clinical relevance of the CYP2C19 polymorphism lies with the efficacy, with a gene-dose effect in disease cure rate demonstrated for 30 mg of lansoprazole,⁸⁶ 20 mg of omeprazole,⁸⁷ and 10 mg of rabeprazole,⁸⁸ but not for a higher 40 mg dose of omeprazole.

Furuta et al.⁸⁹ reported the results of pharmacogenomics-based tailored lansoprazole regimens designed to achieve sufficient acid inhibition for eradication of *Helicobacter pylori*. Based on 24-hour intragastric pH monitoring, lansoprazole dosage regimens that achieved intragastric pH ≥ 5.0 were documented to be 30 mg three times daily for homozygous carriers of the *1 allele, 15 mg three times daily for heterozygous carriers of the *1 allele, and 15 mg twice daily for homozygous carriers of the *2 or *3 alleles. For achieving intragastric pH ≥ 5.8 , the corresponding dosage regimens in the three CYP2C19 genotypes groups were 30 mg four times daily, 15 mg four times daily, and 15 mg twice daily, respectively. Three hundred *H.*

pylori-positive patients were then randomly assigned to receive either the standard regimen consisting of lansoprazole 30 mg, clarithromycin 400 mg, and amoxicillin 750 mg, all given twice daily, or the pharmacogenomics-based regimen consisting of lansoprazole dosed according to patient's CYP2C19 genotype and antibiotic regimen according to genetic testing of bacterial susceptibility to clarithromycin. The eradication rate for the pharmacogenomics-based regimen was 96% (144 of 150 patients), significantly higher than the 70% (105 of 150 patients) achieved with the standard regimen ($P < 0.001$). In addition, the per-patient cost required for successful eradication for the genotype-based regimen (\$669) was similar to that of the standard regimen (\$657), lending support not only to the clinical usefulness, but also the cost-effectiveness of pharmacogenomic-based therapeutic approach.

CYP2D6

The report of a female patient found to be resistant to normal doses of nortriptyline⁹⁰ represented some of the earliest evidence of how altered metabolic capacity can impact drug dosing and response. The clinical observation and subsequent metabolic phenotyping and genotyping identified three extra copies of the CYP2D6 gene in the patient,⁹¹ thereby accounting for her extremely high dose requirement of 500 mg/day for nortriptyline. This and other patients with similar high CYP2D6 activity were subsequently categorized as ultrarapid metabolizers.

Since these clinical observations and molecular discoveries, there has been a dramatic increase in the identification, cloning, and investigation of the functional significance of numerous additional CYP2D6 alleles. To date, it is probably safe to label CYP2D6 as the most studied, yet most variable gene, with significant differences in activity among patients. The presence of multiple alleles with significant interindividual (20% to 96%) and intraindividual (12% to 140%) variabilities in enzyme activity^{92,93} may be partially responsible for the time gap between the nortriptyline case report and subsequent attempts to use metabolic genotyping or phenotyping for antidepressant dose recommendation.⁹⁴ The investigators compared the pharmacokinetic profiles of 32 CYP2D6- and CYP2C19-dependent antidepressants in subjects with different CYP2D6 and CYP2C19 genotypes, took into consideration of the contribution of the polymorphic isoenzymes to the overall elimination of each antidepressant, and provided dose recommendation for 14 of the 32 antidepressants in extensive metabolizers, intermediate metabolizers, and poor metabolizers of CYP2D6 (Fig. 43–2) or CYP2C19. In general, poor metabolizers need approximately 50% of the normal dose of tricyclic antidepressants whereas the dose reduction was smaller for the selective serotonin reuptake inhibitors.

Using the approach proposed by Kirchheiner et al.,⁹⁴ nortriptyline maintenance dose requirements for attainment of comparable systemic exposure or therapeutic plasma concentrations could be estimated to be 50% and up to 230% of the average dose, respectively, in poor metabolizers and ultrarapid metabolizers. In contrast, the dose requirements would be 70% to 90% of the average dose in intermediate metabolizers and 100% to 140% of the average dose in extensive metabolizers. Unfortunately, even though there are multiple literature reports of increased adverse effects in poor metabolizers of CYP2D6, there were no other documented reports of therapeutic failure for CYP-dependent antidepressants in ultrarapid metabolizers. Kirchheiner et al.⁹⁴ acknowledged the lack of data preclude any dose recommendation in ultrarapid metabolizers for most antidepressants, with the exception being nortriptyline, desipramine, and mianserin, and the dose recommendations are based on data from very few patients. They further noted that only 5 of 54 reviewed studies included evaluation of efficacy in relation to genotypes, and only the study of Mihara et al.⁹⁵ showed a significant relationship (P

FIGURE 43-2. Schematic representation of dosage adjustment (percent of normal dose) of selected antidepressants and antipsychotics based on CYP2D6 genotypes (starting from the foreground: poor metabolizer, intermediate metabolizer, extensive metabolizer, and ultrarapid metabolizer). (Data from Kirchheiner J, Brosen K, Dahl M, et al. *Acta Psychiatr Scand Suppl* 2001;104:173–192.)

= 0.023). More recently, Brockmoller et al.⁹⁶ reported that the clearance of *S*-mirtazapine in ultrarapid metabolizers is 12.6-fold higher than in poor metabolizers, and suggested that poor response might occur in ultrarapid metabolizers as a result of lesser degree of presynaptic α_2 -antagonism and lower norepinephrine and serotonin-ergic activities. Despite implying that a higher dosage for this metabolic group was appropriate, there was no specific recommendation.

7 Although significant relationship between CYP2D6 genotype and steady-state antipsychotic pharmacokinetic parameters or drug concentrations have been reported for haloperidol,⁹⁷ perphenazine,⁹⁸ risperidone,⁹⁹ and zuclopenthixol,⁹⁸ there were few studies that evaluated or documented how genetic polymorphism could impact clinical outcome,¹⁰⁰ with most of the data showing a higher incidence of concentration-dependent toxicity in poor metabolizers. The study of Brockmoller et al.⁹⁷ suggested a nonsignificant trend toward better response to haloperidol in poor metabolizers and lesser response in ultrarapid metabolizers, possibly reflecting the difficulty of relating rating-scale-based changes in psychotic symptoms to specific metabolic genotypes. There is no study that evaluates use of genotyping or phenotyping for dose recommendation of antipsychotics.

The formation of the active metabolite *O*-desmethyltramadol from tramadol is dependent on CYP2D6, and similar to the report with codeine, analgesic relief from tramadol is reported to be lower in poor metabolizers.¹⁰¹ Although tramadol also possesses other opioid and nonopioid-dependent mechanisms for its analgesic effect, Stamer et al.¹⁰² showed in a prospective study with 300 patients recovering from abdominal surgery, that there is a significant difference in the per-

centage of nonresponders (based on need for rescue pain medication and patient's satisfaction upon interview) between CYP2D6 poor metabolizers (46.7%) and extensive metabolizers (21.6%) ($P = 0.005$). More importantly, they reported a difference in the loading dose of tramadol between the two groups: 144.7 ± 22.6 mg and 108.2 ± 56.9 mg, respectively ($P < 0.001$). 43.3% of genotypic poor metabolizers, compared to 21.6% of genotypic extensive metabolizers, required rescue medication in the recovery room. The authors concluded that poor metabolizers have a higher analgesic consumption. Even though there are likely other significant pharmacogenetic variables affecting opioid analgesic response, the difference in dosing requirement shown in this study suggest that 30% dose increase might be necessary in poor metabolizers of CYP2D6.

CYP3A

Despite the existence of significant interindividual variability in activity, study evaluations of the role of CYP3A genes (CYP3A4, CYP3A5, and CYP3A7) in mediating disposition and response so far have not been conclusively clarified. The most convincing evidence showing a genetic influence is CYP3A5*3 allele affecting tacrolimus pharmacokinetics. Homozygous carriers of the *3 allele were shown to have a higher plasma tacrolimus concentration than patients with the CYP3A5*1 allele, although considerable overlap exists between the CYP3A5 genotypes and achievable concentration/dose.^{103,104} MacPhee et al.¹⁰⁵ showed that homozygous and heterozygous carriers of the CYP3A5*1 allele required a longer time to achieve thera-

peutic concentration, and suggested these CYP3A5 expressors should be prescribed an initial tacrolimus dose that is twice that given to the CYP3A5 nonexpressors. Given that it is common clinical practice to measure tacrolimus concentrations, this genotype-based dose modification recommendation should be tested in patient populations. Based on current pharmacogenetic information, dosing information cannot be predicted and recommended for cyclosporine and sirolimus.

ALTERATION IN PHASE 2 ENZYMES

Thiopurine Methyltransferase

Thiopurine drugs such as 6-mercaptopurine and azathioprine are used in the management of childhood acute lymphoblastic leukemia and autoimmune and inflammatory diseases such as rheumatoid arthritis. S-methylation of these drugs is mediated by the polymorphic thiopurine S-methyltransferase (TPMT). Poor metabolizers and intermediate metabolizers with two and one deficient *TPMT* alleles, respectively, are prone to significant hematopoietic adverse effects when given standard doses as normal metabolizers. Currently, it is well established that patients with low and intermediate *TPMT* activity need a maximum of 10% and 50%, respectively, of the normal dose of thiopurines,¹⁰⁶ and identification of a patient's *TPMT* genotype prior to therapy initiation has been adopted as a standard procedure in some hospitals in the United States. In a recent study, Fargher et al.¹⁰⁷ showed that 67% of National Health Service clinicians surveyed routinely use *TPMT* phenotyping to guide prescribing and monitoring of azathioprine in England. The lower use of genotyping (5.3%) is attributed to genotyping testing not usually being available to the National Health Service clinicians. Documented cost-effectiveness of the strategy^{108,109} and further availability of commercial tests for determination of *TPMT* genotype and phenotype may make it easier for justifying and implementing genotype-based thiopurine dosing in other medical centers and clinics.

Uridine Diphosphate Glucuronosyltransferase

The polymorphic uridine diphosphate glucuronosyltransferase 1A1 (*UGT1A1*) is important for the glucuronidation of several anticancer drugs including irinotecan. Irinotecan is a prodrug and the pharmacologically active moiety, SN-38, is inactivated by *UGT1A1*. Poor metabolizers of *UGT1A1* have reduced SN-38 inactivation¹¹⁰ and a higher incidence of dose-limiting toxicities such as diarrhea.¹¹¹ In

addition, a prospective clinical pharmacogenetic study has shown a correlation between grade 4 neutropenia and patients who are homozygous carriers of the *UGT1A1**28 allele, and the incidence could decrease to 0% in patients who are not carriers of the *UGT1A1**28 allele.¹¹² In fact, the product label for irinotecan has been updated to reflect the need of a reduced initial dose by at least one level of irinotecan in homozygous carriers of the *UGT1A1**28 allele (Table 43–4).

N-Acetyltransferase

Amonafide is a topoisomerase II inhibitor and DNA intercalating agent used in the treatment of breast cancer and leukemia.¹¹³ Its metabolism is mediated by the polymorphic *N*-acetyltransferase 2, which likely accounts for the variability in toxicity observed in treated patients. The extent of drug-induced myelosuppression is correlated to acetylation extent, and fast acetylators are reported to experience greater toxicity compared to slow acetylators,¹¹⁴ an unexpected phenomenon attributed to inhibition of oxidation of amonafide by the *N*-acetylated metabolite.¹¹⁵ Based on this observation, genotype-based dosing modifications were implemented in a phase I clinical trial, in which fast and slow acetylators received 250 mg/m² and 375 mg/m², respectively.¹¹⁶ Clinical development of amonafide was discontinued secondary to unpredictable toxicity in different patients, and there were no further studies of other drugs to examine the possibility of metabolic genotype-based dosing as a result of *N*-acetyltransferase 2 polymorphism.

PHARMACOGENETIC SCREENING AS A DOSING TOOL TO GUIDE PHARMACOTHERAPY

The examples of different polymorphic enzymes and drugs discussed above show the potential of using pharmacogenetic screening of patients for dosing and optimizing therapy. The value of early detection of patients with deficient metabolic genotype and/or phenotype is clearly demonstrated with the thiopurines and irinotecan, whereas clinical experience with specific tricyclic agents showed that optimal therapeutic response can be achieved earlier with detection of duplicated or amplified *CYP2D6**2 allele. Although there is no documented report of an association between metabolic polymorphisms and selective serotonin reuptake inhibitor efficacy, poor metabolizers do have significant side effects with venlafaxine¹¹⁷ and paroxetine.¹¹⁸ Given the high incidence of nonadherence to antidepressants,^{119,120} one can also make a case that genotype-based dose reduction in poor

TABLE 43-4 Examples of Label Changes Incorporating Pharmacokinetic Data or Therapeutic Response in Patients with Liver Diseases or Genetic Alteration in Metabolic Capacity		
Drug	Relevant Pharmacokinetic Data or Therapeutic Response as a Result of Patient-Specific Alteration in Disposition	Label Information Incorporating Study Data
Atomoxetine	4-fold and 2-fold increases in AUC in patients with Child-Pugh grades C and B classification, respectively	Reduce normal dose by 75% and 50%, respectively, in the two groups of patients.
6-Mercaptopurine (6-MP)	6-MP is inactivated via <i>TPMT</i> to the inactive metabolite methyl-6-MP; <i>TPMT</i> activity is controlled by a genetic polymorphism, with a defined correlation between deficiency in <i>TPMT</i> activity and myelotoxicity	Patients with intermediate <i>TPMT</i> activity may be at increased risk of myelotoxicity if receiving conventional doses of 6-MP. Patients with low or absent <i>TPMT</i> activity are at an increased risk of developing severe, life-threatening myelotoxicity if receiving conventional doses of 6-MP. <i>TPMT</i> genotyping or phenotyping (red blood cell <i>TPMT</i> activity) can help identify patients who are at an increased risk for developing 6-MP toxicity. The optimal starting dose for homozygous-deficient patients has not been established.
Irinotecan	Irinotecan is converted to the active metabolite SN-38, which is subsequently inactivated by <i>UGT1A1</i> ; irinotecan toxicity is related to SN-38 exposure	Individuals homozygous for the <i>UGT1A1</i> *28 allele are at increased risk for neutropenia after irinotecan administration. A reduction in the starting dose by at least 1 level of irinotecan should be considered for patients known to be homozygous for the <i>UGT1A1</i> *28 allele. The appropriate dose reduction in this patient population is unknown.

AUC, area under the curve; *TPMT*, thiopurine S-methyltransferase.

metabolizers might improve therapeutic outcome through a lower incidence of side effects and better adherence to the medication regimen.

Unfortunately, despite the evidence of benefit, the pace of pharmacogenetic-guided individualized therapy is slow.¹²¹ Currently, pharmacogenetic screening of deficiency in TPMT remains one of the few examples of how pharmacogenetics can guide dosing and individualize drug therapy of thiopurines in clinical practice.¹⁰⁷ Even the updated label of irinotecan is lacking specific information of how much the dose reduction should be for homozygous carriers of the *UGT1A1**28 allele. Additionally, genotype-based dosing information is not available for many other drugs. Given the extensive literature on genotype-related differences in drug pharmacokinetics, the lack of dosing information is unfortunate. As an example, clearance of tolbutamide in homozygous carriers of *CYP2C9**3 is 84% lower than in patients with the *CYP2C9**1/*1 genotype, whereas heterozygous carriers of the *2 allele have an approximately 50% lower clearance.¹²² Based on these results, dose reductions of approximately 90% and 50% would seem to be an appropriate recommendation in these patients for controlled clinical trials to evaluate whether the goal of genotype-based therapy could be achieved in clinical practice. However, no such prospective trial has been performed. Since efficacy of the oral sulfonylureas can be evaluated easily in clinical practice, implementation of these dose recommendations in clinics or physician offices in lieu of expensive and time-consuming clinical trials might be the first step to take in achieving pharmacogenetic-based dosing and therapy individualization.

Yet it is clear that not all drugs are candidates for genotype-based dose recommendation. The drug in question not only has to be primarily metabolized by a polymorphic enzyme, it also needs to have a narrow therapeutic index. In the study by Brockmoller et al.,⁹⁷ although there was a trend toward lower efficacy with increasing number of active *CYP2D6* genes and higher efficacy in the poor metabolizers, there was significant overlap in the haloperidol daily doses among the four metabolic groups, with 14 ± 10 mg in ultrarapid metabolizers versus 13 ± 9 mg in the poor metabolizers. This could be a result of the complex metabolic disposition of haloperidol that includes *CYP2D6*- and *CYP3A4*-mediated oxidation, glucuronidation, and interconversion with reduced haloperidol. The clinical usefulness of *CYP2D6* genotyping is further minimized by significant interethnic variabilities in metabolic disposition.¹²³ In addition, as demonstrated with risperidone, the presence of an active metabolite would also make it difficult to demonstrate the clinical relevance of genotype-based dose recommendation for the parent compound.

8 Nevertheless, it is encouraging to find that pharmaceutical companies have chosen to include pharmacogenetic screening to identify special populations for evaluation of pharmacokinetics, pharmacodynamics, and clinical outcomes.¹²⁴ As an example, *CYP2D6* genotype was one of the patient-related variables included in the evaluation of differences in systemic exposure of atomoxetine in specific populations. Although no specific dose recommendation arose from the results, the information was incorporated into the drug labeling, acknowledging the higher incidence of some adverse drug effect being related to the *CYP2D6* poor metabolizer genotype.⁶⁵

As additional data regarding the clinical relevance of pharmacogenetic screening testing for dosing and therapy individualization become available, the information can be incorporated for drug development as well as for approved drugs. It is noteworthy that over the last few years, the FDA has updated the labeling of 6-mercaptopurine, azathioprine, and irinotecan^{125–127} to reflect the risk of toxicity and the need of dosage adjustment in poor metabolizers and intermediate metabolizers of these two polymorphisms. Within the same time period, the FDA has also approved AmpliChip CYP genotyping test for screening of common *CYP2C19* and *CYP2D6* alleles, and the

UGT1A1 Molecular Assay for genotyping *UGT1A1* alleles.^{128,129} Given that the revised label information does not specifically address the precise dose reduction for patients receiving either 6-mercaptopurine, azathioprine, or irinotecan (see Table 43–4) because of lack of study data using patients' individualized *TPMT* or *UGT1A1* genotypes, it is clear much work, similar to the study of Furuta et al.,⁸⁹ needs to be done through additional clinical trials before pharmacogenetics-guided dosing can be achieved in clinical practice.

SECTION 5

RENAL DISORDERS

CHAPTER

44

Quantification of Renal Function

THOMAS C. DOWLING

KEY CONCEPTS

- 1 The stage of chronic kidney disease (CKD) should be determined for all individuals based on the level of kidney function, independent of etiology, according to the National Kidney Foundation (NKF) Kidney Disease/Dialysis Outcome Quality Initiative (K/DOQI) CKD classification system.
- 2 Persistent proteinuria indicates the presence of chronic kidney disease.
- 3 Quantitation of urine protein excretion, such as the measurement of a spot urine albumin-to-creatinine ratio, is recommended for determining the severity of CKD and monitoring the rate of disease progression.
- 4 The glomerular filtration rate (GFR) is the single best indicator of kidney function.
- 5 Measurement of the GFR is most accurate when performed following the exogenous administration of inulin, iothalamate, or radioisotopes such as technetium-99m diethylenetriamine pentaacetic acid (^{99m}Tc -DPTA).
- 6 Measurement of creatinine clearance is not routinely recommended; however, pretreatment with cimetidine improves the accuracy of this "measure" of GFR.
- 7 Equations to estimate creatinine clearance or GFR are commonly used in ambulatory and inpatient settings, and incorporate patient laboratory and demographic variables such as serum creatinine, age, gender, weight, and ethnicity.
- 8 Longitudinal assessment of GFR and proteinuria is important for monitoring the efficacy of therapeutic interventions, such as angiotensin-converting enzyme inhibitors and angiotensin receptor blockers, which are used to slow or halt the progression of kidney disease.
- 9 The measurement of a serum creatinine concentration (S_{Cr}), evaluation of a plot of the reciprocal of S_{Cr} versus time and serum cystatin C concentration should be used with caution to estimate the rate of decline in renal function in CKD patients, as these indices do not consider patient age, lean body mass, gender, diet, concomitant diseases and drug therapy, circadian rhythm, stability of kidney function, or tubular secretion of creatinine.
- 10 Other assessments of the kidney, such as radiography, computed tomography, magnetic resonance imaging, sonography, and biopsy, are predominantly used for determining the diagnosis of a given condition as they provide evidence of the functional and structural changes associated with kidney disease.

Kidney disease is a worldwide health problem. It is estimated that 11% of the U.S. population has impaired renal function, with many cases being undiagnosed. Evaluation of renal function using both qualitative and quantitative methods is an important part of the evaluation of patients and an essential characterization of individuals who participate in clinical research investigations. Estimation of creatinine clearance has been considered the clinical standard for assessment of renal function for more than 40 years. Other tests, such as urinalysis, radiographic procedures, and biopsy, are also valuable tools in the assessment of kidney disease, and these qualitative assessments are useful for determining the pathology and etiology of kidney disease. Urinalysis, for example, may give clues to the primary location, such as glomerular or tubular, of the renal disease. Followup studies, such as imaging procedures or kidney biopsy, may then further differentiate the specific cause, thereby guiding the selection of the optimal therapeutic intervention.

1 Quantitative indices, such as the assessment or estimation of glomerular filtration rate (GFR), is now considered the most useful diagnostic tool for the identification of the presence of chronic kidney disease (CKD).^{1,2} This index, as well as creatinine clearance, can also be used to quantify changes in function that may occur as a result of disease progression, therapeutic intervention, or a toxic insult.³ The measurement or estimation of creatinine clearance, however, remains the most commonly used index for individualizing medication dosage regimens for patients with acute or chronic kidney disease.

Renal “function” includes the processes of filtration, secretion, and reabsorption, as well as endocrine and metabolic functions. Alterations of all five renal functions, whether declining or improving, are associated primarily with GFR. This chapter critically evaluates the various methods that can be used for the quantitative assessment of kidney function in individuals with normal renal function, as well as in those with chronic kidney disease and acute renal failure (Table 44–1). Where appropriate, discussion regarding the qualitative assessment of the renal function is also presented, including specialized tests such as kidney biopsy.

EXCRETORY FUNCTION

The most important contribution of the kidney to overall maintenance of body homeostasis is the urinary excretion of water, electrolytes, endogenous substances such as urea, and environmental toxins. Through the combined processes of glomerular filtration, tubular secretion, and reabsorption, the nephron, as the functional unit of the kidney, regulates the output of water, electrolytes and solutes from the body, and is the key organ responsible for maintenance of homeostasis despite fluctuations in the dietary ingestion.

FILTRATION

Glomerular filtration is a passive process by which water and small-molecular-weight ions (<5 to 10 kDa) and molecules diffuse across the glomerular–capillary membrane into the Bowman capsule and then enter the proximal tubule (Fig. 44–1). Because most proteins are too large (>60 kDa) to be substantially filtered, or their filtration is impeded by the electronegative charge on the epithelial surface of the glomerulus, compounds presented to the glomerulus in the protein-bound state are not filtered and thus remain in the peritubular circulation.

SECRETION

Secretion is an active process that predominantly takes place in the proximal tubule and facilitates the elimination of compounds from the renal circulation into the tubular lumen. Several highly efficient anionic and cationic transport systems for a wide range of endogenous and exogenous substances have been identified and the renal clearance of these actively secreted entities can greatly exceed GFR; for example, their clearance may be in the range of 600 to 1,000 mL/min.

FIGURE 44-1. Structures of the (A) urinary system, (B) kidney, and (C) nephron, the functional unit of the kidney.

Probenecid, *p*-aminohippurate (PAH), and penicillin are examples of anionic substances, whereas creatinine, cimetidine, and procainamide are well-characterized cations.⁴ These transport systems are not mutually exclusive, as probenecid has been observed to compete with the tubular secretion of cimetidine.⁵ Other transport pathways, such as P-glycoprotein and multidrug resistance protein, are also present in several tissues, including the kidney, liver, jejunum, colon, and brain. These efflux proteins are now recognized as important contributors to the renal elimination of many drugs.⁶ For example, P-glycoprotein, which is located on the apical membrane of the proximal tubule, plays an important role in the renal elimination of a wide range of drugs, such as cimetidine, digoxin, and procainamide. Blockade of P-glycoprotein could result in decreased renal elimination of such compounds, leading to an increased drug exposure. Verapamil and cyclosporine are the two most widely studied agents that reduce the activity of this tubular transport mechanism.⁵ Further investigations into the exact role of the P-glycoprotein and multidrug resistance protein efflux pathways on drug elimination are presently underway.

REABSORPTION

Reabsorption of water and solutes occurs throughout the nephron, whereas the reabsorption of most medications occurs predominantly along the distal tubule and collecting duct. Urine flow rate and physicochemical characteristics of the molecule influence these processes: highly ionized compounds are not reabsorbed unless pH changes within the urine increase the fraction unionized, so that reabsorption may be facilitated.

INTACT NEPHRON HYPOTHESIS

The “intact nephron hypothesis” described by Bricker,⁸ which was published more than 40 years ago, proposes that “kidney function” of patients with renal disease is the net result of a reduced number of appropriately functioning nephrons. As the number of nephrons is reduced from the initial complement of 2 million, those which are unaffected compensate; that is, they hyperfunction. The cornerstone of this hypothesis is that glomerulotubular balance is maintained, such that those nephrons capable of functioning will continue to perform in an appropriate fashion. Extensive studies have indeed shown that single-nephron glomerular filtration rate increases in the unaffected nephrons, thus the whole-kidney GFR which represents the sum of the single-nephron glomerular filtration rates of the remaining functional nephrons may remain close to normal until there is extensive injury. Based on this, one would presume that a measure of one component of nephron function could be used as an estimate of all renal functions. This, indeed, has been and remains our clinical approach.

FILTRATION CAPACITY

GFR is dependent on numerous factors, one of which is protein load. Bosch⁹ suggested that an appropriate comprehensive evaluation of renal function should include the measurement of “filtration capacity” of the kidney. This is similar in context to a cardiac stress test. The patient may have no hypoxic symptoms, for example, angina while resting, but it may become quite evident when the patient begins to exercise. Subjects with normal renal function administered an oral or intravenous protein load prior to measurement of GFR have been noted to increase their GFR by as much as 50%.⁹ As renal function declines, the kidneys usually compensate by increasing the single-nephron glomerular filtration rate. The renal reserve, the maximal degree by which GFR can be increased will be reduced in those individuals whose kidneys are already functioning

at higher-than-normal levels because of preexisting renal injury. Thus this may be a complementary, insightful index of renal function reserve for many individuals with as yet unidentified CKD.

Quantification of renal function is not only an important component of a diagnostic evaluation, but it also serves as an important parameter for monitoring therapy directed at the etiology of the diminished function itself, thereby allowing for objective measurement of the success or failure of treatment. Measurement of renal function also serves as a useful indicator of the ability of the kidneys to eliminate drugs from the body. Furthermore, alterations of drug distribution and metabolism have been associated with the degree of renal function. A discussion of pharmacokinetic changes in renal disease is extensively reviewed in Chap. 51. Although several indices have been used for the quantification of filtration capacity or GFR in the research setting, estimation of creatinine clearance and GFR are the primary ones used in the clinical arena.

ENDOCRINE FUNCTION

The kidney synthesizes and secretes many hormones involved in maintaining fluid and electrolyte homeostasis. Secretion of renin by the cells of the juxtaglomerular apparatus and production and metabolism of prostaglandins and kinins are among the kidney's endocrine functions. In addition in response to decreased oxygen tension in the blood which is sensed by the kidney, erythropoietin is produced and secreted by peritubular fibroblasts. Because these functions are related to renal mass, decreased endocrine activity is associated with the loss of viable kidney cells. In the presence of stages 3 to 5 chronic kidney disease and moderate to severe acute renal injuries, secretion of erythropoietin is impaired leading to reduced red blood cell formation; normocytic anemia and symptoms of reduced oxygen delivery to tissues such as fatigue, dyspnea, and angina (see Chaps. 46 and 47). Renal anemia is clearly associated with many comorbidities, such as left ventricular hypertrophy, which is present in more than 40% of CKD patients.¹⁰ Indeed, anemia-induced renal hypoxia results indirectly in erythropoietin gene activation, tubular necrosis, and apoptosis, thereby contributing to further renal cell injury.¹¹ This cyclic relationship between kidney disease, suppression of erythropoietin secretion, and cardiovascular disease is also referred to as the cardio-renal anemia syndrome.

METABOLIC FUNCTION

The kidneys perform a wide variety of metabolic functions, including the activation of vitamin D₃, gluconeogenesis, and metabolism of endogenous compounds such as insulin, steroids, and xenobiotics. Impaired renal function results in decreased formation of activated vitamin D₃ and decreased insulin metabolism. It is common for patients with diabetes and chronic renal failure to have reduced requirements for exogenous insulin,¹² and supplemental therapy with activated vitamin D₃ (calcitriol) or other vitamin D analogs (paricalcitol, doxercalciferol) is often necessary to avert the bone loss and pain associated with renal osteodystrophy.¹³ Cytochrome P450, *N*-acetyltransferase, glutathione transferase, renal peptidases, and other enzymes responsible for the degradation and activation of selected endogenous and exogenous substances have been identified in the kidney. The cytochrome P450 (CYP) system in the kidneys is as active as that in the liver, when corrected for organ mass. In vitro studies have demonstrated impaired function of CYP3A4 and CYP2C9, whereas CYP1A2, CYP2C19, and CYP2D6 are not affected. This data is supported by recent clinical trials in end-stage renal disease patients receiving hemodialysis, where hepatic CYP3A activity was reported to be reduced by 28% from values observed in age-matched controls; partial correction was

TABLE 44-2 Presentation of Chronic Kidney Disease (CKD)		
	Early CKD (Stages 1–2)	Late CKD (Stages 3–4)
General	The patient may not appear in distress	Patient may have edema
Symptoms	Not likely present	The patient may have fatigue, malaise, pruritus, nausea
Signs	Not likely present	May present with fluid retention, anemia, dyspnea, reduced urine output
Laboratory tests	Microalbuminuria Mildly-elevated serum creatine and blood urea nitrogen	Persistent proteinuria Reduced glomerular filtration rate or creatine clearance rate Abnormal urinalysis
Other diagnostic tests		Renal ultrasound shows reduced kidney mass

noted following the hemodialysis procedure.^{14,15} See Chap. 51 for a more detailed discussion.

QUALITATIVE AND SEMIQUANTITATIVE INDICES OF KIDNEY FUNCTION

Patients who develop CKD remain relatively asymptomatic until impairment has progressed to the point that systemic manifestations and/or secondary complications become evident (Table 44–2). As renal function declines, patients may develop de novo or experience an exacerbation of hypertension, edema, electrolyte abnormalities, anemia, or other complications (see Chaps. 46 and 47). The National Kidney Foundation (NKF) currently recommends that all patients with CKD, and those at increased risk for CKD, undergo at least yearly a comprehensive laboratory assessment comprised of (a) serum creatinine to estimate GFR; (b) albumin-to-creatinine ratio in a spot urine specimen; (c) examination of urine sediment for red blood cell and white blood cell counts; (d) renal ultrasonography; (e) serum electrolytes, including sodium, potassium, chloride, and bicarbonate; (f) urine pH; and (g) urine specific gravity.¹⁶ The role of each of these indices in the identification and monitoring of CKD are discussed in detail below.

LABORATORY PROCEDURES TO DETECT THE PRESENCE OF KIDNEY DISEASE

Urinalysis is an important tool for detecting and differentiating various aspects of kidney disease, which often goes unnoticed as the result of its asymptomatic presentation. Urinalysis can be used to detect and monitor the progression of diseases such as diabetes mellitus, glomerulonephritis, and chronic urinary tract infections.^{16–18} A typical urinalysis provides information about physical and chemical composition, most of which can be completed quickly and inexpensively by visual observation (volume and color) and dipstick testing. Microscopic urinalysis requires use of a light microscope to determine cellular content as described below.

Chemical Analysis of Urine

pH The normal urine pH typically ranges from 4.5 to 7.8, and an elevation above this may suggest the presence of urea-splitting bacteria. In patients with renal tubular acidosis, urine pH is usually >5.5 because of impaired hydrogen ion secretion in the distal tubule or collecting duct.

Glucose Glucose is usually not present in the urine because the kidney normally completely reabsorbs all the glucose filtered at the

glomerulus. When a patient’s blood glucose concentration exceeds the maximum threshold for glucose reabsorption in the kidney (~180 mg/dL), glucosuria will be present. Routine assessment of glucosuria has been replaced by newer methods of direct blood glucose measurements. Urine glucose testing is now predominantly used as a screening tool for the detection of diabetes.

Ketones Acetoacetate and acetone are not normally found in the urine; they are however excreted in patients with diabetic ketoacidosis. They are also present under conditions of fasting or starvation. Typically, values of acetone excretion are reported as small (<20 mg/dL), moderate (30 to 40 mg/dL), and large (>80 mg/dL).

Nitrite Nitrite is not usually present in urine. The presence of nitrite is most commonly the result of conversion from urinary nitrate by bacteria present in the urine. The presence of nitrite thus suggests that the patient has a urinary tract infection, commonly caused by gram-negative rods such as *Escherichia coli*. Although false-positive results are very rare, false-negative results are more common and may be caused by lack of dietary nitrate, reduced urine nitrate concentration as a consequence of diuresis, or infections caused by bacteria such as enterococci and *Acinetobacter*, which do not reduce nitrate, and pseudomonads, which convert nitrate to nitrogen gas.

Leukocyte Esterase Leukocyte esterase is released from lysed granulocytes in the urine; its presence is suggestive of urinary tract infection. False-positive tests can result from delayed processing of the urine sample, contamination of the sample with vaginal secretions (such as blood or heavy mucus discharge), or by *Trichomonas* infection (such as trichomoniasis). False-negative tests can be produced by the presence of high levels of protein or ascorbic acid.

Heme The heme test indicates the presence of hemoglobin or myoglobin in the urine. A positive test without the presence of red blood cells suggests either red cell hemolysis or rhabdomyolysis.

Protein or Albumin Persistent proteinuria or albuminuria, that is, observation of its presence on at least three occasions over a period of 3 to 6 months, is now considered the principal marker of kidney damage.^{16,17} Evaluation of urinary protein or albumin is now a standard tool used to characterize the severity of CKD and to monitor the rate of disease progression or regression. Under normal conditions, plasma proteins remain in the glomerular capillaries as blood perfuses the kidney and thus do not cross the glomerular basement membrane or enter the urinary space. Some of these proteins, such as albumin and globulins are not filtered by the glomerulus as a result of charge and size selectivity (>40 kDa). Smaller proteins (<20 kDa) pass across the glomerular basement membrane but are readily reabsorbed in the proximal tubule. Most healthy individuals excrete between 30 and 150 mg/day of total protein consisting of approximately 30 mg/day of albumin. The remainder of the protein in the urine is secreted by the tubules (Tamm-Horsfall, immunoglobulin A, and urokinase) or comprised of smaller proteins such as β_2 -microglobulin, apoproteins, enzymes, and peptide hormones. Increased excretion of these low-molecular-weight proteins in the urine is considered a sensitive marker of tubulointerstitial disease.

Historically, the sulfosalicylic acid test was used as a crude measure of proteinuria. This test is performed by adding sulfosalicylic acid to urine and then visually comparing this admixture with a tube of untreated urine; the presence of turbidity indicates the qualitative presence of proteinuria. Dipstick tests are now the most common means to determine in a semiquantitative fashion a patient’s daily urine protein or albumin excretion. False-positive results can occur in the presence of alkaline urine (pH more than 7.5), when the dipstick is immersed too long, in those with highly concentrated urine, in the presence of drugs such as penicillin, sulfonamides, or tolbutamide, as well as blood, pus, semen, or vaginal secretions. False-negative results occur with dilute urine

(specific gravity <1.015) and when proteinuria is caused by nonalbumin or low-molecular-weight proteins such as heavy or light chains or Bence Jones proteins. The results of these dipstick tests are graded as negative (<10 mg/dL), trace (10 to 20 mg/dL), 1+ (30 mg/dL), 2+ (100 mg/dL), 3+ (300 mg/dL), or 4+ (>1,000 mg/dL). Portable desktop analyzers such as the Chemstrip 101 Urine Analyzer (Roche Diagnostics) and Clinitek 50 Urine Chemistry Analyzer (Bayer Corporation) can also be used as an alternative to visual urinalysis test-strip evaluation.

③ Because most dipstick methods are not specific for albumin, test strips that are specific for low levels of albuminuria (30 to 300 mg/day) should be employed. Microalbuminuria test strips, such as the Chemstrip Micral-Test II (Roche Diagnostics), when dipped into a urine sample assume a color ranging from white (0 mg/L) to red (100 mg/L), depending on the amount of albumin present in the sample. In patients with a positive protein or albumin dipstick test, a 24-hour urine collection with measurement of albumin excretion can be used to further define the degree of albuminuria. However, this method requires a high degree of patient compliance and is being replaced by a similarly accurate but less cumbersome technique: calculation of the ratio of protein or albumin (in milligrams) to creatinine (in grams) obtained from an untimed (spot) urine specimen. The normal ratio is <30 mg albumin or <200 mg protein per gram of creatinine in the urine, with values between 30 and 300 mg of albumin per gram of creatinine considered to be in the microalbuminuria range.¹⁶ Positive test results should be repeated, particularly in patients without an underlying cause for renal disease, such as diabetes or hypertension. Monitoring of the degree of glomerular injury in CKD patients should use the albumin-to-creatinine ratio, whereas for patients with clinical proteinuria, that is, excretion of >500 mg per day or an albumin-to-creatinine ratio >500 mg/g, the protein-to-creatinine ratio can be used.

CLINICAL CONTROVERSY

In the past, measurement of urinary protein excretion rate was accomplished using a 24-hour urine collection in patients who were at risk for CKD. However, many now advocate the use of an untimed “spot” urine sample with either an albumin-specific dipstick or measurement of the albumin-to-creatinine ratio.

Specific Gravity Specific gravity is a measure of urine weight relative to water (1.00) that is performed using a refractometer. Thus, specific gravity is dependent on water intake and urine-concentrating ability. Normal values range from 1.003 to 1.030. Osmolality, which is a measure of the number of solute particles in the urine, is a more accurate measure of the kidney’s ability to make a concentrated urine. Generally the two values correlate; however, when large quantities of heavier molecules, such as glucose, are in the urine, the specific gravity may be elevated relative to the osmolality. These tests are used in the assessment of urine-concentrating ability and are most informative when interpreted along with the hydration status of the patient and plasma osmolality.

Microscopic Analysis of Urine Formed elements that may be detected in the urine include erythrocytes and leukocytes, casts, and crystals. An important consideration in the assessment of hematuria is whether the cells are of renal origin. More than 2 cells per high-power field is abnormal, and the presence of dysmorphic cells suggest renal parenchymal origin either because of damage as they pass through the glomerulus or during exposure to the varying osmotic environments of the tubular lumen. White blood cells may be present in the urine in association with infection or inflammatory conditions, such as interstitial nephritis. More than 1 cell per high-power field is usually considered abnormal. Contamination of

the sample should also be considered when there are many cells and may be a result of the presence of menses or of inadequate sample collection. Casts are cylindrical forms composed of protein, with or without cells that take the shape of the collecting tubules, where they are formed. Casts without cells are labeled *hyaline casts* and consist of the Tamm-Horsfall mucoprotein, secreted by the renal tubules. They are nonspecific and may appear in concentrated urine. In the presence of red or white blood cells, casts may be formed that include the cells, indicating that the cells were of renal origin. Solubility of the Tamm-Horsfall protein is increased as urine pH rises; therefore, sample collection for casts should occur with the first morning void when the urine is most acidic. Otherwise, casts may dissolve and elude detection.

A variety of crystals may be present in the urine, including uric acid, calcium oxalate, calcium phosphate, calcium magnesium ammonium pyrophosphate, and cystine. Many of these have a unique crystalline form, which permits them to be identified with microscopy.

Serum or Blood Urea Nitrogen

Amino acids metabolized to ammonia are subsequently converted in the liver to urea, the production of which is dependent on protein availability (diet) and hepatic function. Urea undergoes glomerular filtration followed by reabsorption of up to 50% of the filtered load in the proximal tubule. The reabsorption rate of urea is predominantly dependent on the reabsorption of water. The excretion of urea may, therefore, be decreased under conditions which necessitate water conservation such as dehydration although the GFR may be normal or only slightly reduced. This condition is evident when a patient exhibits prerenal azotemia, or an increase of the blood urea nitrogen to a greater extent than the serum creatinine. The normal blood urea nitrogen-to-creatinine ratio is 10 to 15:1, and an elevated ratio is suggestive of a decreased effective circulating volume, which stimulates increased water, and hence, urea reabsorption. Creatinine is not reabsorbed to any significant extent by the kidneys. Despite these limitations, the blood urea nitrogen is usually used in combination with the serum creatinine concentration as a simple screening test for the detection of renal dysfunction.

Serum Creatinine

Creatinine is the standard laboratory marker for the detection of kidney disease. The third National Health and Nutrition Examination Survey (NHANES III) revealed a mean serum creatinine of 0.96 mg/dL in women, and 1.16 mg/dL in men in the United States.¹⁹ Values were lower among Mexican Americans, and higher among non-Hispanic blacks. For all groups, the serum creatinine increased with age. The report also noted that among community-dwelling adults, 10.9 million have a serum creatinine greater than 1.5 mg/dL; 3.0 million have a serum creatinine greater than 1.7 mg/dL; and 0.8 million have a serum creatinine greater than 2.0 mg/dL. Although the serum creatinine concentration alone is not an optimal measure of kidney function, it is often used as a marker for referral to a nephrologist. There is presently no accepted single standard for an “abnormal” serum creatinine, as it is gender, race, and age-dependent.

The concentration of creatinine in serum is a function of creatinine production and renal excretion. Creatinine is a product of creatine metabolism from muscle; therefore, its production is directly dependent on muscle mass. At steady state, the “normal” serum creatinine concentration range is 0.5 to 1.5 mg/dL for males and females. Creatinine is eliminated primarily by glomerular filtration, and as GFR declines, the serum creatinine concentration rises (Fig. 44–2).

Several methods are used for the determination of the serum creatinine concentration, most of which use the nonspecific Jaffe reaction, a colorimetric method based on the reaction of creatinine

FIGURE 44-2. Relationship between serum creatinine and creatinine clearance.

with alkaline picrate. This nonspecific method also reacts with noncreatinine chromogens in the serum, which may result in a falsely increased serum creatinine concentration.¹⁷ The noncreatinine chromogens are not present in the urine in sufficient quantities to interfere with the urinary creatinine measurement, because the concentration of creatinine in urine is several-fold greater than the serum concentration. The impact of this interference is seen with the creatinine clearance (CL_{cr}) calculation:

$$CL_{cr} = (U_{cr} \times V) / S_{cr} \times t$$

where U_{cr} = urine creatinine concentration, V = urine volume, S_{cr} = serum creatinine concentration, and t = duration of the urine collection.

This “normal” interference results in an increase in the serum creatinine concentration of approximately 10% and thereby the measured creatinine clearance would underestimate the true GFR by 10%. In subjects with normal renal function, this tends to counterbalance the effect of the contribution of tubular secretion of creatinine, which increases urine creatinine by nearly 10%. Thus, CL_{cr} has been proposed to serve as a good measure of GFR in subjects with normal renal function. However, this false increase in serum creatinine becomes less noticeable as the true creatinine concentration rises, due to the increasing contribution of tubular secretion to the renal clearance of creatinine.²⁰ This becomes of major importance when kidney function is reduced to less than 50% of normal.

Diabetic ketoacidosis may produce increased concentrations of acetoacetate, which serves as a chromophore in the Jaffe reaction, thereby increasing the serum creatinine concentration. Other substances that also react with this procedure in the serum include glucose, protein, pyruvate, fructose, uric acid, and ascorbic acid (Table 44–3). In addition, some cephalosporin antibiotics are associated with a false increase in the serum creatinine concentration, including cephalothin, cefazolin, cephalixin, cefoxitin, cefaclor, and cephadrine,²¹ whereas other antibiotics, such as the fluoroquinolones (ciprofloxacin, fleroxacin, lomefloxacin, ofloxacin, levofloxacin, sparfloxacin, and temafloxacin), do not produce a false elevation in serum creatinine.²² The degree of interference is dependent on the serum concentration of the antibiotic, so blood samples for creatinine should be obtained when the antibiotic concentration is lowest (at the end of a dosing interval). These interferences are not observed when the serum creatinine is measured using an enzymatic technique. The antifungal agent 5-flucytosine causes an increase in the serum creatinine when measured using the Ektachem enzymatic system, but does not interact with the Jaffé method.²³ Daly et al.²⁴ reported a false-negative effect of dobutamine and dopamine on the serum creatinine value when measured using the Ektachem system.

TABLE 44-3 Factors That May Alter Creatinine Clearance Determinations

Analytical	Physiologic
Acetoacetate	Age, weight, gender
Ascorbic acid	Diet
Cephalosporins (cephalothin, cefazolin, cephalixin, cefoxitin, cefaclor, cephadrine)	Diurnal variation
Dobutamine	Cimetidine
Dopamine	Trimethoprim
5-Flucytosine	Probenecid
Fructose	Exercise
Glucose	
Protein	
Pyruvate	
Uric acid	

The interference is concentration dependent and results in a 10% to 100% decrease of the serum creatinine concentration. The authors hypothesized that both drugs compete with the chromogenic dye for oxidation by hydrogen peroxide in a concentration-dependent manner. The problem is most evident when blood samples are contaminated with residual IV solution containing the interfering drug. These differences emphasize the need to standardize a method within the clinic setting and require the clinician to be aware of the methods employed in the laboratory for the determination of creatinine concentrations.

Other compounds are known to interfere with the serum creatinine concentration by inhibition of the active tubular secretion of creatinine. Among these are cimetidine and trimethoprim, which compete for creatinine secretion at the cationic transport system in a dose-dependent fashion. Cimetidine, given as a single 400-mg dose can result in a reduction of the CL_{cr}-to-inulin clearance ratio from 1.30 to 1.03, without a change in inulin clearance. Ranitidine, an H₂-receptor antagonist similar to cimetidine, however, does not have a similar effect on creatinine secretion following single doses of 300 to 1,200 mg.²⁵

The serum creatinine concentration is dependent on the “input” function, or formation rate, and “output” function, or elimination rate. Its formation rate depends on the zero-order production from creatine metabolism, as well as input from other sources, such as dietary intake. Creatine metabolism is directly proportional to muscle mass; therefore, individuals with more muscle mass have a higher serum creatinine concentration at any given degree of kidney function than those with less muscle mass. Strenuous exercise is associated with an increase of approximately 10% in the serum creatinine concentration. In contrast, cachectic patients, as the result of minimal muscle mass, will have very low serum creatinine concentrations, as do those with spinal cord injuries.²⁶ Elderly patients and those with poor nutrition may also have low serum creatinine concentrations (<1.0 mg/dL) secondary to decreased muscle mass. Other factors that influence the serum creatinine concentration include the dietary intake of creatine. During the cooking of meat, some creatine is converted to creatinine, which is rapidly absorbed following ingestion.

Serum creatinine concentrations may rise as much as 50% within 2 hours of a meat meal and remain elevated for as long as 8 to 24 hours.²⁷ Ingestion of creatine as an ergogenic dietary supplement is currently popular. There are conflicting reports as to the effect of creatine ingestion on the serum creatinine concentration. Poortsma et al.²⁸ evaluated a short-term regimen of 20 g creatine per day for 5 days in healthy subjects, and reported no significant change in the serum creatinine, creatinine excretion rate, or creatinine clearance. Robinson et al.,²⁹ however, reported a 25% to 40% increase in the serum creatinine concentration after ingestion of 20 g creatine per day for either 5 days or 8 weeks. The renal excretion rate of creatinine was not measured. The issue of whether creatine inges-

tion adversely affects kidney function was studied by Edmonds et al.³⁰ They noted that creatine supplementation led to an increase in renal disease progression in a rat model for renal cystic disease, suggesting that creatine supplementation may be a risk factor in patients with preexisting renal disease. These conditions present a problem only when a single serum creatinine concentration is used to represent the entire 24-hour collection period, which is usually the case. An alternative is to obtain multiple samples and calculate the area under the serum concentration time curve and divide this by the collection time interval to obtain the average plasma creatinine concentration. This is rarely done in clinical practice, but points out the need to question patients regarding dietary intake for the 24 hours preceding the measurement of CL_{cr} .

Diurnal variation in serum creatinine concentration may also affect the accuracy of the CL_{cr} determination. Although the fluctuation is minimal, the observed peak plasma creatinine concentration generally occurs at approximately 7:00 PM, whereas the nadir is in the morning. To minimize this effect, the CL_{cr} is usually performed over a 24-hour period with the plasma creatinine obtained in the morning, as long as the patient has stable kidney function. Collection of urine remains a limiting factor in the 24-hour CL_{cr} because of incomplete collections, and interconversion between creatinine and creatine that can occur if the urine is not maintained at a pH <6.

Cystatin C

Cystatin C is a 132-amino-acid (13.3-kDa) cysteine protease inhibitor produced by all nucleated cells of the body that is being investigated as a potential biomarker of renal function. It is freely filtered at the glomerulus and undergoes some reabsorption and catabolism in the proximal tubule. However, it has been shown that serum cystatin C concentrations can be altered by many factors other than kidney function, such as age, nutritional status, gender, weight, height, cigarette smoking, serum C-reactive protein levels, steroid therapy, and rheumatoid arthritis.^{31–33} Originally introduced in Europe, it has been recommended as a test of kidney function because of findings that serum concentrations significantly correlated with GFR as well as serum creatinine. The recent development of an automated immunoassay technique has resulted in the development of suggested reference ranges of 0.70 to 1.38 mg/L in children older than 1 year of age, and 0.54 to 1.21 mg/L in adults. Its sensitivity as an indicator of renal function relative to other markers such as serum creatinine is yet to be fully defined. Early evidence suggests that it may be a more sensitive index of kidney disease; comparison of ¹²⁵I-iothalamate with serum creatinine and cystatin C showed that the serum creatinine began to increase when the GFR was 75 mL/min/1.73 m² as compared to 88 mL/min/1.73 m² for cystatin C.³¹ However, Keevil et al.³⁴ reported that serum cystatin C had greater intraindividual variability than serum creatinine in healthy individuals, which may limit its use in longitudinal evaluations of renal function.

Several recent studies suggest that there is still much to discover before we know whether this test will be a replacement for creatinine or a confounding ancillary test. In a 4-year longitudinal study in 30 Pima Indians without CKD, the reciprocal cystatin C index (100/cystatin C) was shown to be a better predictor of declining GFR than was reciprocal serum creatinine, estimated GFR, or CL_{cr} .³⁵ However in patients being treated for malignant disease, Page et al.³⁶ reported increased cystatin C concentrations that were independent of CL_{cr} . Cystatin C concentrations were also noted to be independent of GFR and weakly associated with measured creatinine clearance, in pediatric and adult renal transplant recipients, possibly due to the formation of cystatin–immunoglobulin complexes or reduced tubular catabolism.^{37,38} Two additional studies have shown a strong association between serum cystatin C and cardiovascular disease in elderly and non-CKD patients, suggesting that it may provide useful prognostic information in some popula-

tions.^{39,40} It appears that cystatin C is a nonspecific marker of GFR that likely is a more sensitive index than serum creatinine of early changes in GFR. Further longitudinal evaluations will be necessary to clarify its usefulness as a prognostic index of trends in renal function and/or cardiovascular outcomes.

MEASUREMENT OF KIDNEY FUNCTION

The gold standard quantitative index of kidney function is a measured GFR. A variety of methods may be used to measure and estimate kidney function in the acute care and ambulatory settings. Estimation of GFR is important for early recognition and monitoring of patients with chronic kidney disease. Estimation of CL_{cr} is important as a guide for drug dose adjustment in the presence of renal impairment.

It is important to recognize conditions that may alter renal function independent of underlying renal pathology. For example, protein intake, such as oral protein loading or an infusion of amino acid solution, may increase GFR.⁹ As a result, inter- and intraindividual variability must be considered when it is used as a longitudinal marker of renal function. Dietary protein intake has been demonstrated to correlate with GFR in healthy subjects. Brändle et al.⁴¹ evaluated renal function in four groups of healthy volunteers, each ingesting a diet controlled for protein over a 4-month period. The GFR was nonlinearly related to the urine nitrogen excretion, with an observed maximum of 181.7 mL/min at a urinary nitrogen excretion rate of 20 g/day, or 125 g/day protein intake. Subjects who are vegetarian have a lower GFR than individuals who consume a similar caloric but normal-protein-content diet because of their reduced dietary protein intake. When challenged with a protein load, the vegetarian subjects are able to increase their GFR to the “normal” range.⁹ Findings from the Nurses’ Health Study⁴² indicate that longitudinal changes in GFR are independent of the source of protein (nondairy animal, dairy, or vegetable) in women with normal renal function. However, women with mild renal insufficiency (GFR 71 ± 7 mL/min) who consumed the highest amount of protein (93 g/day) had a threefold greater risk of a ≥ 5 -mL/min decline in GFR compared to the lowest protein group (60 g/day); rates of decline were highest in those consuming nondairy animal protein. The increased GFR following a protein load is the result of renal vasodilation accompanied by an increased renal plasma flow. The exact mechanism of the renal response to protein is unknown, but may be related to extrarenal factors such as glucagon, prostaglandins, and angiotensin II, or intrarenal mechanisms, such as tubular transport and tubuloglomerular feedback.^{43,44} Despite the evidence of a “renal reserve,” standardized evaluation techniques have not been developed. Therefore, assessment of the standard GFR measurement technique must consider the dietary protein status of the patient at the time of the study.

CLINICAL CONTROVERSY

Estimation of creatinine clearance in vegetarians is controversial. Some clinicians advocate use of the 24-hour creatinine clearance in these patients since this method is based on the renal clearance of creatinine. The six-variable Modification of Diet in Renal Disease Study equation, which incorporates nutritional parameters such as blood urea nitrogen and albumin, has yet to be evaluated in this non-CKD population.

MEASUREMENT OF GLOMERULAR FILTRATION RATE

4 A measured GFR remains the single best index of functioning renal mass. As renal mass declines in the presence of age-related loss

of nephrons or coexisting disease states such as hypertension or diabetes, there is a progressive decline in GFR. The rate of decline in GFR can be used to predict the time to onset of stage 5 CKD, as well as the risk of complications of CKD. Accurate measurement of GFR in clinical practice is a critical variable for the individualization of the dosage regimens of renally excreted medications so as to maximize their therapeutic efficacy and avoid potential toxicity.

The GFR is expressed as the volume of plasma filtered across the glomerulus per unit time, based on total renal blood flow and capillary hemodynamics. The normal values for GFR are 127 ± 20 mL/min/1.73 m² and 118 ± 20 mL/min/1.73 m² in healthy men and women, respectively. For example, if the normal renal blood flow were approximately 1.0 L/min/1.73 m², plasma volume was 60% of blood volume, and filtration fraction across the glomerulus was 20%, then the normal GFR would be approximately 120 mL/min/1.73 m².

Because GFR cannot be measured directly in humans, clearance methods that use substances that are freely filtered without additional clearance because of tubular secretion or reduction as the result of reabsorption are required. Additionally, the substance should not be susceptible to metabolism within renal tissues and should not alter renal function. Given these conditions, the GFR is equivalent to the renal clearance of the solute marker:

$$\text{GFR} = \text{renal CL} = (A_e) / \text{AUC}_{0-t}$$

where renal CL is renal clearance of the marker, A_e is the amount of marker excreted in the urine in a specified period of time, t , and AUC_{0-t} is the area under the plasma-concentration-versus-time curve of the marker.

Under steady-state conditions, for example during a continuous infusion of the marker, the expression simplifies to

$$\text{GFR} = \text{renal CL} = (A_e) / [C_{ss} \times t]$$

where C_{ss} is the steady-state plasma concentration of the marker achieved during continuous infusion. The continuous infusion method can also be employed without urine collection, where plasma clearance is calculated as $\text{CL} = \text{infusion rate}/C_{ss}$. Requirements of this method include steady-state plasma concentrations and accurate measurement of infusate concentrations. Plasma clearance can also be determined following a single-dose intravenous injection with multiple sampling of blood to estimate area under the curve ($\text{AUC}_{0-\infty}$). Here, clearance is calculated as $\text{CL} = \text{dose}/\text{AUC}$. These plasma clearance methods commonly yield clearance values 10% to 15% higher than urine collection methods.^{45,46}

The GFR marker is most often administered as a combination of IV loading dose and continuous infusion, designed to achieve the desired target plasma concentration. Following an equilibration period, sequential measurements of GFR are made over three or more 30 to 60 minute time periods. Urine is collected, and blood samples are collected at the beginning and end of each urine collection period. It is necessary to maintain adequate hydration during the test because GFR is dependent on renal blood flow and it assures adequate urine output during the procedure. A relatively constant urine flow will decrease the variability among repeated measurements and should be within the range of 1 to 5 mL/min. Carefully timed renal clearance studies should ensure adequate bladder emptying and accurate measurement of urine volume. In patients with impaired bladder emptying, such as those with benign prostatic hypertrophy or neurogenic bladder, urinary catheterization may be required.

5 Several markers have been used for the measurement of GFR and include both exogenous and endogenous compounds. Those administered as exogenous agents, such as inulin, iothalamate, iothexol, and radioisotopes, require specialized administration techniques and detection methods for the quantification of function, but generally provide a more accurate measure of GFR. Methods that employ endogenous compounds, such as creatinine, require

TABLE 44-4 Sensitivity and Clinical Utility of Renal Function Tests

	Accuracy	Clinical Utility	Cost
Inulin clearance	++++	+	\$\$\$\$
Radiolabeled markers	+++	+	\$\$\$
Nonisotopic contrast agents	+++	++	\$\$\$
Creatinine clearance	++	+++	\$\$
Serum creatinine	+	++++	\$

+, least acceptable; ++, adequate; +++, better; +++++, best.

less-technical expertise, but produce results with greater variability. The marker of choice depends on the purpose and cost of the test (e.g., ¹²⁵I-iothalamate costs \$2,000 per vial [Glofil-125, QOL Medical]); research protocols will generally use a more accurate test than one used in the clinical setting (Table 44-4).

Inulin Clearance

Inulin is a relatively large fructose polysaccharide (5,200 daltons), obtained from plant tubers of the Jerusalem artichoke, dahlia, and chicory plants. It is not bound to plasma proteins, is freely filtered at the glomerulus, is not secreted or reabsorbed, and is not metabolized by the kidney. The volume of distribution of inulin approximates extracellular volume, or 20% of ideal body weight. Because it is eliminated by glomerular filtration, its elimination half-life is dependent on renal function and is approximately 1.3 hours in subjects with normal renal function. Measurement of plasma and urine inulin concentrations can be performed using high-performance liquid chromatography.⁴⁷ Sinistrin, another polyfructosan, has similar characteristics to inulin; it is filtered at the glomerulus and not secreted or reabsorbed to any significant extent. It is a naturally occurring substance derived from the root of the North African vegetable red squill, *Urginea maritima* that has a much higher degree of water solubility than inulin. Assay methods for sinistrin have been described using enzymatic procedures, as well as high-performance liquid chromatography with electrochemical detection.⁴⁸

Iothalamate Clearance

Alternatives have been sought for inulin as a marker for GFR because of the problems of availability, high cost, sample preparation, and assay variability. Iothalamate is an iodine-containing radiocontrast agent that is available in both radiolabeled (¹²⁵I) and nonradiolabeled forms. This agent is handled in a manner similar to that of inulin; it is freely filtered at the glomerulus and does not undergo substantial tubular secretion or reabsorption. The nonradiolabeled form is most widely used to measure GFR in ambulatory and research settings, and can safely be administered by IV bolus, continuous infusion, or subcutaneous injection.⁴⁹ Plasma and urine iothalamate concentrations can be measured using high-performance liquid chromatography.⁵⁰ Plasma iothalamate clearance methods that do not require urine collections have been shown to be highly correlated with iothalamate renal clearance. The observed positive bias of approximately 10 mL/min suggests that there is some degree of nonrenal clearance of this agent. If one “corrects” the plasma clearance value by subtracting the population mean nonrenal clearance, the resultant estimate of GFR is well-suited for longitudinal evaluations of renal function.⁴⁵

Iothexol

Iothexol, a nonionic, low osmolar, iodinated contrast agent, has also been used for the determination of GFR. It is eliminated almost entirely by glomerular filtration, and plasma and renal clearance values are similar to observations with other marker agents: strong correlations of 0.90 or greater and significant relationships such as $\text{CL}_{\text{iothexol}} = 0.90 \text{ CL}_{\text{iothalamate}} + 6.8 \text{ mL/min}$ have been reported.⁵¹⁻⁵³

These data support iothexol as a suitable alternative marker for the measurement of GFR. One key advantage of this agent is that a single plasma sample can be used to quantify iothexol, clearance provided sufficient time has elapsed since injection. For patients with a reduced GFR more time must be allotted—more than 24 hours if the estimated GFR is less than 20 mL/min.⁵¹

Radiolabeled Markers

The GFR has also been quantified using radiolabeled markers, such as ¹²⁵I-iothalamate (614 daltons, radioactive half-life of 60 days), ^{99m}Tc-diethylenetriamine pentaacetic acid (^{99m}Tc-DTPA; 393 daltons, radioactive half-life of 6.03 hours), and ⁵¹Cr-ethylenediaminetetraacetic acid (⁵¹Cr-EDTA; 292 daltons, radioactive half-life of 27 days).⁵⁴ These relatively small molecules are minimally bound to plasma proteins and do not undergo tubular secretion or reabsorption to any significant degree. ¹²⁵I-iothalamate and ^{99m}Tc-DTPA are used in the United States, whereas ⁵¹Cr-EDTA is used extensively in Europe. The use of radiolabeled markers allows one to determine the individual contribution of each kidney to total renal function.⁵⁵ Various protocols exist for the administration of these markers and subsequent determination of GFR using either plasma or renal clearance calculation methods. The nonrenal clearance of these agents appears to be low (3 to 8 mL/min), suggesting that plasma clearance is an acceptable technique except in patients with severe renal insufficiency (GFR <30 mL/min). Indeed, highly significant correlations between renal clearance among radiolabeled markers has been demonstrated.⁵⁶ Although total radioactive exposure to patients is usually minimal, use of one of these agents does require compliance with radiation safety committees and appropriate biohazard waste disposal.

Estimation of GFR

A series of equations proposed by Levey and colleagues^{2,57–59} have gained widespread support for the estimation of GFR in many patient populations. These equations were derived from multiple regression analysis of data obtained from the 1,628 patients enrolled in the Modification of Diet in Renal Disease Study (MDRD). The initial regression model yielded the following six-variable Modification of Diet in Renal Disease Study (MDRD6) equation:

$$\text{GFR} = 170 \times (\text{P}_{\text{cr}})^{-0.999} \times [\text{Age}]^{-0.176} \times [0.762 \text{ if patient is female}] \times [1.180 \text{ if patient is black}] \times [\text{SUN}]^{-0.170} \times [\text{Alb}]^{0.318}$$

where P_{cr} = plasma creatinine, SUN = serum nitrogen concentration, and Alb = serum albumin concentration. Comparison of various prediction equations showed that the new equation ($r^2 = 90.2\%$) provided a more precise estimate of GFR than measured CL_{cr} ($r^2 = 86.6\%$) or CL_{cr} estimated by the Cockcroft-Gault equation ($r^2 = 84.2\%$) in the MDRD population. More recently,¹⁶ a modified, four-variable version of the original MDRD equation (MDRD4) has been shown to provide a similar estimate of GFR results compared to its six-variable predecessor:

$$\text{GFR} = 186 \times (\text{P}_{\text{cr}})^{-1.154} \times (\text{Age})^{-0.203} \times [0.742 \text{ if patient is female}] \times [1.210 \text{ if patient is black}]$$

This equation, based on plasma creatinine, age, sex, and race, was validated in the MDRD study sample and is now recommended by the NKF and the National Kidney Disease Education Program (NKDEP) for calculating the estimated GFR (eGFR) in patients with a history of CKD risk factors and a GFR <60 mL/min/1.73 m². The performance of MDRD6, and more recently the MDRD4, has been assessed in a variety of patient populations. In renal transplant patients with severe renal insufficiency ($\text{CL}_{\text{cr}} < 30 \text{ mL/min/1.73 m}^2$), the MDRD6 equation was highly correlated with mean CL_{cr} and urea clearances, less biased, and more precise than the Cockcroft-Gault equation.⁵⁸ However, this equation was less accurate than the Cockcroft-Gault equation in

healthy subjects, diabetic patients with normal GFR (88 to 182 mL/min/1.73 m²), and healthy potential kidney donors.^{59,60} In cirrhotic patients being evaluated for liver transplant (GFR $58 \pm 5.1 \text{ mL/min/1.73 m}^2$) the MDRD4, MDRD6, and Cockcroft-Gault equations significantly overestimated GFR by 30% to 50%, and were imprecise estimates of GFR before and after liver transplantation.^{61,62} In a small study of elderly subjects (age >68 years) with mild/moderate CKD (GFR $53 \pm 18 \text{ mL/min/1.73 m}^2$) the MDRD6 equation was slightly positively biased compared to the Cockcroft-Gault equation (8% vs. 10%), but precision was similar between methods relative to measured GFR.⁶³ Beddhu et al. reported that the MDRD6 equation, like the Cockcroft-Gault equation, is dependent on creatinine production and is susceptible to bias in malnourished patients with end-stage renal disease.⁶⁴ The MDRD equations should not be used in ill, hospitalized patients,⁶⁵ nor in individuals with normal renal function,⁶⁰ and should be used with caution in children, the elderly, and those with extremes in muscle mass (cachectic and obese) until further performance data is available. The MDRD equations also should not be used for renal drug dose adjustment until further studies evaluating the relationship between eGFR and drug clearance/elimination are conducted. Several online resources are available to assist clinicians with eGFR calculations, such as the NKDEP.⁶⁶

CLINICAL CONTROVERSY

Some practitioners are advocating the use of the MDRD4 equation in patients without CKD, although it appears to have a weaker correlation with GFR than the Cockcroft-Gault equation. However, recent evidence suggests that the MDRD4 equation should be reserved for patients with a GFR <60 mL/min. The use of standardized isotope dilution mass spectrometry traceable creatinine assays may improve the performance of the MDRD4 equation in patients with GFR >60 mL/min.

A recent approach to standardize and reduce analytical errors associated with serum creatinine assays, and thereby improve the accuracy of eGFR results, has been proposed for implementation in clinical laboratories.⁵⁹ This assay calibration, called isotope dilution-mass spectrometry, will likely reduce the inter-laboratory variability in serum creatinine values. In settings using the isotope dilution-mass spectrometry assay, a revised MDRD eGFR equation is recommended, which accounts for an approximate 5% reduction in creatinine values. The NKDEP also recommends reporting serum creatinine values in mg/dL to two decimal places (e.g., 0.93 mg/dL), and values in $\mu\text{mol/L}$ to the nearest whole number (e.g., 84 $\mu\text{mol/L}$). This practice will likely reduce rounding errors that in the past contributed to bias between creatinine-based GFR or CL_{cr} estimates. However the impact of this approach on the accuracy of eGFR results or renal drug dose adjustments remains to be determined.

CLINICAL CONTROVERSY

Drug-dose individualization is often required in patients with CKD. Approved drug labeling typically includes a dose-adjustment table based on the patient's estimated CL_{cr} using the Cockcroft-Gault method. With many hospital laboratories now reporting MDRD eGFR values, the usefulness of this measure as a guide for drug-dose adjustments needs to be clarified.

Measured Creatinine Clearance

6 Despite the common use of a measured (24-hour) CL_{cr} as an index of renal function, its use is now more controversial than ever. Short-duration witnessed CL_{cr} correlates with iothalamate clearance performed using the single-injection technique. In a multicenter

study⁶⁷ of 136 patients with type I diabetic nephropathy, the correlations of simultaneous CL_{cr} , Cockcroft-Gault CL_{cr} , and 24-hour CL_{cr} (compared to $CL_{\text{iothalamate}}$) were 0.81, 0.67, and 0.49, respectively, indicating increased variability with the 24-hour clearance determination. In a selected group of 110 patients, measurement of a 4-hour CL_{cr} during water diuresis provided the best estimate of the GFR as determined by the $CL_{\text{iothalamate}}$. Furthermore, the ratio of CL_{cr} to $CL_{\text{iothalamate}}$ did not appear to increase as the GFR decreased. These data suggest that a short collection period with a water diuresis may be the best method for estimation of GFR by creatinine clearance.

A limitation of using creatinine as a filtration marker is that it undergoes varying degrees of tubular secretion. Tubular secretion augments the filtered creatinine by approximately 10% in subjects with normal kidney function. If the nonspecific Jaffe reaction is used, which overestimates the serum creatinine concentration by approximately 10% because of the noncreatinine chromogens, then the creatinine clearance is a very good measure of GFR in patients with normal kidney function. Tubular secretion, however, increases to as much as 100% in patients with renal insufficiency.²⁰ As renal impairment develops, the remaining nephrons hypertrophy, and the degree of tubular secretion decreases less than the decrease in filtration. The result is an overestimation of creatinine clearance as a function of GFR assessed by inulin or iothalamate clearance. For example, Bauer et al.²⁰ reported that the CL_{cr} -to- CL_{inulin} ratio in subjects with mild impairment was 1.20; for moderate impairment, it was 1.87; and for severe impairment, it was 2.32. Thus, creatinine clearance is a poor indicator of GFR in patients with moderate to severe renal insufficiency.

Because cimetidine blocks the tubular secretion of creatinine the potential role of several oral cimetidine regimens to improve the accuracy and precision of creatinine clearance as an indicator of GFR has been evaluated. The CL_{cr} -to- CL_{DPTA} ratio declined from 1.33 with placebo to 1.07 when 400 mg of cimetidine was administered four times a day for 2 days prior to and during the clearance determination.⁶⁸ Similar results were observed when a single 800-mg dose of cimetidine was given 1 hour prior to the simultaneous determination of CL_{cr} and $CL_{\text{iothalamate}}$; the ratio of CL_{cr} to $CL_{\text{iothalamate}}$ was reduced from a mean of 1.53 to 1.12.⁶⁹ Thus a single oral dose of cimetidine 800 mg should provide adequate blockade of creatinine secretion to improve the accuracy of a creatinine clearance measurement as an estimate GFR in patients with stages 3 to 5 CKD.

Estimation of Creatinine Clearance

7 Many equations describing the mathematical relationships between various patient factors and CL_{cr} have been reported over the past 3 decades. Most equations incorporate factors such as age, gender, weight, and serum creatinine concentration, without the need for urine collection. The most widely used of these estimators is the Cockcroft-Gault equation,⁷⁰ which identified age and body mass as factors which significantly contribute to the estimate of CL_{cr} . This relationship was based on observations from 249 male patients with stable kidney function in whom the creatinine production rates were estimated.

For obese individuals, that is those weighing more than 30% above their ideal body weight (IBW), it is recommended that IBW be used in place of actual body weight (ABW)⁷¹ in the Cockcroft-Gault equation, where:

$$IBW(\text{kg, males}) = 50 + 2.3 (\text{Height in inches} > 60)$$

$$IBW (\text{kg, females}) = 45 + 2.3 (\text{Height in inches} > 60)$$

An alternative approach for estimating CL_{cr} (mL/min) in obese patients is the Salazar-Corcoran equation which has been shown to be unbiased and superior to the Cockcroft-Gault equation in this population.^{71,72}

Luke et al.⁷³ evaluated the ability of the Cockcroft-Gault method and four other methods to predict CL_{cr} , with inulin clearance being considered the standard measure of GFR. The simultaneously determined inulin and creatinine clearances correlated best, $r^2 = 0.85$, and the CL_{cr} overestimated CL_{inulin} by approximately 15% due to tubular secretion of creatinine. For the five calculated clearances, Cockcroft-Gault and Mawer et al.⁷⁴ correlated the best with inulin clearance. The Cockcroft-Gault method showed a linear relationship with CL_{inulin} equal to 1.121 of CL_{cr} plus 20.6 mL/min ($r^2 = 0.66$), whereas for Mawer et al. the relationship was CL_{inulin} equal to 1.051 of CL_{cr} plus 18.3 mL/min ($r^2 = 0.66$). Other methods, such as Jelliffe⁷⁵ and Hull et al.,⁷⁶ consistently underestimated the CL_{cr} . As kidney function declined, there was an increase in the fraction of creatinine eliminated by secretion as measured by the CL_{cr} -to- CL_{inulin} ratio, consistent with earlier reports. This limitation should be taken into consideration when attempting to use CL_{cr} for the estimation of renal function and the individualization of drug dosage regimens. Gault et al.⁷⁷ also evaluated the performance of the Cockcroft-Gault estimator of renal function compared with inulin and ^{99m}Tc-DPTA. Except for conditions of unstable kidney function, it performed similar to the 24-hour creatinine clearance method (Table 44-5).

Patients undergoing screening for participation in the African American Study of Kidney Disease (AASK) were evaluated for kidney function based on an estimated CL_{cr} compared with the simultaneous CL_{cr} and ¹²⁵I-iothalamate, and 24-hour CL_{cr} .⁷⁸ The simultaneous CL_{cr} provided the best estimate of GFR. The Cockcroft-Gault method was the preferred method for estimation of GFR, based on performance and ease of use. This method was noted to underestimate the GFR by 9%, perhaps because of the increased excretion rate of creatinine by black patients.^{78,79}

Administration of cimetidine has also resulted in improved performance of the Cockcroft-Gault equation to predict GFR. Ixkes et al.⁸⁰ gave patients three 800-mg doses of cimetidine in 24 hours, and measured creatinine plasma levels from 3 to 7 hours following the final dose. During this 4-hour period, the $CL_{\text{iothalamate}}$ was determined as the measure of GFR. The Cockcroft-Gault calculations were performed with the plasma creatinine measurement 3 hours after the last dose of cimetidine. The ratio of the Cockcroft-Gault estimated CL_{cr} -to- $CL_{\text{iothalamate}}$ decreased from 1.28 ± 0.21 to 0.98 ± 0.11 in the presence of cimetidine. This cimetidine dosing schedule also improved the accuracy of Cockcroft-Gault estimates relative to GFR in renal transplant patients with GFR values ranging from 20 to 80 mL/min/ 1.73m^2 .^{81,82}

TABLE 44-5 Equations for the Estimation of Creatinine Clearance in Adults with Stable Renal Function

Cockcroft and Gault ⁸⁰	Men: $CL_{cr} = (140 - \text{age}) \text{ ABW} / (S_{cr} \times 72)$ Women: $CL_{cr} \times 0.85$
Jelliffe ⁸⁹	Men: $CL_{cr} = (100/S_{cr}) - 12$ Women: $CL_{cr} = (80/S_{cr}) - 7$
Jelliffe ⁹⁰	Men: $CL_{cr} = 98 - [0.8 (\text{age} - 20)]/S_{cr}$ Women: $CL_{cr} \times 0.9$
Mawer et al. ⁸⁸	Men: $IBW [29.3 - (0.203 \times \text{age})] [1 - (0.03 \times S_{cr}) / (14.4 \times S_{cr})]$ Women: $IBW [25.3 - (0.175 \times \text{age})] [1 - (0.03 \times S_{cr}) / (14.4 \times S_{cr})]$
Hull et al. ⁹¹	Men: $CL_{cr} = [(145 - \text{age})/S_{cr}] - 3$ Women: $CL_{cr} \times 0.85$
Levey et al. (MDRD6) ⁷²	$GFR = 170 \times (S_{cr})^{-0.999} \times [\text{age}]^{-0.176} \times [0.762 \text{ if patient is female}] \times [1.180 \text{ if patient is black}] \times [\text{SUN}]^{-0.170} \times [\text{Alb}]^{0.318}$
Levey et al. (MDRD4) ⁷⁴	$GFR = 186 \times (S_{cr})^{-1.154} \times (\text{Age})^{-0.203} \times (0.742 \text{ if patient is female}) \times (1.210 \text{ if patient is black})$

Alb, serum albumin concentration (g/dL); CL_{cr} , creatinine clearance in mL/min; IBW, ideal body weight (kg); S_{cr} , serum or plasma creatinine (mg/dL); SU, serum urea nitrogen concentration (mg/dL).

Liver Disease

The prediction of CL_{cr} or eGFR is particularly problematic in patients with preexisting liver disease and renal impairment. Lower-than-expected serum creatinine values may result from reduced muscle mass, protein-poor diet, diminished hepatic synthesis of creatine (a precursor of creatinine), and fluid administration can lead to significant overestimation of creatinine clearance. Orlando et al.⁸³ evaluated 10 healthy subjects, 10 patients with mild liver disease, and 10 with severe liver disease, and observed a measured CL_{cr} -to- CL_{inulin} ratio of 1.05, 1.03, and 1.04 for each group, respectively. When the CL_{cr} of patients with severe liver disease was estimated using the Cockcroft-Gault equation, the resultant ratio (CL_{cr} Cockcroft-Gault-to- CL_{inulin}) was 1.23. Lam et al.⁸⁴ likewise noted an overprediction by Cockcroft-Gault of the measured CL_{cr} in patients with severe disease, by 40% to 100%.

Studies of renal function in patients with severe hepatic disease confirm the earlier observations of Hull et al.⁷⁶ and Caregaro et al.⁸⁵ who reported that measured CL_{cr} overestimated GFR by 50% in hepatic patients with a GFR of 56 ± 19 mL/min/1.73 m² because of increased tubular secretion of creatinine. The effect of cimetidine administration on measured CL_{cr} was recently evaluated in a small study by Sansoe et al.⁸⁶ In 12 patients with compensated cirrhosis, serum creatinine values increased from 0.68 ± 0.11 to 0.94 ± 0.14 mg/dL during coadministration of cimetidine (1,000 mg given as $400 \text{ mg} \times 1$ then 200 mg every 3 hours) during a 9-hour clearance period. The CL_{cr} was reduced from 138 ± 20 to 89 ± 13 mL/min, with no change in measured GFR.

CLINICAL CONTROVERSY

In patients with liver disease, falsely low serum creatinine values frequently occur as a result of malnourishment, muscle wasting, and tubular secretion of creatinine. Preliminary data suggests that the use of cimetidine may improve the accuracy of measured creatinine clearance compared to measured GFR in patients with cirrhosis. However, the effect of this approach on methods to estimate CL_{cr} or GFR is unknown.

DeSanto et al.⁸⁷ studied 19 patients with mild liver disease whose inulin and creatinine clearances were 90 ± 4.4 and 122 ± 7 mL/min/1.73 m², respectively. The degree of overestimation of GFR by creatinine clearance was inversely correlated with GFR ($r = 0.452$, $P < 0.04$). Thus, measurement of renal function in patients with hepatic disease should be performed by using a method specific for glomerular filtration, and estimation of creatinine clearance should be avoided.

Other Special Populations

Davis and Chandler⁸⁸ confirmed the accuracy of the Cockcroft-Gault equation to predict CL_{cr} in trauma patients with stable kidney function, and Thakur et al.²⁶ demonstrated its successful use in 42 paraplegic subjects. Renal transplant recipients are frequently monitored for renal function, as numerous complications may occur during the life of the allograft. Goerdet et al.⁸⁹ assessed the bias and precision with which several nomographic methods predicted GFR (iohexol clearance) in 127 patients with stable kidney function. The Cockcroft-Gault method performed poorly, overestimating iohexol clearance. This is expected, as iohexol clearance provides a true measure of GFR, whereas the Cockcroft-Gault CL_{cr} estimate is falsely high because of the tubular secretion of creatinine. Huang et al.⁹⁰ reported the inability of several CL_{cr} equations to predict renal function in hospitalized patients with advanced human immunodeficiency virus (HIV) disease. All of the prediction methods overestimated the measured 24-hour CL_{cr} . The reasons for the poor

predictability of these methods are unclear, although 24-hour collection methods result in increased variability, often because of inadequate collection of urine.

Renal function assessment during pregnancy is usually performed using a 24-hour creatinine clearance determination. Quadri et al.⁹¹ evaluated the Cockcroft-Gault method during each trimester in 34 pregnant women and compared these estimates with the measured 24-hour CL_{cr} . Prepregnancy weights were used throughout the study for the Cockcroft-Gault method, and results correlated well with the measured clearances ($r^2 = 0.76$). The maximal CL_{cr} occurred during the second trimester for both methods.

Unstable Renal Function

Patients with unstable kidney function present a unique situation because serum creatinine values are changing, and steady state cannot be assumed when estimating CL_{cr} . It can take several days for serum creatinine values to reach steady state in early acute renal failure, but this time can be reduced when renal function is improving. In patients with previously normal renal function, a change in the serum creatinine concentration of more than 50% over a period of 1 day is suggestive of unstable renal function. In patients with preexisting CKD ($S_{cr} > 2.0$ mg/dL) an increase in serum creatinine by 30% or more than 1.0 mg/dL over a 24- to 48-hour period indicates the presence of acute renal failure. Methods to measure GFR in this population, such as ¹²⁵I-iothalamate clearance, are cumbersome and costly especially in the acute care setting. Table 44–6 lists several equations for estimating renal function under these conditions.^{92–94} Although these equations are commonly used to estimate CL_{cr} in patients with acute renal failure, a rigorous evaluation of the accuracy and precision of each of these proposed methods is lacking. Also lacking is a method to estimate GFR, an equivalent to the MDRD equation for patients with CKD, for patients with acute renal failure.

The equation proposed by Jelliffe is a revised dynamic model of creatinine kinetics based on theoretical estimates of creatinine production and adjusted for age and changes in serum creatinine; however, its ability to predict changes in drug clearance (and dose adjustments) has not been evaluated.⁹² In the acute setting, factors previously discussed that may alter the serum creatinine concentration must be evaluated to avoid misinterpretation. The inappropriate use of the Cockcroft-Gault equation in those with acute renal failure can significantly overestimate the value of CL_{cr} when compared to equations that are designed to account for changes in serum creatinine in patients with unstable renal function. It is thus, ultimately, most important to recognize that renal function in patients with acute renal failure is generally markedly lower than one would estimate using steady-state methods, and dose adjustments should be made if necessary to avoid drug toxicity (see Chap. 45 and Tables 44–7 and 44–8).

CLINICAL CONTROVERSY

Serum creatinine values can fluctuate widely in patients with unstable renal function. Although some practitioners advocate use of the Cockcroft-Gault equation using the highest of the two serum creatinine values, most recommend calculation of CL_{cr} using either the Brater or Jelliffe equations.

Kidney Function in Children

Kidney function in the neonate is difficult to assess because of difficulty in urine and blood collection, the frequent presence of a non-steady-state serum creatinine, and apparent disparity between development of glomerular and tubular function. Preterm infants demonstrate significantly reduced GFR prior to 34 weeks, which

rapidly increases and becomes similar to term infants within the first week of life.⁹⁵ Evaluation of GFR in preterm infants on day 3 of life, using an inulin infusion, failed to identify a relationship between patient weight and GFR. Gestational age, which ranged from 23.4 to 36.9 weeks (mean: 30.2 weeks), however, correlated with both GFR and reciprocal of serum creatinine. The inulin clearance increased from 0.67 to 0.85 mL/min in those with gestational age <28 weeks versus those of 32 to 37 weeks of age, while S_{cr} decreased from 1.05 to 0.73 mg/dL, respectively. Creatinine was measured using a specific enzymatic method to avoid interference from bilirubin or drugs.⁹⁶ Creatinine clearance has also been evaluated in infants younger than 1 week of age, and values of 17.8 mL/min/1.73 m² on day 1 increased to 36.4 mL/min/1.73 m² by day 6.⁹⁷ In light of these rapid changes in GFR, estimation of GFR is not recommended for infants younger than 1 week of age. Kidney function expressed as GFR standardized to body surface area increases with age and stabilizes at approximately 1 year. In older children, GFR is best assessed using standard measurement techniques for GFR. Subcutaneous administration of ¹²⁵I-iothalamate

has been effectively used to measure GFR in children ranging in age from 1 to 20 years.⁹⁸

Estimation of CL_{cr} as described by Schwartz et al.⁹⁹ is dependent on the child's age and length:

GFR = [length (cm) × k] / S_{cr}

where k is defined by age group: infant (1 to 52 weeks) = 0.45; child (1 to 13 years) = 0.55; adolescent male = 0.7; and adolescent female = 0.55.

Subsequent studies verified these relationships in children with normal renal function or mild renal impairment. However, variability increases at clearance values <50 mL/min. Al-Harbi and Lireman¹⁰⁰ reported a good correlation of the predicted CL_{cr} with measured 4-hour CL_{cr} and ^{99m}Tc-DPTA (r = 0.75) in 48 pediatric renal allograft recipients 3 to 19 years of age. However, predictive performance measures of bias and precision were not reported. Fong et al.¹⁰¹ evaluated the method in critically ill children (mean age: 5.6 years; range: 0.1 to 20.8 years) and concluded that the method significantly overestimated the measured CL_{cr} (bias = 45%). Peirrat et al. recently compared the MDRD, Schwartz, and Cockcroft-Gault equations in

TABLE 44-7 Scenario A (Worsening Renal Function)

J.R. is a 50-year-old male (weight: 70 kg; body surface area: 1.73m ²), admitted to the intensive care unit following an automobile accident. His renal function was normal prior to admission; however his serum creatinine has increased from 0.6 mg/dL to 3.0 mg/dL in the past 24 hours.		
Equation	CL _{cr}	Assumptions
Jelliffe ¹⁰⁵	21.9 mL/min/1.73 m ²	E ^{ss} = 1341.2 mg/day E ^{ss} _{corr} = 1241 mg/day S _{cr} = 1.8 mg/dL S _{cr1} = 0.6 mg/dL S _{cr2} = 3.0 mg/dL Δt = 1 day Wt = 70 kg
Brater ¹⁰⁷	19.1 mL/min	S _{cr1} = 0.6 mg/dL S _{cr2} = 3.0 mg/dL Δt = 1 day
Cockcroft-Gault ⁸⁰	29.2 mL/min	S _{cr2} = 3.0 mg/dL Wt = 70 kg

TABLE 44-8 Scenario B (Improving Renal Function)

J.R. has been in the intensive care unit for 1 week, and his status is improving. His serum creatinine has decreased from 3.0 mg/dL to 1.0 mg/dL in the past 24 hours.		
Approach	CL _{cr}	Assumptions
Jelliffe ¹⁰⁵	64.5 mL/min/1.73 m ²	E ^{ss} = 1341.2 mg/day E ^{ss} _{corr} = 1297.7 mg/day S _{cr} = 2.0 mg/dL S _{cr1} = 3.0 mg/dL S _{cr2} = 1.0 mg/dL Δt = 1 day Wt = 70 kg
Brater ¹⁰⁷	78.7 mL/min	S _{cr1} = 3.0 mg/dL S _{cr2} = 1.0 mg/dL Δt = 1 day
Cockcroft-Gault ⁸⁰	87.5 mL/min	S _{cr} = 1.0 mg/dL Wt = 70 kg

CL_{cr}, creatinine clearance rate; Δt, time between S_{cr1} and S_{cr2}; E^{ss}, steady-state creatinine excretion; E^{ss}_{corr}, steady-state creatinine excretion corrected; S_{cr}, serum creatinine; S_{cr1}, first serum creatinine value; S_{cr2}, second serum creatinine value; Wt, weight.

children 3 to 19 years of age.¹⁰² In children <12 years, the Schwartz and MDRD equations were significantly more biased than Cockcroft-Gault, and Cockcroft-Gault provided the best prediction of GFR in children >12 years. Because the MDRD equation was developed in the adult population, the results of these investigations suggest that further studies will be needed to clarify the value of any of these predictive methods in children. Dose adjustments and other therapeutic decisions based on kidney function warrant appropriate measures of renal status to avoid incorrect decisions.

Kidney Function in the Elderly

Cross-sectional studies demonstrate decreased GFR as a function of age when GFR is measured as inulin, iothalamate, or creatinine clearance.^{70,103} The Baltimore Longitudinal Study on Aging,¹⁰⁴ an evaluation of 254 normal healthy subjects, revealed that creatinine clearance decreases at the rate of approximately 0.75 mL/min/1.73 m²/y beginning at the fourth decade of life. These subjects were evaluated prospectively for up to 23 years. Interestingly, approximately one-third of the subjects showed no change in renal function from their baseline value, and a small number showed an increased clearance. These changes may be a result of normal physiologic changes or of subclinical insults to the kidneys initiating the events leading to chronic progressive loss of renal function. Fliser et al.¹⁰⁵ studied renal functional reserve in healthy young (23 to 32 years) and elderly (61 to 82 years) volunteers using an amino acid infusion technique. Inulin clearance was used as the measure of GFR, which increased 16% in young and 17% in elderly subjects following the infusion. Renal functional reserve thus appears to be maintained in healthy elderly individuals.

Interpretation of the serum creatinine concentration alone is difficult in the elderly patient primarily because of the decreased muscle mass and resultant lower production rate of creatinine. Thus, the serum creatinine often remains within the normal range despite a reduction in the number of functional nephrons. As renal function declines, the kidneys excrete a larger fraction of creatinine. This perpetuates the “normal” serum creatinine. Recent recommendations such as the adoption of standardized creatinine assays by clinical laboratories and reporting of serum creatinine values to two decimal places, will likely improve the accuracy of renal function estimation in the elderly population.⁵⁹

The Cockcroft-Gault formula⁷⁰ can be used to estimate the CL_{cr} of elderly patients. Smythe et al.¹⁰⁶ estimated CL_{cr} in 23 patients >60 years of age using seven different methods, and compared the results to a measured 24-hour CL_{cr} determination. Estimations were performed with the actual serum creatinine concentration and also with the serum creatinine rounded up to 1.0 mg/dL if the actual value was <1.0 mg/dL. Rounding the serum creatinine to 1.0 mg/dL resulted in a significantly lower (bias = 28.8 mL/min) estimate of GFR, as compared with the actual clearance, than when the unadjusted serum creatinine (bias = 2.3 mL/min) was used. These data strongly suggest that one should not arbitrarily fix the serum creatinine concentration in elderly patients at 1.0 mg/dL. An alternative to the estimation of GFR or a 24-hour clearance determination is a 4-hour clearance performed during water diuresis.⁶⁷ This correlated with the inulin clearance as well as with an inpatient 24-hour CL_{cr}. However, one must be aware of the potential risk of hyponatremia in the geriatric patient who is unable to tolerate an oral water load, as well as the need for complete bladder emptying to ensure accurate results. O’Connell et al.¹⁰⁷ assessed the accuracy of 2- and 8-hour urine collections compared with 24-hour creatinine clearance determinations in 45 hospitalized patients >65 years old with indwelling urethral catheters. Single, timed urine collections for CL_{cr} showed minimal bias with the 8-hour collection as compared with the 24-hour value, whereas the 2-hour determination was both biased and imprecise.

Assessment of Progression

Chronic kidney disease (see Chap. 46) will eventually lead to end-stage renal disease (see Chap. 47), necessitating dialysis or transplantation for survival (see Chaps. 48 and 92). The rate of progression can be slowed and in some cases halted through dietary modification, strict blood pressure control, initiation of angiotensin-converting enzyme inhibitor or angiotensin receptor blocker therapy to reduce urinary protein excretion, and improved glucose control in patients with diabetes mellitus (see Chap. 46). The efficacy of these interventions is optimally assessed with the sequential measurement of an accurate and sensitive index of GFR such as iothexol, iothalamate, or radioisotope clearance.¹⁰⁸

8 Alternatively, use of newer methods to estimate GFR, such as the MDRD4 equation, or traditional methods, such as the linear decline in the reciprocal of the serum creatinine concentration as a function of time, are simple clinical tools that can be used to evaluate the rate of progression of renal disease and to predict the time when dialysis will be needed.^{2,19} It is known that serum creatinine concentration is a function of input from the breakdown of creatine or the ingestion of dietary sources and elimination occurs predominantly through glomerular filtration and tubular secretion. Under steady-state conditions, the formation rate of creatinine equals the elimination rate (R), and CL_{cr} is inversely related to S_{cr} as:

$$S_{cr} = R/CL_{cr}$$

The reciprocal relationship between S_{cr} and CL_{cr} is then expressed as:

$$1/S_{cr} = 1/R \times CL_{cr}$$

9 Figure 44–3A depicts the reciprocal relationship between S_{cr} and CL_{cr}. As renal function declines, the reciprocal of the serum creatinine concentration decreases as a linear function of the CL_{cr}, and the slope of the relationship is the reciprocal of the elimination rate of creatinine. Clinicians can use the reciprocal serum creatinine plotted as a function of time as a prognostic tool, to predict when dialysis may be needed (when 1/S_{cr} ~0.1) or as a marker for evaluating the success of therapeutic interventions to alter the rate of decline in renal function (Fig. 44–3B). Several factors, such as changes in dietary intake of creatinine and decreased muscle mass, which are associated with a reduction in the production of creatinine, may alter the utility of the relationship. Furthermore, if tubular secretion increases in response to nephron hypertrophy disproportionately to filtration, or if nonrenal routes of elimination of creatinine, such as metabolism by intestinal bacteria, become more important, then changes in the slope of the reciprocal creatinine versus time relationship may be altered. It is most important to be aware of the limitations of serum creatinine measurement and to realize that it is not an adequate test to detect early chronic renal disease or to precisely estimate the rate of progression.

Microalbuminuria has been identified as an early marker of renal disease in patients with diabetic nephropathy¹⁰⁹ and numerous other conditions, such as hypertension and obesity.^{110,111} Albuminuria is a more sensitive marker than total protein for monitoring CKD progression, as well as a modifiable risk factor for renal disease progression and cardiovascular disease.³⁹ Thus patients with microalbuminuria (30 to 300 mg/day) on at least two or three occasions or overt albuminuria (>300 mg/day) should begin to receive pharmacotherapy. For children, microalbuminuria is considered present if albumin excretion exceeds 0.36 mg/kg/day, and overt albuminuria has been defined as an excretion rate that exceeds 4 mg/kg/day. The urinary albumin-to-creatinine ratio is also an accurate predictor of 24-hour proteinuria, a marker of renal disease. Guidelines for monitoring indicate that a urine albumin to creatinine ratio of >30 mg/g places the patient at increased risk of developing diabetic

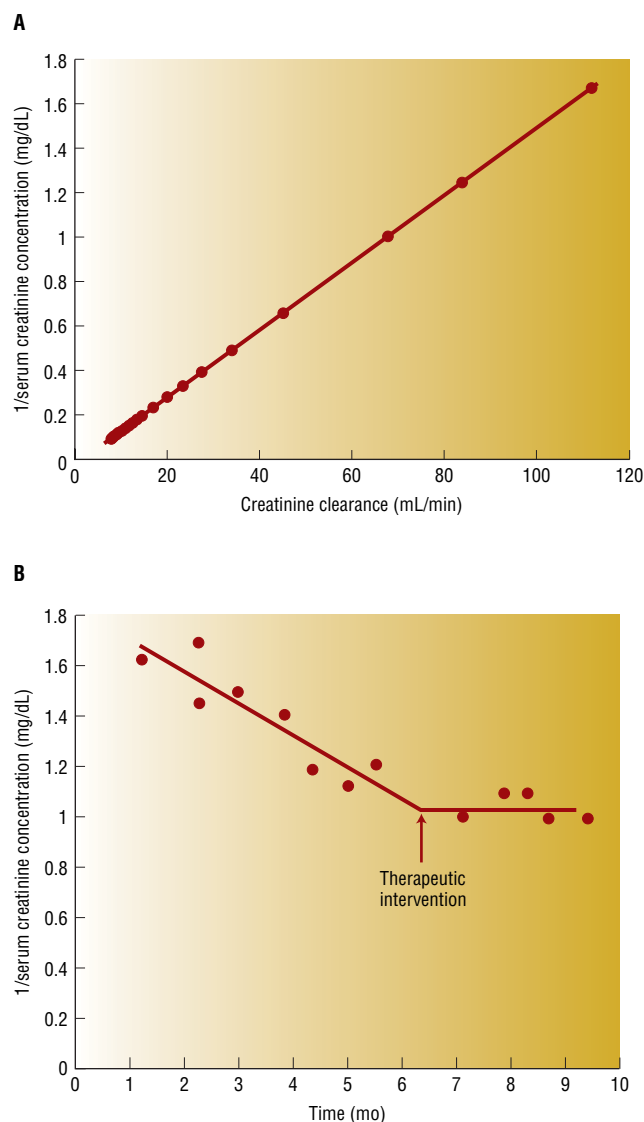

FIGURE 44-3. Linear relationship between 1/serum creatinine concentration and creatinine clearance (A) and 1/serum creatinine concentration as a function of time in a hypothetical patient with progressive renal impairment (B). The arrow indicates a change in the rate of progression, which may be related to a therapeutic intervention.

nephropathy and is an indication for the initiation of pharmacotherapeutic intervention.¹⁸ Microalbuminuria has also been suggested as a risk factor for renal dysfunction among patients with essential hypertension.¹¹²

Measurement of Renal Plasma and Blood Flow

Measurement of renal plasma and blood flow is rarely if ever determined in the clinical setting; rather, it is reserved for research settings to evaluate hemodynamic changes related to disease or drug therapy. The kidneys receive approximately 20% of cardiac output and representative values of renal blood flow in men and women of about $1,200 \pm 250$ and $1,000 \pm 180$ mL/min/ 1.73 m^2 have been reported, respectively.¹¹³ Renal plasma flow (RPF) is estimated to be 60% of blood flow if it is assumed that the average hematocrit is 40% and that it can be measured by the use of model compounds that are eliminated from the plasma compartment on a single pass through the kidneys. Because only 20% of the plasma is filtered at the glomerulus, the compound must undergo active tubular secretion and minimal to no reabsorption to be completely eliminated. To accurately reflect RPF, the extraction through the kidney must

be nearly 100%. PAH is an organic anion that has been used extensively for the quantification of renal plasma flow. PAH is approximately 17% bound to plasma proteins and is eliminated extensively by active tubular secretion. Because PAH elimination is active, saturation of the transport processes should be anticipated, and concentrations of PAH in plasma should not exceed 10 to 20 mg/L. Dowling et al.¹¹⁴ used a sequential infusion technique and observed concentration-dependent renal clearance of PAH at concentrations above 100 mg/dL. Furthermore, PAH is also metabolized, possibly within the kidney, to *N*-acetyl-PAH, and it is important for the analytical method to differentiate the parent compound and metabolite.⁵⁰ Prescott et al.¹¹⁵ noted that the renal clearance of PAH decreases at low plasma concentrations, while the clearance of the acetyl metabolite increases. Further studies are necessary to evaluate the mechanisms and significance of these findings. The extraction ratio (ER) for PAH is 70% to 90% at plasma concentrations of 10 to 20 mg/L, hence the term “effective” renal plasma flow (ERPF) has been used when the clearance of PAH is not corrected for the extraction ratio or if it is assumed to be 1.⁴ Normal values are about 650 ± 160 mL/min for men and 600 ± 150 mL/min for women.¹¹³ Children will reach normalized adult values by 3 years of age, and ERPF will begin to decline as a function of age after 30 years, reaching about one-half of its peak value by 90 years of age. The method for calculation of ERPF is based on the relationship between organ clearance, ER, and flow:

$$\text{ERPF} = \text{renal PAH CL} = \text{RPF} \times \text{ER}$$

Effective renal blood flow (ERBF) can be estimated from ERPF by assuming the extraction ratio is 1 and correcting for the red blood cell volume of the blood (hematocrit [HCT]):

$$\text{ERBF} = \text{ERPF}/(1 - \text{HCT})$$

ERPF can also be measured using the radioisotopes ^{131}I -orthoiodohippurate (^{131}I -OIH) or $^{99\text{m}}\text{Tc}$ -mercaptoacetyl triglycine ($^{99\text{m}}\text{Tc}$ -MAG3).¹¹⁶ One important advantage of this method is its ability to measure ERPF in total or for each kidney independently, as well as its ability to produce renal images. Russell and Dubovsky,¹¹⁷ using a single-injection technique, compared clearance methods with and without urine collection and showed similar results with each method.

QUANTITATIVE ASSESSMENT OF TUBULAR FUNCTION

Although GFR is the best overall indicator of renal function, it may not provide an accurate measure of tubular function, either secretory capacity or cellular function, suitable for use in the research environment.¹¹⁸ Tubular secretory function can be assessed by measuring PAH transport as the prototype marker of the organic anion secretory system. *N*¹-methylnicotinamide (NMN) and tetraethylammonium are prototype compounds secreted by the cationic transport system and may be used as markers of cationic secretory capacity.^{4,118} Edwards et al.¹¹⁹ demonstrated delayed recovery of NMN clearance among patients with psoriasis treated with low-dose cyclosporine, as compared with the recovery of GFR and renal blood flow. Earlier studies with NMN suggested its use to assess the effects of selected renal diseases on drug handling by the kidneys.¹²⁰ Dowling et al.¹¹⁴ explored the usefulness of famotidine as a marker for cationic transport, but was unable to demonstrate saturation, perhaps due to the contribution from other secretory pathways such as P-glycoprotein.

Furthermore, Karyekar et al.¹²¹ demonstrated that itraconazole, a P-glycoprotein inhibitor, significantly reduced the renal tubular secretion of cimetidine in healthy individuals, suggesting that cimetidine may be used as an *in vivo* probe of renal P-glycoprotein function. It should also be recognized that these transport systems

are not necessarily mutually exclusive. Indeed, probenecid, which is secreted by the anionic pathway, inhibits the secretion of cationic compounds. Quantitative measures of tubular transport capacity are currently limited primarily to the research setting.

Other measures of tubular function are less specific and are regarded primarily as indices of damage within the nephron. Schentag and Plaut¹²² demonstrated a delay in the increase of serum creatinine following aminoglycoside toxicity when compared to markers for tubular damage such as the low-molecular-weight protein β_2 -microglobulin (11.8 kDa) and urinary enzymes. The rise in β_2 -microglobulin is related to an early functional defect in the proximal tubular cell. This is followed by a rise in the excretion of enzymes released as a result of structural damage of the cells, and, finally, by the formation and excretion of cellular casts. Other low-molecular-weight proteins used as markers of tubular function include retinol-binding protein (21 kDa) and protein HC (also known as α_1 -microglobulin, 27 kDa).¹²³ These proteins are normally freely filtered at the glomerulus and then completely reabsorbed by the proximal tubule. Increases in their excretion are thus suggestive of tubular dysfunction but are not diagnostic, as an increased production rate or GFR of less than 30 mL/min may lead to increased excretion. In both cases, the maximal reabsorptive capacity may be exceeded, leading to net excretion of the protein. Retinol-binding protein and protein HC are elevated with tubular damage and may be more appropriate markers than β_2 -microglobulin.

Numerous urinary enzymes such as *N*-acetylglucosaminidase, alanine aminopeptidase, alkaline phosphatase, γ -glutamyltransferase, pyruvate kinase, glutathione transferase, lysozyme, and pancreatic ribonuclease have been used as diagnostic markers for renal disease. Jung et al.¹²⁴ compared the ability of five enzymes (*N*-acetylglucosaminidase, alanine aminopeptidase, alkaline phosphatase, γ -glutamyltransferase, and lysozyme) to detect early rejection episodes in kidney transplant patients. Only *N*-acetylglucosaminidase and alanine aminopeptidase were early predictors of rejection. *N*-acetylglucosaminidase is an enzyme contained within the lysosome of the tubular cell and is released when the lysosome is damaged, whereas alanine aminopeptidase is an enzyme of the brush border. Both markers were increased approximately 2 days earlier than serum creatinine in patients with transplant rejection.

QUALITATIVE DIAGNOSTIC PROCEDURES

Radiologic Studies

10 The etiology of kidney disease can be evaluated using several qualitative diagnostic techniques, including radiography, ultrasonography, magnetic resonance imaging, and biopsy. The standard radiograph of the kidneys, ureters, and bladder provides a gross estimate of kidney size and identifies the presence of calcifications.⁵⁴ Although an easy test to perform, the value of the information is minimal, and more detailed evaluations are often necessary. The intravenous urogram (formerly known as intravenous pyelogram) involves the administration of a contrast agent to facilitate visualization of the urinary collecting system. It is primarily used in the assessment of structural changes that may be associated with hematuria, pyuria, or flank pain, resulting from recurrent urinary tract infections, obstruction, or stone formation. For patients with low GFRs, retrograde administration of dye into the ureters may be performed to facilitate visualization of the collecting system. Contrast agents are also employed during renal angiography for the assessment of renovascular disease. As a test for the diagnosis of renovascular hypertension, the captopril (angiotensin-converting enzyme inhibitor) test is a useful adjunct. Under conditions of unilateral renal artery stenosis, the affected kidney produces large quantities of angiotensin II, which constricts the efferent arteriole to maintain GFR. The administration of an angiotensin-converting

enzyme inhibitor results in reduced uptake of the contrast agent because the efferent arteriole is dilated, thereby decreasing the perfusion pressure of the affected kidney. For patients with bilateral disease, a decrease in uptake is observed in both kidneys.¹²⁵ Computed tomography is a cross-sectional anatomic imaging procedure based on x-ray data. The procedure is frequently performed with contrast to enhance imaging. Spiral, or helical, computed tomography, a more recent technique, provides for three-dimensional reconstruction of tissues. Computed tomography is performed as a test for the evaluation of obstructive uropathy, malignancy, and infections of the kidney.

Renal Ultrasonography

Ultrasonography uses sound waves to generate a two-dimensional image. The echogenicity of the kidney is compared with that of an adjacent organ—liver on the right and spleen on the left—with an increased echogenicity indicating an abnormal finding. Ultrasonography can distinguish the renal pyramids, medulla, and cortex, and abnormalities in structure, such as occurs with obstruction. Renal ultrasonography is also used as a guide for site localization during percutaneous kidney biopsy.

Magnetic Resonance Imaging

Magnetic resonance imaging is based on aligning hydrogen nuclei in the body with the use of a powerful magnet and applying radiofrequency pulses. The signals emitted by the hydrogen nuclei during realignment on repeated pulses allows for generation of the tissue image. Realignment times can also be altered with the use of contrast agents (gadolinium, gadopentetate), leading to increased signal intensity and improved imaging. Magnetic resonance imaging is useful for the assessment of obstruction, malignancy, and renovascular lesions. The relative advantages and limitations of these procedures are discussed in more detail in recent reviews.^{54,126}

Biopsy

Renal biopsy is used in several conditions to facilitate diagnosis when clinical, laboratory, and imaging findings prove inconclusive. Proteinuria and hematuria are both associated with renal parenchymal disease. When less-invasive studies are unsuccessful in differentiating the cause and the possible causes have different therapeutic approaches, biopsy may be indicated. Functional status of the kidney is not assessed with biopsy, and severity of disease and progression is best measured using quantitative tests discussed above. Contraindications to renal biopsy include a solitary kidney, severe hypertension, bleeding disorder, severe anemia, cystic kidney, and hydronephrosis, among others. Complications resulting from biopsy primarily include hematuria, which may last for several days, and perirenal hematoma.¹⁸

CONCLUSIONS

The prevalence of kidney disease has increased dramatically over the past two decades, indicating a need for early identification, risk classification and monitoring of renal function in CKD patients. Comprehensive approaches to evaluating renal function in CKD patients in the clinical setting include the Cockcroft-Gault equation for estimating creatinine clearance and drug dosing, the MDRD4 equation to estimate GFR, and measurement of urinary protein excretion or albumin-to-creatinine ratio as a marker of the integrity of the glomerular basement membrane. Accurate measurement of GFR using exogenous administration of inulin, iothalamate, or radioisotope techniques such as ^{99m}Tc-DPTA is typically reserved for research settings to assess drug therapy outcomes and progression of disease. Use of qualitative assessments of renal function,

such as radiography, computed tomography, magnetic resonance imaging, sonography, and biopsy, can help to determine the underlying cause of kidney disease.

ABBREVIATIONS

AUC: area under the plasma concentration vs. time curve

CKD: chronic kidney disease

CL: clearance

CL_{cr}: creatinine clearance

C_{ss}: concentration of a substance in plasma under steady-state conditions

CT: computerized tomography

ER: extraction ratio

ERBF: effective renal blood flow

ERPF: effective renal plasma flow

GFR: glomerular filtration rate

HCT: hematocrit

IBW: ideal body weight

MDRD: Modification of Diet in Renal Disease study

NKF: National Kidney Foundation

PAH: para-aminohippuric acid

S_{cr}: serum creatinine

U_{cr}: urine creatinine concentration

WILLIAM DAGER AND ANNE SPENCER

KEY CONCEPTS

- 1 Acute renal failure (ARF) is a common complication in the hospitalized patient and is associated with a high mortality rate.
- 2 ARF is predominantly categorized based on the anatomic area of injury or malfunction: (a) prerenal—decreased renal blood flow, (b) intrinsic—a structure within the kidney is damaged, and (c) postrenal—an obstruction is present within the urine collection system.
- 3 Risk factors for ARF include advanced age, acute infection, pre-existing chronic respiratory or cardiovascular disease, dehydration, and chronic kidney disease.
- 4 ARF lacks a specific and sensitive sign to herald its onset. Hence, a thorough patient history, including medications, recent procedures and illnesses, physical examination, and laboratory assessment of serum and urine are necessary components of an ARF evaluation after an elevated serum creatinine (S_{Cr}) is noted.
- 5 Prevention is key; there are very few therapeutic options for the therapeutic management of established ARF.
- 6 Supportive management remains the primary approach to prevent or reduce the complications associated with ARF. Supportive therapies include: renal replacement therapies (RRTs), nutritional support, avoidance of nephrotoxins, and blood pressure and fluid management.
- 7 For those patients with prolonged or severe ARF, RRTs are the cornerstone of support and facilitate an aggressive approach to fluid, electrolyte and waste management.
- 8 Diuretic resistance is a common phenomenon in the patient with ARF and can be addressed with aggressive sodium restriction, combination diuretic therapy, or a continuous infusion of a loop diuretic.
- 9 Drug-dosing regimens for ARF patients receiving intermittent hemodialysis (IHD) are predominantly extrapolated from data derived from patients with chronic kidney disease (CKD); however, important pharmacokinetic differences exist in patients with ARF that should be considered.
- 10 Drug dosing guidelines for ARF patients receiving continuous renal replacement therapies (CRRTs) are poorly characterized and individualized doses may need to be determined by esti-

imating the clearance of medications associated with a high risk of toxicity by the patient and the CRRT procedure.

The development of acute renal failure (ARF) presents a difficult challenge to the clinician because there are many possible causes and the onset is often asymptomatic. In the ambulatory setting, patients may not notice ARF symptoms for days to weeks. Changes in clinical and laboratory markers of its presence can be subtle and are often overlooked. Despite its often insidious presentation, the consequences of ARF can be serious, especially in hospitalized patients, among whom mortality rates of up to 60% have been reported.^{1,2}

Supportive therapy is the focus of management for those with established ARF, as there is no therapy that directly reverses the injury associated with the numerous causes of ARF. Management goals include maintenance of blood pressure, fluid, and electrolyte homeostasis, all of which may be dramatically altered in the presence of ARF. Additional therapies designed to eliminate or minimize the insult that precipitated ARF include discontinuation of the offending drug (i.e., the nephrotoxin), cardiac support of the failing heart, removal of the obstruction from the urinary collection system, corticosteroids to minimize any intrinsic inflammatory process, antibiotic therapy to treat any infection, or other specific maneuvers to limit or reverse the kidney injury. Because of the poor clinical outcomes and lack of specific therapies, the importance of preventing ARF cannot be overemphasized. Individuals at highest risk, such as those with chronic kidney disease (CKD) and the elderly with chronic medical conditions, need to be identified and their exposure to harmful diagnostic or therapeutic procedures or medications minimized.

Renal replacement therapies (RRTs) such as hemodialysis and peritoneal dialysis have been available for decades, but have not resulted in dramatic improvements in the outcomes of patients with ARF. However, newer RRT modalities including an array of continuous renal replacement therapies (CRRTs) appear to offer some benefits, although available resources may limit their use and drug dosing is handicapped by a paucity of data. Careful patient monitoring for response to these therapies and attention to pharmacokinetic alterations make it possible to develop rational drug-dosing regimens for these complex patients. Despite the supportive care that CRRTs offer, development of ARF is frequently a catastrophic event. In this chapter, the epidemiology and multiple etiologies of ARF, as well as the clinical features associated with the most common types of ARF, are presented. Methods to recognize and identify the extent of functional loss are also discussed. Finally preventative strategies and management approaches for those with established ARF are reviewed.

Learning objectives, review questions, and other resources can be found at

DEFINITION OF ACUTE RENAL FAILURE

ARF is broadly defined as a decrease in glomerular filtration rate (GFR), generally occurring over hours to days, sometimes over weeks,

that is associated with an accumulation of waste products, including urea and creatinine. This relatively abrupt decline in renal function is in contrast to CKD, which is defined by the presence of proteinuria/albuminuria for at least 3 months, in combination with a GFR of <90 mL/min/1.73 m².³ A decrease in urine output is often observed, but is not required for ARF to be present.⁴ Compared to a normal urine output of $\geq 1,200$ mL/day, patients with ARF are often categorized as being anuric (urine output <50 mL/day), oliguric (urine output <500 mL/day), or nonoliguric (urine output >500 mL/day).

Currently, there is no universally accepted definition of ARF in clinical practice: in fact, more than 30 definitions for ARF are reported in the medical literature.⁵ Many of these definitions incorporate selective aspects of ARF observed in different patient populations. Comparisons between studies that describe incidences, treatment effects, and patient outcomes can thus be difficult, if not impossible to interpret. Although a serum creatinine (S_{cr}) or calculated creatinine clearance (Cl_{cr}) may not provide a reliable characterization of renal function in all ARF situations, clinicians frequently use some combination of the absolute S_{cr} value, change in S_{cr} value over time, and/or urine output as the primary criteria for diagnosing the presence of ARF.^{4,6} The commonly used and highly variable definitions for ARF are nonspecific and open to various interpretations. On a patient-by-patient basis, the semantics of the ARF definition are relatively meaningless. However, to move the prevention and treatment of ARF forward, consistent definitions must be employed. Without them, clinicians will be unable to accurately use any data generated because the nonspecific classification of ARF will be an insurmountable barrier to the identification of who was studied, and hence, to whom the data apply. A means to standardize the various aspects of the clinical presentation is necessary to allow integration of the literature observations to bedside management. A new consensus-derived definition and classification system for ARF was recently proposed, and is currently being validated (Fig. 45–1).^{7,8} This three-tiered classification uses both GFR and urine output, plus two clinical outcomes that may occur subsequent to an episode of ARF as components of the paradigm. Definitions of risk of dysfunction (R), injury to the kidney

(I), and failure of the kidney (F) are outlined. The clinical outcomes of loss of function (L), and end-stage renal disease (E) complete the RIFLE acronym. Thus far, validation studies have confirmed the value of these criteria in predicting hospital mortality, although further assessment is still necessary.^{9,10}

EPIDEMIOLOGY

ARF is an uncommon condition in the community-dwelling, generally healthy population, with an annual incidence of approximately 0.02% (Table 45–1).¹¹ In individuals with preexisting CKD, however, the incidence may be as high as 13%. In nonhospitalized patients, dehydration, exposure to selected pharmacologic agents such as contrast media, and the presence of heart failure are associated with an increased risk of ARF. Additionally, trauma, rhabdomyolysis, vessel thrombosis, and drugs are common culprits in the development of ARF.¹¹ The pharmacologic agents commonly associated with ARF, including contrast media, chemotherapeutic agents, nonsteroidal antiinflammatory drugs (NSAIDs), angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and antiviral medications are discussed in detail in Chap. 49.^{11,12}

① The hospitalized individual is at high risk of developing ARF; the reported incidence is 7%.¹³ The incidence of ARF is markedly higher in critically ill patients, ranging from 6% to 23%.⁶ The high mortality rate related to ARF, which is reported to range from 35% to 80%, is a significant clinical concern that has been relatively unresponsive to therapeutic intervention over the last four decades. Although the relative contribution of ARF to mortality rates of the underlying disease states is unclear given that current illness and ARF cannot be reliably quantified, it is certain that the presence of ARF will independently contribute significantly to overall mortality.⁶ For survivors of ARF, subsequent morbidity or development of some degree of CKD is also a consideration. Although 90% of individuals recover enough renal function to live normal lives, approximately half of these are left with subclinical deficits. Five percent will not regain

TABLE 45-1 Incidence and Outcomes of Acute Renal Failure Relative to Where It Occurs

	Community-Acquired	Hospital-Acquired	ICU-Acquired
Incidence	Low (<1%)	Moderate (2%–5%)	High (6%–23%)
Cause	Single	Single or multiple	Multifactorial
Overall survival rate	70%–95%	30%–50%	10%–30%
Worsened outcome if:	RRT required Poor preadmission health Other failed organ systems	RRT required Poor preadmission health Ischemic ARF cause Other failed organ systems	Intrinsic renal disease Ischemic ARF cause Septic RRT required Poor preadmission health Other failed organ systems
Better outcome if:	Nonoliguric	Nonoliguric Nephrotoxic cause	Prerenal cause Postrenal cause Nonoliguric Nephrotoxic cause Hyperglycemia prevented

ARF, acute renal failure; RRT, renal replacement therapy.

sufficient renal function to live independently and thus require long-term peritoneal or hemodialysis or transplantation. An additional 5% will suffer from a progressive deterioration in kidney function after initial recovery, likely as a consequence of hyperfiltration and sclerosis of the remaining glomeruli.¹⁴

ETIOLOGY

2 The etiology of ARF can be divided into broad categories based on the anatomic location of the injury associated with the precipitating factor(s). The management of patients presenting with this disorder is largely predicated on identification of the specific etiology responsible for the patient's current acute kidney injury (Table 45–2). Traditionally, the causes of ARF have been categorized as (a) prerenal, which results from decreased renal perfusion in the setting of undamaged parenchymal tissue, (b) intrinsic, the result of structural damage to the kidney, most commonly the tubule from a ischemic or toxic insult, and (c) postrenal, caused by obstruction of urine flow downstream from the kidney (Fig. 45–2).

3 The most common cause of hospital-acquired ARF is prerenal ischemia as the result of reduced renal perfusion secondary to sepsis, reduced cardiac output, and/or surgery. Drug-induced ARF may account for 18% to 33% of in-hospital occurrences. Other risk factors for developing ARF while hospitalized include advanced age (>60 years of age), male gender, acute infection, and preexisting chronic diseases of the respiratory or cardiovascular systems.⁶

PATHOPHYSIOLOGY

PSEUDORENAL AND FUNCTIONAL ACUTE RENAL FAILURE

In selected situations there can be a rise in either the blood urea nitrogen (BUN) or the S_{cr} , suggesting presence of renal dysfunction when in fact GFR is not diminished. This could be the result of cross-reactivity with the assay used to measure the BUN or S_{cr} , or selective inhibition of the secretion of creatinine into the proximal tubular lumen (see Chap. 44). The initiation or discontinuation of such agents should be considered in the assessment for acute changes in renal function, and should be looked for as part of the work up in any patient who is suspected to have ARF.

In functional ARF, a decline in GFR secondary to a reduced glomerular hydrostatic pressure, which is the driving force for the formation of ultrafiltrate, can occur without damage to the kidney itself. The decline in glomerular hydrostatic pressure may be a direct consequence of changes in glomerular afferent (vasoconstriction)

and efferent (vasodilation) arteriolar circumference. These clinical conditions are most commonly seen in individuals who have reduced effective blood volume (e.g., heart failure, cirrhosis, severe pulmonary disease, or hypoalbuminemia) or renovascular disease (e.g., renal artery stenosis) and who cannot compensate for changes in afferent or efferent arteriolar tone. A decrease in efferent arteriolar resistance as the result of initiation of angiotensin-converting enzyme inhibitor or angiotensin receptor blocker therapy is a common cause of this syndrome. The hepatorenal syndrome is also included in this classification because the kidney itself may be damaged, and there is intense afferent arteriolar vasoconstriction leading to a decline in glomerular hydrostatic pressure. In all the above conditions, the urinalysis is no different from its baseline state and the urinary indices suggest prerenal azotemia.

Functional ARF is very common in individuals with heart failure who receive an angiotensin converting enzyme inhibitor or an angiotensin receptor blocker in an attempt to improve their left ventricular function. Because the decline in efferent arteriolar resistance resulting from the inhibition of angiotensin II occurs within days, if the dose of the angiotensin-converting enzyme inhibitor is increased too rapidly, a decline in GFR with a concomitant rise in the serum creatinine will be noticeable. If the increase in the serum creatinine is mild to moderate (an increase of less than 30% from baseline) the medication can be continued.

PRERENAL ACUTE RENAL FAILURE

Prerenal ARF results from hypoperfusion of the renal parenchyma, with or without systemic arterial hypotension. Renal hypoperfusion with systemic arterial hypotension may be caused by a decline in intravascular or effective blood volume that can occur in those with acute blood loss (hemorrhage), dehydration, hypoalbuminemia, or diuretic therapy. Renal hypoperfusion without systemic hypotension is most commonly associated with bilateral renal artery occlusion, or unilateral occlusion in a patient with a single functioning kidney. The initial physiologic responses to a reduction in effective blood volume by the body includes activation of the sympathetic nervous and the renin–angiotensin–aldosterone systems, and release of antidiuretic hormone if hypotension is present. These responses work together to directly maintain blood pressure via vasoconstriction and stimulation of thirst to increase fluid intake and the promotion of sodium and water retention. Additionally, GFR may be maintained by afferent arteriole dilation and efferent arteriole constriction. In concert, these homeostatic mechanisms are often able to maintain arterial pressure and renal perfusion, potentially averting the progression to ARF.¹⁵ If, however, the decreased renal perfusion is severe or prolonged, these compensatory mechanisms may be overwhelmed and ARF will then

Category	Abnormality Causing Acute Renal Failure	Possible Causes	Category	Abnormality Causing Acute Renal Failure	Possible Causes
Prerenal	Intravascular volume depletion resulting in arterial hypotension	Dehydration	Intrinsic	Vascular damage	Vasculitis
		Inadequate fluid intake			Polyarteritis nodosa
		Excessive vomiting, diarrhea or gastric suctioning			Hemolytic uremic syndrome-thrombotic thrombocytopenic purpura
		Increased insensible losses (e.g., fever, burns)			Emboli
		Diabetes insipidus			Atherosclerotic
		High serum glucose (glucosuria)			Thrombotic
		Overdiuresis			Accelerated hypertension
		Hemorrhage			Systemic lupus erythematosus
		Decreased cardiac output			Poststreptococcal glomerulonephritis
		Hypoalbuminemia			Antiglomerular basement membrane disease
		Liver disease			Ischemic
		Nephrotic syndrome			Hypotension
	Arterial hypotension (regardless of volume status)	Anaphylaxis		Vasoconstriction	
		Sepsis		Exogenous toxins	
		Excessive antihypertensive use		Contrast dye	
	Decreased cardiac output	Heart failure		Heavy metals	
		Sepsis		Drugs (amphotericin B, aminoglycosides, etc.)	
		Pulmonary hypertension		Endogenous toxins	
Isolated renal hypoperfusion	Aortic stenosis (and other valvular abnormalities)	Myoglobin			
	Anesthetics	Hemoglobin			
	Bilateral renal artery stenosis (unilateral renal artery stenosis in solitary kidney)	Drugs			
	Emboli	Penicillins			
	Cholesterol	Ciprofloxacin			
	Thrombotic	Sulfonamides			
	Medications	Infection			
	Cyclosporine	Viral			
	Angiotensin-converting enzyme inhibitors	Bacterial			
	Nonsteroidal antiinflammatory drugs	Prostatic hypertrophy, infection, cancer			
Radiocontrast media	Improperly placed bladder catheter				
Hypercalcemia	Anticholinergic medication				
Hepatorenal syndrome	Cancer with abdominal mass				
Postrenal	Bladder outlet obstruction	Retroperitoneal fibrosis			
		Nephrolithiasis			
		Nephrolithiasis			
	Ureteral	Oxalate			
		Indinavir			
		Sulfonamides			
	Renal pelvis or tubules	Acyclovir			
		Uric acid			

Although smaller vessels can also be obstructed by atheroemboli or thromboemboli, the damage is limited to the vessels involved, and the development of significant ARF is unlikely. However, these small vessels are susceptible to inflammatory processes that lead to microvascular damage and vessel dysfunction when the renal capillaries are affected. Neutrophils invade the vessel wall, causing damage that can include thrombus formation, tissue infarction, and collagen deposition within the vessel structure. Diffuse renal vasculitis can be mild or severe, with severe forms promoting concomitant ischemic acute tubular necrosis (ATN). The S_{cr} is usually elevated as the lesions are diffuse, and thus the area of damage is large. Accelerated hypertension that is not treated may also compromise renal microvascular blood flow, and thus cause diffuse renal capillary damage.

FIGURE 45-2. Physiologic classification of ARF. Blood flows through the afferent arteriole, to the glomerulus and exits through the efferent arteriole. The formation of glomerular ultrafiltrate is dependent on the surface area of the capillaries within the glomerular region, their permeability, and the net hydrostatic pressure across the capillary wall. A decrease in blood flow and renal perfusion can lead to a prerenal reduction in renal function. Under conditions in which renal blood flow is diminished, the kidney maintains glomerular ultrafiltration by vasodilating the afferent and vasoconstricting the efferent arterioles. Medications that may interfere with these processes might result in an abrupt decline in glomerular filtration. Damage to the glomerular or tubular regions leads to intrinsic ARF. Obstruction of urine flow once in the collecting tubule, ureter, bladder, or urethra is termed postrenal failure.

Glomerular Damage

Only 5% of the cases of intrinsic ARF are of glomerular origin. The glomerulus is one of two capillary beds in the kidney, and serves to filter fluid and solute into the tubules while retaining proteins and other large blood components in the intravascular space. Because it's a capillary system, glomerular damage can occur by the same mechanisms described for the renal vasculature, and one additional mechanism, that is, severe inflammatory processes specific to the glomerulus. The pathophysiology and specific therapeutic approaches used to combat the inflammatory processes are described in detail in Chap. 50.

Tubule Damage

Approximately 85% of all cases of intrinsic ARF are caused by ATN, of which 50% are a result of renal ischemia, often arising from an extended prerenal state. The remaining 35% are the result of exposure to direct tubule toxins, which can be endogenous (myoglobin, hemoglobin, or uric acid) or exogenous (contrast agents, heavy metals, or aminoglycoside antibiotics). The tubules located within the medulla of the kidney are particularly at risk from ischemic injury, as this portion of the kidney is metabolically active and thus has high oxygen requirements, yet even in the best of situations, receives relatively low oxygen delivery (as compared to the cortex). Thus, ischemic conditions caused by severe hypotension or exposure to vasoconstrictive drugs preferentially affect the tubules more than any other portion of the kidney.

The clinical evolution of ATN is characterized by the initial injury causing tubule epithelial cell necrosis or apoptosis, followed by an extension phase with continued hypoxia and an inflammatory response involving the nearby interstitium.¹⁷ The onset of ATN can occur over days to weeks, and rarely longer than that depending on the factors responsible for the damage to the tubular epithelial cells.¹⁸ Once tubular cells die, they slough off into the tubular lumen. The debris causes increased tubular pressure and reduces glomerular filtration.¹⁹ Additionally, the loss of epithelial cells leaves only the basement membrane between the filtrate and the interstitium, which results in dysregulation of fluid and electrolyte transfer across the tubular epithelium. Regard-

less of the etiology, tubular injury leads to a loss in the ability to concentrate urine, to defective distal sodium reabsorption, and, ultimately, to a reduction in the GFR.²⁰ Continued kidney hypoxia or toxin exposure after the original insult kills more cells, and propagates the inflammatory response and can extend the injury and delay the recovery process. With prolonged ischemia, the tubular epithelial cells in the corticomedullary junction are damaged and die. When the toxin or ischemia is removed, a maintenance phase ensues (typically 2 to 3 weeks), followed by a recovery phase (2 to 3 weeks) during which new tubule cells are regenerated. The recovery phase is associated with a notable diuresis, which requires attention to fluid balance to ensure that a secondary prerenal injury does not occur. However, if the ischemia or injury is extremely severe or prolonged, cortical necrosis may occur, preventing any tubule cell regrowth in the affected areas.

Interstitial Damage

The interstitium of the kidney is rarely the primary cause of end-stage renal disease (ESRD), but it can become severely inflamed and lead to ARF. Acute interstitial nephritis is most commonly caused by medications (see Chap. 49), or bacterial or viral infections.²¹ Up to 30% of cases have no identifiable cause.²² Whatever the inciting event, interstitial nephritis is characterized by lesions comprised of monocytes, macrophages, B cells, or T cells, clearly identifying an immunologic response as the injurious process affecting the interstitium.²³ Because of the interwoven nature of the interstitium and the tubules, the widespread inflammation and edema affect the function of the tubules, and may cause fibrosis if the administration of the nephrotoxin is not discontinued and inflammation quickly controlled.²⁴

POSTRENAL ACUTE RENAL FAILURE

Postrenal ARF may develop as the result of obstruction at any level within the urinary collection system from the renal tubule to urethra (see Table 45-2). However, if the obstructing process is above the bladder, it must involve both kidneys (one kidney in a patient with a single functioning kidney) to cause significant ARF. Bladder outlet

obstruction, the most common cause of obstructive uropathy, is often caused by a prostatic process (hypertrophy, cancer or infection) causing a physical impingement on the urethra and thereby preventing the passage of urine. It may also be the result of an improperly placed urinary catheter. Neurogenic bladder or anticholinergic medications may also prevent bladder emptying and cause ARF. The blockage may occur at the ureter level, secondary to nephrolithiasis, blood clots, a sloughed renal papillae, or physical compression by an abdominal process such as retroperitoneal fibrosis, cancer, or an abscess. Crystal deposition within the tubules from oxalate and some medications severe enough to cause ARF is uncommon, but is possible in patients with severe volume contraction and in those receiving large doses of a drug with relatively low urine solubility (see Chap. 49). In these cases, patients have insufficient urine volume to prevent crystal precipitation in the urine.²⁵ Extremely elevated uric acid concentrations from chemotherapy-induced tumor lysis syndrome should be minimized by the initiation of an aggressive fluid regimen and pharmacologic preventative therapies in at-risk patients. Wherever the location of the obstruction, urine will accumulate in the renal structures above the obstruction and cause increased pressure upstream. The ureters, renal pelvis, and calyces all expand, and the net result is a decline in GFR. If renal vasoconstriction ensues, a further decrement in GFR will be observed.

CLINICAL PRESENTATION

4 The initiating sign or symptom prompting the eventual diagnosis of ARF is highly variable, depending on the etiology. It may be an elevated S_{cr} , decreased urine output, blood in the urine, pain during voiding, or severe abdominal or flank pain. The first step is to determine if the renal complication is acute, chronic, or the result of an acute change in a patient with known CKD. BUN, potassium, phosphorous, and, potentially, magnesium concentrations in serum will likely become elevated and should be promptly evaluated. For those presenting in the outpatient environment it may be difficult to determine when the onset was as the initial presentation of ARF may have been asymptomatic. The onset of ARF may, in fact, trigger independently symptoms of a concurrent medical condition or excessive drug response from a renally eliminated agent.

PATIENT ASSESSMENT

A past medical history for renal disease-related chronic conditions, such as poorly controlled hypertension or diabetes mellitus, previous laboratory data documenting the presence of proteinuria or an elevated S_{cr} , and the finding of bilateral small kidneys on renal ultrasonography suggests the presence of CKD. A thorough medical history and a review of past medical records, if available, that includes recent procedures and illnesses, should be done as soon as possible. The medication and recent procedure history may suggest causes for acute interstitial nephritis or other nephrotoxic effects. An exhaustive review of their recent prescription, as well as nonprescription, complementary, and alternative medications, should be completed. Special attention should be focused on diuretics, NSAIDs, antihypertensives, recent contrast dye exposure and any other recent additions or changes in the patient's medications. Patients may have noticed an acute change in their voiding habits with an increase in urinary frequency or nocturia, both suggesting a urinary concentrating defect. A decrease in the force of the urinary stream may suggest an obstruction. The presence of cola-colored urine also often stimulates people to seek medical care and its presence is indicative of blood in the urine, a finding commonly associated with acute glomerulonephritis. The onset of flank pain is suggestive of a urinary stone; however, if bilateral, it may suggest swelling of the kidneys secondary to acute glomerulonephritis or acute interstitial nephritis. Complaints of severe headaches may suggest the presence of severe hypertension as a result of ARF. A recent

increase in the patient's weight or complaints of tight-fitting rings secondary to salt and water retention also may be helpful in defining the time of onset of renal failure.

Patients who develop renal insufficiency while hospitalized usually have an acute initiating event that can be identified from a review of the laboratory data, urine output record, and the medication administration and procedure records. In addition to its prognostic significance, changes in urine output may be helpful in characterizing the cause of the patient's ARF. Acute anuria is typically caused by either complete urinary obstruction or a catastrophic event (e.g., shock or acute cortical necrosis). Oliguria (<500 mL/day of urine output), which often develops over several days, suggests prerenal azotemia, whereas nonoliguric (>500 mL/day of urine output) renal failure usually results from acute intrinsic renal failure or incomplete urinary obstruction.

CLINICAL PRESENTATION OF ACUTE RENAL FAILURE

General

- Community-dwelling patients often are not in acute distress.
- Hospitalized patients may develop ARF after either a notable reduction in blood pressure or intravascular volume, significant insult to the kidney, or sudden obstruction after catheterization. Generally, an acute reduction in urine output coinciding with a rise in BUN and S_{cr} is observed.

Symptoms

- *Outpatient:* Change in urinary habits, sudden weight gain, or flank pain.
- *Inpatient:* Typically, ARF is recognized by clinicians before the patient, who may not experience any obvious symptoms.

Signs

- Patient may have edema; urine may be colored or foamy; orthostatic hypotension in volume-depleted patients, hypertension in the fluid-overloaded patient or in the presence of acute or chronic hypertensive kidney disease.

Laboratory Tests

- Elevations in the serum potassium, BUN, creatinine, and phosphorous, or a reduction in calcium and the pH (acidosis), may be present. The clinical findings are different based on the cause of the ARF.
- An increased serum white blood cell count may be present in those with sepsis-associated ARF, and eosinophilia suggests acute interstitial nephritis.
- Urine microscopy can reveal cells, casts, or crystals that help distinguish among the possible etiologies and/or severities of ARF.
- An elevated urine specific gravity suggests prerenal ARF, as the tubules are concentrating the urine. Urine chemistry also indicates the presence of protein, which suggests glomerular injury, and blood, which can result from damage to virtually any kidney structure.

Other Diagnostic Tests

- Renal ultrasonography or cystoscopy may be needed to rule out obstruction; renal biopsy is rarely used, and is reserved for difficult diagnoses.

A physical examination, including assessment of the patient's volume and hemodynamic status, is an important step in evaluating individuals with ARF. Table 45–3 lists common physical findings in patients with ARF. The physical exam should be thorough, as clues regarding the etiology of the patient's ARF can be evident from the patient's head (eye exam) to toe (evidence of dependent edema).

TABLE 45-3 Physical Examination Findings in Acute Renal Failure

Physical Examination Finding	Possible Diagnosis	Category of Acute Renal Failure
Vital signs		
Orthostatic hypotension	Volume depletion	Prerenal
Febrile	Sepsis	Intrinsic—tubule necrosis
Skin		
Tenting	Volume depletion	Prerenal
Rash	Hypersensitivity reaction	Intrinsic—interstitial nephritis
Petechiae	Thrombotic thrombocytopenic purpura	Intrinsic—vasculitis
	Hemolytic uremic syndrome	
	Sepsis	Intrinsic—tubule necrosis
Splinter hemorrhages	Endocarditis	Intrinsic—glomerulonephritis
Janeway lesions		
Osler nodes		
Edema	Total-body volume overload	Intrinsic or prerenal because of heart failure Other types of prerenal unlikely
HEENT		
Hollenhorst plaque	Cholesterol emboli	Intrinsic—vascular
Roth spots	Endocarditis	Intrinsic—glomerulonephritis
Elevated jugular venous pressure	Heart failure	Prerenal
	Pulmonary hypertension	
Heart		
S ₃ heart sound	Heart failure	Prerenal
New or increased murmur	Endocarditis	Intrinsic—glomerulonephritis
Lung		
Rales	Heart failure	Prerenal
Abdomen		
Renal artery bruit	Renal artery stenosis	Prerenal
Ascites	Liver failure or right-heart failure	Prerenal Hepatorenal syndrome
Bladder distension	Bladder outlet obstruction	Postrenal
Genitourinary		
Prostatic enlargement	Prostatic hypertrophy or cancer	Postrenal
Gynecologic		
Abnormal bimanual examination	Possible bilateral ureteral obstruction or cervical cancer	Postrenal

HEENT, head, eyes, ears, nose, and throat.

Observations will either support or refute the cause as prerenal, intrinsic or postrenal. In those with prerenal ARF, low effective arterial blood volume may be evidenced by the presence of postural hypotension and decreased jugular venous pressure (JVP). Fluid overload as a consequence of ATN on the other hand is often reflected by rales in the lower lung fields and/or the presence of peripheral edema. If ascites or pulmonary edema is present, the effective arterial blood volume perceived by the kidneys may be low and thus suggest the diagnosis of functional ARF.

When the interstitium of the kidney is damaged (e.g., acute allergic interstitial nephritis), the concentrating gradient within the kidney may be attenuated and ammonia handling disrupted, resulting in a very dilute-appearing urine. Consequently, patients presenting with acute interstitial nephritis frequently are unable to concentrate the urinary solutes. Blood pressure should be evaluated for elevations that may accompany intrinsic renal damage. Any recent history of an infection may suggest postinfective glomerulonephritis. Although uncommon, thromboembolism occurring in the renal artery or vein can potentially result in ischemic damage, and should be a component of the physical assessment. Physical examination may detect

TABLE 45-4 Diagnostic Parameters for Differentiating Causes of Acute Renal Failure

Laboratory Test	Prerenal Azotemia	Acute Intrinsic Renal Failure	Postrenal Obstruction
Urine sediment	Normal	Casts, cellular debris	Cellular debris
Urinary RBC	None	2–4+	Variable
Urinary WBC	None	2–4+	1+
Urine sodium	<20	>40	>40

Urine/serum osmolality	>1.5	<1.3	<1.5
Urine/S _{cr}	>40:1	<20:1	<20:1
BUN/S _{cr}	>20	~15	~15

ARF, acute renal failure; BUN, blood urea nitrogen; FE_{Na}, fractional excretion of sodium; S_{cr}, serum creatinine; RBC, red blood cell; WBC, white blood cell.

Common laboratory tests are used to classify the cause of ARF. Functional ARF, which is not included in this table, would have laboratory values similar to those seen in prerenal azotemia. However, the urine osmolality-to-plasma osmolality ratios may not exceed 1.5, depending on the circulating levels of antidiuretic hormone. The laboratory results listed under acute intrinsic renal failure are those seen in acute tubular necrosis, the most common cause of acute intrinsic renal failure.

possible postrenal obstruction, such as the presence of a urinary catheter, an enlarged prostate in males or cervical/uterine abnormalities in females. Renal artery stenosis can be identified via Doppler ultrasound by measuring changes in flow distal to the narrowing if visible, or by computed tomography (CT) angiography, which can describe the anatomy of the renal vessels.

LABORATORY TESTS AND INTERPRETATION

The commonly available laboratory tests used to evaluate the patient with renal insufficiency are described in Chap. 44, and those of particular value in the assessment of renal function in patients with ARF are highlighted in Table 45–4. There is currently no consensus on the degree and time frame of changes in S_{cr} values that clearly defines the presence of ARF. The difficulty of using S_{cr} as a diagnostic laboratory test for patients with ARF is its lack of sensitivity to rapid changes in GFR. An abrupt cessation in glomerular filtration will not yield an immediate measurable change in S_{cr}. The reasons for this are: creatinine generation and accumulation is relatively slow, there is a lag time between test and clinical event, lab tests may not be very sensitive to small changes in GFR, and fluid retention that commonly accompanies ARF dilutes the retained creatinine.²⁶ Additionally, when decreased filtration of creatinine occurs, functional tubules can increase the secretion of creatinine into the urine, further complicating the interpretation of S_{cr}.

An example of this phenomenon is illustrated by an acute renal artery thrombus that results in abrupt cessation of GFR in one kidney as a consequence of the complete obstruction of blood flow to that kidney (Fig. 45–3). Although 5 minutes following the event GFR is decreased 50% (assuming the other kidney is functioning and unaffected), the serum creatinine remains unchanged. Assuming a standard daily creatinine production of approximately 20 mg/kg of lean body weight, one can expect approximately 1.4 g of creatinine production in a 24-hour period in a 70-kg individual. In pharmacokinetic terms, daily creatinine production is analogous to a continuous infusion, and GFR determines the elimination rate of creatinine. In the patient with normal renal function (GFR of 120 mL/min), the half-life of creatinine is 3.5 hours with 95% of steady state achieved in approximately 14 hours. If GFR declines to 60, 30, or 12 mL/min, the half-life of creatinine increases, resulting in prolongation of the time to reach 95% of steady state, specifically taking 1, 2, and 4 days, respectively.²⁷

Other biomarkers for acute renal injury and failure are being explored. One such marker, serum cystatin C (see Chap. 44) has been explored as a more sensitive and rapid means to detect renal dysfunction and injury.²⁸ Although an elevation in serum creatinine or

FIGURE 45-3. Glomerular filtration rate (GFR; mL/min) and serum creatinine (S_{cr} ; g/dL) versus time following acute renal injury. Prior to time 0, a GFR of 120 mL/min and a S_{cr} of 1.0 g/dL exist. At time 0, an abrupt renal artery thrombus forms, depriving one kidney of renal blood flow. Composite GFR immediately declines by 50% to approximately 60 mL/min. However, S_{cr} does not increase immediately, as it is dependent on creatinine production and attainment of steady-state serum concentrations.

cystatin C may be clearly indicative of a reduction in renal function, these are not quantitative indices that allow one to ascertain the degree of remaining function the patient has. Although several methods, such as the Cockcroft-Gault or one of the Modification of Diet in Renal Disease equations (see Table 44-4), have been extensively used to estimate GFR in patients with CKD, they are not applicable for ARF patients with changing S_{cr} values because by the nature of the condition, renal function is unstable. In ARF, these equations can overestimate GFR when the ARF is worsening, and underestimate it when the ARF is resolving. To avoid missing changes in renal function when relying on equations to predict renal function, consider looking at the sequence of S_{cr} values to determine if renal function is potentially improving (values declining) or worsening (values rising). The most recent S_{cr} value reflects the time-averaged kidney function over the preceding time period. Assessment of urine output can assist in verifying observed serum laboratory values, as well as providing an up-to-the-moment means of identifying any changes in the kidney function. While dependent on several factors such as hydration status and medications, urine output measured over a finite period of time (e.g., 4 hours) is a useful short-term assessment of kidney function. An abrupt decline or increase compared to previous values is highly suggestive of a change in functional status. Because of the shortcomings associated with serum creatinine, urine output is an extremely useful parameter in the assessment of the patient with ARF. Anuria, defined as <50 mL/day of urine, suggests complete kidney failure. Conversely, oliguria (<17 mL/h urine output) certainly indicates kidney damage; however, some function is present. In the setting of ARF, any urine production >17 mL/h indicates the presence of nonoliguric ARF. Despite reasonable urine output, the quality of the urine being produced is not reliably composed of the expected waste products and solutes. Damaged tubules may allow substantial urine to be produced; however, the electrolyte, protein, and acid-base functions of the kidney may be severely compromised. For these reasons, urine output alone is an unreliable marker of kidney function.

Instead of using fixed numbers to determine renal function, changes in the value, even if it remains within the normal range, may indicate marked impairment of renal function. For example, patients with reduced creatinine production, such as those with low muscle mass either because of being bedridden for long periods of time or a concurrent emaciated state, may have very low baseline S_{cr} values (<0.6 mg/dL) and thus the presence of a gradual S_{cr} rise to normal values (0.8 to 1.2 mg/dL) may actually indicate reduced GFR. When coupled with a decline in urine output, this might suggest the presence of ARF. However, in the presence of improved nutrition and an expanding muscle mass, it may be a true representation of the person's current renal status. In contrast, a high S_{cr} value may be present if

drawn prior to removal of a postrenal obstruction, such as a nonfunctional Foley catheter, with liters of urine now being voided over a relatively short period of time (hours). S_{cr} and BUN are extensively removed during acute hemodialysis treatments, so when assessing any change in these parameters in the ARF patient, one must pay close attention to when the lab specimens were collected relative to the dialysis procedure.

Several mathematical approaches to estimate GFR in patients with unstable S_{cr} that incorporate the principles of creatinine accumulation and elimination have been proposed²⁹⁻³¹ and are discussed in detail in Chap. 44. These methods have not been extensively validated in the setting of acute alterations in renal function and their value for adjusting medication dosing is questionable. Additionally, these equations are complex, rendering bedside implementation difficult and highly likely to be complicated by calculation errors.

Another approach to measuring renal function when S_{cr} values alone are not reflective of function is to directly measure urine Cl_{cr} over a short period of time, such as 4 to 12 hours.³² Although potentially precise and fairly simple to do, accuracy is questionable because the urine output is generally low and if the collection is incomplete, the lost urine can have a dramatic impact on the clearance determination.

To facilitate its diagnosis and management, ARF can be classified into several broad categories based on precipitating factors (see Table 45-2). Traditionally this includes prerenal (resulting from decreased renal perfusion), acute intrinsic (resulting from structural damage to the kidney), and postrenal failure (obstruction of urine from removal). A fourth category, functional acute renal failure, is characterized by hemodynamic changes at the glomerulus independent of decreased perfusion or structural damage. Identifying the cause of ARF, which strongly influences potential outcomes and therapies, is of paramount importance.

Selected blood tests in addition to BUN and S_{cr} can be quite valuable in differentiating the cause of ARF and also contribute to optimal patient management. For example, infectious causes of ARF can be assessed using a complete blood cell count with differential. Serum electrolyte values are likely to be abnormal because of the acute decline of the kidney's ability to regulate electrolyte excretion, and particular attention should be paid to serum potassium and phosphorus values, which can be markedly elevated and cause life-threatening complications.

In individuals with normal renal function, the ratio between the BUN and S_{cr} is usually less than 15:1. In the presence of prerenal ARF, reabsorption of BUN exceeds that of creatinine and thus one often sees a ratio greater than 20:1. Given the limited usefulness of solely using S_{cr} or BUN concentrations to differentiate the etiology of ARF, urinary electrolytes and osmolality should be determined, and both a micro-

TABLE 45-5 Urine Analysis Findings as a Guide to the Etiology of Acute Renal Failure

Presence of	Suggestive of

Urobilinogen	Hemolysis-associated tubular necrosis

scopic and chemical analysis of the urine should be performed (Table 45–5). The finding of a high urinary specific gravity, in the absence of glucosuria or mannitol administration, suggests an intact urinary concentrating mechanism, and that the cause of the patient's ARF is likely prerenal azotemia. The presence of urinary protein is often difficult to interpret, especially in the setting of acute on chronic renal failure. A patient with CKD may have a baseline proteinuria, thus clouding the clinical presentation, unless this is known at the time of ARF assessment. Classically, proteinuria is a hallmark of glomerular damage. However, tubular damage can also result in proteinuria, as the tubules are responsible for reabsorbing small proteins that are normally filtered by all glomeruli. The presence of blood also results in a positive urine protein test, so this confounder must always be assessed for when a positive urine protein is obtained. Hematuria suggests acute intrinsic ARF secondary to glomerular or injury to other kidney tissue. On microscopic examination, the key findings are cells, casts, and crystals, and the presence of one or more of these suggests specific etiologies of the ARF (Table 45–6). The presence of crystals may suggest nephrolithiasis and a postrenal obstruction. If red blood cells or red blood cell casts are present, one should consider the presence of a physical injury to the glomerulus, renal parenchyma or vascular beds. The finding of white blood cells or white blood cell casts suggests interstitial inflammation (i.e., interstitial nephritis), which can be secondary to an allergic, granulomatous, or infectious process.

Simultaneous measurement of urine and serum electrolytes is also helpful in the setting of ARF (see Table 45–4). From these values a fractional excretion of sodium can be calculated. The equation for the calculation of the fractional excretion of sodium (FeNa) is:

$$\text{FeNa} = (\text{excreted Na}/\text{filtered Na}) \cdot 100 = (U_{\text{vol}} \cdot U_{\text{Na}})/(GFR \cdot S_{\text{Na}}) \cdot 100$$

where

$$GFR = (U_{\text{vol}} \cdot U_{\text{cr}})/(S_{\text{cr}} \cdot t)$$

Thus

$$\text{FeNa} = (U_{\text{Na}} \cdot S_{\text{cr}} \cdot 100)/(U_{\text{cr}} \cdot S_{\text{Na}})$$

where U_{vol} is urine volume; U_{cr} is urine creatinine concentration; U_{Na} is urine sodium; S_{cr} is serum creatinine concentration; S_{Na} is serum sodium concentration, which usually does not vary much; GFR is the glomerular filtration rate; and t is the time period over which the urine is collected.

The fractional excretion of sodium is one of the better diagnostic parameters to differentiate the cause of ARF. A low urinary sodium concentration (<20 mEq/L) and low fractional excretion of sodium (<1%) in a patient with oliguria suggest that there is stimulation of the sodium-retentive mechanisms in the kidney and that tubular function

TABLE 45-6 Differential Diagnosis of Acute Renal Failure on the Basis of Urine Microscopic Examination Findings

Urine Sediment	Suggestive of

is intact. These findings are most characteristic of prerenal azotemia. Unfortunately, diuretic use in the preceding days limits the usefulness of the fractional excretion of sodium calculation by increasing natriuresis, even in hypovolemic patients. The fractional excretion of urea (FeUrea), which can be calculated similarly to the FeNa, is sometimes used as an alternative means to assess tubule function.

The inability to concentrate urine results in a high fractional excretion of sodium (>2%), suggesting tubular damage is the primary cause of the intrinsic ARF. Diagnosing the type of ARF using fractional excretion of sodium is not absolute, as there are some intrinsic causes that can be associated with a low fractional excretion of sodium (e.g., contrast nephropathy, myoglobinuria, and interstitial nephritis). Highly concentrated urine (>500 mOsm/L) suggests stimulation of antidiuretic hormone and intact tubular function. These findings are consistent with prerenal azotemia.

DIAGNOSTIC PROCEDURES

When the source of renal failure is unclear after a history, physical examination, and assessment of laboratory values, then imaging techniques such as abdominal radiography (kidneys, ureters, and bladder), CT, or ultrasonography may be helpful. These may reveal small, shrunken kidneys indicative of CKD, and postrenal obstruction can often be identified with a renal ultrasonogram and/or CT scan. Renal ultrasonography is a useful means to detect obstruction or hydronephrosis. Nephrolithiasis as small as 5 mm, or narrowing of the ureteral tract can be detected by ultrasonography. No contrast dye is required, and it is noninvasive, simple, portable, and rapid to accomplish. In selected conditions under the guidance of a nephrologist, more invasive procedures, such as cystoscopy or biopsy, may be considered to detect the presence of malignancy, prostate hypertrophy, uterine fibroids, nephrolithiasis or ureterolithiasis.

If insertion of a urinary catheter into the patient's bladder after the patient has voided or attempted to void does not yield a large volume of urine (>500 mL), then one can usually exclude postrenal obstruction distal to the bladder as the cause of ARF. Cystoscopy with retrograde pyelography may be helpful if the possibility of obstruction exists, and the insertion of a catheter did not result in a significant volume of urine.

In cases in which the cause of ARF is not evident, renal biopsies are useful in determining the cause in the majority of patients.³³ Because of the associated risk of bleeding, a renal biopsy is rarely undertaken and should only be performed in those rare circumstances when a definitive diagnosis is needed to guide therapy, such as the precise etiology of glomerulonephritis (see Chap. 50).

PREVENTION AND TREATMENT

Acute Renal Failure

■ DESIRED OUTCOME

5 Given the dismal outcome of established ARF, prevention is critical. In some cases, the risk of developing ARF may be predictable, such as decreased perfusion secondary to abdominal surgery, coronary bypass surgery, acute blood loss in trauma, and uric acid nephropathy, where preventative strategies can be effective. When patients with risk factors for developing ARF are scheduled for surgery, the clinician should be aware that the likelihood of the patient developing ARF is high and consider preventative measures, including discontinuation of medications that may enhance the likelihood of renal damage (e.g., NSAIDs, angiotensin-converting enzyme inhibitors). Consequently the goals are (a) to prevent ARF, (b) avoid or minimize further renal insults that would worsen the existing injury or delay recovery, and (c) provide supportive measures until kidney function returns.

■ GENERAL APPROACH TO PREVENTION

The general approach to the prevention of ARF is dependent on the setting the patient is in. To prevent the development of ARF, healthcare professionals should educate the patient on preventative measures. The patient should receive guidance regarding their optimal daily fluid intake (approximately 2 L/day) to avoid dehydration, and if they are to receive any treatment that can pose a risk for insult to the kidney (e.g., chemotherapy or uric acid nephropathy). The patient's fluid balance can be evaluated by measuring acute changes in weight, as other typical sources for weight changes in an adult occur over more prolonged periods, and blood pressure changes. If the patient has a history of nephrolithiasis, they may benefit from dietary restrictions, depending on the type of stones that were present in the past. If a patient has a Foley catheter in place, proper care and monitoring needs to be performed to ensure that postobstructive ARF does not develop. Selected strategies to prevent drug-related ARF are discussed briefly below and in detail in Chap. 49.

■ NONPHARMACOLOGIC THERAPIES

There are many situations in which administration of a nephrotoxin cannot be avoided, such as when radiocontrast dye is to be administered. In these settings, one of several nonpharmacologic therapies can be employed in an attempt to prevent the development of ARF. Adequate hydration and sodium loading prior to radiocontrast dye administration have been shown to be beneficial therapies. A trial comparing infusions of 0.9% NaCl or 5% dextrose with 0.45% NaCl administered prior to radiocontrast dye infusion conclusively demonstrated that normal saline was superior in preventing ARF.³⁴ The intravenous solution infusion rate used in this study was 1 mL/kg per hour beginning the morning that the radiocontrast dye was going to be given, and all subjects were encouraged to drink fluids liberally as well. The benefits of 0.9% NaCl infusions have been found in similar studies,³⁵ suggesting this regimen should be used in all at-risk patients who can tolerate the sodium and fluid load. In addition to the correction of dehydration, saline administration may result in dilution of contrast media, prevention of renal vasoconstriction leading to ischemia, and avoidance of tubular obstruction. The results of one recent study suggest that hydration with sodium bicarbonate provides more protection than saline, perhaps by reducing the formation of pH-dependent oxygen free radicals.³⁶

In some cases, when nephrotoxic agent use cannot be avoided, there may be ways to administer them in a manner that reduces their nephrotoxic potential. A good example of this is the use of amphotericin B to treat fungal infections. Amphotericin is a highly nephro-

toxic agent, causing ARF in approximately 30% of patients who receive it.³⁷ However, there are many infections for which no good alternative treatment exists. The nephrotoxic potential of amphotericin B deoxycholate can be reduced significantly simply by slowing the infusion rate from a standard 4-hour infusion to a slower 24-hour infusion of the same dose.³⁸ In a patient with risk factors for the development of ARF, liposomal forms of amphotericin B can be used. These liposomal formulations are more expensive, but have been associated with a lower incidence of kidney damage.³⁹

Preventive Dialysis

A novel approach to reducing the incidence of nephrotoxicity associated with radiocontrast dye administration is to provide RRT prophylactically to patients who are at high risk of ARF. Hemofiltration initiated prior to and continued for 24 hours after dye administration has resulted in a significant reduction in mortality and a reduced need for dialysis.⁴⁰ In contrast, the use of hemodialysis within 1 hour of contrast dye infusion did not yield an improvement in nephrotoxicity rates, possibly because the toxicity caused by dye occurs within minutes of its administration.⁴¹ Overall, evidence to date does not support any consistent significant benefit with the routine use of extracorporeal blood purification to prevent radiocontrast dye-induced nephropathy over standard medical therapy.⁴²

■ PHARMACOLOGIC THERAPIES

Dopamine and Diuretics

Given the dismal outcome of established ARF, many drugs have been investigated for its prevention. Almost all of these approaches have been shown to be of little to no value. Low doses of dopamine (≤ 2 mcg/kg/min) increase renal blood flow and might be expected to increase GFR. Theoretically, this could be considered beneficial, as an enhanced GFR might flush nephrotoxins from the tubules, minimizing their toxicity. Furthermore, loop diuretics may decrease tubular oxygen consumption by reducing solute reabsorption.⁴³ Despite these theoretical suggestions, controlled studies have not supported these theories. Dopamine (2 mcg/kg/min) worsened renal perfusion indices compared to saline in a crossover study in patients with ARF.⁴⁴ A blinded and randomized trial conducted in patients who were undergoing cardiac surgery compared dopamine at 2 mcg/kg/min, furosemide at 0.5 mcg/kg/min, and a 0.9% NaCl given at initiation of surgery to determine whether any of these interventions is beneficial.⁴⁵ Postoperative increases in S_{cr} occurred significantly more often in the furosemide-treated patients than in the other two groups. Dopamine afforded no benefit compared to the 0.9% NaCl infusion, and thus also should not be used routinely in this manner.

CLINICAL CONTROVERSIES

Despite most studies not showing improved patient outcomes with its use, low-dose dopamine continues to be commonly used. The risks associated with dopamine use (extravasation and the potential for significant dosing errors) suggest that its use should be avoided whenever possible.

Giving low-dose dopamine infusions (≤ 2 mcg/kg/min) for the prevention of ARF is a surprisingly common practice given the paucity of data to support its use. Although most studies do report an increase in urine output when low-dose dopamine is administered, almost none report that this practice yields a benefit to the patient. A meta-analysis of all low-dose dopamine studies conducted from 1966 to 2000 concluded that low-dose dopamine does not prevent ARF and its use cannot be justified.⁴⁶

The use of diuretics to prevent nephrotoxicity may actually result in intravascular volume depletion and thereby increase the risk of ARF. A trial of forced diuresis, in which mannitol, furosemide, and/or dopamine were given, and the resultant urinary losses were replaced with intravenous solutions, found that diuretic use resulted in little benefit compared to the administration of IV solutions alone.⁴⁷ Interestingly, these investigators noted that patients who were unable to increase their urine output after diuretic administration were more likely to develop ARF than were patients who did respond to diuretics. While this unresponsiveness to diuretics might simply be an indication of preexisting kidney damage, similar reports have linked diuretic unresponsiveness to increased mortality rates in critically ill patients with ARF.⁴⁸

Fenoldopam

Fenoldopam mesylate is a selective dopamine A-1 receptor agonist that increases blood flow to the renal cortex that has been investigated for its ability to prevent the development of ARF in many settings including contrast dye induced nephropathy (CIN). Originally approved for use as an intravenous antihypertensive agent, several small studies suggested that fenoldopam had salutary properties for the prevention of drug-induced nephrotoxicity. The largest, multicenter, randomized, placebo-controlled trial of fenoldopam conducted to date in patients with CKD found that fenoldopam use did not reduce the risk of CIN.⁴⁹ Indeed, the CIN Consensus Working Panel stated that, fenoldopam along with dopamine, calcium channel blockers, atrial natriuretic peptide, and 1-arginine, were not effective preventative therapies to reduce the incidence of CIN.⁵⁰ However, a recent systematic review of randomized controlled trials of critically ill patients or those undergoing major surgery, revealed that fenoldopam significantly reduced the risk of acute kidney injury and the need for renal replacement therapy. This analysis suggests that fenoldopam may be a viable entity to prevent the development of ARF in some clinical settings.⁵¹ A prospective, appropriately powered trial will need to be performed to validate this observation.

Acetylcysteine

N-acetylcysteine is a thiol-containing antioxidant that may effectively reduce the risk of developing CIN in patients with pre-existing kidney disease, although a therapeutic benefit has not been consistently demonstrated.^{52,53} The mechanism for N-acetylcysteine's ability to reduce the incidence of contrast dye induced nephrotoxicity is not clear, but likely is due to its antioxidant effects. Given the consistent findings of its efficacy and its relatively low cost, N-acetylcysteine should be given to all patients at risk for CIN.^{52,54–57} The recommended N-acetylcysteine dosing regimen for prevention of CIN is 600 mg orally every 12 hours for 4 doses with the first dose administered prior to contrast exposure. Several other drugs have been investigated for the prevention of ARF with varying degrees of success.^{42,52,53}

Theophylline may reduce the incidence of CIN with an efficacy that is perhaps comparable to that reported in studies of N-acetylcysteine. However, findings are inconsistent across studies.⁵⁸ A large, well-designed trial that incorporates the evaluation of clinically relevant outcomes is required to more adequately assess the role of theophylline in CIN prevention.

Glycemic Control

Perhaps the most promising agent for the prevention of hospital-acquired ARF is a very old drug, but its use in the prevention of ARF is new. Van den Berghe et al. randomized patients in a surgical intensive care unit to receive either standard control (<200 mg/dL) or intensive glucose control measures (goal blood glucose concentrations of 80 to 110 mg/dL).⁵⁹ Tight blood glucose resulted in significant improvements in mortality and a 41% reduction in the

development of ARF. While it appears that blood glucose control was the key factor associated with the mortality benefit, the reduction in ARF may have been a consequence of the total dose of insulin used to treat the patient, suggesting a direct protective effect of insulin.⁶⁰ Strict glycemic control is recognized as an important goal for outpatient diabetics⁶¹; however, intensive insulin therapy may now also become the standard of care for all critically ill patients to prevent ARF and improve mortality.

MANAGEMENT

Established Acute Renal Failure

■ DESIRED OUTCOMES

Short-term goals include minimizing the degree of insult to the kidney, reducing extrarenal complications, and expediting the patient's recovery of renal function. The ultimate goal is to have the patient's renal function restored to their pre-ARF baseline.

■ GENERAL APPROACH TO TREATMENT

Prerenal sources of ARF should be managed with hemodynamic support and volume replacement. If the cause is immune related, as may be the case with interstitial nephritis or glomerulonephritis, appropriate immunosuppressive therapy must be promptly initiated. Postrenal therapy focuses on removing the cause of the obstruction. It is important to approach the treatment of established ARF with an understanding of the patient's comorbidities and baseline renal function. Loss of kidney function combined with other clinical conditions, such as cardiac and liver failure, are associated with higher mortality than that associated with the development of ARF alone.⁶² At times, the most efficacious remedy for ARF is management of the comorbid precipitating event. Appreciation of the baseline renal function is also important at the outset of ARF management, because the presence of CKD indicates the highest degree of renal function that can be attained after ARF resolution. Finally, the presence of CKD indicates that the kidneys have less reserve, and thus there is a greater likelihood that the individual may not fully recover from the current insult.

6 Once acute renal failure is established, the cause is known, and any specific therapy implemented, supportive care is the mainstay of ARF management regardless of etiology. RRT may be necessary to maintain fluid and electrolyte balance while removing accumulating waste products. The slow process of renal recovery cannot begin until there are no further insults to the kidney. In the case of ATN, the recovery process typically occurs within 10 to 14 days after resolution of the last insult. The recovery period will be prolonged if the kidney is exposed to repeated insults.

■ NONPHARMACOLOGIC

Initial modalities to reverse or minimize prerenal ARF include removal of medications associated with diminished renal blood flow or the physical removal of a prerenal obstruction. If dehydration is evident, then appropriate fluid replacement therapy, as described below, should be initiated. Moderately volume-depleted patients can be given oral rehydration fluids; however, if intravenous fluid is required, isotonic normal saline is the replacement fluid of choice, and large volumes may be necessary to provide adequate fluid resuscitation. Typically, IV fluid challenges are initiated with 250 to 500 mL of normal saline over 15 to 30 minutes with an assessment after each challenge of the patient's volume status. Unless profound dehydration is present, as may be seen in diabetic ketoacidosis or hyperosmolar hyperglycemic states, 1 to 2 L is usually adequate. Patients with diabetic ketoacidosis or a hyperosmolar hyperglycemic state often have a 10% to 15% total-body water deficit, and more

aggressive fluid replacement is necessary. The patient should be monitored for pulmonary edema, peripheral edema, adequate blood pressure (diastolic blood pressure >60 mm Hg), normoglycemia and electrolyte balance. Urine output may not be promptly observed, as the kidney continues to retain sodium and water until rehydration is achieved. Up to 10 L may be required in the septic patient during the first 24 hours, because of the profound increase in vascular capacitance and fluid leakage into the extravascular, interstitial space.⁶³

Patients with ARF on top of preexisting CKD should not be expected to produce urine beyond their preexisting baseline. In patients with anuria or oliguria, slower rehydration, such as 250-mL boluses or 100 mL/h infusions of normal saline, should be considered to reduce the risk for pulmonary edema, especially if heart failure or pulmonary insufficiency exists. Other replacement fluids may be considered if the dehydration is accompanied by a severe electrolyte imbalance amenable to large and relatively rapid infusions. For example, dehydration resulting from severe diarrhea is often accompanied by metabolic acidosis caused by bicarbonate losses. A reasonable IV rehydration fluid in this situation is 5% dextrose with 0.45% NaCl plus 50 mEq of sodium bicarbonate per liter, administered as boluses as described above, followed by a brisk continuous infusion (200 mL/h) until rehydration is complete, acidosis corrected, and diarrhea resolved. This fluid will remain mostly in the intravascular space, providing the necessary perfusion pressure to the kidneys, and also provide a substantial amount of bicarbonate to correct the acidosis.

If the prerenal ARF is a result of blood loss, or complicated by symptomatic anemia, red blood cell transfusion to a hematocrit no higher than 30% is the treatment of choice.⁶⁴ Although albumin is sometimes used as a resuscitative agent, its use should be limited to individuals with severe hypoalbuminemia (e.g., liver disease, nephritic syndrome) who are resistant to crystalloid therapy. These patients have severe hypoalbuminemia-associated third spacing that complicates fluid management, and albumin may be useful in this setting.

The most common interventions that must be made when treating patients with intrinsic or postobstructive ARF involve fluid and electrolyte management. Most patients with these types of ARF, as well as those with a prerenal cause who are excessively fluid resuscitated ultimately become fluid overloaded. This means drug infusions and nutrition solutions must be maximally concentrated. So-called keep vein open or maintenance intravenous infusions should be minimized unless the patient is euolemic or is receiving RRT to maintain fluid balance. Supportive care goals for the hospitalized patient with any type of ARF include maintenance of adequate cardiac output and blood pressure to allow adequate tissue perfusion. However, a fine balance must be maintained in anuric and oliguric patients unless the patient is hypovolemic or is able to achieve fluid balance via RRT. If fluid intake is not minimized, edema may rapidly develop, especially in hypoalbuminemic patients. In contrast, vasopressors, like dopamine at doses of ≥ 2 mcg/kg/min or norepinephrine when used to maintain adequate tissue perfusion, may also induce kidney hypoxia as the result of a reduction in renal blood flow. Consequently, Swan-Ganz monitoring may be necessary for critically ill patients (see Chap. 25).

7 Because there is no current definitive therapy for ARF, supportive management remains the primary approach to prevent or reduce associated complications or death. In the presence of severe ARF, RRTs are commonly prescribed to manage uremia, metabolic acidosis, hyperkalemia and complications of excess fluid retention, such as pulmonary edema or accumulation of renally cleared medications. Although precise indications for starting RRT are unclear, some general guidelines for therapy have been proposed (Table 45–7).

Renal Replacement Therapies

RRTs can be administered either intermittently or continuously. The optimal mode for hemodialysis is unclear, and varies depending on the clinical presentation of the patient. It is unclear in many

TABLE 45-7 The AEIOUs That Describe the Indications for Renal Replacement Therapy

Indication for Renal Replacement Therapy	Clinical Setting
A Acid-base abnormalities	Metabolic acidosis resulting from the accumulation of organic and inorganic acids
E Electrolyte imbalance	Hyperkalemia, hypermagnesemia
I Intoxications	Salicylates, lithium, methanol, ethylene glycol, theophylline, phenobarbital
O fluid Overload	Postoperative fluid gain
U Uremia	High catabolism of acute renal failure

situations if dialysis can improve survival in ARF. Some recent data suggest that more aggressive approaches using RRTs in a more liberal fashion may improve survival in critically ill ARF patients.⁶⁵ The choice of whether continuous therapies or intermittent RRTs are used is a matter of debate and is usually determined by physician preference and the resources available at the hospital.

Intermittent Hemodialysis

Intermittent hemodialysis (IHD) is the most frequently used RRT and has several advantages. IHD machines are readily available in most acute care facilities and healthcare workers are familiar with their use. Hemodialysis treatments usually last 3 to 4 hours with blood flow rates to the dialyzer typically ranging from 200 to 400 mL/min. Advantages of IHD include rapid removal of volume and solute, and rapid correction of most of the electrolyte abnormalities associated with ARF. IHD can be scheduled at times to maximize staffing availability and treatments per day per machine, while minimizing inconvenience to the patient. The primary disadvantage is hypotension, typically caused by rapid removal of intravascular volume over a short period of time. Venous access for dialysis can be difficult in hypotensive patients and can limit the effectiveness of IHD, leading to ineffective solute clearance, lack of acidosis correction, continued volume overload, and delayed recovery because of further renal ischemia insults. If hemodialysis is carefully monitored and hypotension avoided, better patient outcomes can be achieved.⁶⁶ Patients with stage 5 CKD generally achieve adequate solute and volume control with thrice-weekly dialysis, but hypercatabolic, fluid-overloaded patients with ARF may require daily hemodialysis treatments.⁶⁷ The use of daily versus thrice-weekly IHD in the setting of ARF patients is associated with a reduction in dialysis-related hypotension and a shorter period of time to full recovery of kidney function.⁶⁸ Chapter 48 provides a more detailed explanation of the principles and processes of hemodialysis.

Continuous Renal Replacement Therapies

In contrast to IHD, CRRTs that were developed over the past 15 years have proven to be a viable management approach for hemodynamically unstable patients with ARF.⁶⁹ Several CRRT variants have been developed, including continuous venovenous hemofiltration (CVVH), continuous venovenous hemodialysis (CVVHD), and continuous venovenous hemodiafiltration (CVVHDF). They differ in the degree of solute and fluid clearance that can be clinically achieved as a result of the use of diffusion, convection, or a combination of both. Although solute removal is slower, a greater amount can be removed over a 24-hour period compared to IHD, which is associated with improved outcomes in critically ill patients with ARF.⁷⁰

In CVVH, solute and fluid clearance is primarily a result of convection where passive diffusion of fluids containing solutes is removed while volume absent of the solutes is replaced to the patient (Fig. 45–4). Continuous venovenous hemodialysis (CVVHD) provides extensive solute removal primarily by diffusion, where solute molecules at a higher concentration (plasma) pass through the dialysis membrane to a lower concentration (dialysate) and some fluid is removed as a

FIGURE 45-4. Several RRTs are commonly utilized in ARF patients including one of the three primary CRRT variants: (a) continuous veno-venous hemofiltration (CVVH), (b) continuous veno-venous hemodialysis (CVVHD), (c) continuous veno-venous hemodiafiltration (CVVHDF), and the hybrid intermittent hemodialysis therapy (d) slow extended daily dialysis (SLEDD). The blood circuit in each diagram is represented in red, while the hemofilter/dialyzer membrane is yellow and the ultrafiltration/dialysate compartment is depicted in brown. Excess body water and accumulated endogenous waste products are removed solely by convection when CVVH is employed. With CVVHD, waste products are predominantly removed as the result of passive diffusion from the blood where they are in high concentration to the dialysate. The degree of fluid removal which is accomplished by convection is usually minimal. CVVHDF utilizes convection to a degree similar to that employed during CVVH as well as diffusion, and thus is often associated with the highest clearance of drugs and waste products. Finally, SLEDD employs lower blood and dialysate flow rates than IHD, but due to its extended duration it is a gentler means of achieving adequate waste product and fluid removal.

function of the ultrafiltration coefficient of the dialyzer. Because the dialysate flows in a countercurrent direction to the plasma flow on the other side of the membrane, the concentration gradient is maximized. This procedure is associated with a lower incidence of clotting than CVVH because of reduced hemoconcentration as there is less fluid removal during the process. CVVHDF combines both hemofiltration and hemodialysis, achieving even higher solute and fluid removal rates (Fig. 45-4). The ultrafiltration rate is an important determinant of the effectiveness of all three forms of CRRT: achievement of a removal rate of 35 mL/kg/h is associated with improved survival.⁷⁰

Because of the reduced blood flow rates relative to IHD, thrombosis is a significant concern with CRRT, and thus some form of anticoagulation is generally necessary for almost all patients. Typical anticoagulation is achieved by the administration of unfractionated heparin, or in some cases, a low-molecular-weight heparin, a direct thrombin inhibitor, or citrate solution.⁷¹ Replacement fluids can be infused either just before or after the dialyzer/hemofilter. Infusing fluids after the hemofilter can result in hemoconcentration within the filter, a factor associated with an increased risk of thrombosis of the dialyzer. Replacing fluids before the filter reduces thrombosis risk, but also reduces solute clearance.

Disadvantages of CRRT are that not all hospitals have the special equipment necessary to provide these treatments, they require intensive nursing care around the clock, and they are more expensive than IHD because of the need to individualize the intravenous replacement and dialysate fluids. There is also very little known about drug-dosing requirements for those who are receiving these therapies. CRRT use is most commonly considered for those patients with higher acuity because of their intolerance of IHD-associated hypotension. In one meta-analysis, no difference in clinical outcomes between the two approaches was seen until there was an adjustment for severity of illness. CRRT was then found to be associated with a lower mortality rate.⁷² Because patients treated with continuous therapies are almost always more critically ill than those treated by IHD, comparisons of outcome must control for illness severity.

CLINICAL CONTROVERSY

Some clinicians believe that CRRTs are preferable to IHD because they provide more consistent fluid and waste product removal. Others suggest that IHD is preferable because the nursing and medical staff is more familiar with its use and round-the-clock nursing is not needed. New hybrid approaches with slower removal over a prolonged time period may potentially appeal to both groups.

CRRT and hybrid extended-duration intermittent hemodialysis are now being commonly used for critically ill patients with ARF. With CRRT, more solute and water removal can be achieved than with the thrice-weekly hemodialysis treatments used for patients with ESRD. This has influenced how dialysis is prescribed in the intensive care unit for hypercatabolic patients with ARF. Daily IHD is associated with improved survival and faster resolution of ARF compared to dialysis given every other day.⁶² Daily delivery of IHD presents challenges to clinicians prescribing drug and nutrition therapy, as most of these dosing guidelines are based on thrice-weekly dialysis, and application of these guidelines may yield inappropriate outcomes.

Hybrid IHD therapies have a variety of names, with the two most common being sustained low-efficiency dialysis⁷³ and slow, extended, daily dialysis (see Fig. 45–4).⁷⁴ These therapies use slower blood (150 to 200 mL/min) and dialysate flow rates (300 mL/min) with extended treatment periods of 6 to 12 hours. Unlike CRRT, these therapies do not require any new equipment.⁷⁴ Anticoagulation is still required, but the amount necessary compared to CRRT is lower.⁷⁴ Although the use of hybrid hemodialysis therapies is increasing, our knowledge of the impact of these therapies on drug removal is very limited.^{75,76}

■ PHARMACOLOGIC

Once the kidney has been damaged by an acute insult (e.g., reduced perfusion or exposure to exogenous or endogenous nephrotoxins), initial therapies should be directed to prevent further insults to the kidney, thereby minimizing extension of the injury.²⁰ If sepsis is present, antibiotic therapy regimens should be adjusted for decreased renal elimination, the potential for increased elimination if the agent is removed by hemodialysis, and the ability to treat the infection to prevent further damage to the kidney. The time to recovery from ARF is determined from the most recent insult to the kidney, not the first insult. Hospitalized patients with ARF are at high risk for repeated episodes of kidney injury as the result of repeated exposures to nephrotoxic agents and hypotensive episodes, among other problems. These increased risks, coupled with the fact that no drugs have been found to accelerate ARF recovery, dictate the way clinicians approach the ARF patient.

To date, no pharmacologic approach to reverse the decline or accelerate the recovery of renal function has been proven to be clinically useful. Many agents have looked promising in animal trials, only to be

found ineffective in human trials. Numerous agents have been investigated and shown no benefit in the treatment of established ARF.⁷⁷ In recent years thyroxine,⁷⁸ dopamine,^{79,80} and loop diuretics^{47,81,82} have all been documented to either be of no help or to worsen patient outcomes. For example, a 77% increase in mortality or nonrecovery of renal function was reported in patients with ARF who received a loop diuretic compared to patients who did not receive loop diuretics.⁴⁷ These findings may be explained by the fact that sicker, fluid-overloaded patients may be more likely to receive diuretics, nonetheless no benefit to loop diuretic use could be found in any subanalysis. Consequently, loop diuretic use should be reserved for fluid-overloaded patients who make adequate urine in response to diuretics to merit their use.⁸¹ Prevention of pulmonary edema is an important goal, and it is preferable that it be accomplished with diuretics instead of more invasive RRTs, despite the previously mentioned finding that diuretic use may be associated with diminished outcomes.⁴⁷ The most effective drugs in producing diuresis in the patient with ARF, mannitol and the loop diuretics, have distinct advantages and disadvantages. Mannitol, which works as an osmotic diuretic, can only be given parenterally. A typical starting dose is mannitol (20%) 12.5 to 25 g infused intravenously over 3 to 5 minutes. It has little nonrenal clearance, so when given to anuric or oliguric patients, mannitol will remain in the patient, potentially causing a hyperosmolar state. Additionally, mannitol may cause ARF itself, so its use in ARF must be monitored carefully by measuring urine output and serum electrolytes and osmolality.⁸³ Because of these limitations of mannitol, some clinicians recommend that it be reserved for the management of cerebral edema.⁸⁴

Furosemide, bumetanide, and torsemide are the most frequently used loop diuretics in patients with ARF. Ethacrynic acid is typically reserved for patients who are allergic to sulfa compounds. Furosemide is the most commonly used loop diuretic because of its lower cost, availability in oral and parenteral forms, and reasonable safety and efficacy profiles. A disadvantage with furosemide is its variable oral bioavailability in many patients and potential for ototoxicity with high serum concentrations that may be attained with rapid, high-dose bolus infusions. Consequently, initial furosemide doses, which should not exceed 40 to 80 mg, are usually administered intravenously to assess whether the patient will respond. Torsemide and bumetanide have better oral bioavailability than furosemide. Torsemide has a longer duration of activity than the other loop diuretics, which allows for less-frequent administration but which also may make it more difficult to titrate the dose. Loop diuretics all work equally well provided that they are administered in equipotent doses. In a patient who is unresponsive to aggressive intravenous loop diuretic therapy, switching to another loop diuretic is unlikely to be beneficial.

Diuretic Resistance

8 Inability to respond to administered diuretics is common in ARF and is associated with a poor patient outcome (Table 45–8).⁴⁷ An effective technique to overcome diuretic resistance is to administer loop diuretics via continuous infusions instead of intermittent boluses. Less natriuresis occurs when equal doses of loop diuretics are given as a bolus instead of as a continuous infusion. Furthermore, adverse reactions from loop diuretics (myalgia and hearing loss) occur less frequently in patients receiving continuous infusion compared to those receiving intermittent boluses, ostensibly because higher serum concentrations are avoided. However, these adverse effects still may occur with continuous infusion of loop diuretics and should be monitored.⁸⁵ The finding that the continuous infusions of loop diuretics have efficacy that is at least as good as intermittent bolus dosing, with fewer adverse effects, appears to be consistent for all agents, including furosemide,⁸⁶ bumetanide,⁸⁷ and torsemide.⁸⁸ When a continuous loop diuretic infusion is used, an initial loading dose is given (equivalent to furosemide 40 to 80 mg) prior to the initiation of a continuous infusion at 10 to 20 mg/h of furosemide or its equivalent. Patients with low

TABLE 45-8 Common Causes of Diuretic Resistance in Patients with Acute Renal Failure

Causes of Diuretic Resistance	Potential Therapeutic Solutions
Excessive sodium intake (sources may be dietary, IV fluids, and drugs)	Remove sodium from nutritional sources and medications
Inadequate diuretic dose or inappropriate regimen	Increase dose, use continuous infusion or combination therapy
Reduced oral bioavailability (usually furosemide)	Use parenteral therapy; switch to oral torsemide or bumetanide
Nephrotic syndrome (loop diuretic protein binding in tubule lumen)	Increase dose, switch diuretics, use combination therapy
Reduced renal blood flow	
Drugs (NSAIDs ACEIs, vasodilators)	Discontinue these drugs if possible
Hypotension	Intravascular volume expansion and/or vasopressors
Intravascular depletion	Intravascular volume expansion
Increased sodium resorption	
Nephron adaptation to chronic diuretic therapy	Combination diuretic therapy, sodium restriction
NSAID use	Discontinue NSAID
Heart failure	Treat the heart failure, increase diuretic dose, switch to better-absorbed loop diuretic
Cirrhosis	High-volume paracentesis
Acute tubular necrosis	Higher dose of diuretic, diuretic combination therapy, add low-dose dopamine

ACEIs, angiotensin-converting enzyme inhibitors; NSAIDs, nonsteroidal antiinflammatory drugs.

creatinine clearances may have much lower rates of diuretic secretion into the tubular fluid; consequently, higher doses are generally used in patients with renal insufficiency.⁸⁴ Diuretic resistance may occur simply because excessive sodium intake overrides the ability of the diuretics to eliminate sodium. However, other reasons for diuretic resistance often exist in this population. Patients with ATN have a reduced number of functioning nephrons on which the diuretic may exert its action. Other clinical states, like glomerulonephritis, are associated with heavy proteinuria. Intraluminal loop diuretics cannot exert their effect in the loop of Henle because they are extensively bound to proteins present in the urine. Still other patients may have greatly reduced bioavailability of oral furosemide because of intestinal edema, often associated with high preload states, which further reduces oral furosemide absorption. Table 45-8 includes possible therapeutic options to counteract each form of diuretic resistance. Combination therapy of loop diuretics plus a diuretic from a different pharmacologic class may be an alternative approach in the setting of ARF.⁸⁹ Loop diuretics increase the delivery of sodium chloride to the distal convoluted tubule and collecting duct. With time, these areas of the nephron compensate for the activity of the loop diuretic and increase sodium and chloride resorption. Diuretics that work at the distal convoluted tubule (chlorothiazide and metolazone) or the collecting duct (amiloride, triamterene, and spironolactone) may have a synergistic effect when administered with loop diuretics by blocking the compensatory increase in sodium and chloride resorption. The combination of loop diuretics and usual doses of thiazide diuretics may be effective in renal disease despite the accumulation of endogenous organic acids in renal disease that blocks the transport of loop diuretics into the lumen. If oral thiazides cannot be given to the patient, chlorothiazide 500 mg can be administered parenterally.

Several drug combinations with loop diuretics have been investigated, including the addition of one or more of the following: theophylline, acetazolamide, spironolactone, thiazides, or metolazone.⁸³ Of these combinations, oral metolazone is used most frequently with furosemide. Metolazone, unlike other thiazides, produces effective diuresis at a GFR below 20 mL/min. This combination of metolazone and a loop diuretic has been used successfully in the management of fluid overload in patients with heart failure, cirrhosis, and nephrotic syndrome. Despite a lack of supporting evidence, oral metolazone at a

dose of 5 mg is commonly administered 30 minutes prior to an intravenous loop diuretic to allow time for absorption. Additionally, this combination has been found to be efficacious in pediatric patients in addition to adults.⁹⁰ The combination of mannitol plus intravenous loop diuretics is used by some practitioners,⁵¹ but no convincing evidence of the superiority of this combination regimen to conventional dosing of either diuretic alone exists.

■ ELECTROLYTE MANAGEMENT

Hyponatremia and fluid retention are frequent complications of ARF, and thus sodium restriction is a necessary intervention. In general, patients should receive no more than 3 g of sodium per day from all sources, including intravenous fluids, drugs, and enteral intake. Clinicians should be vigilant about sources of sodium. Excessive sodium intake is a common reason diuretic therapy fails. Commonly administered intravenous antibiotics, as well as other medications, may contain significant amounts of sodium; for example, 1 L of 0.9% NaCl yields 154 mEq (3.5 g) of sodium. At usual doses, intravenous metronidazole provides 1.3 g of sodium per day, ampicillin up to 800 mg, piperacillin approximately 700 mg, and fluconazole 500 mg. The cumulative effect of a few sodium-containing medications and fluids can be significant.

In continuous and intermittent RRTs there usually is less concern about hyponatremia developing because these therapies often incorporate isonatremic (135 to 140 mEq/L of sodium) solutions as the dialysate or ultrafiltrate replacement solutions. Serum sodium concentrations should be monitored daily. Hyperkalemia, hyperphosphatemia, and, to a lesser extent, hypermagnesemia are electrolyte disorders that are frequently seen in patients with ARF. This is generally not a serious concern in those who are receiving RRT, but electrolytes should be monitored closely in all patients with ARF.

The most common electrolyte disorder encountered in ARF patients is hyperkalemia, as more than 90% of potassium is renally eliminated. Life-threatening cardiac arrhythmias may occur when the serum potassium is over 6 mmol/L, so potassium restriction is essential. All patients with ARF should have serum potassium monitored at least daily, and twice daily for those who are seriously ill. This frequency is a consequence of the seriousness of the potential arrhythmias, the dynamic nature of potassium serum concentrations in the acutely ill patient, the potential for metabolic acidosis leading to increased extracellular potassium concentrations, and potassium's ubiquitous presence in foods and some medications. Commonly encountered medications that contain substantial amounts of potassium include oral phosphorous replacement powders (e.g., Neutra-Phos and Neutra-Phos-K) and alkalizers (Polycitra). Many foods are high in potassium, including potatoes, beans, and various fruits. Some medications may promote potassium retention by the kidneys, and should also be avoided or closely monitored (see Chap. 54). Typically no potassium should be added to parenteral solutions unless hypokalemia is documented. Patients receiving enteral nutrition should be limited to a 3-g potassium diet. Patients receiving RRT should also have their serum potassium concentration measured at least daily. Some centers add no potassium to their CRRT solutions and hypokalemia can result unless one is prospectively monitoring for its development. Chapter 54 discusses the treatment of hyperkalemia in detail.

Other electrolytes that require monitoring include phosphorous and magnesium. Both are eliminated by the kidneys and are not removed efficiently by dialysis. In the early stages of ARF, hyperphosphatemia might be more common than hypophosphatemia. Patients who have significant tissue destruction (e.g., trauma, rhabdomyolysis, tumor lysis syndrome) may have significant phosphorus released from the destroyed tissue. Treatment of the hyperphosphatemic state can include CRRT. Calcium-containing antacids should be avoided to prevent precipitation of calcium phosphate in the soft tissues. Typically, the dietary intake of phosphorous and magnesium is restricted,

but in patients receiving prolonged renal replacement, deficiency states can occur, particularly in pediatric patients because of their reduced body stores. In contrast to the patient with CKD, calcium balance is usually not an important issue for the ARF patient because of the limited duration of the illness. One exception to this is in patients who are receiving CRRT with citrate as the anticoagulant. Citrate binds to serum calcium and without an adequate concentration of calcium, blood cannot form a clot. Citrate is thus typically infused before the dialyzer/hemofilter to maintain the dialyzer circuit calcium levels between 0.35 and 0.50 mmol/L. Calcium chloride (10 g of CaCl diluted in 500 mL normal saline), or gluconate (20 g of calcium gluconate to 500 mL normal saline) is then administered prior to returning the blood to the patient to maintain systemic ionized calcium levels between 1.11 to 1.31 mmol/L.⁹² The citrate that reaches the systemic circulation is subsequently metabolized by the liver. Severe hypocalcemia can result in arrhythmias, and even death, so frequent monitoring of unbound serum calcium concentrations is essential.

■ NUTRITIONAL INTERVENTIONS

Baseline nutritional status is a strong predictor of outcomes in patients with ARF.⁹³ The provision of enteral nutrition to patients with ARF in intensive care units is associated with an improvement in outcomes.⁹⁴ Parenteral nutrition, however, has not demonstrated the same benefit and some have questioned whether it should be used in this population.⁹⁵ (see Chapter 147 for a detailed discussion.)

Because fluid intake often must be restricted in severely volume-overloaded ARF patients, the design and provision of adequate parenteral or enteral nutrition are problematic (see Chap. 147). Septic patients with ARF usually are hypercatabolic and normalized protein catabolic rates of up to 1.75 g/kg/day have been reported, but this value varies widely among patients.⁹⁶ Most patients with ARF have difficulty tolerating the amount of intravenous fluid required to replace catabolized protein unless they are receiving CRRT or daily hemodialysis.

Although patients with ARF typically experience elevated levels of potassium, magnesium, and phosphorus, which often necessitate restriction of these from nutrition formulas, it is not uncommon for deficiency states to occur in patients receiving CRRT, despite incorporation of these electrolytes into the replacement fluid solutions. The effect of CRRT on the delivery and removal of macro- and micronutrients must also be taken into account. The dextrose contained in CRRT replacement solutions may contribute a significant amount of calories to the patient's regimen. The removal of protein during dialysis, especially during peritoneal dialysis, may necessitate an increase of the protein intake up to 2.5 g/kg/day in some patients (see Chap. 147).

Another nutritional consideration for patients receiving CRRT is the heat losses as a consequence of the cooling of the patient's blood as it traverses the extracorporeal circuit and as a result of the use of room-temperature intravenous ultrafiltrate replacement solutions.⁹⁷ The energy loss for patients who are receiving continuous hemofiltration is estimated to be as high as 800 kcal/day.⁹⁸ Most of this heat loss can be attenuated by warming the intravenous ultrafiltrate replacement solution.⁹⁸ However, many hospitals are unable to heat intravenous solutions as they are infused, so recognition of this large source of energy loss is necessary so that the clinician can design an adequate nutritional prescription.

■ DRUG-DOSING CONSIDERATIONS

9 Optimization of drug therapy for patients with ARF is often quite challenging. The multiple variables influencing responses to the drug regimen include the patient's residual drug clearance, the accumulation of fluids, which can markedly alter a drug's volume of distribution, and delivery of CRRT or IHD, which can increase drug clearance and impact the patient's fluid status to further complicate the clinician's

projection of the optimal dosage regime. For renally eliminated drugs (>30% excreted unchanged in the urine), particularly for agents with a narrow therapeutic range, serum drug concentration measurements and assessment of pharmacodynamic responses are likely to be necessary. If hepatic function is intact, choosing an agent eliminated primarily by the liver may be preferred. However, any renally eliminated active metabolites may accumulate to a point where they can elicit an undesired pharmacologic effect. Renal failure can also independently impair drug metabolism.⁹⁹ Clinical experiences and pharmacokinetic studies in patients with established ARF are fairly limited. The use of dosing guidelines based on data derived from patients with stable CKD, however, may not reflect the clearance and volume of distribution in critically ill ARF patients (see Chap. 51).¹⁰⁰

Edema, which is common in ARF, can significantly increase the volume of distribution of many drugs, particularly water-soluble ones with relatively small volumes of distribution. Increased fluid distribution into the tissues (i.e., sepsis, anasarca in heart failure) can also contribute to a larger volume of distribution for many drugs and thereby reduce the proportion of drug in the plasma that is available to be removed by CRRT or IHD. ARF frequently occurs in critically ill patients and thus multisystem organ failure must often be contended with. Reductions in cardiac output or liver function in addition to volume overload can significantly alter the pharmacokinetic profile of many drugs such as vancomycin, aminoglycosides, and low-molecular-weight heparins.^{101,102}

In almost all cases where rapid onset of activity is desired, a loading dose may be necessary to promptly achieve desired serum concentrations because the expanded volume of distribution and the prolonged elimination half-life result in an extended time (3.5 times the half-life) until steady-state concentrations are achieved. Maintenance dosing regimens should be reassessed frequently and be based on the patient's current renal function. A dose that provides the desired serum concentration on one day may be inappropriate only a few days later if the patient's fluid status or renal function has changed dramatically.

CLINICAL CONTROVERSY

In the volume-depleted patient requiring a renally eliminated medication, dosing regimens based on the initial S_{cr} prior to fluid therapy have the potential to underestimate renal function and drug elimination, resulting in subtherapeutic serum concentrations. Although not accepted as a standard practice, an initial 24-hour dosing regimen with a bolus might be optimal for many patients.

Drug therapy individualization for the ARF patient who is receiving any form of renal replacement therapy is complicated by the fact that patients with ARF may have a higher residual nonrenal clearance than CKD patients who have a similar CL_{cr} . This has been reported with some drugs, such as ceftriaxone, imipenem, and vancomycin.^{103–106} Alterations in the activity of some, but not all, cytochrome P450 enzymes have been demonstrated in patients with CKD.⁹⁹ The nonrenal clearance of imipenem in patients with ARF (91 mL/min) is between the values observed in stage 5 CKD patients (50 mL/min) and those with normal renal function (130 mL/min).¹⁰⁶ This may be the result of less accumulation of uremic waste products that may alter hepatic function. A nonrenal clearance value in a patient with ARF that is higher than anticipated based on data from individuals with CKD would result in lower-than-expected, possibly subtherapeutic, serum concentrations. For example, to maintain comparable serum concentrations, the imipenem dose requirement in patients with ARF would be 2,000 mg/24 hours as compared to the recommended dosage for patients with ESRD of 1,000 mg/24 hours.¹⁰⁶ As ARF persists, the nonrenal clearance values appear to approach those observed in patients with CKD.^{107,108} Finally, the clearance of ami-

noglycosides has been reported to be higher and the elimination half-life shorter in those with severe ARF compared to ESRD patients requiring hemodialysis.¹⁰⁰ Thus, application of dosing regimens derived from studies in patients with CKD and ESRD may result in underdosing of these agents and thereby contribute to less than optimal clinical outcomes.

IHD Compared to CRRT

In addition to patient-specific differences, there are marked differences between IHD and the three primary types of CRRT—CVVH, CVVHD, and CVVHDF—with regard to drug removal.^{109–111}

CRRT During CVVH, drug removal primarily occurs via convection/ultrafiltration (the passive transport of drug molecules at the concentration at which they exist in plasma water into the ultrafiltrate). Convective removal is most efficient for smaller agents, typically less than 15,000 daltons in size, and those that are primarily unbound in the plasma. The clearance of a drug by either of these methods is thus a function of the membrane permeability for the drug, which is called the sieving coefficient (SC) and the rate of ultrafiltrate formation (UFR). Alteration in the pore size of the filter and surface charge relative to the molecule being removed may vary between different dialyzers. If diffusion of the drug is not dependent on the filter pore size, then the SC can be calculated as follows:

$$SC = (2 \times C_{UF}) / [(C_a) + (C_v)]$$

where C_a and C_v are the concentrations of the drug in the plasma going into and returning from the dialyzer/hemofilter, respectively, and C_{UF} is the concentration in the ultrafiltrate. The SC is often approximated by the fraction unbound (f_u) because this information may be more readily available. Thus the clearance by CVVH can be calculated as:

$$Cl_{CVVH} = UFR \times SC$$

or approximated as:

$$Cl_{CVVH} = UFR \times f_u$$

In CVVHDF, clearance is a combination of both diffusion and convection. The Cl_{CVVHDF} can be mathematically approximated providing the blood flow rate is greater than 100 mL/min and the dialysate flow rate (DFR) is between 8 and 33 mL/min as:

$$Cl_{CVVHDF} = (UFR \times f_u) + Cl_{diffusion}$$

where $Cl_{diffusion}$ is the clearance via diffusion from plasma water to the dialysate. In the clinical setting, it is not possible to separate these two components (UFR and DFR) of Cl_{CVVHDF} . In essence the Cl_{CVVHDF} is calculated as the product of the combined ultrafiltrate and dialysate volume (V_{df}) and the concentration of the drug in this fluid (C_{df}) divided by the plasma concentration (C_p^{mid}) at the midpoint of the V_{df} collection period.

10 Individualization of therapy for a patient receiving CRRT therapy is dependent on the patient's residual renal function and the clearance of the drug by the mode of CRRT the patient is receiving. There are differences in the rate of drug removal, not only between the three primary modes of CRRT, but also within each mode.^{105,109–112} This is a result of differences in the filter membrane composition, variable degrees of drug binding to the membrane, and the permeability characteristics of the membrane.^{113–116} The primary factors that influence drug clearance during CRRT are thus ultrafiltration rate, blood flow rate, and dialysate flow rate. For example, clearance in CVVH is directly proportional to the ultrafiltration rate, whereas clearance during CVVHDF, which depends on both the ultrafiltration rate and the dialysate flow rate, increases as either flow rate increases. An increase in ultrafiltration flow rate (5 to 45 mL/min) and dialysate flow rate (8.3 to 33.3 mL/min), however, can have dramatic effects on clearance of

FIGURE 45-5. The effect of increasing ultrafiltration rate (UFR in milliliters per minute) and dialysate flow rate (DFR in milliliters per minute) on the clearance of ceftazidime. (Adapted from reference 116.)

agents such as ceftazidime during CVVH and CVVHD, respectively (Fig. 45-5).¹¹⁶

Another readily apparent factor that changes drug dosing is the type of RRT used in the patient. CRRT can rapidly remove excess fluid from edematous patients, thereby changing the volume of distribution (V_D) of drugs with limited distribution (low V_D suggesting a greater proportion in the plasma or extracellular fluid) fairly rapidly. Drug clearances attained by IHD, CRRTs, and hybrid RRTs all differ from each other and must be added to any endogenous drug clearance that the patient generates.¹⁰⁵ An algorithmic approach for drug dosage adjustment in patients undergoing CRRT has been proposed.¹¹⁰ In CRRT, the clearance of a given agent may be ascertained from published reports.^{110,117,118} Table 45-9 summarizes the

TABLE 45-9 Predicted and Measured Sieving Coefficients of Selected Drugs

Drug	Predicted	Measured
Amikacin	0.95	0.88
Amphotericin	0.01	0.32–0.4
Ampicillin	0.80	0.6–0.69
Cefepime	0.97	0.47–0.97
Cefoperazone	0.10	0.27–0.69
Cefotaxime	0.62	0.55–1.1
Cefoxitin	0.30	0.32
Ceftazidime	0.90	0.38–0.78
Ceftriaxone	0.10	0.71–0.82
Clindamycin	0.25	0.49–0.98
Digoxin	0.75	0.96
Erythromycin	0.25	0.37
5-Fluorocytosine	0.96	0.98
Gentamicin	0.95	0.81–0.75
Imipenem	0.80	0.78
Metronidazole	0.80	0.80
Mezlocillin	0.68	0.68
N-acetylprocainamide	0.80	0.92
Nafcillin	0.20	0.47

sieving coefficients of frequently used drugs. These data can be used to design initial dosage regimens for patients receiving CVVH.^{109,112}

For example, IM is a 48-year-old, 60-kg male with a S_{cr} that has increased from 2.3 mg/dL to 7.2 mg/dL over 3 days. The residual Cl_{cr} value in this patient, calculated using the Jelliffe and Jelliffe equation (see Chap. 44) is 4.8 mL/min. The consulting nephrologist recommends that CVVHDF be initiated using a Fresenius F-80 filter at blood, ultrafiltrate, and dialysate flow rates of 150, 15, and 33.3 mL/min, respectively. The patient is to receive cefepime while on CVVHDF. The patient's residual cefepime clearance (Cl_{RES}) can be estimated using the following regression equation relating Cl_{cr} and cefepime clearance:

$$Cl_{RES} \text{ (mL/min)} = [0.96 \times (Cl_{cr})] + 10.9$$

$$Cl_{RES} = [0.96 \times (4.8)] + 10.9 = 15.5 \text{ mL/min}$$

The total clearance while on CVVHDF would be the sum of the patient's residual clearance and the cefepime clearance associated with CVVHDF (which can be approximated as described above) as follows:

$$Cl_{CVVHDF} = [(UFR + DFR) \times f_u]$$

$$Cl_{CVVHDF} = [(15 + 33) \times 0.97]$$

$$Cl_T = Cl_{RES} + Cl_{CVVHDF}$$

$$Cl_T = 15.5 \text{ mL/min} + 47 \text{ mL/min} = 62.1 \text{ mL/min}$$

This patient's clearance value can be used to adjust the cefepime dose as described below. The cefepime clearance in a patient with normal renal function would be calculated as:

$$Cl_{norm} \text{ (mL/min)} = [0.96 \times (Cl_{cr})] + 10.9$$

$$Cl_{norm} = [0.96 \times 120] + 10.9$$

$$Cl_{norm} = 126.1$$

The dosage adjustment factor would then be:

$$Q = Cl_T / Cl_{norm}$$

$$Q = 62.1 \div 126 = 0.49$$

For this patient's situation, the normal regimen of cefepime would be 2,000 mg (D_n) every 12 hours (τ_n). If one wanted to maintain D_n and extend the dosing interval, then τ_f would be calculated as:

$$\tau_f = \tau_n / Q$$

$$\tau_f = 12 \text{ hours} / 0.49$$

$$\tau_f \approx 24 \text{ hours}$$

This approach suggests the patient should receive cefepime 2,000 mg every 24 hours. If the additional clearance associated with CVVHDF (40.2 mL/min) was not considered, the calculated dosing interval would have been considerably longer. Several variables can impact the outcome of these calculations, including the multiple variables within the dialysis therapy—for example, UFR, blood flow rate, and DFR—and interpatient variability in nonrenal and renal drug clearance, to name just two.

Intermittent Hemodialysis Limitations of IHD-based dosing charts include variability in the patients' individual pharmacokinetic parameters, differences in the dialysis prescription, such as dialyzer blood flow or duration, and the use of new IHD dialyzers. The approach to hemodialysis may also change on a daily basis, especially in unstable individuals with ARF. This could include, for example, the dialyzer/filter used, the duration, the degree of hemofiltration compared to convection, and blood flow rate. Individualization of a

dosing regimen may require daily assessment of the clinical status of the patient and any planned or recently administered hemodialysis.

CLINICAL CONTROVERSY

Some clinicians use a standard ESRD dosage regimen despite the fact that renal function can fluctuate such that the patient may be in one dosing range one day and in another the next. Others believe, however, that the patient's clinical need for the drug and any change in the volume of distribution or the RRT therapy should be considered if one has any chance of achieving the target serum concentrations.

Overall, there are a tremendously large number of potential pharmacokinetic and pharmacodynamic alterations to be aware of in the patient with ARF. Unfortunately, there is a dearth of data to quantify these changes, and even less evidence to prove that if one incorporates these considerations into patient care that the associated outcomes will be improved.

EVALUATION OF THERAPEUTIC OUTCOMES

Vigilant monitoring of patients with ARF is essential, particularly in those who are critically ill (Table 45–10). Once the laboratory-based tests (e.g., urinalysis, fractional excretion of sodium calculations) have been conducted to diagnose the cause of ARF, they usually do not have to be repeated. In established ARF, daily measurements of urine output, fluid intake, and weight should be performed. Vital signs should be monitored at least daily, more often if patient acuity of illness is high. Daily blood tests for electrolytes, BUN, and a complete blood cell count should be considered routine for hospitalized patients.

Therapeutic drug monitoring should be performed for drugs that have a narrow therapeutic window that can be measured by the hospital laboratory. If results from these serum drug concentrations cannot be obtained in a timely fashion (<24 hours) to the patient's care team, then their value is limited. When considering approaches to measuring serum concentrations, consensus is limited. Measuring a serum drug concentration prior to hemodialysis has the advantage of allowing time for the result to be reported and redosing done shortly

TABLE 45-10 Key Monitoring Parameters for Patients with Established Acute Renal Failure

Parameter	Frequency
Fluid ins/outs	Every shift
Patient weight	Daily
Hemodynamics (blood pressure, heart rate, mean arterial pressure, etc.)	Every shift
Blood chemistries	
Sodium, potassium, chloride, bicarbonate, calcium, phosphate, magnesium	Daily
Blood urea nitrogen/serum creatinine	Daily
Drugs and their dosing regimens	Daily
Nutritional regimen	Daily
Blood glucose	Daily (minimum)
Serum concentration data for drugs	After regimen changes and after renal replacement therapy has been instituted
Times of administered doses	Daily
Doses relative to administration of renal replacement therapy	Daily
Urinalysis	
Calculate measured creatinine clearance	Every time measured urine collection performed
Calculate fractional excretion of sodium	Every time measured urine collection performed
Plans for renal replacement	Daily

after dialysis with minimal delay. This is especially important if the desired pharmacologic effects are lost during or after hemodialysis is complete because the serum concentrations have become subtherapeutic. Knowledge based on previous observations of how a particular agent is removed for a given dialysis approach and any prehemodialysis serum concentration of the agent can assist in estimating the amount removed and predicting any necessary postdialysis dose. Serum concentrations drawn after hemodialysis may reflect plasma concentrations that are transiently depressed until the drug can reequilibrate from the tissues (plasma rebound effect). The advantage with an after-dialysis level is the greater accuracy in determining how much drug was cleared during hemodialysis, but may delay reestablishing target effects. Greater therapeutic drug monitoring may be necessary in patients with ARF than what is done routinely for other patients because of the potential changes in dynamic status (changing volume status, changing renal function, and RRTs) of ARF patients.

PHARMACOECONOMIC CONSIDERATIONS

ARF is a large financial burden on the healthcare system. Much of this cost is because many of these patients are in intensive care units where daily costs are high. It is estimated that the average total hospital cost of a patient with ARF who requires RRT is approximately \$50,000.¹¹⁹ Most patients who survive ARF regain life-sustaining renal function, but the 5% who do not regain renal function¹⁴ continue to incur the economic and personal costs of dialysis or kidney transplantation. The financial burden is estimated to be \$50,000 per year greater than the non-dialysis-dependent patient whose kidneys recovered from ARF. Nonetheless, patients who required RRT for their ARF generally have a good quality of life after recovery.¹¹⁹

Medical intervention costs can be normalized to assess total costs using quality-adjusted life-years (QALYs) gained by the intervention. The use of a QALY approach to treatment of critically ill patients with ARF indicates that treating these patients is very expensive relative to other common medical interventions.¹²⁰ For example, in 2001, the treatment of critically ill ARF patient cost per QALY was \$168,711, compared to treatment of acute myocardial infarction cost per QALY of \$45,000, and the routine treatment of hypertension cost per QALY of \$31,321.⁶ A typical cost per QALY of <\$100,000 is considered cost-effective. Although nobody is suggesting that serious ARF not be treated, it is clear that research needs to be done to improve the ARF survival rate to reduce this cost per QALY. Furthermore, it underscores the need to prevent the occurrence of ARF in the first place.

CONCLUSIONS

The unique characteristics of ARF compared to CKD can lead to notable differences in how renal function is measured and how treatment regimens are developed. Most management approaches currently involve prevention and support of the patient once ARF is established, so as to minimize the potential for additional harm to either the patient or kidney. Understanding the constantly changing status inherent to ARF, and how to adjust management regimens is a key component to optimizing therapy.

ACKNOWLEDGMENT

We gratefully acknowledge Bruce Mueller, PharmD, FCCP, BCPS, for his contributions to the prior editions of this chapter.

ABBREVIATIONS

ARF: acute renal failure

ATN: acute tubular necrosis

BUN: blood urea nitrogen

CKD: chronic kidney disease

CL_{cr}: creatinine clearance

CRRT: continuous renal replacement therapy

CT: computed tomography

CVVH: continuous venovenous hemofiltration

CVVHD: continuous venovenous hemodialysis

CVVHDF: continuous venovenous hemodiafiltration

FE_{Na}: fractional excretion of sodium

GFR: glomerular filtration rate

IHD: intermittent hemodialysis

NSAID: nonsteroidal antiinflammatory drug

QALY: quality-adjusted life-year

RRT: renal replacement therapy

S_{cr}: serum creatinine

Chronic Kidney Disease: Progression-Modifying Therapies

MELANIE S. JOY, ABHIJIT KSHIRSAGAR, AND NORA FRANCESCHINI

KEY CONCEPTS

- 1 The prevalence of chronic kidney disease (CKD) is estimated at nearly 19 million people in the United States.
- 2 Because the development of CKD is a complex phenomenon, the Kidney Disease Outcomes Quality Initiative (K/DOQI) has recommended categorizing risk factors associated with CKD as susceptibility, initiation, and progression factors.
- 3 Reduction of kidney mass, development of glomerular hypertension, and intratubular proteinuria are key mechanisms responsible for the progression of chronic kidney disease.
- 4 CKD is classified into five stages based on the presence of kidney structural damage (e.g., proteinuria) and/or kidney function (glomerular filtration rate); Stage 1 is indicative of mild structural changes with “normal” kidney function while Stage 5 is analogous to end stage renal disease for which dialysis or kidney transplantation may be necessary.
- 5 Serum creatinine is not a reliable marker of kidney function among the elderly, the malnourished, and children. Therefore, it is important to estimate the glomerular filtration rate rather than just measuring the serum creatinine, especially in these three populations.
- 6 Stage 5 CKD manifests as asterixis, pruritus, dysgeusia, nausea, vomiting, anorexia, weight loss and susceptibility to bleeding. These signs and symptoms of uremia are foundational to the decision to implement kidney replacement therapy.
- 7 The progression of CKD can be limited by optimal control of hyperglycemia and hypertension.
- 8 Diabetic patients with or without hypertension who demonstrate persistent microalbuminuria despite intensive insulin therapy should have their ACEI or ARB dose titrated to achieve maximal suppression of urinary albumin excretion to halt or slow CKD progression.
- 9 Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) are key pharmacologic treatments of chronic kidney disease because of their hemodynamic and blood pressure reduction effects, which help to limit kidney disease progression.

- 10 Supportive therapies that may help to slow the rate of CKD progression include dietary protein restriction, lipid-lowering medications, smoking cessation, and anemia management.

Under normal conditions each of the two million nephrons of the kidneys work in an organized fashion to filter, reabsorb, and excrete various solutes and water. The kidney is a primary regulator of sodium and water balance, as well as of acid–base homeostasis. The kidney also produces hormones necessary for red blood cell synthesis and calcium homeostasis. Impairment of kidney function is often referred to as CKD. Based on the time course of development, CKD is divided into two broad categories. Acute renal failure refers to the rapid loss of kidney function over days to weeks. Chronic kidney disease, also called chronic renal insufficiency or progressive kidney disease by some, is defined as a progressive loss of function occurring over several months to years, and is characterized by the gradual replacement of normal kidney architecture with interstitial fibrosis.

The working group of the National Kidney Foundation’s (NKF) Kidney Dialysis Outcomes and Quality Initiative (K/DOQI) has developed a CKD classification system based on the presence of structural kidney damage and/or functional changes in glomerular filtration rate (GFR) present for a period of 3 months or more.¹ CKD is categorized by the level of kidney function (as defined by GFR) into stages 1 through 5, with each increasing number indicating a more advanced stage of the disease (Table 46–1).¹ The use of GFR versus serum creatinine to define the stages of CKD was chosen because the serum creatinine is an inaccurate index of GFR, and there is marked variability in GFR between subjects with similar serum creatinine values (see Chap. 44). Although the stages are defined functionally by the GFR, the classification system also accounts for structural evidence of kidney damage. Normal kidney function in adults is approximately 120 mL/min/1.73 m² of GFR. Even though a GFR of >90 mL/min/1.73 m² is considered normal kidney function, a patient can be diagnosed with CKD if the patient has proteinuria, hematuria, or evidence of structural damage from a kidney biopsy. Stage 5 CKD was previously referred to as end-stage renal disease (ESRD) or end-stage kidney disease.

EPIDEMIOLOGY OF CKD

The epidemiology of stage 5 CKD has been well documented through the efforts of the United States Renal Data System (USRDS), a national data system that collects, analyzes, and distributes information about U.S. patients on hemodialysis and peritoneal dialysis, as well as kidney transplant recipients.² Information on the epidemiology of the earlier stages of CKD is less-well characterized. In the United States alone, there are several major epidemiologic studies currently in progress or in development to elucidate the natural history of CKD, its progression, and concurrent morbid-

TABLE 46-1 Definition and Prevalence of the Stages of Chronic Kidney Disease		
Stage	Glomerular Filtration Rate ^a	Prevalence ^c
1	≥90 ^b	10,500,000
2	60–89	7,100,000
3	30–59	7,600,000
4	15–29	400,000
5	<15 (includes patients on dialysis)	300,000

^aGlomerular filtration rate in mL/min per 1.73 m² body surface area.
^bChronic kidney disease can be present with a normal or near normal GFR if other markers of kidney disease are present, such as proteinuria, hematuria, biopsy results showing kidney damage, or anatomic abnormalities (e.g., cysts).
^cBased on measurement of an elevated albumin-to-creatinine ratio.

ities. One study targets individuals with polycystic kidney disease,³ while another study targets African Americans with hypertensive nephrosclerosis.⁴ The CKD Cohort study, funded by the National Institutes of Health,⁵ and an Amgen Inc. and Fresenius cosponsored study (Stride Registry)⁶ are investigating progressive CKD and its relationship with comorbid cardiovascular disease. The National Kidney Foundation has recognized the importance of early detection and has initiated the Kidney Early Evaluation Program⁷ to identify, educate, and provide free screening for people at increased risk of developing kidney disease. Furthermore, U.S. governmental agencies have targeted CKD as one of 28 major focus areas for improvement by the year 2010, as set forth in the Healthy People 2010 document.⁸ Over the next decade, as a result of these initiatives, our understanding of the epidemiology, pathophysiology, and management of mild (stage 1) to moderate (stage 4) CKD will undoubtedly increase.

1 CKD has been described as a silent epidemic⁹ and is a worldwide public health problem.¹⁰ Three different national surveys have estimated that CKD affects 5% of the adult U.S. population when CKD is defined by a serum creatinine concentration greater than 1.2 to 1.5 mg/dL.^{11–13} The Third National Health and Nutritional Examination Survey (NHANES III), a nationally representative sample of the U.S. adult population, projected that at least 10.9 million people had reduced kidney function as evidenced by serum creatinine concentrations equal or higher than 1.5 mg/dL.¹¹ When data on the presence of microalbuminuria and proteinuria was included, the estimated prevalence of CKD is 10.9% of U.S. population age 20 years or older, or 19 million individuals.¹ The prevalence of CKD is thus similar to that of other chronic conditions such as hypertension, diabetes mellitus, and cardiovascular disease.

Incidence estimates of stage 5 CKD are obtained from the USRDS.² During the two decades spanning 1980 to 2000, the number of patients entering stage 5 (and requiring renal replacement therapy) increased by 5% to 10% per year. However, beginning in 2003 and continuing to the present, the rate of increase has declined to less than 1%.¹⁴ The main factor attributed to this decline has been the implementation of angiotensin-converting enzyme inhibitor (ACEI) and angiotensin receptor blocker (ARB) therapy as a standard of care for those with early stage CKD.¹⁴ The role and impact of ACEI and ARB therapy for patients with hypertension- and diabetes mellitus-associated renal disease is discussed in detail later in this chapter. The four most common causes of incident (new cases of) stage 5 CKD in the United States are diabetes mellitus, hypertension, glomerulonephritis, and polycystic kidney disease. The causes and incidence rates include diabetic nephropathy (150 cases/million), hypertensive nephropathy (80 cases/million), glomerulonephritis (22 cases/million), and polycystic kidney disease (5 cases/million).² Individuals over 65 years of age and black race are at higher risk of CKD.² For example, the rate of stage 5 CKD is fourfold higher for blacks as compared to whites.²

It is often assumed that all early stages of CKD progress continuously toward stage 5. Thus, information on risk factors obtained

from USRDS data is assumed to be generalizable to all stages of CKD. The validity of this approach to projecting future incidence data has not been tested. Further complicating these issues is the fact that the development and progression of the early stages of CKD is a complex phenomenon.¹⁵ The risk factors associated with CKD are numerous and varied and many of these are not those one would traditionally consider as having a direct influence on the causal pathway. The working group of K/DOQI has recommended categorizing CKD risk factors as susceptibility factors, initiation factors, or progression factors to help clinicians stratify the overall risks of individual patients (Table 46–2).¹⁰

The focus of the current chapter is on the initiation and progression of CKD. Because diabetes mellitus and hypertension are the two most prevalent etiologies for CKD, a considerable amount of attention is given to discussing the course and treatments designed to slow the progressive kidney function decline that is commonly observed in patients with either of these two diseases. This chapter focuses on the early CKD stages, that is, stages 1, 2, and 3, which are the critical battleground if one hopes to minimize the number of patients who ultimately require renal replacement therapy. CKD is a continuous and progressive disease state that often results in the appearance of several concomitant complications that commence at various stages in the disease. Chapter 47 will address the pathophysiology and consequences and complications of CKD that tend to become evident in those with stage 4 or 5 CKD. The treatment options for these conditions and monitoring parameters are also discussed.

ETIOLOGY

SUSCEPTIBILITY FACTORS

Susceptibility factors to CKD are advanced age,^{16–18} low income or education,^{19,20} and racial/ethnic minority status,^{21–23} as well as reduced kidney mass, low birth weight,²⁴ and family history of CKD.^{25,26} These factors have not been proven to directly cause kidney damage. Novel proposed susceptibility factors are systemic inflammation^{27,28} and dyslipidemia.^{29,30} Although most of these susceptibility factors may not be amenable to pharmacologic or lifestyle interventions, they may be useful for identifying populations that are at high risk of CKD.

INITIATION FACTORS

③ Initiation factors are conditions that directly result in kidney damage, and are modifiable by pharmacologic therapy. Diabetes mellitus, hypertension, autoimmune diseases, polycystic kidney disease, systemic infections, urinary tract infections, urinary stones, lower urinary tract obstructions, and drug toxicity are all considered initiation factors. Because diabetes mellitus, hypertension, and glomerular diseases are, respectively, the three most common causes of CKD in the United States, the following discussion focuses on these conditions.

Diabetes Mellitus

Individuals with type 1 diabetes mellitus have a 40% lifetime risk of developing CKD of any stage,³¹ whereas individuals with type 2 diabetes mellitus have a 50% lifetime risk.³² Given the greater prevalence of type 2 diabetes mellitus as compared to type 1—generally a 10:1 ratio exists in most countries³³—the majority of CKD from diabetes would be among individuals with type 2 disease. Although not all individuals with diabetic nephropathy progress to stage 5 CKD, the lifetime risk is considerable. A prospective study of over 300,000 individuals screened from the Multiple Risk Factor Intervention Trial estimated that approximately 3% of individuals with diabetes mellitus will develop stage 5 CKD during their lifetime.³⁴ Thus diabetic subjects have a 12-fold greater relative risk of developing stage 5 CKD than does someone without diabetes. Subjects with diabetes also have an increased risk of nondiabetic causes of CKD, suggesting an underlying genetic susceptibility to kidney diseases.³⁵

Hypertension

Hypertension also increases the risk of CKD although the exact role as a cause or consequence is often debated as the kidney has a role in the development and modulation of high blood pressure.^{36–38} Therefore, the interpretation of epidemiologic studies regarding the presence of high blood pressure and the risk of progressive kidney disease may be limited by reverse causation. Hypertension generally develops concomitantly with progressive kidney disease. For example, hypertension is present in 40% of individuals with a GFR of 90 mL/min per 1.73 m²; in 55% of those with a GFR of 60 mL/min per 1.73 m²; and 75% of individuals with a GFR of 30 mL/min per 1.73 m².²¹ Furthermore, in the NHANES III survey, a serum creatinine of 1.6 mg/dL or higher for men and 1.4 mg/dL or higher for women was more common in persons with hypertension (9.1%) than in persons without hypertension (1.1%).³⁹

Conversely, prospective studies have shown that elevated blood pressure increases the risk for the development of CKD among subjects without initial kidney disease.^{40,41} A recent prospective study of 316,675 adult managed care patients showed increased odds of incident ESRD (stage 5 CKD) in those with increased baseline blood pressure. The odds of CKD development were 2.0 (95% confidence interval [CI] 1.6 to 2.5) for blood pressure ranges of 120 to 129 mm Hg systolic over 80 to 84 mm Hg diastolic, and 4.3 (95% CI 2.6 to 6.9) for blood pressure higher than 210/120 mm Hg as compared to blood pressure lower than 120/80 mm Hg. Patients were devoid of baseline kidney disease in this study.⁴¹

In the Multiple Risk Factor Intervention Trial, a primary prevention trial to test the effect of an intervention program on mortality from coronary heart disease, the overall lifetime risk of developing stage 5 CKD for individuals with hypertension was 5.6%.⁴² The risk varied dramatically by level of blood pressure, from 0.33% at stage 1 hypertension (systolic blood pressure 140 to 150 mm Hg and/or diastolic blood pressure 90 to 100 mm Hg) to 4.5% for systolic blood pressure levels greater than 180 mm Hg or diastolic blood

pressure levels greater than 110 mm Hg over a followup period of approximately 16 years.⁴²

Glomerulonephritis

Glomerular diseases are also considered initiation factors of CKD. The epidemiology and pathophysiology of glomerular diseases are variable and thus all diseases should not justifiably be lumped into one disease category. Some conditions, such as Goodpasture's disease or Wegener's granulomatosis, may progress rapidly to stage 5 CKD, and thus may best be categorized as causes of acute renal failure. Other conditions, such as immunoglobulin (Ig) A nephropathy, membranous nephropathy, focal segmental glomerulosclerosis, lupus nephritis, and others, are more indolent diseases, and are considered causes of CKD (see Chap. 50). The chronic glomerular diseases progress at variable rates, with the loss of GFR ranging from 1.4 to 9.5 mL/min per year.^{43–46}

PROGRESSION FACTORS

④ Progression risk factors are those associated with further kidney damage. This is generally evident as an increase in the rate of decline in kidney function in those who already have damaged kidneys. The most important predictors of progressive CKD are the persistence of underlying initiation factors (e.g., diabetes mellitus, hypertension, glomerulonephritis, and polycystic kidney disease), and the progression factors of proteinuria, elevated blood pressure, and smoking.

Proteinuria

Numerous studies have documented the importance of proteinuria in the progression of both diabetic^{47–50} and nondiabetic^{51,52} kidney disease. Most of these findings are from secondary analyses of intervention trials. In diabetic kidney disease (types 1 and 2), an albumin excretion rate higher than 30 mg per 24 hours (microalbuminuria) strongly predicted the development of overt nephropathy (proteinuria) and subsequent loss of kidney function.^{47–49,53} In nondiabetic kidney disease, the Modification of Diet in Renal Disease Study (MDRD), a randomized clinical trial examining the effects of oral protein restriction and blood pressure control on the progression of CKD among individuals with preexisting CKD, demonstrated that a patient's baseline level of proteinuria strongly predicted future loss of GFR.⁵¹ Furthermore, individuals with the highest levels of baseline proteinuria benefited the most from pharmacologic reduction of blood pressure. A recent study of more than 1,800 individuals with varying stages of CKD demonstrated a strong, graded risk of CKD based on the level of proteinuria; a fivefold increased risk of progression was observed for each 1.0 g/day increase in proteinuria.⁵²

The joint role of blood pressure and proteinuria in the progression of CKD was investigated by Jafar et al. using data from 11 randomized, controlled trials that compared the efficacy of antihypertensive regimens for patients with predominantly nondiabetic kidney disease.⁵⁴ The increased risk for CKD progression at higher systolic blood pressure levels was greater in patients with urine protein excretion greater than 1.0 g/day ($P < 0.006$).⁵⁴

Hypertension

The early treatment of hypertension and the achievement of aggressive target values has been demonstrated to slow the rate of progression of CKD.^{51,52,55–59} Bakris et al. demonstrated a direct correlation between the level of achieved blood pressure and preservation of kidney function in diabetic patients.⁶⁰ The analysis included 10 studies in which diabetic patients were treated with various antihypertensive agents. The change in GFR was measured

during each study. An inverse linear relationship between the average attained blood pressure at study completion and average GFR was observed; and the lower final mean arterial blood pressure resulted in a lower average decline in GFR. For example, a systolic blood pressure of 180 mm Hg was associated with a 14 mL/min per year decline in GFR, whereas patients with a systolic blood pressure of 135 mm Hg had only a 2 mL/min per year decline in GFR.⁶⁰

A recent extended followup analysis of the MDRD original cohort showed that patients assigned to lower blood pressure target (mean arterial pressure: <92 mm Hg) were 32% less likely to develop stage 5 CKD than those in the usual target blood pressure (mean arterial pressure: <107 mm Hg).⁶¹ Therefore, low blood pressure slowed the progression of nondiabetic kidney disease in patients with an existing moderately to severely decreased GFR.

Diabetes Mellitus

Hyperglycemia is an initiation and progression risk factor for CKD. Two large prospective studies performed in the early 1990s showed the benefits of blood glucose control in both the development and progression of microvascular complications.^{62,63} These findings were confirmed by two additional British studies.^{55,56} The largest of these studies, the Diabetes Control and Complications Trial (DCCT) enrolled 1,441 patients with type 1 diabetes mellitus who were randomized to conventional blood glucose control or to intensive glucose control.⁶³ Conventional control consisted of up to two insulin injections per day guided by blood glucose levels. Intensive control consisted of administration of insulin three or more times daily by injection or by external pump to achieve a hemoglobin A_{1c} ≤6.0%. The main outcome measure of efficacy was retinopathy, a marker of microvascular disease that is usually associated with diabetic nephropathy among individuals with type 1 diabetes mellitus. Roughly half of the patients had mild retinopathy. Primary prevention was defined as a reduction in new occurrence of retinopathy among patients with no baseline retinopathy, and secondary prevention was defined as a reduction in the rate of progression of retinopathy among individuals with baseline retinopathy. A primary risk reduction of retinopathy of 76% and secondary risk reduction of 54% were noted with intensive control. The intensive therapy was associated with a 39% reduction in the risk for the development of “microalbuminuria” (urinary albumin excretion ≥40 mg/day), and a 54% reduction in the development of “frank albuminuria” (urinary albumin excretion ≥300 mg/day) compared to conventional therapy. The beneficial effect of intensive therapy on the development of proteinuria remained after completion of the randomized phase of the DCCT.⁶⁴ Individuals initially randomized to the intensive therapy had a 59% reduction in the development of new microalbuminuria, and 84% reduction in the development of albuminuria compared to the conventional group 7 to 8 years after completion of the DCCT.

Smoking

Recent studies suggest that smoking may promote initiation and progression of CKD in subjects with type 1 and type 2 diabetes.^{65–68} Smoking increased the rate of CKD progression in diabetes by approximately twofold in one study.⁶⁹ The “cigarette pack years” was an independent predictive factor for CKD progression among diabetic subjects.⁷⁰ In addition, smoking has also been associated with CKD in hypertension,⁷¹ especially among hypertensive black subjects.⁷² Some studies have demonstrated an association between smoking and microalbuminuria and the development of stage 5 CKD.^{73–75} Smoking has also been identified as a risk factor for progression in patients with IgA nephropathy, polycystic kidney disease, and systemic lupus erythematosus.^{76,77}

Hyperlipidemia

Dyslipidemia may be associated with kidney disease. Three epidemiologic studies^{29,30,78} demonstrated that dyslipidemia predicts incident CKD among individuals considered at low risk for CKD.⁷⁹ CKD with or without nephrotic syndrome is frequently accompanied by abnormalities in lipoprotein metabolism. The prevalence of hyperlipidemia appears to increase as kidney function declines and hyperlipidemia is a characteristic of the nephrotic syndrome.⁸⁰ In 85% to 90% of patients with decreased kidney function and proteinuria greater than 3 g/day, elevated plasma total and low-density lipoprotein cholesterol occurs. Approximately 50% of these patients have low levels (<35 mg/dL) of high-density lipoprotein cholesterol, and 60% have triglyceride concentrations greater than 200 mg/dL.⁸⁰ Lipid-lowering agents can decrease the extent of glomerular injury in animal models with hyperlipidemia and kidney disease.⁸¹ Therefore, treatment of lipid abnormalities in patients with CKD may have a beneficial effect on slowing the rate of progression of the kidney disease.

Obesity

Recent studies show an association of obesity with development of stage 5 CKD.^{82,83} Iseki et al. examined the relationship between body mass index (BMI) and the development of ESRD among 47,504 men and 53,249 women using data from a 1983 community-based screening in Okinawa, Japan.⁸³ BMI was associated with an increased risk of the development of ESRD in men (odds ratio [OR] 1.3; 95% CI 1.1 to 1.4) but not in women. Another large population study using data from Kaiser Permanente revealed an increased risk of ESRD in overweight (relative risk [RR] 1.9; 95% CI 1.6 to 2.1 for BMI 25 to 29.9 kg/m²) and obese subjects (RR 3.6 [95% CI 3.1 to 4.2] for those with a BMI of 30 to 34.9 kg/m²; RR 6.1 [95% CI 5.0 to 7.5] for those with a BMI of 35 to 39.9 kg/m²; and RR 7.1 [95% CI 5.4 to 9.3] for those with a BMI greater than 40 kg/m²). Higher baseline BMI remained an independent predictor for ESRD after adjustments for baseline blood pressure level as well as presence of diabetes mellitus.⁸²

A recent population-based study showed that a BMI ≥25 kg/m² at age 20 years is associated with a threefold increase in risk of CKD compared to a BMI lower than 25 kg/m². Obesity (BMI ≥30) among men and morbid obesity (BMI ≥35) among women was associated with three- to fourfold increases in risk.⁸⁴

Other Factors

Other identified risk factors for progression are lead exposure⁸⁵ and illicit drug use.⁸⁶ A recent population-based study suggested that apolipoprotein E genetic variants are also associated with progression of CKD in both whites and blacks.⁸⁷

PATHOPHYSIOLOGY

Kidney damage can result from heterogeneous causes. For example, diabetic nephropathy is characterized by glomerular mesangial expansion; in hypertensive nephrosclerosis, the kidney's arterioles have arteriolar hyalinosis; and renal cysts are present in polycystic kidney disease. Therefore, the initial structural damage may depend on the primary disease affecting the kidney. However, the majority of progressive nephropathies share a final common pathway to irreversible renal parenchymal damage and ESRD (Fig. 46–1).^{88,89} The key elements of this pathway are: (a) loss of nephron mass; (b) glomerular capillary hypertension; and (c) proteinuria.

The exposure to any of the initiation risk factors can result in loss of nephron mass. The remaining nephrons hypertrophy to compensate for the loss of renal function and nephron mass.⁹⁰ Initially, this compensatory hypertrophy may be adaptive. Over time, the hyper-

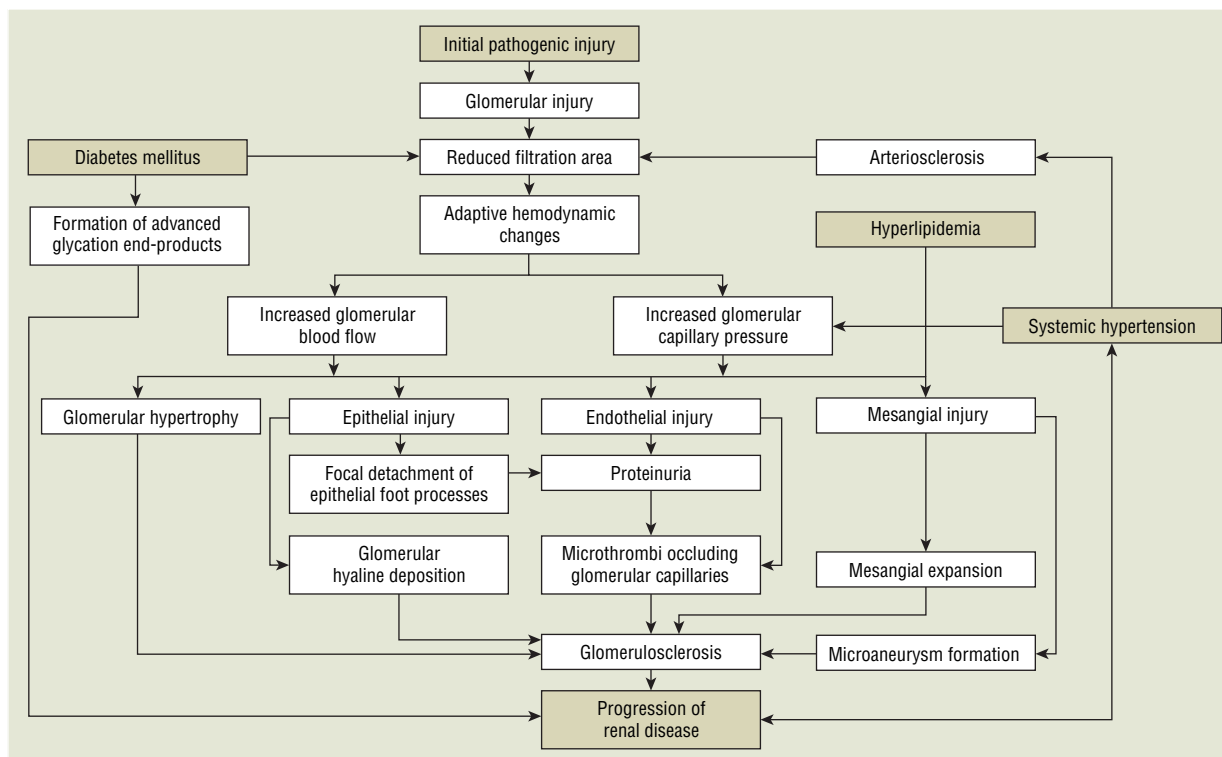

FIGURE 46-1. Proposed mechanisms for progression of renal disease.

trophy can lead to the development of intraglomerular hypertension, possibly mediated by angiotensin II.^{91,92} Angiotensin II is a potent vasoconstrictor of both the afferent and efferent arterioles, but preferentially affects the efferent arterioles, leading to increased pressure within the glomerular capillaries and consequent increased filtration fraction. The development of intraglomerular hypertension usually correlates with the development of systemic arterial hypertension. Animal studies have demonstrated that high intraglomerular capillary pressure impairs the size-selective function of the glomerular permeability barrier, resulting in increased urinary excretion of albumin and frank proteinuria.^{93,94} Angiotensin II may also mediate renal disease progression through nonhemodynamic effects.⁹⁵

Proteinuria alone may promote progressive loss of nephrons as a result of direct cellular damage.^{88,95} Filtered proteins such as albumin, transferrin, complement factors, immunoglobulins, cytokines, and angiotensin II are toxic to kidney tubular cells. Numerous studies have demonstrated that the presence of these proteins in the renal tubule activates tubular cells which leads to the upregulated production of inflammatory and vasoactive cytokines, such as endothelin, monocyte chemoattractant protein (MCP-1), and RANTES (regulated upon activation, normal T-cell expressed and secreted).^{88,96–99} Proteinuria is also associated with the activation of complement components on the apical membrane of proximal tubules.¹⁰⁰ Accumulating evidence now suggests that intratubular complement activation may be the key mechanism of damage in the progressive proteinuric nephropathies.^{101–103} These events ultimately lead to scarring of the interstitium, progressive loss of structural nephron units, and reduction in GFR.

CLINICAL PRESENTATION

CKD is often asymptomatic, and should be suspected in individuals with conditions such as diabetes, hypertension, genitourinary abnormalities, and autoimmune diseases. In addition, individuals of older age and those with a family history of kidney disease should be

considered for CKD screening. Recommended screening studies include serum creatinine and GFR measurement, urinalysis, and/or imaging studies of the kidneys. Abnormal elevations of serum creatinine, reflecting decreases in GFR, or presence of urinary or imaging study abnormalities are indications for a full evaluation of CKD.¹

5 The rate of GFR loss can vary in CKD because of differences in the underlying disease process and extent of kidney damage, treatment responsiveness, and compliance with therapies. The NKF K/DOQI developed a classification system that divides CKD into five stages, with each increasing number indicating a more advanced stage of the disease, as defined by GFR¹ (see Table 46–1). These stages are based on kidney function and evidence of kidney damage. Therefore, one can have CKD with a normal GFR (>90 mL/min per 1.73 m²) if there is evidence of structural damage to the kidneys (e.g., presence of proteinuria). The GFR rather than serum creatinine was used to define kidney function in this official classification system because the serum creatinine is an inadequate measure of kidney function (see Chap. 44).

The NKF K/DOQI defines kidney damage as the presence of clinical proteinuria. Table 46–3 summarizes the methods available to detect and interpret proteinuria and albuminuria. In addition, Chap. 44 provides a detailed discussion of the relative merits of the various methods currently available for the detection of urinary protein.

CLINICAL PRESENTATION OF CKD STAGES 1 TO 4

General

■ CKD development and progression may be insidious in onset, often without noticeable symptoms. The diagnosis of CKD requires measurement of serum creatinine, estimation of GFR, and assessment of the urine (urinalysis) for protein and/or albumin excretion. CKD stages 3, 4, and 5 require further workup for CKD complications of anemia, cardiovascular disease, metabolic bone disease, malnutrition, and disorders of fluids and electrolytes.

TABLE 46-3 Quantification of Proteinuria by Various Methods

Category	24-Hour Collection (Milligrams of protein or albumin per 24-hour period)	Spot Collection: Protein: Creatinine Ratio (Milligrams of protein per gram of creatinine)	Spot Collection: Albumin-to- Creatinine Ratio (Micrograms of albumin per milligram of creatinine ^a)	Timed Collection (Micrograms of protein per minute ^b)
Normal	<300 mg/day protein or <30 mg/ day albumin	<200 mg/g	<30 mcg/mg	<20 mcg/min
Microalbuminuria	30–300 mg/day albumin	Not applicable	30–299 mcg/mg	20–199 mcg/min
Clinical proteinuria or albuminuria	≥300 mg/day protein or albumin	>200 mg/g	≥300 mcg/mg	≥200 mcg/min

^aMicrograms of albumin per milligram of creatinine is equal, as a ratio, to milligrams of albumin per gram of creatinine. The National Kidney Foundation recommendations cite gender differences for values of spot albumin-to-creatinine ratios that are not included here.

^bIf one converts the rate of micrograms per minute to milligrams per day by multiplying by 1,440 minutes in a day, the values obtained are very near those listed under the 24-hour collection column of milligrams per day of albumin, as expected.

Symptoms

- Symptoms are generally absent in CKD stages 1 and 2, and may be minimal during stages 3 and 4. General symptoms associated with stages 1 to 4 include edema, cold intolerance, shortness of breath, palpitations, cramping and muscle pain, depression, anxiety, fatigue, and sexual dysfunction. Chapter 47 highlights the classic symptoms associated with stage 5 CKD.

Signs

- **Cardiovascular–pulmonary:** Edema and worsening hypertension, electrocardiographic evidence of left ventricular hypertrophy, arrhythmias, hyperhomocysteinemia, and dyslipidemia
- **Gastrointestinal:** Gastroesophageal reflux disease, weight loss
- **Endocrine:** Secondary hyperparathyroidism, decreased vitamin D activation, β_2 -microglobulin deposition, and gout
- **Hematologic:** Anemia of CKD, iron deficiency, and bleeding
- **Fluid/electrolytes:** Hyper- or hyponatremia, hyperkalemia, and metabolic acidosis

Patients with stage 1 or 2 CKD disease usually do not have any symptoms or metabolic derangements such as acidosis, anemia, and bone disease. In addition, the most common measure of impairment of kidney function, serum creatinine, may be only slightly elevated in these early CKD stages. Consequently, estimation of the GFR is imperative for recognition of early stages of CKD.

6 Because the early stages of CKD are often undetected, the diagnosis requires a high level of suspicion in patients with chronic conditions such as hypertension and diabetes. Signs and symptoms associated with CKD become more prevalent in stages 3, 4, and 5. Anemia, abnormalities of calcium and phosphorus metabolism (secondary hyperparathyroidism), malnutrition, and fluid and electrolyte abnormalities become more common as kidney function deteriorates (see Chap. 47).

ANEMIA

Because the kidneys secrete 90% of the endogenous hormone erythropoietin, an endogenous hormone necessary for erythropoiesis, declining kidney function can lead to erythropoietin deficiency and anemia. The prevalence of anemia at specific stages of CKD is difficult to ascertain because of limited available data and use of various definitions.¹ Estimates of anemia (hemoglobin of less than 12 g/dL) prevalence in patients with a GFR greater than 80 mL/min per 1.73 m² are between 1% and 30%.¹⁰⁴ The true prevalence rate estimation is unclear as other factors, such as ethnicity, age, and gender, can also contribute to anemia. The prevalence of a hemoglobin less than 13 g/dL increases considerably in stages 3 to 5 CKD.¹ Anemia can lead to symptoms of fatigue, weakness, and

shortness of breath. However, mild anemia, especially when present for a prolonged time period, can be asymptomatic. The NKF K/DOQI guidelines recommend evaluating hemoglobin levels in all patients with CKD, noting the increase in anemia prevalence beginning with stage 3.¹⁰⁵ The treatment of anemia can improve or resolve symptoms and may help to stabilize kidney function.¹⁰⁶ Chapter 47 discusses the management of anemia in CKD.

CARDIOVASCULAR DISEASE

CKD is associated with a high rate of cardiovascular morbidity and mortality.¹⁰⁷ A recent epidemiologic study of more than 300,000 individuals demonstrated a strong relationship between GFR and cardiovascular disease: the lower the level of GFR, the higher the incidence of cardiovascular events.¹⁰⁸ In fact, individuals with stages 2 to 4 CKD were more likely to die from cardiovascular disease complications than to survive to the initiation of renal-replacement therapy;¹⁰⁹ consequently, monitoring for the presence or development of cardiovascular disease in patients with CKD is an important aspect of their care. It is established that patients with CKD have 16% to 37% of the life expectancy of a matched population without kidney disease.¹¹⁰ Appropriate traditional and nontraditional cardiovascular risk factor assessments are necessary in the evaluation of the patient with CKD. Guidelines for the evaluation, monitoring, and treatment of cardiovascular diseases in patients with CKD have been published and a detailed discussion can be found in the cited reference.¹⁰⁷

DISORDERS OF CALCIUM AND PHOSPHORUS HOMEOSTASIS

Abnormalities in calcium and phosphorus metabolism typically occur in stages 3 to 5 CKD. Secondary hyperparathyroidism, however, can develop earlier despite normal serum calcium and phosphorus levels, at a GFR of 80 mL/min per 1.73 m² or below.¹¹¹ Thus, to detect secondary hyperparathyroidism and limit the bone complications, it is recommended that parathyroid hormone concentration, vitamin D levels, and calcium and phosphorus be monitored beginning in stage 3 CKD.¹¹² Additional systemic benefits of correcting abnormalities in calcium, phosphorus, and parathyroid hormone may include cardiovascular risk reduction. Chapter 47 discusses the management of bone disease caused by CKD.

MALNUTRITION

Anorexia and malnutrition are complications of CKD. Although there are limited data defining at exactly which stage malnutrition develops, the NKF K/DOQI guidelines recommend evaluating for signs of malnutrition when the GFR is lower than 60 mL/min per 1.73 m² (stages 3, 4, and 5).¹¹³ An investigation for malnutrition should include a dietary assessment for protein and calorie intake,

serum albumin, and/or assessment of protein appearance in the urine (as a marker of protein intake). Chapter 143 discusses the interpretation of these tests and Chap. 147 discusses nutritional recommendations for patients with CKD.

TREATMENT

Chronic Kidney Disease

■ GOAL OF THERAPY

The goal of therapy is to delay the progression of CKD, thereby minimizing the development or severity of associated complications including cardiovascular disease. Nonpharmacologic and pharmacologic interventions are available to slow the rate of CKD progression and they may also decrease the incidence and prevalence of ESRD.

7 Usually the patient with CKD will benefit from modest dietary protein restriction (as a nondrug therapy) as well as pharmacologic therapy. The pharmacologic therapy's main purpose is to control the underlying conditions, such as diabetes mellitus and hypertension, that have precipitated the kidney damage so as to prevent further declines in function. Patients generally require a multimodality treatment approach irrespective of the cause of their kidney disease. Therapy with ACEIs and/or ARBs is a key therapeutic component for almost all patients.

■ NONPHARMACOLOGIC THERAPY

Dietary Protein Restriction

Experimental studies of kidney disease in animals suggest that dietary protein restriction delays the rate of progression of kidney function decline.¹¹⁴ This hypothesis was tested in humans in the MDRD study, a randomized controlled trial that evaluated the benefits of dietary protein restriction and blood pressure reduction on the rate of CKD progression.^{51,115} Most enrolled subjects had nondiabetic kidney disease and 24% of them had a diagnosis of polycystic kidney disease. Subjects with moderate CKD (GFR of 25 to 55 mL/min per 1.73 m²) were randomized by dietary protein intake groups (1.3 g/kg per day or 0.58 g/kg per day), in addition to blood pressure grouping (usual mean arterial pressure [MAP] [107 mm Hg] or low MAP [92 mm Hg]), for a total of four groups. Subjects with advanced CKD (GFR 13 to 24 mL/min per 1.73 m²) were randomized to a low-protein diet (0.58 g/kg/day) or a very-low-protein diet (0.28 g/kg/day) with a ketoamine acid supplement, in addition to the usual and low MAP as defined above for a total of four groups. After a mean followup of 2.2 years, protein restriction failed to show a statistical benefit in slowing the progression of CKD in any of the study groups. However, a secondary analysis of the MDRD study was conducted and revealed that in those patients with a GFR of less than 25 mL/min per 1.73 m², a protein intake of 0.6 g/kg per day was significantly associated with a decreased rate of progressive renal disease.¹¹⁵ In addition, this analysis showed that the rate of progression to ESRD was significantly reduced by 41% for each 0.2 g/kg per day reduction in dietary protein intake. The discrepancy in results between the primary and secondary analyses can be explained by the different statistical methods used in each of the two analyses, in that the later analysis evaluated participants who were actually compliant with their dietary prescription.

Because of concerns of inadequate power of individual studies, meta-analyses have been performed to determine effect of protein restriction on the progression of CKD. Two notable meta-analyses, using almost the same individual studies have come to somewhat varying conclusions.^{116,117} The first, by Pedrini et al., used only randomized, controlled trials of protein restriction, and demonstrated 33% risk reduction in the development of renal failure or death among

nondiabetic patients, and a 44% risk reduction in the progression of proteinuria or CKD among diabetic individuals.¹¹⁶ The second meta-analysis demonstrated a statistically beneficial effect of protein restriction on the progression of CKD; yet the authors concluded that the absolute effect, a reduction in the rate of decline of GFR by 0.53 mL/min per year after the addition of a low-protein diet does not compare well to other strategies.¹¹⁷

Thus, the available data suggests only a relatively small benefit from dietary protein restriction in CKD patients. Because low protein diets may lead to malnutrition in patients with advanced CKD and those with nephrotic-range proteinuria, the NKF K/DOQI has advocated a dietary protein intake of 0.6 g/kg per day in patients with a GFR <25 mL/min per 1.73 m².¹¹³ Titration of protein intake up to 0.75 g/kg per day is suggested for patients who cannot achieve or maintain adequate nutritional status with the lower-protein (0.6 g/kg per day) diet.¹¹³

■ PHARMACOLOGIC THERAPY

Guidelines for CKD treatment usually recognize the differences in pathogenesis and course of diabetic and nondiabetic CKD. Consequently, pharmacologic interventions are discussed separately for these conditions within this chapter. The major focus of this chapter is on the impact of ACEI and ARB therapies on progressive CKD. Pharmacologic therapies specific for glomerulonephritis are discussed in Chap. 50, while therapies for the treatment of complications of kidney disease are covered in Chap. 47.

Diabetic Chronic Kidney Disease

■ INTENSIVE INSULIN THERAPY

The DCCT was the first study to show the long-term benefits of intensive insulin therapy (IIT) on kidney and other diabetes-related outcomes.⁶³ IIT was achieved by administration of three or more times daily insulin injections or by insulin pump infusion so as to attain preprandial and postprandial blood glucose levels of 70 to 120 mg/dL and <180 mg/dL, respectively. IIT effectively reduced the incidence of microalbuminuria as compared to standard therapy in both the primary prevention and secondary prevention groups, as described previously.⁶³ However, IIT was associated with at least one episode of hypoglycemia in 65% of patients as compared to 35% in the standard treatment group.⁶³ Other studies confirm the beneficial effects of IIT in prevention and progression of diabetic complications.^{118,119} A meta-analysis of 16 clinical studies showed a benefit in reducing the frequency and severity of diabetic complications, and delaying the development and progression of diabetic nephropathy with intensive blood glucose control in type 1 diabetes.¹¹⁸ A 4-year followup study of the DCCT participants, the Epidemiology of Diabetes Interventions and Complications study, showed a continued benefit of IIT on the risk of diabetic nephropathy with a 53% reduction in microalbuminuria.¹¹⁹

The United Kingdom Prospective Diabetes Study's Intensive Glucose Control Study also presented data on prevention of microvascular complications among individuals with type 2 diabetes mellitus.⁵⁵ Individuals newly diagnosed with type 2 diabetes mellitus ($n = 3,867$) were randomized to intensive therapy (goal fasting plasma glucose of <6 mmol/L) or conventional therapy (goal fasting plasma glucose of <15 mmol/L) after a 3-month period of dietary counseling. Individuals in either group could use oral sulfonylureas or insulin. After 10 years of followup, the intensive group was associated with an 11% reduction in median hemoglobin A_{1c} and a 12% reduction in any diabetes-related end point compared to the conventional group. Most of the observed benefit was in a reduction in microvascular end points, primarily proliferative retinopathy.⁵⁵

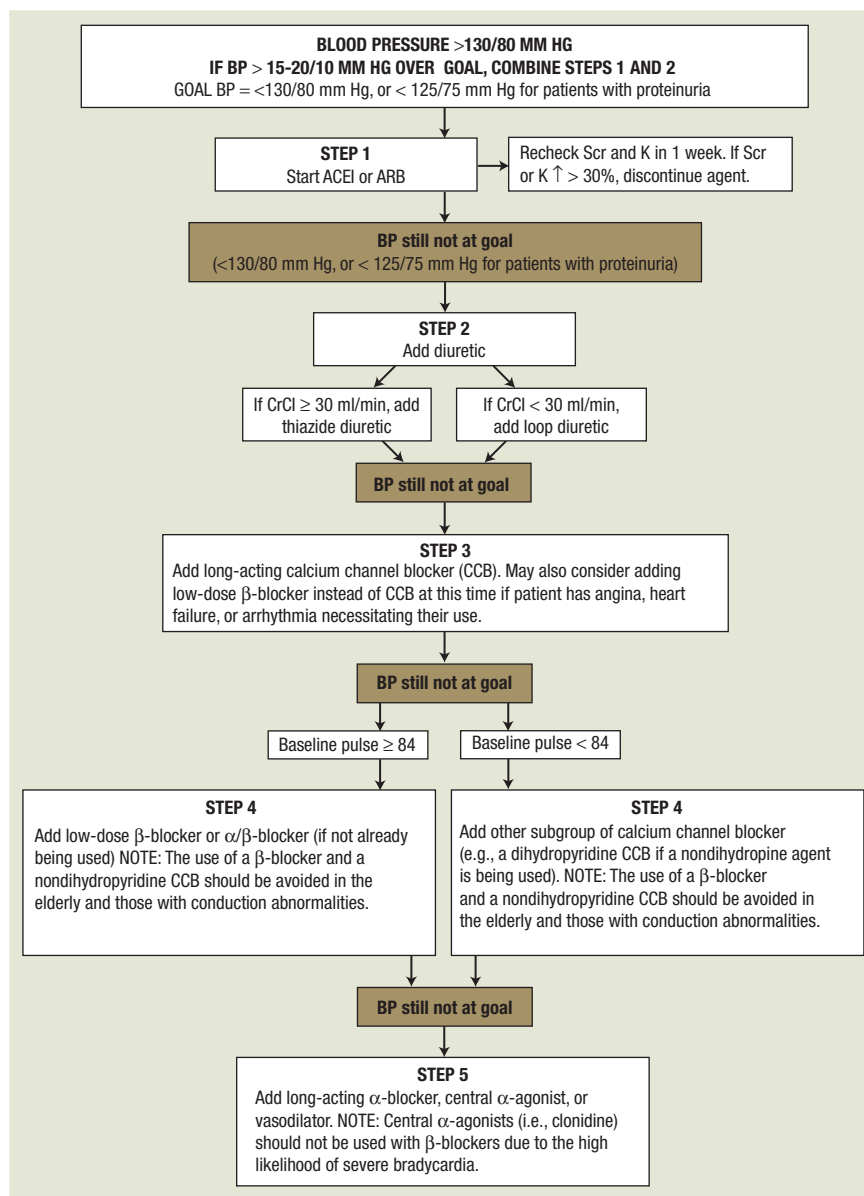

FIGURE 46-2. Hypertension management algorithm for patients with CKD. Dosage adjustments should be made every 2 to 4 weeks as needed. The dose of one agent should be maximized before another is added. (ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BP, blood pressure; CAD, coronary artery disease; CCB, calcium channel blocker; CHF, congestive heart failure; MI, myocardial infarction; UP:Cr, urinary protein-to-creatinine ratio.) (Adapted from reference 136 with permission.)

The data from the DCCT, meta-analyses, and United Kingdom Prospective Diabetes Study provide levels of support for reducing microvascular complications, including nephropathy, by instituting intensive therapy for patients with type 1 and type 2 diabetes mellitus. Intensive therapy can include insulin or oral drugs, but employ the testing of blood sugar at least three times daily. Furthermore, the goals of therapy include an A_{1c} of <7%, and preprandial plasma and peak postprandial blood glucose of 92 to 130 mg/dL and <180 mg/dL, respectively.¹²⁰ The clinician is encouraged to review Chap. 77 for a thorough review of dosing, monitoring, and goals of therapies to treat diabetes mellitus.

■ OPTIMAL HYPERTENSION CONTROL

Reduction of blood pressure in type 1 and type 2 diabetic patients has been associated with lower rates of CKD progression.^{58,59,121–130} The United Kingdom Prospective Diabetes Study⁵⁹ was a randomized trial of captopril or atenolol among 1,148 hypertensive type 2 diabetic patients designed to evaluate the effect of blood pressure reduction to a level of <150/85 mm Hg versus <180/105 mm Hg on macrovascular and microvascular outcomes. Reductions of 24% in diabetes-related end points, 32% in deaths related to diabetes, 44%

in strokes, and 37% in microvascular end points were observed after a median follow up of 8.4 years.⁵⁹ The benefit of blood pressure control has been confirmed in subsequent studies of type 2 diabetic subjects with microalbuminuria.^{121,122,127,131–134} These studies used either ACEI (Table 46–4) or ARB (Table 46–5) classes of drugs, which likely have nonhemodynamic beneficial effects on CKD progression, as discussed below, as well as blood-pressure-lowering effects. In type 1 diabetes with nephropathy, a rigorous blood pressure goal (MAP of ≤92 mm Hg) leads to decreased proteinuria.¹²⁹

The Seventh Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure recommends a goal blood pressure of <130/80 mm Hg for patients with CKD.¹³⁵ Elevated blood pressure is often more difficult to control in patients with CKD than in those with normal kidney function. Therefore, to achieve adequate blood pressure goals, three or more different blood pressure medications are usually required.¹³⁶ Figure 46–2 depicts the proposed algorithm for the management of hypertension in people with CKD and diabetes. The selection of individual classes of drugs for limiting progression of CKD is presented in the following sections.

TABLE 46-4 Summary of Angiotensin-Converting Enzyme Inhibitor Studies in Diabetic Patients

Drug, Dose, and Study Design	Baseline Renal Characteristics	Number of Subjects and Disease	Study Duration	Outcome	Reference and Study Name
Captopril 25 mg three times a day; randomized, placebo-controlled trial	UPE ≥ 500 mg/day, $S_{cr} \leq 2.5$ mg/dL	409 Type 1 DM	3 years	Risk reduction of doubling S_{cr} was 48% with captopril treatment; subanalysis showed a larger risk reduction with more elevated S_{cr} (76% when the S_{cr} was 2 g/dL)	Lewis et al. ¹²³
Enalapril once daily; randomized, placebo-controlled trial	Normotensive, UAE 20–200 mcg/min	103 Type 2 DM	5 years	Risk reduction of 66.7% for progression to clinical albuminuria with enalapril	Ahmad et al. ¹²⁴
Enalapril 10 mg once daily; randomized, placebo-controlled trial	Normotensive, UAE ≤ 30 mg/day	156 Type 2 DM	6 years	Risk reduction of 12.5% for microalbuminuria with enalapril treatment; GFR reductions were two times greater in the placebo-treated patients at 6 years	Ravid et al. ¹²⁵
Lisinopril 10 mg once daily with titration to BP; placebo-controlled trial	Normotensive patients with either normoalbuminuria or microalbuminuria	530 Type 1 DM	2 years	18.8% lower UPE with lisinopril treatment; greater treatment effect in those with baseline microalbuminuria (34.2 mcg/min vs. 1 mcg/min)	EUCLID Study Group ¹²⁶
Ramipril 10 mg once daily; randomized, placebo-controlled trial	Normoalbuminuria or microalbuminuria	3,577 Type 2 DM	4.5 years	Ramipril lowered risk of overt nephropathy with and without baseline microalbuminuria (relative risk of 0.8); lower UP:Cr at 1 and 4.5 years with ramipril treatment	HOPE and MICROHOPE ¹²⁷
Captopril 50 mg twice a day; randomized, placebo-controlled trial	Normotensive patients with microalbuminuria	143 Type 1 DM	2 years	Risk reduction of 67.8% for clinical proteinuria with captopril treatment; GFR reductions of 7.9 mL/min per 1.73 m ² per year in placebo group while stable in captopril group	North American Microalbuminuria Study Group ¹²⁸
Enalapril 5 mg once daily, titrated to BP; placebo-controlled trial	Hypertensive, GFR of 30–100 mL/min per 1.73 m ²	121 Type 2 DM	3 years	Clinical albuminuria progression in 7% of enalapril vs. 21% of placebo group; enalapril therapy preserved GFR, whereas placebo treatment resulted in a loss of 0.33 mL/min per 1.73 m ² per month	Lebovitz et al. ¹³⁰

BP, blood pressure; DM, diabetes mellitus; GFR, glomerular filtration rate; S_{cr} , serum creatinine; UAE, urinary albumin excretion; UP:Cr, urinary protein-to-creatinine ratio; UPE, urinary protein excretion.

Patients diagnosed with both hypertension and diabetes mellitus have been estimated to have up to a sixfold higher risk of developing ESRD than do those patients with diabetes mellitus alone.¹³⁶ Adequate blood pressure control can reduce the rate of decline in GFR and the degree of albuminuria in hypertensive type 1 and type 2 diabetic patients.¹³⁶ Although interventions that reduce blood pressure have

historically shown reductions in urinary albumin and protein excretion, the ACEIs were the first agents shown to reduce glomerular capillary pressure and volume, which, in animal models and human studies, have resulted in preservation of renal function.^{137–139} Table 46–6 summarizes the documented effects of the other various available antihypertensive agents on renal blood flow and GFR.^{140,141}

TABLE 46-5 Summary of Angiotensin Receptor Blocker Studies in Diabetic Patients

Drug, Dose, and Study Design	Baseline Characteristics	Number of Subjects and Disease	Duration	Outcomes	Reference and Study Name
Irbesartan 300 mg once daily; amlodipine 10 mg once daily; randomized, placebo-controlled trial	Hypertensive, UPE ≥ 900 mg/day	1,715 Type 2 DM	2.6 years	Irbesartan therapy resulted in a 20% (for placebo) and 23% (for amlodipine) risk reduction in primary composite end point of doubling of S_{cr} , development of ESRD, or death	Lewis et al. ¹³⁴
Irbesartan 150 mg once daily; irbesartan 300 mg once daily; randomized, placebo-controlled trial	Hypertensive, AER of 20–200 mcg/min	590 Type 2 DM	2 years	Irbesartan 150 mg resulted in a 24% reduction in UAE; irbesartan 300 mg resulted in a 38% reduction in UAE; placebo resulted in a 2% decrease; hazard ratio for diabetic nephropathy was 0.56 and 0.32 in the 150-mg and 300-mg irbesartan groups, respectively	Parving et al. ¹³³
Losartan 50–100 mg once daily; randomized placebo-controlled trial	Hypertensive, UA:U _{cr} of at least 300 and S_{cr} 1.3–3 mg/dL	1,513 Type 2 DM	3.4 years	Losartan therapy resulted in a 16% risk reduction of primary composite end point of doubling of S_{cr} , ESRD, or death; level of proteinuria declined by 35% with losartan therapy	Brenner et al. ¹³²
Irbesartan 150 mg twice a day; randomized, placebo-controlled trial, crossover study	Hypertensive and normotensive, microalbuminuria	128 Type 2 DM	120 days	Irbesartan had a beneficial effect on reducing AER in both hypertensive and normotensive patients with type 2 diabetes	Sasso et al. ¹³¹

AER, albumin excretion rate; DM, diabetes mellitus; ESRD, end-stage renal disease; S_{cr} , serum creatinine; UA:U_{cr}, urinary albumin-to-urinary creatinine ratio; UAE, urinary albumin excretion; UPE, urinary protein excretion.

TABLE 46-6 Effects of Antihypertensive Agents on Renal Blood Flow (RBF) and Glomerular Filtration Rate (GFR)		
Antihypertensive Agent	Mechanism of Action	Effects on Renal Hemodynamics
Diuretics	Sodium and volume depletion	↓ GFR and RBF
	↑ Vasodilatory prostaglandin levels (IV loop diuretics)	↑ RBF
	Renal vasoconstriction (IV thiazide diuretics)	↓ GFR and RBF
β-Adrenergic blockers	↓ Cardiac output	↓ GFR and RBF
	↑ Renal vascular resistance (nonselective agents)	↓ GFR and RBF
	↑ Renal vascular resistance (β ₁ -selective agents)	No change in GFR and RBF
Centrally acting antiadrenergic drugs	↓ Renal vascular resistance (methyldopa)	No change in GFR and RBF
	↓ Renal perfusion pressure (clonidine, α ₂ -adrenergic agonist)	↓ GFR and RBF
Peripherally acting antiadrenergic drugs	Direct vasodilation (postsynaptic α ₁ -adrenoreceptor blocking agents)	No change in GFR and RBF
Direct vasodilator agents	↓ Renal vascular resistance (hydralazine, minoxidil)	↑ RBF and no effect on GFR
	Arterial vasodilation plus dilatation of venous capacitance vessels (nitroprusside)	↓ GFR and RBF (acute effect)
Calcium channel blockers	↓ Renal vascular resistance by vasodilation of afferent arterioles (hypertensive patients)	↑ RBF and no change in GFR

↓, decrease; ↑, increase.

Antihypertensive Drug Choice

8 Several studies have confirmed the beneficial effects of ACEIs on renal function in patients with and without diabetes. Table 46-4 shows the results of the key studies that evaluated more than 100 diabetic subjects followed over 2 to 6 years.^{123–125,127,128,130,142} These studies show that the benefit of ACEI use in CKD is seen in both type 1 and 2 diabetic subjects, across different degrees of kidney damage (normoalbuminuria, microalbuminuria, frank proteinuria, and reduction in GFR), and are drug-class specific. These findings consistently support the role of ACEI therapy in the management of CKD. It is customary to begin at low doses and increase the dose at 4-week intervals to control the level of proteinuria. The dose is usually increased until proteinuria is reduced by 30% to 50% or the development of side effects such as elevations in serum creatinine or potassium occurs.

A meta-analysis that pooled several of the small and large randomized, controlled studies showed beneficial effects of ACEI therapy on diabetic nephropathy.¹⁴³ Progression to proteinuria was reduced by 65% in patients with diabetes mellitus and microalbuminuria, and progression of nephropathy (doubling of serum creatinine) was reduced by 40% in patients with overt proteinuria (comprised of 30% diabetics and 70% nondiabetics; Fig. 46-3).¹⁴³ However, a recent meta-analysis of 127 studies with more than 30,000 subjects suggests that the benefit of ACEIs and ARBs over other pharmacologic agents is related to blood pressure attained during the study rather than to special properties of the ACEI or ARB (e.g., antiproteinuric effects).¹⁴⁴

Some of the discrepancy in these results may be due to aldosterone escape in renin-angiotensin-aldosterone system blockade. Type 2 diabetic subjects with nephropathy who had increased aldosterone plasma levels during a mean 35-month treatment with losartan had a faster decline in the rate of GFR compared to those without aldosterone escape.¹⁴⁵ Combination therapy of ACEI and ARBs or addition of an aldosterone inhibitor to ACEI or ARB was recently suggested to improve suppression of the renin-angiotensin-aldosterone system.¹⁴⁶

FIGURE 46-3. A. Relative risk for developing microalbuminuria with 95% confidence intervals (CIs) in each study, and the aggregate relative risk with 95% CIs for all studies (N = 642 with diabetes). B. Relative risk for doubling serum creatinine concentration or development of ESRD with 95% CIs in each study, and aggregate relative risk with 95% CIs for all studies (N = 1,277; 479 with diabetes). (ACE, angiotensin-converting enzyme.) (From reference 143 with permission.)

Another study exploring the addition of an aldosterone receptor blocker to ACEI or ARB for renoprotection in type 1 diabetes was recently published.¹⁴⁷ This study, conducted in 20 patients with proteinuria, showed a reduction in albuminuria by 30% with a significant daytime reduction of blood pressure in patients treated with spironolactone 25 mg once daily. The results are intriguing and need to be confirmed with larger numbers of patients with close monitoring for complications such as hyperkalemia.

The ARBs have also been shown to slow the progression of diabetic kidney disease.^{131–134} Table 46-5 summarizes data from several studies (with at least 100 patients) evaluating ARB efficacy in type 2 diabetes. All patients in these trials had at least a level of proteinuria consistent with microalbuminuria and all were hypertensive. With the exception of one, the studies were of a sufficiently long duration to determine the beneficial effects of ARBs on nephropathy. Of note, the beneficial effect of delaying the onset of diabetic nephropathy was significant in type 2 diabetic patients who received irbesartan 300 mg daily for up to 2 years.¹³³ A similar trend (although not statistically significant) was observed in those subjects who received a lower dose of irbesartan (150 mg daily). The Evaluation of Losartan in the Elderly (ELITE) study, which assessed losartan versus captopril in diabetics and nondiabetics, showed comparable renal benefits of both ARBs and ACEIs in a population of heart failure patients.¹⁴⁸ Currently, the data show efficacy of both ACEIs and ARBs in type 2 diabetes, whereas only ACEIs have been adequately evaluated in patients with type 1 diabetes. Thus, until head-to-head trials with these agents are assessed, they should not be considered interchangeable in all forms of diabetes.¹⁴⁹

Because ACEIs and ARBs have demonstrated efficacy in patients with diabetes, the possibility of using both agents in type 2 diabetes has been investigated.¹⁵⁰ A short-term (12 to 24 week) study evaluated lisinopril (20 mg once daily) and candesartan (16 mg once daily) versus the combination in 199 patients. The reduction of urinary albumin-to-creatinine ratios was greater with combination therapy (50%) than with either lisinopril (39%) or candesartan (24%) alone. However, blood pressure reduction was also significantly greater in the combination therapy patients, making it unclear if the combination produced an enhanced antiproteinuric effect or if the reduction in the albumin-to-creatinine ratio could be attributable to the greater reduction in blood pressure.¹⁵⁰

Studies suggest that no individual ACEI drug is superior to any other ACEI.¹⁴³ In patients with hypertension, the primary goal is to optimally treat the blood pressure to target, and the secondary goal is to control proteinuria. For normotensive patients with microalbuminuria, one should titrate the ACEI to reduce the degree of microalbuminuria. The antihypertensive ceiling effect noted for ACEI dosage titration has not been confirmed for lowering urinary protein excretion. However, patients with hypertension and proteinuria can still exhibit side effects associated with blood pressure lowering, and hence dosages should be titrated to the maximal level of proteinuria reduction without reducing the blood pressure to a level associated with adverse events including renal function compromise. Patients should be initiated on the lowest possible dose of ACEI and titrated to blood pressure control and proteinuria reduction. A specific recommendation regarding the dose to initiate therapy with a specific ACEI has not been established; consequently, the lowest recommended dose for the management of hypertension may be appropriate until such information is available. The clinician needs to evaluate the insurance coverage of specific agents in specific patients. In addition, one needs to consider the presence of other concomitant diseases and past history of treatment, as well as any side effects demonstrated with particular agents. Generally, ACEIs are more cost-effective than ARBs because of the availability of generic formulations. If and when patients exhibit adverse effects such as cough and/or hyperkalemia, a switch to an ARB is appropriate.

Because the clearance of all ACEIs (with the exception of fosinopril) is reduced in CKD, it is prudent to commence therapy at lower initial doses and subsequently titrate to achieve the optimal therapeutic effects and minimize potential toxicity.¹⁵¹ The antiproteinuric effects of ACEIs are not necessarily attained at the same doses as the antihypertensive effects. Thus patients who have reached their blood pressure goals may require further dosage adjustments to achieve maximal reductions in urinary protein excretion. Serum potassium needs to be monitored when initiating therapy with ACEIs, especially when patients are concurrently receiving drugs that may increase the risk of hyperkalemia, such as nonsteroidal antiinflammatory agents. Chapter 15 has a thorough discussion of dose, dose titration, monitoring, and adverse effects of ACEIs and ARBs.

Some calcium channel blockers (CCBs) decrease glomerular injury without negatively changing renal hemodynamics.¹³⁸ The postulated mechanisms for this decrease in renal injury include suppression of glomerular hypertrophy, inhibition of platelet aggregation, and decreased salt accumulation.¹³⁸ Although the data regarding dihydropyridine calcium channel blockers do not suggest any beneficial effects beyond those attributable to reducing blood pressure, there is some suggestion that the nondihydropyridine agents (diltiazem and verapamil) may have beneficial effects on proteinuria that are similar to those of ACEIs.^{152–154} A few studies suggest that the efficacy of combination therapy with ACEIs and nondihydropyridine CCBs may be superior in terms of proteinuria reduction than the use of either agent alone.¹⁵⁵ Most clinicians, however, tend to use the combination of ACEI plus ARBs instead of

either of the former agents plus a nondihydropyridine CCB. In general, nondihydropyridine CCBs are used as second-line antiproteinuric drugs when ACEIs or ARBs are not tolerated.

CLINICAL CONTROVERSY

Some clinicians believe that combinations of ACEI and ARB medications or ACEI and nondihydropyridine calcium channel blockers are additive in terms of reductions in proteinuria reduction over single therapy, whereas others believe that single-agent therapy with ACEI or ARB is adequate.

Nondiabetic Chronic Kidney Disease

■ ANTIHYPERTENSIVE AGENTS

9 Reduction of blood pressure is key to decreasing cardiovascular and renal sequelae. However, all antihypertensive agents are not equal in their ability to preserve kidney function despite similar efficacy in terms of blood pressure reduction. Among the different antihypertensives available, ACEIs and ARBs are currently considered the first choice in patients with CKD because they reduce intraglomerular pressure. Several short- and long-term clinical trials have assessed the effect of ACEIs on renal function in patients without diabetes; Table 46–7 summarizes these trials.^{142,156–159} These studies vary in length from 12 weeks to 7 years, and several enrolled a small number of subjects. Most patients had nephropathy associated with proteinuria and advanced CKD. Significant reductions in the risk of doubling serum creatinine, requirement for dialysis, and/or proteinuria were demonstrated for patients receiving the ACEIs. In one study, ramipril (1.25 to 5 mg daily) reduced proteinuria and the rate of GFR decline to a greater extent than that expected from blood pressure reduction alone.¹⁴² The proteinuria reduction was greatest in those patients with the highest baseline levels of proteinuria. A limitation of this study was that the additional antihypertensive agents that were administered to study participants were not specified. A subsequent study in patients with mean proteinuria of 3 g/day showed that the relative risk of developing ESRD was 2.3 times higher in the conventional therapy plus placebo arm as compared to the conventional therapy plus ramipril arm.¹⁵⁹ These studies and the summary results of a meta-analysis revealed that ACEIs conferred a 40% reduction in the risk of developing ESRD or doubling of serum creatinine in patients with overt proteinuria (>300 mg protein/24 hours) and renal disease of various etiologies; see Fig. 46–3).¹⁴³ However, a recent meta-analysis failed to show a significant benefit of ACEI and/or ARBs over other antihypertensive agents in CKD progression.¹⁴⁴ A post hoc analysis of the African American Study of Kidney Disease and Hypertension (AASK), which evaluated two different blood pressure targets and three different treatment regimens in subjects with a GFR between 20 and 65 mL/min per 1.73 m², showed that the change in the level of proteinuria over 6 months of treatment predicted the progression of hypertensive CKD.¹⁶⁰ In addition, a post hoc analysis of the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), where hypertensive subjects were randomized to chlorthalidone, amlodipine, or lisinopril for a mean of 4.9 years, revealed similar incident rates of ESRD in the three treatment groups irrespective of the cause of renal disease.¹⁶¹ Therefore, although the drug class versus absolute blood pressure reduction is an evolving area of investigation, current treatment guidelines recommend use of ACEI or ARBs in subjects with CKD.

The ARBs, although evaluated to a lesser extent than ACEIs, appear to have similar efficacy in terms of kidney protection in patients with

TABLE 46-7 Summary of Studies with Angiotensin-Converting Enzyme Inhibitors in Patients without Diabetes

Drug, Dose, and Study Design	Baseline Characteristics	Number of Subjects and Disease	Duration	Outcomes	Reference and Study Name
Benazepril 10 mg once daily; randomized, placebo-controlled trial	Mild (46–60 mL/min GFR) and moderate (30–45 mL/min GFR) renal insufficiency	583 Patients with various renal disorders including diabetes mellitus	3 years	Benazepril afforded a 53% risk reduction in primary end point of doubling of S_{cr} or requirement for dialysis; 71% and 46% risk reductions in the mild and moderate renal insufficiency groups, respectively	Maschio et al. ¹⁵⁶
Ramipril 2.5 mg once daily and titrated to BP; randomized, placebo-controlled trial	GFR 20–70 mL/min per 1.73 m ² UPE ≥ 1 g/day	352 Proteinuric patients	5 years	Rate of loss of GFR was 0.89 mL/min per month in placebo group versus 0.39 mL/min per month in ramipril group; twice the numbers of patients receiving placebo vs. ramipril reached primary composite end point of doubling of S_{cr} or ESRD	The GISEN Group ¹⁴²
Enalapril 20 mg once daily vs. losartan 50 mg once daily; randomized trial	Proteinuria	93 Hypertensives	12 weeks	UP:Cr was reduced by 43% in losartan group vs. 23% in enalapril group ($P = 0.05$)	Nielsen et al. ¹⁵⁷
Enalapril 5–40 mg daily vs. other antihypertensive agents; randomized, controlled trial	UPE ≥ 0.5 g/day $S_{cr} \geq 1.5$ mg/dL	44 IgAN patients	7 years	Renal survival was significantly better in the enalapril group (100%) versus the other antihypertensive group (70%) after 4 years, and 92% vs. 55% respectively, after 7 years; proteinuria significantly decreased in the enalapril group, whereas it tended to increase in the control group	Praga et al. ¹⁵⁸
Ramipril 1.25–5 mg daily vs. conventional therapy; randomized controlled trial	Proteinuria 1–3 g/day	186 Chronic nephropathies	31 months	Progression to use ESRD was half as common in the ramipril group; patients with GFR ≤ 45 mL/min per 1.73 m ² and proteinuria ≥ 1.5 g/24 hours had the greatest benefit from ramipril therapy	Ruggenenti et al. ¹⁵⁹

several forms of glomerulonephritis (Table 46–8).^{162,163} Proteinuria reduction on the order of 25% to 47% was shown with ARB therapy. However, these studies employed small numbers of patients with short followup time frames as compared to studies in diabetic patients. Despite these limitations, most clinicians use either ACEI or ARB therapy as the standard of care in patients with nondiabetic CKD and proteinuria. The combination use of ARBs with ACEIs has been proposed and preliminary data suggest that this approach is safe and results in a greater decrease in proteinuria than that seen with either agent alone.¹⁶⁴ A recent study prospectively evaluated the use of losartan 100 mg daily alone, trandolapril 3 mg daily alone, or the combination of the two in 336 patients with nondiabetic kidney diseases. The primary end point, time to doubling of serum creatinine or ESRD, was observed in 11% of combination therapy patients and in 23% of each of the single-agent treatment groups.¹⁶⁵ The selection of ACEIs versus ARBs in the control of proteinuria in nondiabetic

kidney disease is essentially predicated on cost of therapy, patient tolerance, and clinician preference.

The CCBs are also effective treatments for hypertension in patients with nondiabetic CKD. However, as was mentioned previously, only the nondihydropyridine CCBs have been studied and shown to reduce the rate of decline of kidney function.^{152,166} There are currently no data to suggest that higher doses of nondihydropyridine CCBs are needed to elicit a reduction in proteinuria as compared to a reduction in blood pressure.

Although diuretics are commonly used to treat fluid overload and hypertension in patients with CKD, there are no compelling data to suggest any renal protection in terms of proteinuria regression or a reduction in the rate of progression. Chapter 52 addresses the use of diuretics for managing volume overload. Other available antihypertensive agents are used to control blood pressure in patients with kidney disease. Additional central and peripherally acting antihy-

pertensive agents can be used in patients with CKD. One must consider the need for dosage reductions caused by reductions in GFR for drugs that are excreted by the kidneys and/or supplemental doses as a consequence of dialysis removal of hydrophilic β -blockers such as nadolol, acebutolol, and atenolol.

Regardless of the treatment regimen, hypertension should be treated to the currently accepted targets in patients with CKD. If proteinuria is present, the use of ACEIs, ARBs, and possibly nondihydropyridine CCBs may be superior to conventional agents in decreasing proteinuria and glomerular hypertension.

As precipitous reductions in blood pressure may be deleterious to kidney function in patients with underlying CKD, blood pressure targets in these patients should be achieved over several weeks to allow the kidney to adapt to reduced perfusion pressures.¹³⁵ Typically there is an acute but sustained reduction in GFR of approximately 25% to 30% within 3 to 7 days after initiation of ACEI therapy as a result of a reduction in intraglomerular pressure.¹⁶⁷ If a sustained increase in the serum creatinine by more than 30% after ACEI therapy initiation is observed, ACEI therapy discontinuation should be strongly considered (see Chap 49). It is necessary to realize that although ACEI therapy may be effective in reducing the rate of nephropathy progression, one needs to consider their propensity for hyperkalemia and potential for acute GFR reduction especially in patients who already have compromised GFR.

CLINICAL CONTROVERSY

Some clinicians fail to prescribe ACEI or ARB medications when the GFR is less than 20 to 30 mL/min per 1.73 m² because of fear of the patient developing a further elevation in serum creatinine, whereas other clinicians prescribe these medications and just evaluate serum creatinine closely after therapy initiation and dosage increases.

OTHER INTERVENTIONS TO LIMIT DISEASE PROGRESSION

10 Other interventions such as lipid-lowering regimens, smoking cessation, and anemia management may also slow the progression of CKD.

HYPERLIPIDEMIA TREATMENT

Although several drugs are available for lipid lowering, the β -hydroxy- β -methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors and gemfibrozil have been most often used in dyslipidemic patients with CKD with and without proteinuria.⁸⁰ The primary goal of treatment is to adequately treat hyperlipidemia so as to decrease the risk for progressive atherosclerotic cardiovascular disease. However, a meta-analysis of 13 studies of lipid-lowering agents showed a reduction in the rate of CKD progression by only 0.156-mL/min per month.¹⁶⁸ The mechanisms for this effect are unknown, but HMG-CoA may reduce monocyte infiltration, mesangial cell proliferation, mesangial matrix expansion, and tubulointerstitial inflammation and fibrosis.¹⁶⁹ Consequently, a secondary goal of lipid-lowering treatment is to reduce proteinuria and renal function decline. Additional therapies that show favorable benefits on lipids are carnitine, fish oil, low-molecular-weight heparins, and exercise.¹⁷⁰ The National Cholesterol Education Program III and NKF K/DOQI guidelines should be consulted for a thorough review of lipid reduction and cardiovascular disease in patients with CKD.^{112,171}

SMOKING CESSATION

Although the adverse cardiovascular disease health risks of smoking are well documented, only recently have the adverse effects of smoking on the progression of CKD been recognized. Smoking is

associated with an acute reduction in GFR, and increased heart rate and blood pressure, likely secondary to nicotine exposure.¹⁷² Nicotine has also been associated with an increase in urinary albumin excretion.^{69,172} Although the effectiveness of smoking cessation on limiting progressive CKD has not been prospectively evaluated, one study suggested that smoking cessation resulted in a protective effect against proteinuria and reduced GFR.¹⁷³ This later study showed that although current smokers had a significantly higher albumin excretion (and reduced GFR) versus nonsmokers, those patients who quit smoking had a statistical association with only microalbuminuria.¹⁷³ Based on the evolving data concerning the detrimental effects of smoking on the kidney, it is prudent to educate patients regarding this risk, and institute appropriate therapeutic options for smoking cessation as discussed in Chap. 69.

ANEMIA TREATMENT

Prolonged anemia is associated with left ventricular hypertrophy and heart failure. It has been suggested that anemia may increase the rate of CKD progression.¹⁷⁴ Researchers have coined the phrase “cardiorenal anemia syndrome” to describe the interrelationship between anemia, heart failure, and CKD.¹⁷⁴ It has been hypothesized that the treatment of heart failure and anemia may reduce the progression of both heart failure and CKD.^{175,176}

A study in renal transplant recipients showed an absence of renal function decline in newly anemic patients who had erythropoietin therapy initiated and a reduction in the loss of further renal function in patients who had ongoing anemia for a short time period and subsequently received therapy with erythropoietin.¹⁷⁷ Longer renal graft survival in erythropoietin-treated patients was also reported. These data support further study of the potential role of anemia management in reducing CKD progression. Tissue hypoxia associated with anemia may be a stimulus for continued renal injury in those with stages 3 to 5 CKD. In addition, anemia-related alterations of renal sympathetic nerve activity and related increases in oxidative stress have been reported.¹⁷⁸ Chapter 47 discusses anemia as a complication of CKD.

PHARMACOECONOMIC CONSIDERATIONS

The financial and societal costs of the care of individuals with CKD are high, especially the care of those with ESRD—this population of beneficiaries comprises only 0.5% of the total Medicare population, yet accounts for 5% of all Medicare expenditures.¹⁷⁹ Annualized expenditures per beneficiary ranged from \$36,000 for those 24 years of age and younger to \$51,000 for those 75 years of age and older.¹⁷⁹ These costs for the care of advanced CKD are estimated to increase dramatically over the next decade, reaching an estimated \$28 billion dollars by the year 2010 for Medicare alone.¹⁸⁰

There have been a few evaluations of the potential pharmacoeconomic impact of screening for microalbuminuria and the subsequent initiation of various pharmacotherapeutic regimens in type 1 diabetic patients.^{181,182} According to one study, the historical standard approach to proteinuria reduction was considered to be treatment with hydrochlorothiazide at the time of hypertension diagnosis, while the newer treatment approach assumed three different screening and treatment strategies with ACEIs. The results from this evaluation suggested that with early screening and treatment of persistent microalbuminuria with ACEIs, it is possible to realize a cost-effectiveness of \$7,900 to \$16,500 per year of life saved. This amount is similar to the cost-effectiveness associated with treating hypertension in the general population. A similar cost-effectiveness analysis using different strategies but the same basic model was also performed¹⁸² and projected that treating all patients with an ACEI 5 years after the diagnosis of diabetes was as cost-

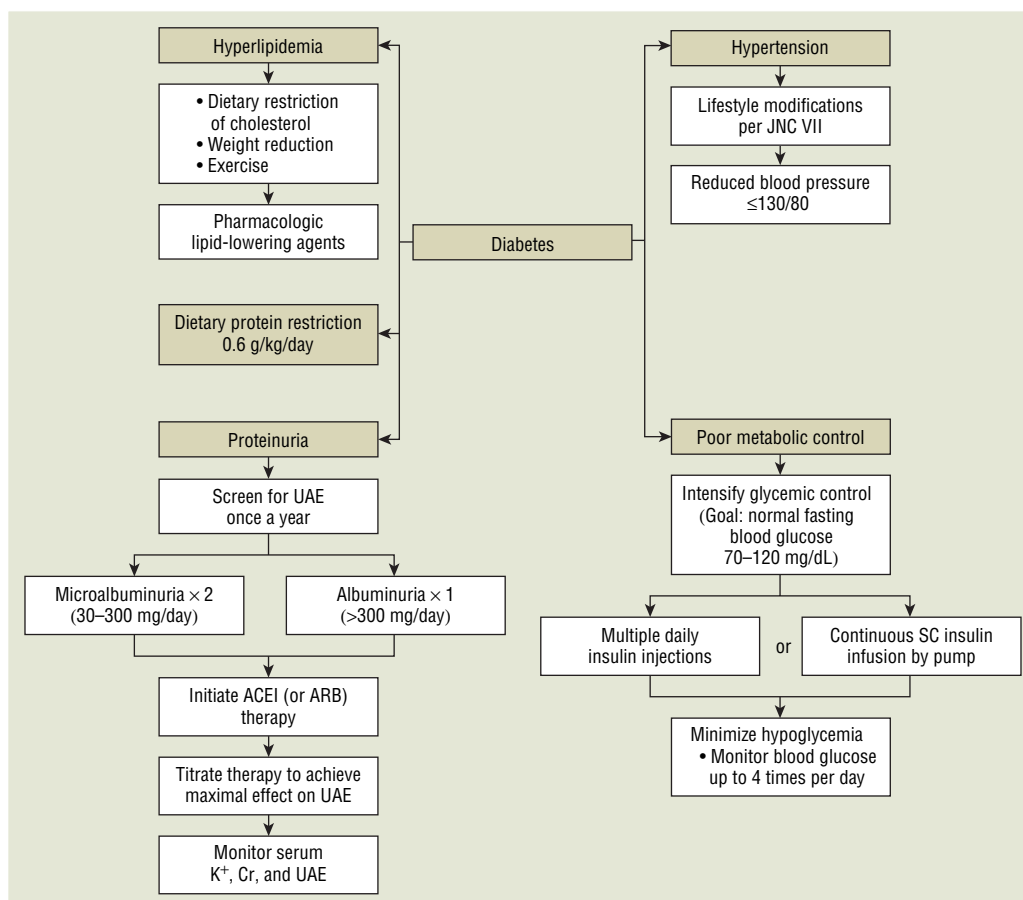

FIGURE 46-4. Therapeutic strategies to prevent progression of renal disease in diabetic individuals. (ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; JNC VII, the seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure; SC, subcutaneous; UAE, urinary albumin excretion.)

effective as annual screening for microalbuminuria beginning 5 years after diagnosis, with the initiation of an ACEI when and if persistent microalbuminuria was detected. The DCCT Research Group evaluated the cost-effectiveness of intensive insulin therapy as compared with conventional diabetes treatment.¹⁸³ The analysis demonstrated that implementing intensive insulin therapy would result in an incremental cost per year of life gained of \$28,661, which represents a good value to the healthcare system. Overall, it appears that aggressive insulin therapy, as well as treatment with ACEIs when persistent microalbuminuria is identified, reduces complications and ultimately increases length of life at reasonable costs to society. The results of these simulated analyses remain to be prospectively confirmed.

The United Kingdom Prospective Diabetes Study also included a cost-effectiveness study that compared tight blood pressure control (ACEI and β -blocker therapy) with less-optimized control. The main outcomes included use of healthcare resources and the time free from diabetes-related end points. The investigators concluded that tight blood pressure control in patients with type 2 diabetes and hypertension produced a positive cost-effectiveness ratio as a result of reducing the cost of complications and increasing the interval without complications.¹⁸⁴ Another study concluded that all middle-aged patients with newly diagnosed type 2 diabetes should be treated with an ACEI rather than be screened for microalbuminuria and then treated.¹⁸⁵ That study determined that this treatment method would provide additional benefit with only a modest increase in cost.

CONCLUSIONS

DIABETICS

Based on the available clinical and experimental data, pharmacologic interventions can help to limit the progression of CKD in diabetic patients. Figure 46-4 summarizes these interventions. All patients with type 1 diabetes of more than 5 years' duration and all type 2 diabetics should be screened yearly for microalbuminuria (urinary albumin excretion or urinary albumin-to-creatinine ratio).¹²⁰ Blood glucose should be maintained within or close to the normal range by frequent insulin doses or by using a continuous subcutaneous insulin infusion, while minimizing the risk of hypoglycemia by frequent blood glucose monitoring.¹²⁰ ACEI therapy should be initiated in normotensive and hypertensive type 1 or type 2 diabetic patients with persistent microalbuminuria (30 to 300 mg/day) or overt albuminuria (>300 mg/day). ACEIs should be titrated every 1 to 3 months to achieve a maximal reduction in urinary albumin excretion. Within 1 week of initiating or increasing the dose of an ACEI, serum creatinine and potassium should be evaluated to detect abrupt reductions in GFR or development of hyperkalemia. ARBs should be considered as another first-line therapy in type 2 diabetic patients for the reduction of persistent proteinuria or albuminuria. A nondihydropyridine CCB may be an effective secondary alternative agent in patients who are unable to tolerate either an ACEI or an ARB. A combination of an ACEI with

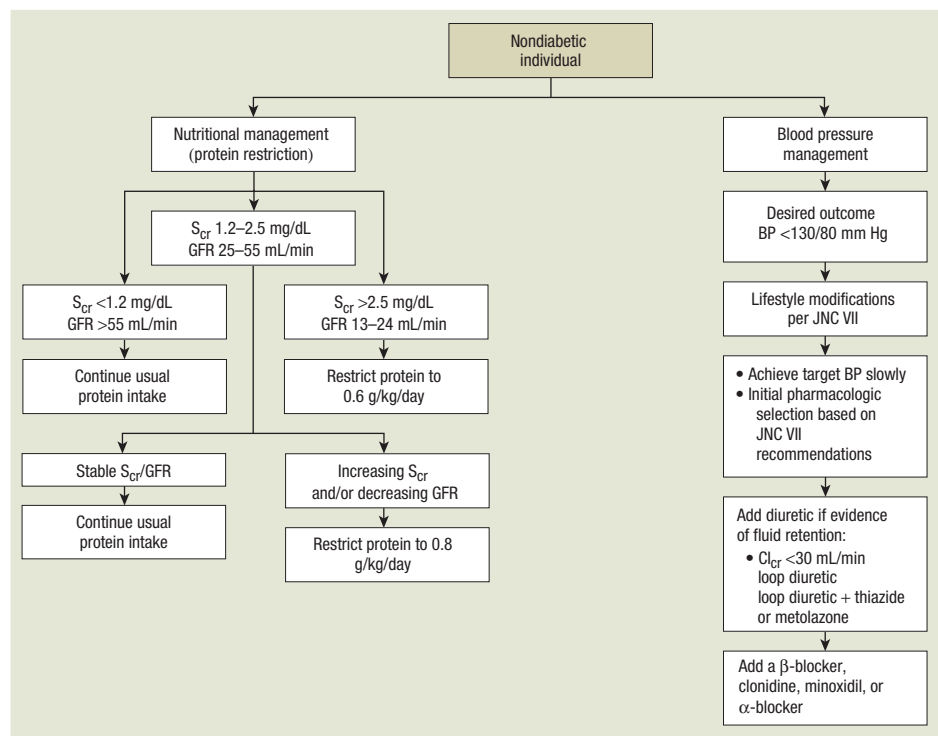

FIGURE 46-5. Therapeutic strategies to prevent progression of renal disease in nondiabetic individuals. an ARB may result in a greater reduction in proteinuria or albuminuria than either agent alone, and thus may be a therapeutic alternative in patients who are not maximally responding to single-agent therapy. Addition of an aldosterone receptor blocker may be considered in subjects with documented aldosterone escape.

NONDIABETIC PATIENTS

Figure 46–5 summarizes therapeutic interventions for nondiabetic patients with CKD. Nutritional management should be monitored frequently, regardless of the amount of protein intake prescribed, to avoid malnutrition. Based on the results of the MDRD study, a low-protein diet is of variable benefit in patients with moderate kidney dysfunction (GFR 25 to 55 mL/min per 1.73 m²). Thus it is probably reasonable to prescribe a standard-protein diet unless the patient develops rapid progression of their kidney disease.¹⁸⁶ For patients with severe kidney dysfunction, as defined by the MDRD study as a GFR of 13 to 24 mL/min per 1.73 m², a low-protein diet of 0.6 g/kg per day may reduce the rate of decline in kidney function, time to reach end-stage kidney disease, and onset of uremic symptoms.¹¹⁵

Blood pressure control should target normotensive levels of <130/80 mm Hg in patients with CKD.^{120,187} In patients with proteinuria above 3 g/day and CKD, an ACEI or ARB is still considered to be first-line therapy. Hyperlipidemia should also be treated to decrease cardiovascular risks and the suggested association between lipid abnormalities and CKD progression.

As kidney function decreases and subjects approach CKD stage 4, the patient should begin to get prepared for renal-replacement therapy. Hemodialysis, peritoneal dialysis, and renal transplantation need to be discussed (see Chaps. 48 and 92). Early referral to a nephrologist or other clinician specializing in the care of patients with progressive CKD may allow the proper dialysis vascular access placement, evaluation for uremia symptoms, and may allow for identification and treatment of the complications including anemia, and metabolic abnormalities.¹⁸⁸

ABBREVIATIONS

- ACEI: angiotensin-converting enzyme inhibitor
 ARB: angiotensin receptor blocker
 CCB: calcium channel blocker
 CKD: chronic kidney disease
 DCCT: Diabetes Control and Complications Trial

Chronic Kidney Disease: Management of Complications

JOANNA Q. HUDSON

KEY CONCEPTS

- 1 The number of patients with chronic kidney disease (CKD) is increasing, and it is expected that the number of patients with end-stage renal disease (ESRD) will double by 2020.
- 2 Common complications of stages 4 and 5 CKD include anemia, hyperphosphatemia, secondary hyperparathyroidism, fluid and electrolyte abnormalities, metabolic acidosis, and malnutrition.
- 3 Cardiovascular complications are prevalent in the CKD population and are the leading cause of mortality in patients with ESRD. For this reason, all ESRD patients at the initiation of dialysis should be assessed for cardiovascular disease, which includes assessment for coronary artery disease, cardiomyopathy, valvular heart disease, cerebrovascular disease, and peripheral vascular disease in addition to screening for both traditional and nontraditional cardiovascular risk factors.
- 4 The management of CKD and the associated secondary complications should be initiated prior to development of ESRD.
- 5 Guidelines by the National Kidney Foundation Kidney Disease/Dialysis Outcomes Quality Initiative (NKF-K/DOQI) should be used as a basis for the workup of CKD and the design of appropriate therapy for associated complications.
- 6 Patient education plays a critical role in the appropriate management of patients with stage 4 or 5 CKD and related complications. A multidisciplinary team structure is a rational approach to provide this education and effectively design and implement the extensive nonpharmacologic and pharmacologic interventions required.
- 7 Anemia of CKD, which is primarily caused by a deficiency in the production of endogenous erythropoietin by the kidney, is a common complication observed in patients with stages 4 and 5 CKD and contributes to cardiovascular disease.
- 8 Management of anemia includes administration of erythropoietic-stimulating agents (ESAs) (epoetin alfa and darbepoetin alfa) and regular iron supplementation (oral or intravenous administration) to achieve a target hemoglobin of at least 11 g/dL and to potentially prevent the development of left ventricular hypertrophy if therapy is initiated early. The target upper limit of hemoglobin is not clearly defined, but evidence does not support exceeding a hemoglobin of 12 g/dL.

- 9 Hyperphosphatemia, changes in calcium homeostasis, and secondary hyperparathyroidism are common in patients with CKD and contribute to extravascular calcifications and an increased risk of cardiovascular mortality.
- 10 Management of hyperphosphatemia, calcium balance, and secondary hyperparathyroidism includes dietary phosphorus restriction, prudent use of phosphate binding agents, vitamin D, and calcimimetic therapy.

The clinical syndrome that develops insidiously as kidney function declines to the most severe stages, stages 4 and 5 chronic kidney disease (CKD), begins with nonspecific symptoms such as nausea and vomiting, which become progressively worse as the glomerular filtration rate (GFR) drops below 15 mL/min. It is at this stage that renal replacement therapy, either dialysis (see Chap. 48) or transplantation (see Chap. 92), is indicated to remove uremic toxins and to maintain hemodynamic stability. The patient with stage 5 CKD requiring chronic dialysis or renal transplantation for relief of uremic symptoms is said to have end-stage renal disease (ESRD). In this chapter, ESRD refers specifically to patients who are receiving chronic dialysis.

The staging system for CKD is designed not only to trigger implementation of appropriate interventions to delay progression of CKD, as discussed in Chap. 46, but also as an index of when to consider initiating management of the complications of CKD. The most frequent complications of CKD discussed here include fluid and electrolyte abnormalities, anemia, secondary hyperparathyroidism and renal osteodystrophy, hypertension and hyperlipidemia, metabolic acidosis, and miscellaneous complications resulting from the effects of CKD on other organ systems, including malnutrition, pruritus, and uremic bleeding (Table 47–1 lists other complications of CKD). Diagnostic and therapeutic approaches to the management of fluid and electrolyte abnormalities, hypertension, hyperlipidemia, and metabolic acidosis in patients without CKD are presented elsewhere in this text. Cardiovascular disease as a common complication in patients with CKD also requires early and aggressive intervention.¹ Often complications of CKD are unrecognized or are inappropriately managed, and for many patients lead to significant morbidity, premature mortality, or a poor prognosis by the time they reach ESRD.² This chapter discusses the epidemiology of ESRD and the pathophysiology and pharmacotherapeutic management of the complications and comorbidities that occur frequently in patients with stages 4 and 5 CKD (including ESRD).

EPIDEMIOLOGY

- 1 In 2000, approximately 19 million people in the United States were estimated to have CKD: 8 million of this total had an estimated GFR less than 60 mL/min per 1.73 m² (stage 3, 4, or 5 CKD), the

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

TABLE 47-1 Other Complications of Chronic Kidney Disease	
Organ System or Complication	Effects
Amyloidosis	Accumulation of β_2 -microglobulin Manifests as carpal tunnel syndrome
Bleeding	Potentially result of platelet abnormalities
Endocrine	Thyroid function – symptoms of hypothyroidism Hypothermia Glycemic control – \uparrow in hypoglycemic episodes as kidney disease progresses (result of \downarrow degradation of insulin by the kidney)
Gastrointestinal	Nausea, vomiting, diarrhea, anorexia, GI bleeding
Immune system	Impaired cell-mediated immunity Lymphopenia
Neurologic	Peripheral neuropathies Restless leg syndrome Uremic encephalopathy

point at which secondary complications are more prevalent.³ In 2005, the latest year for which data are available, a total of more than 106,000 new cases of ESRD were reported and the prevalence as of the end of the year was 484,693, including 341,000 patients on dialysis and 143,693 with a functioning kidney after transplantation.² Incidence rates are higher in blacks (fourfold higher), Native Americans (twofold higher), and Hispanics (twofold higher) compared to whites, a trend that has persisted over the last decade.² The incidence has also increased dramatically in patients 65 years of age and older. Although the overall number of patients with ESRD is substantial now, it is projected that by the year 2020 the number will exceed 780,000 patients, the majority of cases attributable to diabetes.

ESRD patients have a mortality rate up to four times higher than comparable patients age 65 years or older without kidney disease.² Associated predictors of mortality at the start of dialysis include a lower estimated GFR, decreased serum albumin, and the presence of comorbidities, such as diabetes and cardiovascular disease.⁴ Lower hemoglobin levels and body mass index are also associated with increased mortality. The association of mortality with these factors highlights the need to address complications as soon as they are detected and ideally prior to the time of consideration for renal replacement therapy.

ETIOLOGY

Many clinical conditions and diseases lead to progressive kidney damage and ESRD (see Chap. 46). Diabetes mellitus continues to be the leading cause of CKD and, ultimately, of ESRD in the United States.² The incidence rate of ESRD attributed to diabetes has doubled, while the prevalence has more than tripled, in the last 10 years, although the incidence rate has remained fairly stable since 2001. Diabetes is particularly common in Native Americans. Approximately 80% of Native Americans diagnosed with ESRD have diabetes, classified as either a primary cause of ESRD or a comorbid condition.²

Hypertension, the second leading cause of ESRD in the United States, was also associated with an almost 50% increase in incident rate in the last decade, with the greatest increase being in the black population.² Glomerulonephritis which includes a wide variety of glomerular lesions caused by immunologic, vascular, and other idiopathic diseases (see Chap. 50) is the third leading cause of ESRD in the United States. Other diseases and conditions, such as cystic kidney disease, Wegener granulomatosis, vascular diseases, and acquired immunodeficiency syndrome (AIDS) nephropathy account for relatively few cases of ESRD compared to diabetes and hyperten-

sion.² The increase in the incidence of AIDS nephropathy was most dramatic between 1991 and 1995, but has since stabilized.

PATHOPHYSIOLOGY

Progression of CKD to ESRD occurs over years to decades in the majority of cases, with the precise mechanism of kidney damage dependent on the etiology of the disease (see Chaps. 46 and 50); however, the consequences and complications of marked reductions in kidney function are fairly uniform irrespective of the underlying etiology. The mechanisms of progression of CKD and measures to delay progression are essential elements for primary care clinicians to consider as they design intervention strategies for their patients. Those clinicians who care for patients with ESRD or stages 4 and 5 CKD must also have a clear understanding of the pathogenesis, clinical presentation, and management strategies for secondary complications and comorbidities to improve quality of care and outcomes.

No single toxin is responsible for all of the signs and symptoms of uremia observed in patients with stage 4 or 5 CKD. Accumulation of one or several of these known and potential toxins may be the result of increased secretion, as with the biologically active substances such as parathyroid hormone (PTH) and atrial natriuretic peptide; decreased clearance because of reduced metabolism within the kidney for compounds such as PTH, gastrin, growth hormone, glucagon, somatostatin, prolactin, calcitonin, and insulin; and/or decreased renal clearance of metabolic by-products of protein metabolism. The buildup of these uremic toxins ultimately results in altered organ and immune function, and leads to a myriad of secondary complications.

2 Altered fluid and electrolyte homeostasis, metabolic acidosis, anemia of CKD, secondary hyperparathyroidism and renal osteodystrophy, and cardiovascular disease are among the common complications associated with a substantial decline in GFR. The pathophysiology of these complications is described here.

FLUID AND ELECTROLYTE ABNORMALITIES

Sodium and Water

In persons with normal kidney function, sodium balance is maintained at a sodium intake of 120 to 150 mEq/day. The fractional excretion of sodium (FeNa) is approximately 1% to 3%. Water balance is also maintained, with a normal range of urinary osmolality of 50 to 1,200 mOsm/kg (average range 500 to 800 mOsm/kg). An osmotic diuresis occurs with an increase in FeNa leading to obligatory water losses and impairment in the kidney's ability to dilute or concentrate urine (urinary osmolality is often fixed at that of plasma or approximately 300 mOsm/L). Nocturia is present relatively early in the course of CKD (stage 3) secondary to the defect in urinary concentrating ability. In patients with severe CKD (stages 4 and 5), serum sodium concentration is generally maintained as the result of an increase in FeNa by as much as 30%, but results in a volume-expanded state.⁵ Total renal sodium excretion decreases despite an increase in sodium excretion by remaining nephrons. Volume overload with pulmonary edema can result, but the most common manifestation of increased intravascular volume is systemic hypertension.

Potassium Homeostasis

Serum potassium is freely filtered at the glomerulus, reabsorbed in the proximal tubule and loop of Henle, and actively secreted into the urine at the cortical collecting duct. The kidneys normally excrete 90% to 95% of the daily potassium dietary load. The fractional excretion of potassium (FE_K) is approximately 25%. Normally only 5% to 10% of ingested potassium is excreted through the gut. Potassium homeostasis is also maintained by shifting extracellular potassium intracellularly immediately following ingestion of a potas-

sium load. In patients with CKD, potassium balance is maintained by an increase in distal tubular potassium secretion in which aldosterone plays an important role; FE_K can increase to as high as five times normal.⁵ Thus the serum potassium concentration is usually maintained in the normal range until the GFR is less than 20 mL/min per 1.73 m² body surface area, at which point mild hyperkalemia is likely to develop. A significant increase in potassium secretion by the colon also contributes to the maintenance of potassium balance, but this adaptation cannot compensate fully for the decrease in renal potassium excretion.

METABOLIC ACIDOSIS

Individuals with normal kidney function generate enough hydrogen ion to reclaim all filtered bicarbonate and to secrete approximately 1 mEq/kg per day of hydrogen ions, which are generated from the metabolism of dietary proteins (see Chap. 55). As a result, they maintain a constant body fluid pH through the buffering of hydrogen ion by proteins, hemoglobin, phosphate, and bicarbonate. Renal ammoniogenesis and phosphate excretion buffer the urine and facilitate acid excretion. In severe CKD, all filtered bicarbonate is reclaimed, but the ability of the kidneys to synthesize ammonia is impaired. This decrease in urinary buffer results in decreased net acid excretion and continuous positive hydrogen ion balance; consequently, metabolic acidosis develops. A clinically significant metabolic acidosis is commonly seen when the GFR drops below 20 to 30 mL/min (stage 4 CKD). In these patients, the plasma bicarbonate concentration tends to stabilize at 15 to 20 mEq/L.

ANEMIA OF CHRONIC KIDNEY DISEASE

7 The primary cause of anemia in CKD patients is a decrease in production of the hormone erythropoietin by the progenitor cells of the kidney, where 90% of production typically occurs. Plasma concentrations of erythropoietin increase exponentially in individuals with normal kidney function as hemoglobin/hematocrit decline (i.e., in response to decreased oxygenation). In contrast, there is no correlation between the degree of anemia and erythropoietin concentrations in anemic ESRD patients. The result is a normochromic, normocytic anemia, unless the individual has concomitant iron deficiency, which

can result in a microcytic anemia, or a folate or B₁₂ deficiency, which can result in a macrocytic anemia. Additional factors contributing to the development of anemia of CKD are the decreased red cell life span in the presence of uremia (from the normal of 120 days to approximately 60 days in ESRD), iron deficiency, blood loss from regular laboratory testing, and blood loss with hemodialysis for patients requiring this modality of renal replacement therapy. Iron deficiency is the primary cause of resistance to therapy with erythropoietic-stimulating agents (ESAs; i.e., epoetin alfa or darbepoetin alfa).

SECONDARY HYPERPARATHYROIDISM AND RENAL OSTEODYSTROPHY

9 Calcium and phosphorus balance is mediated through the complex interplay of hormones and their effects on bone, the GI tract, kidney, and parathyroid gland. What begins as relatively minor imbalances in phosphorus and calcium homeostasis leads to secondary hyperparathyroidism (sHPT) in the short-term and ultimately renal osteodystrophy (ROD) if these metabolic abnormalities are not corrected (Fig. 47-1). ROD progresses insidiously for several years before patients become symptomatic. When symptoms such as bone pain and skeletal fractures occur, the disease is not easily amenable to treatment.

As kidney function declines there is a decrease in phosphorus elimination, which results in hyperphosphatemia and when severe a reciprocal decrease in serum calcium concentration. Hypocalcemia is the primary stimulus for release of PTH by the parathyroid glands, the effects of which are mediated by the interaction of ionized calcium with the calcium-sensing receptor on the chief cells of the parathyroid gland. Hyperphosphatemia also increases PTH synthesis and release through its direct effects on the parathyroid gland and production of prepro-PTH messenger RNA.⁶ In an attempt to normalize ionized calcium, PTH decreases phosphorus reabsorption and increases calcium reabsorption by the proximal tubules of the kidney (at least until the GFR falls to less than approximately 30 mL/min), and also increases calcium mobilization from bone. The result is a correction in calcium and phosphorus, at least in the early stages of CKD; however, this occurs at the expense of an elevated PTH ("the trade-off hypothesis"). The increase in PTH is most notable when GFR is less than 60 mL/min per 1.73 m² (stage 3 CKD) and worsens as kidney function further declines.⁷

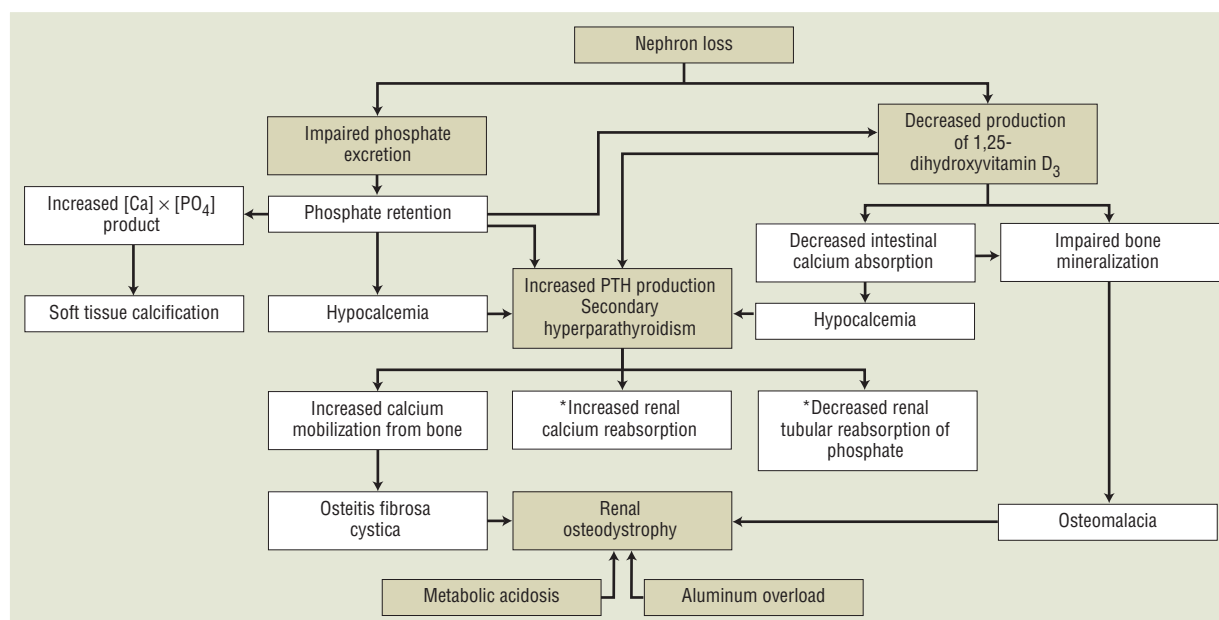

FIGURE 47-1. Pathogenesis of secondary hyperparathyroidism and renal osteodystrophy in patients with chronic kidney disease. (*These adaptations are lost as kidney disease progresses.) PTH, parathyroid hormone.

Active vitamin D (1,25-dihydroxyvitamin D₃ or calcitriol) promotes increased intestinal absorption of calcium, which helps to normalize ionized calcium. Calcitriol also works directly on the parathyroid gland to suppress PTH production. The enzyme 1 α -hydroxylase is responsible for the final hydroxylation and conversion of the vitamin D precursor, 25-hydroxyvitamin D, to the active form in the kidney. As kidney disease progresses this conversion is impaired and vitamin D deficiency results. Calcitriol levels decrease significantly before there is a perceptible rise in PTH in CKD patients.⁷ Other differences in vitamin D metabolism observed in patients with CKD that lead to deficiencies in the 25-hydroxyvitamin D precursor include decreased dermal synthesis of vitamin D, decreased exposure to sunlight, and reduced dietary intake of vitamin D.⁸ In patients with stage 3 or 4 CKD, 25-hydroxyvitamin D levels of <30 ng/mL are associated with increased PTH.⁸ As a result of such findings, evaluation of 25-hydroxyvitamin D levels and supplementation in patients with observed deficiencies are recommended for stages 3 and 4 CKD.⁸

A multiplicity of metabolic disorders in patients with CKD contributes to worsening sHPT and the associated consequences (see Fig. 47–1). The continuous production of PTH by the parathyroid glands leads to parathyroid hyperplasia (nodular or diffuse). Nodular tissue demonstrates more rapid growth potential and appears to be associated with fewer vitamin D and calcium-sensing receptors, resulting in resistance to the effects of calcium and vitamin D therapy and subsequent development of ROD.⁶ Bone loss can be detected in patients with early stages of kidney disease and multiple types of bone lesions have been identified from bone biopsies of patients on dialysis.⁹ The skeletal complications associated with ROD include osteitis fibrosa cystica (high bone turnover disease), osteomalacia (low bone turnover disease), and adynamic bone disease. Osteitis fibrosa cystica is characterized by areas of peritrabecular fibrosis. Dynamic measurements show a high bone formation rate, which results from high circulating concentrations of PTH. Bone marrow fibrosis and decreased erythropoiesis are also consequences of severe osteitis fibrosa cystica. Osteomalacia was historically caused by aluminum toxicity in hemodialysis patients, a finding less common today with decreased use of aluminum-containing phosphate binders and changes in the processing of dialysate solutions to decrease aluminum absorption. Adynamic lesions are characterized by low amounts of fibrosis or osteoid tissue and low bone formation rates. The incidence of adynamic lesions has increased over the last 10 years and may be present in as many as 50% of dialysis patients.¹⁰ Multiple risk factors for the development of this bone disease have been identified: aluminum toxicity; high concentrations of dialysate calcium along with high doses of calcium-containing phosphate binders; aggressive management with vitamin D therapy; diabetes; and advanced age.¹⁰ Symptoms often occur late, when significant skeletal damage has developed; consequently, prevention is the key to management and control of long-term complications.

sHPT as evidenced by PTH levels >495 pg/mL in CKD patients is associated with increased morbidity and mortality and sudden death in hemodialysis patients.¹¹ Other adverse consequences of sHPT include alterations in lipid metabolism, insulin secretion, resistance to erythropoietic therapy, and myocardial and skeletal muscle function, as well as alterations in neurologic and immune functions.¹² An elevated calcium times phosphorus product ($\text{Ca} \times \text{P}$) is also associated with poor outcomes, including vascular calcification, cardiovascular disease, calciphylaxis, and death.¹³ In two, large, national, cross-sectional samples of hemodialysis patients who had received dialysis for at least 1 year, elevated serum phosphorus levels and $\text{Ca} \times \text{P}$ were associated with increased risk of death.^{13,14} Patients with a $\text{Ca} \times \text{P}$ above 72 mg²/dL² were found to have a 34% higher risk of death compared with patients with a $\text{Ca} \times \text{P}$ in the reference range of 43 to 52 mg²/dL².¹³ Calcium scores, as measured by electron-beam computed tomography, were significantly higher in hemodialysis patients

than in patients without kidney disease who had proven coronary artery disease. Intake of calcium from calcium-based binders also appears to be a significant contributor to coronary artery calcification, even in young dialysis patients.¹⁵ These data underscore the need to consider all the consequences of elevated PTH and $\text{Ca} \times \text{P}$, not only their consequences on bone.

CARDIOVASCULAR DISEASE

3 Patients with CKD are at increased risk of cardiovascular disease, independent of the etiology of their kidney disease. Although a clearly unique pathogenesis of cardiovascular disease specific to CKD has not been identified, it is known that manifestations of kidney disease are contributory.¹⁶ In addition, uremic toxins can induce pericarditis, a potentially fatal complication. Currently, screening of this high-risk population for cardiovascular risk factors is not routinely considered.^{16,17}

Mortality secondary to cardiovascular disease is 10 to 30 times greater in dialysis patients than in the general population.¹⁶ In addition to traditional cardiac risk factors such as hypertension and hyperlipidemia, diabetes, tobacco use, and physical inactivity, patients with kidney disease have other unique risk factors. Among these are hyperhomocysteinemia, elevated levels of C-reactive protein, increased oxidant stress, and hemodynamic overload.¹ Complications such as anemia and metabolic disorders (i.e., abnormalities in Ca, P, and PTH) of CKD are also contributory. In particular, arterial vascular disease (e.g., atherosclerosis) and cardiomyopathy are the primary types of cardiovascular disorders present in the CKD population.^{1,16} These disorders lead to development of ischemic heart disease and its manifestations including myocardial infarction. As a predominant comorbidity, cardiovascular disorders and their sequela are the leading cause of death in the ESRD population.^{1,2}

Hypertension

As a primary cause or consequence of progressive loss of kidney function, hypertension is prevalent in the majority of patients with CKD (see Chap. 46). Approximately 50% to 60% of dialysis patients are hypertensive, defined as a predialysis blood pressure greater than 150/90 mm Hg, and only a small percentage of dialysis patients do not require antihypertensive therapy.¹ Hypertension induced by volume expansion and increased systemic vascular resistance increases myocardial work and contributes to development of left ventricular hypertrophy (LVH). A “U-shaped” relationship between blood pressure and mortality has been observed, such that higher mortality is associated with the highest and lowest levels of blood pressure.¹ The pathogenesis of hypertension in CKD is multifactorial, but in many hypertensive dialysis patients, fluid retention is a major contributor. In addition to the general pathophysiologic mechanisms responsible for the development of hypertension, patients with ESRD may also have increased sympathetic activity, decreased activity of vasodilators such as nitric oxide, elevated levels of endothelin-1, chronic use of an ESA such as epoetin alfa, hyperparathyroidism, and structural changes in the arteries (e.g., metastatic calcification) as contributing factors.¹

Patients with ESRD also display an abnormal diurnal blood pressure rhythm as evidenced by the fact that their blood pressure does not decrease during the nighttime hours.¹ It is unclear what causes this disturbance in the diurnal rhythm, but this “nondipping” phenomenon indicates sustained elevations in blood pressure are present over a prolonged period of time when compared to the general population.

Hyperlipidemia

CKD with or without nephrotic syndrome is frequently accompanied by abnormalities in lipoprotein metabolism. It is well estab-

lished that dyslipidemias cause atherosclerotic cardiovascular disease and there are many compelling reasons to aggressively treat these disorders.¹⁸ A clear association between hypercholesterolemia, hypertriglyceridemia, or other lipoprotein changes in patients with CKD and the high incidence of cardiovascular disease has not been demonstrated in large prospective studies. However, it is likely that the same lipoprotein abnormalities that confer increased risk of cardiovascular disease in the general population would also be harmful to patients with kidney disease. A low or declining serum cholesterol in patients with ESRD also is associated with higher mortality, a paradoxical effect.^{1,19} These findings beg the question of whether aggressive lipid lowering is warranted in this population. Further analysis, however, shows that low cholesterol levels were observed in conjunction with inflammation and malnutrition, factors that increase mortality. In the absence of these confounding factors, it is the higher cholesterol levels, not lower levels, that were associated with increased mortality, thus supporting treatment of hypercholesterolemia in ESRD patients.¹

The lipid panel generally observed in patients with CKD without nephrotic syndrome is a normal total and low-density lipoprotein (LDL) cholesterol, low high-density lipoprotein (HDL), and high triglycerides (plasma concentrations >200 mg/dL).²⁰ Although the concentrations of LDL are not uniformly increased in patients with kidney disease, these patients appear to produce small, dense LDL particles that are more susceptible to oxidation and more atherogenic than larger LDL subfractions. Other lipoprotein abnormalities include changes in apoprotein content of lipoprotein molecules and increased very-low-density and intermediate-density lipoproteins. For patients with CKD and a urinary protein excretion greater than 3 g/day, the major lipid abnormalities are elevation of plasma total and LDL cholesterol, with or without low HDL cholesterol (<35 mg/dL) and elevated triglycerides. Treatment of proteinuria resolves the hyperlipidemia in most patients with nephrotic syndrome.

CLINICAL PRESENTATION

Damage to the kidney has detrimental consequences on many other organ systems, particularly once patients develop ESRD. The subjective and objective findings of CKD that may be present in an individual are dependent on the severity of disease (i.e., stage of CKD). At the time of referral to a nephrologist patients may present with some, but rarely all, of the signs and symptoms associated with uremia and secondary complications of CKD, unless they are in the more advanced stages of the disease (stage 4 or 5 CKD). It is apparent that management of CKD requires treatment of multiple secondary complications.

CLINICAL PRESENTATION OF STAGE 4 OR 5 CHRONIC KIDNEY DISEASE

Symptoms

- Uremic symptoms (fatigue, weakness, shortness of breath, mental confusion, nausea and vomiting, bleeding, and loss of appetite), as well as itching, cold intolerance, weight gain, and peripheral neuropathies are common in patients with stage 5 disease.

Signs

- Edema, changes in urine output (volume and consistency), “foaming” of urine (indicative of proteinuria), and abdominal distension.

Laboratory Tests^a

- *Decreased:* creatinine clearance, bicarbonate (metabolic acidosis), hemoglobin/hematocrit (anemia), iron stores (iron

deficiency), vitamin D levels, albumin (malnutrition), glucose (may result from decreased degradation of insulin with impaired kidney function or poor oral intake), calcium (in early stages of CKD), HDL.

- *Increased:* serum creatinine, blood urea nitrogen, potassium, phosphorus, PTH, blood pressure (hypertension is a common cause and result of CKD), glucose (uncontrolled diabetes is a cause of CKD), low-density lipoprotein and triglycerides, T₄ levels (hypothyroidism), calcium (in ESRD)
- *Other:* May be Hemocult-positive if GI bleeding occurs secondary to uremia.

Other Diagnostic Tests

- Left ventricular hypertrophy may be observed, as well as increased homocysteine levels and increased C-reactive protein.

^aIndicative of common secondary complications of CKD.

Recommendations for the evaluation and workup of several of the most common secondary complications of CKD are described in detail in the remainder of this chapter.

ANEMIA OF CHRONIC KIDNEY DISEASE

All patients with CKD should have their hemoglobin (Hb) measured at least annually. Testing should be conducted more frequently in individuals with more severe CKD, as well as in those at any stage who are diagnosed with anemia. If the Hb is less than 12 g/dL in adult females or less than 13.5 g/dL in adult males, a complete workup for anemia of CKD should be done.²¹ This includes evaluation of other causes of anemia such as bleeding, deficiencies in vitamin B₁₂ or folate, or other disease states that contribute to anemia, including human immunodeficiency virus infection and malignancies. As the primary cause of resistance to therapy for anemia of CKD, iron status must be evaluated. Red blood cell indices and iron indices should be measured, including the red blood cell indices (mean corpuscular hemoglobin, mean corpuscular volume, mean corpuscular hemoglobin concentration), white blood cell count, differential and platelet count, absolute reticulocyte count, transferrin saturation (TSat) or content of hemoglobin in the reticulocytes, and serum ferritin. A stool guaiac test should also be performed to rule out GI bleeding.

Iron deficiency manifests as a microcytic anemia and is accompanied by a low mean corpuscular volume, whereas deficiencies in vitamin B₁₂ and folate present as a macrocytic anemia with an increase in mean corpuscular volume. The TSat is calculated as ([serum iron/TIBC] × 100), where TIBC is the total iron-binding capacity. If the TSat and serum ferritin values are below the desired threshold (see Table 47–2), iron supplementation is warranted prior to starting ESA therapy. If all other causes of anemia are ruled out and the anemia persists despite iron supplementation, patients should be treated with either epoetin alfa or darbepoetin alfa.

Iron supplementation is required by most patients with ESRD because of the increased iron demand that results from stimulation of red blood cell production with ESAs. As CKD worsens, a progressive decline in Hb despite ESA therapy may be observed. Consequently, regular followup of Hb and iron status is warranted to ensure the desired outcomes are met and to make necessary dose adjustments in ESAs and iron therapy (see Treatment of Anemia of Chronic Kidney Disease below).

The effects of anemia and decreased oxygen delivery on other comorbid conditions, including LVH, must also be considered given the burden of cardiovascular complications in this population.²² The negative effects of anemia on quality of life are also important from a patient perspective and a compelling reason for early and aggressive treatment.²³

SECONDARY HYPERPARATHYROIDISM AND RENAL OSTEODYSTROPHY

Disorders of calcium and phosphorus homeostasis including sHPT are prevalent in the CKD population. A recent evaluation of a cohort of outpatients found elevated PTH levels in approximately 21% of patients with an estimated GFR between 60 and 69 mL/min/1.73 m² and in 56% of patients with stage 3, 4, or 5 CKD (estimated GFR less than 60 mL/min/1.73 m²).⁷ Calcitriol deficiency was observed at all levels of GFR, but was more prevalent (greater than 60%) in the group with an estimated GFR of less than 30 mL/min/1.73 m². These percentages are even higher in the ESRD population.^{8,14} Consequently, preventative measures should be initiated in patients in the early stages of CKD.

The workup for sHPT and the associated metabolic abnormalities includes evaluation of serum phosphorus, calcium, Ca × P product, and PTH. These labs should be assessed at least every 3 months in the patient with stage 4 CKD. For the ESRD population, PTH should be evaluated at least every 3 months and the calcium and phosphorus assessed at least monthly. Many dialysis facilities have developed protocols that call for evaluation of all these parameters on a monthly basis. Measurement of the active vitamin D precursor, 25-hydroxyvitamin D, is recommended in patients with stage 4 CKD who have elevated PTH levels to determine the appropriate form of vitamin D supplementation required (see Treatment of Secondary Hypoparathyroidism below).

Bone mineral density and serum calcium and calcitriol concentrations decrease progressively, whereas serum PTH, osteocalcin, bone-specific alkaline phosphatase, and phosphorus concentrations increase as GFR declines.^{7,9} Evaluation of bone histology may be warranted in patients with severe sHPT or in symptomatic stage 4 or 5 CKD patients. Bone disease can be diagnosed using iliac crest bone biopsy and bone histomorphometric analysis. Bone mineral densitometry studies may also be used to detect bone loss in patients with CKD and are useful to monitor response to therapeutic interventions. Coronary artery calcification can be evaluated by noninvasive means using electron-beam computed tomography. Invasive procedures such as coronary angiography can also be used to ascertain the degree of damage if the newer technology is not available.

Monitoring of serum aluminum levels should be done at least annually and as frequently as every 3 months in patients receiving aluminum-containing phosphate binders or other aluminum-based medications, although regular use of these agents is not recommended in patients with CKD.⁸ If aluminum concentrations are elevated (60 to 200 mcg/L) a deferoxamine test should be done. The deferoxamine infusion test is based on the concept that the amount of aluminum mobilized following a single dose of deferoxamine is representative of the total-body burden of aluminum. A dose of 5 mg/kg of deferoxamine is administered, generally over the last hour of dialysis for hemodialysis patients. The serum aluminum level predose and 2 days postdose are compared. A change in serum aluminum concentration of ≥50 mcg/L is considered a positive test. A change of this magnitude in conjunction with an intact parathyroid hormone (iPTH) of <150 pg/mL is indicative of aluminum bone disease, which should then be confirmed by bone biopsy.⁸

PTH is secreted from the parathyroid gland as intact PTH, an 84-amino-acid peptide chain (1–84 PTH) that is biologically active, and as smaller carboxy-terminal PTH fragments.²⁴ Circulating levels of these fragments (e.g., 7–84 PTH) may increase substantially in patients with CKD and actively antagonize the effects to 1–84 PTH. Available immunoradiometric and immunochemiluminescent assays for measurement of intact PTH, such as the Nichols Institute Allegro immunoradiometric assay (IRMA), measure not only the intact molecule, but also fragments, which may lead to overestimation of biologically active PTH. The goal iPTH based on this assay

method in ESRD patients is three to five times the upper limits of normal (approximately 200 to 300 pg/mL). Clinicians involved in the care of patients with CKD should become familiar with available assays used in their facilities so as to provide optimal care for their patients.

METABOLIC ACIDOSIS

Serum electrolytes should be measured routinely in patients with stage 4 and 5 CKD. If the results suggest the presence of an acidotic state, arterial blood gases should be measured. These patients should also have a complete medical history and review of medications to determine if there are other potential causes of acid–base disturbances (e.g., diabetic ketoacidosis, ingestion of toxins, or GI disorders). The anion gap, indicating the differences in unmeasured anions and cations, should also be calculated (see Chap. 55). An elevated anion gap (>17 mEq/L) is often present in patients with stage 4 or 5 CKD because of the accumulation of organic anions, phosphates, and sulfates. Treatment of metabolic acidosis in patients with CKD generally includes administration of bicarbonate to correct acidemia, the time course of which depends on the severity of the acidosis. Asymptomatic patients with mild acidosis (bicarbonate of 12 to 20 mEq/L; pH of 7.2 to 7.4) generally do not require emergent therapy and gradual correction over days to weeks is appropriate.

CARDIOVASCULAR DISEASE

The Kidney Disease/Dialysis Outcomes Quality Initiative (K/DOQI) guidelines on cardiovascular disease in dialysis patients recommend that all patients starting dialysis be assessed for cardiovascular disease (including coronary artery disease, cardiomyopathy, valvular heart disease, cerebrovascular disease, and peripheral vascular disease) and be screened for traditional (e.g., hypertension and hyperlipidemia) and nontraditional cardiovascular risk factors.¹

Hypertension

Patients with stages 4 and 5 CKD should have their blood pressure evaluated at every clinic visit and at home, if appropriate. Patients with ESRD should have blood pressure monitored at every scheduled clinic visit (or hemodialysis session) and they should be encouraged to learn how to monitor their blood pressure while at home. Patients who have required extensive surgeries in both arms to establish vascular accesses should have blood pressure measured in the thighs or legs. Blood pressure monitoring with an appropriate-size cuff should be measured prior to insertion of the needles for hemodialysis.

Hyperlipidemia

A complete fasting lipid profile including total cholesterol, LDL, HDL, and triglycerides should be done in all CKD patients. Lipoprotein levels may be influenced by several factors, including GFR and proteinuria. It is recommended that CKD patients have their lipid profile assessed more frequently than the general population to identify abnormalities and treat them early. In patients on hemodialysis the lipid profile should be done prior to dialysis or on nondialysis days.²⁵ Patients should also be evaluated for other conditions that are known to cause dyslipidemias (e.g., liver disease).

TREATMENT

Chronic Kidney Disease

Once a patient is diagnosed with CKD, implementation of therapy to address the primary cause (e.g., diabetes, hypertension, or glomeru-

lonephritis) and potentially delay progression is a priority. Chapter 46 discusses the key concepts involved in the management of these critical issues in detail. When patients reach stage 4, progression to ESRD is almost inevitable, although the process may be delayed if appropriate therapy is initiated. It is during stage 4 CKD that plans for renal replacement therapy (hemodialysis or peritoneal dialysis) need to be made, and patients educated about dialysis modalities and options for transplantation if they are candidates.

④ Regardless of the stage of CKD at which the patient presents, the management of secondary complications (e.g., anemia and secondary hyperparathyroidism) and comorbid conditions, if they are present, is critical to maximize the length and optimize the quality of the patient's life. Historically, these conditions have not been appropriately managed.²⁶ Laboratory data to diagnose such complications (e.g., iron studies and PTH levels) are often not evaluated until the patient has reached ESRD. According to data from the 2007 United States Renal Data System report, the likelihood of a CKD patient receiving calcium and phosphorus testing (1.0 being ideal) was 0.29 and the probability of lipid monitoring was 0.64 for those with Medicare coverage.² Medicare patients with both diabetes and hypertension were more likely to be tested. With regard to anemia of CKD, based on claims data to evaluate care of CKD patients, it was determined that in the year prior to initiation of dialysis only 10.5% of patients had received an ESA and 6.8% a prescription iron product, despite more than 40% having been diagnosed with anemia.²⁷ Lack of attention to the disorder, problems with payment for drug therapy by third-party payers, and the logistics of maintaining the regular followup necessary for therapy with ESAs contribute to this poor management. Late referral to a nephrologist may in part account for this poor management; however, even in ideal clinical environments such as nephrology clinics, these secondary complications may be overlooked.

■ DESIRED OUTCOME

The overall goal of therapy is to optimize the patient's duration and quality of life. Patients who reach CKD stage 4 almost inevitably experience progression to ESRD and thus require dialysis to sustain their life. Chapter 48 discusses the considerations involved in selecting from among the dialysis options available for the management of ESRD. The following discussion thus focuses on minimizing the risks associated with the development of the consequences and complications of ESRD and their management.

■ GENERAL APPROACH TO PATIENT CARE

To delay the development of the consequences and secondary complications of ESRD frequent medication reviews are paramount to reduce the risk of drug-related problems and exposure of these patients to nephrotoxic agents (see Chap. 49). Drug-dosing guidelines based on the degree of kidney function should be followed, and a complete medication history of prescription and nonprescription medications, as well as herbals and nutritional supplements, should be obtained and routinely updated. Chronic use of nonsteroidal antiinflammatory drugs and cyclooxygenase-2 inhibitors should be avoided when possible. Patients should be instructed on all brand and generic names of these classes of medications to reduce the risk of exposure. Appropriate measures should also be taken for hospitalized patients to decrease the risk of nephrotoxicity from radiocontrast agents (for procedures requiring such dyes), and antibiotics such as aminoglycosides, as well as from nonsteroidal antiinflammatory drugs and angiotensin-converting enzyme inhibitors (ACEIs) (see Chaps. 45 and 49).

Continued patient education, initiated prior to development of ESRD, is essential to help patients become active participants in their own care and knowledgeable about medications, which they often

require on a chronic basis. Pharmacists involved with the dialysis population have identified many specific drug-related problems (e.g., inappropriate dose or indication for a medication, adverse drug reactions) that commonly occur in the ESRD population and have demonstrated that the provision of clinical pharmacy services reduce such problems and contributes to improvements in patient quality of life.^{28–30}

⑤ When a patient with stage 4 or 5 CKD is initially evaluated, one of the most important steps is an early evaluation for the presence of secondary complications, as outlined in the Clinical Presentation above. Prompt initiation of management based on available consensus guidelines and the best clinical practices such as those developed by the National Kidney Foundation (K/DOQI) offer the most likely avenue for a successful patient outcome. The guidelines and recommendations were developed based on evidence, when available and the opinion of the expert group of individuals when the evidence was sparse. This process, although a standard approach to developing a consensus on patient care, is subject to criticism, especially those recommendations based solely or primarily on opinion. The K/DOQI guidelines should not replace clinical judgment, but rather provide a basis upon which treatment decisions can be made in the context of both evidence and opinion. The secondary complications that are addressed in the currently available clinical practice guidelines include anemia of CKD, bone metabolism and disease, cardiovascular disease in dialysis patients, dyslipidemias, hypertension, and nutrition.

⑥ Appropriate management of secondary complications of CKD usually involves a multidisciplinary approach to manage the non-pharmacologic and pharmacologic interventions, dietary education, and social/financial concerns. The typical team includes physicians (primary care physicians and nephrologists), nurses, dietitians, and social workers in outpatient dialysis facilities. In some outpatient dialysis centers pharmacists are also active members of the care team, although this is more common in institutionalized environments. A strong emphasis on patient education by all clinicians cannot be overemphasized.^{28–30}

■ FLUID AND ELECTROLYTE ABNORMALITIES

Maintenance of fluid volume, osmolarity, electrolyte balance, and acid–base status are all regulated in large part by the kidney, and their homeostasis is altered in patients with impaired kidney function. Chapters 52, 53, and 54 provide a comprehensive discussion of fluid and electrolyte disorders and treatment options. The unique aspects of treatment of sodium, water, and potassium disorders in stage 4 CKD and dialysis patients are highlighted here.

Desired Outcomes

Sodium and Water Homeostasis The goal is to maintain a normal serum sodium concentration (135 to 145 mEq/L) while maintaining euvolemia. By achieving these goals, the risk of developing or worsening hypertension secondary to volume overload is reduced.

Potassium Homeostasis The focus is on prevention of the acute adverse consequences, particularly cardiac effects, while maintaining potassium concentrations of approximately 4 to 5.5 mEq/L. This is often achieved through dietary restriction of potassium, minimizing exposure to medications that may increase serum potassium, and use of sodium–potassium exchange resins when indicated. If hyperkalemia develops, management options are based on the degree to which potassium is elevated (see Chap. 54).

Nonpharmacologic Therapy

Sodium and Water Balance The ability of the kidney to adjust to abrupt changes in sodium intake is greatly diminished in patients

with severe CKD. Sodium restriction beyond a no-added-salt diet should not be recommended except in the face of hypertension or edema. The kidney maintains the ability to lower urinary sodium content to essentially zero, but this can only be accomplished by very gradual sodium restriction over a period of several days. Hospitalized patients should not routinely be sodium restricted because they have adapted to their outpatient intake. Negative sodium balance and its resultant volume contraction can result in decreased perfusion to the kidney and a subsequent further acute decline in GFR.

Fluid restriction is generally unnecessary for all but those patients with stage 5 CKD provided sodium intake is controlled. An intact thirst mechanism maintains total-body water and effective plasma osmolality near normal. Large amounts of free water administered orally or as IV fluid may induce hyponatremia and volume overload. Sodium retention and volume expansion also contribute to hypertension in many patients with severe CKD, and diuretic therapy may be necessary to control edema or blood pressure. When the patient develops ESRD, dialysis (specifically ultrafiltration) or a kidney transplant becomes necessary to maintain normovolemia.

Potassium Homeostasis Hyperkalemia is more common in patients with stage 5 CKD and in those who require dialysis. The majority of patients can be managed with a dietary potassium restriction of 50 to 80 mEq/day and a reduction in dialysate potassium concentrations for patients receiving hemodialysis or peritoneal dialysis (see Chap. 48). Hyperkalemia is less common, however, in the peritoneal dialysis population because of the more extensive removal of potassium by the peritoneal dialysis procedure and, in general, these patients are allowed more liberal dietary potassium intake.

Pharmacologic Therapy

Sodium and Water Balance Diuretic therapy is often necessary to prevent edema and the associated symptoms from volume overload. Loop diuretics increase urine volume and renal sodium excretion even in those with stage 4 CKD. A combination of a loop diuretic with a thiazide diuretic (such as hydrochlorothiazide or metolazone) can result in a profound excretion of sodium and water. Saline-containing IV solutions should be used cautiously in patients with CKD because the kidney's ability to excrete a salt load is impaired and thus they are prone to volume overload.

Potassium Homeostasis The definitive treatment of severe hyperkalemia for an ESRD patient is hemodialysis. In reality, there is often a delay between diagnosis of hyperkalemia and institution of dialysis, which necessitates the use of other temporizing measures, such as IV calcium gluconate, insulin and glucose, nebulized β_2 -adrenergic agonists (albuterol), and sodium polystyrene sulfonate (see Chap. 54). Unfortunately, shifting potassium into the intracellular fluid compartment with insulin and glucose or with albuterol makes removal of potassium via dialysis more difficult. Multiple dialysis sessions may be necessary following potassium redistribution to the extracellular space. Sodium polystyrene sulfonate (with sorbitol), a potassium-sodium exchange resin, can be given orally in doses of 25 to 50 g to increase potassium excretion via the ileum and colon. Lastly, sodium bicarbonate therapy is no longer advocated in the treatment of ESRD hyperkalemia unless severe metabolic acidosis is also present, because the potassium-lowering effect is unreliable. Loop diuretics, a standard pharmacologic treatment option for hyperkalemia, are ineffective in patients with ESRD.

A review of medications to identify those that increase serum potassium should also be done regularly. This includes potassium-sparing diuretics, β -blockers, which interfere with the extrarenal translocation of potassium into cells, and ACEIs, which may cause hyperkalemia by reducing aldosterone production. Polycitra, used

for the treatment of metabolic acidosis, contains potassium citrate and should not be prescribed for patients with severe CKD. The contribution of dialysis modalities to potassium homeostasis in patients with ESRD must also be considered (see Chap. 48). Constipation in patients with CKD can interfere with colonic potassium excretion; therefore a good bowel regimen is also important.

CLINICAL CONTROVERSY

Spironolactone and eplerenone decrease cardiovascular mortality in patients with severe heart failure. However, because data on use of these agents in patients with ESRD are very limited, and because these agents contribute to hyperkalemia, they should be used with great caution in patients with ESRD. It may be prudent to avoid prescribing these agents until additional studies are reported supporting their safety in the ESRD population.

Evaluation of Therapeutic Outcomes

Monitoring of volume status and serum electrolyte levels should be done at each followup visit in patients with stages 4 and 5 CKD, particularly given the risk and detrimental consequences of volume overload and extracellular fluid volume expansion (e.g., hypertension and pulmonary edema) and hyperkalemia (e.g., arrhythmias). Clinicians should evaluate patients for signs and symptoms of volume overload (e.g., pitting edema, rales, ascites, shortness of breath, and increased weight). Blood pressure monitoring in the clinic setting and at home, if feasible, to monitor the efficacy of the antihypertensive regimen is also warranted. As kidney disease progresses dietary intervention and diuretic therapy (based on the degree of kidney function) will likely become necessary. Laboratory evaluation of serum potassium is warranted to identify hyperkalemia. The patient should also be instructed about how to do a self-evaluation for signs and symptoms of edema and about nonpharmacologic interventions to prevent volume overload and hyperkalemia.

Patients with stage 5 CKD on hemodialysis are seen in the dialysis facilities much more frequently (three times per week) than patients with early stage CKD and peritoneal dialysis patients. Assessment of electrolytes is generally done once per month, although this is evaluated more frequently if necessary. Other pertinent observations in this population include a rise in the predialysis weight over a relative short period of time and shortness of breath, both indicative of volume overload. In these situations, the dialysis prescription may be altered acutely to remove more volume during the dialysis procedure (see Chap. 48) and the patient will require counseling on appropriate dietary intake of sodium and water.

■ ANEMIA OF CHRONIC KIDNEY DISEASE

Desired Outcome

The desired outcomes of anemia management are to increase oxygen-carrying capacity, thereby decreasing dyspnea, orthopnea, and fatigue, and to prevent long-term consequences such as LVH and cardiovascular mortality. To achieve these goals one must have adequate iron, folate, and B_{12} , and sufficient levels of ESAs. Other factors that contribute to worsening of anemia, such as blood loss and other causes of resistance to ESA therapy, should also be identified and corrected if possible. Specific targets for hemoglobin and iron indices, recommendations for appropriate use of ESAs and iron preparations, and recommendations on adjuvant therapy for anemia management based on the K/DOQI guidelines and clinical practice recommendations are discussed in the following sections. Table 47-2 lists the target hemoglobin and iron indices.

Target Hemoglobin The Hb is the preferred monitoring parameter for anemia because hematocrit (HCT) fluctuates with volume

TABLE 47-2 Target Parameters for Anemia Management in Chronic Kidney Disease

Parameter	Stage 4 CKD and Peritoneal Dialysis Patients	Hemodialysis Patients
Hb	11–12 g/dL	11–12 g/dL
TSat ^a	>20%	>20%
ChR	—	>29 pg/cell
Serum ferritin ^a	>100 ng/mL	>200 ng/mL

ChR, content of hemoglobin in reticulocytes; CKD, chronic kidney disease; Hb, hemoglobin; TSat, transferrin saturation.

^aNo upper limit defined; be aware of the risk of iron overload.

Data from KDOQI Clinical Practice Guidelines and Clinical Practice Recommendations for Anemia in Chronic Kidney Disease. *Am J Kidney Dis* 2006;47:S11–145.

status and may be falsely elevated if the blood sample has been stored for a prolonged period of time. The lower end of the target hemoglobin concentration (Hb) range in patients treated for anemia of CKD prior to March 2007 had been greater than 11 g/dL (corresponding HCT 33%), a value lower than that accepted in patients without CKD. However, no absolute ceiling Hb was recommended; rather, there was a statement in the guidelines that there is insufficient evidence to recommend maintaining Hb levels at 13.0 g/dL or greater.

A higher mortality rate for ESRD patients with Hb/HCT values above the target ranges has been reported, particularly in patients with cardiac disorders;³¹ however, beneficial effects of increasing the HCT up to 39% have also been observed, including improvements in cardiac function, cognitive ability, and quality of life.³² Hence, the target Hb range in CKD patients continues to be debated. Two recently published randomized clinical trials have provided more information, yet stimulated more debate, on the target Hb in early stage CKD. In the Correction of Hemoglobin and Outcomes in Renal Insufficiency (CHOIR) trial, patients with an estimated GFR of 15 to 50 mL/min/1.73 m² were treated with human erythropoietin (epoetin alfa) to achieve a high Hb (13.5 g/dL) or a lower Hb (11.3 g/dL) to evaluate differences in risk of complications from cardiovascular causes and death; primary end points were time to the composite of death, myocardial infarction, hospitalization for congestive heart failure (excluding renal replacement therapy), or stroke.³³ After 16 months there were 125 events in the high Hb group (n = 715), achieved Hb was 12.6 g/dL, and 97 events in the low Hb group (n = 717), achieved Hb was 11.3 g/dL, indicating a higher risk of adverse events with a higher Hb (hazard ratio: 1.34; 95% confidence interval: 1.03 to 1.74; *P* = 0.03). Those who reached the target Hb in the higher Hb group received larger doses of epoetin alfa (10,694 units) compared to those who achieved the target Hb in the lower Hb group (6,057 units). In the Cardiovascular Risk Reduction by Early Anemia Treatment with Epoetin Beta (CREATE) trial, the effect of complete anemia correction (Hb 13.0 to 15.0 g/dL) versus partial anemia correction (Hb 10.5 to 11.5 g/dL) on cardiovascular outcomes (time to first cardiovascular event) in patients with an estimated GFR of 15 to 35 mL/min/1.73 m² was evaluated.³⁴ After 3 years of treatment there was no significant difference in the risk of a first cardiovascular event between the complete correction (n = 301) and partial correction (n = 302) groups (hazard ratio: 0.78; 95% confidence interval: 0.53 to 1.14; *P* = 0.20).

Based on these data and more recent observations, the FDA and the manufacturer of these products agreed, in March 2007, on revised product labeling that includes updated warnings, a new boxed warning, and modifications to the dosing instructions. The new boxed warning advises health care providers to monitor Hb and to adjust the ESA dose to maintain the lowest hemoglobin level needed to avoid blood transfusions. Health care providers and patients should carefully weigh the risks of ESAs against risks of transfusion. Other recently completed studies describe an increased risk of death, blood clots, strokes, and heart attacks in patients with

chronic kidney failure when ESAs were given at higher than recommended doses. Based on the most currently available, albeit controversial, information, the target upper limit for Hb in patients treated for anemia of CKD should be individualized based on the patient's condition and dosage regimen adjusted to avoid Hb values greater than 12 g/dL until further evidence is available.

Additional information about treatment of anemia with ESAs will likely be available in the near future. The Trial to Reduce Cardiovascular Events with Aranesp Therapy (TREAT) is currently ongoing, with a planned enrollment of 4,000 patients. This is a randomized, placebo-controlled study in patients with type 2 diabetes and an estimated GFR of less than 60 mL/min/1.73 m² to evaluate differences in the composite primary end point of cardiovascular death, heart failure, myocardial infarction, stroke, and hospitalization for unstable angina treatment for patients who receive darbepoetin alfa (Aranesp) to achieve a target Hb of 13 g/dL versus a target Hb greater than 9 g/dL. Patients in the latter group will receive darbepoetin if the Hb falls to less than 9 g/dL, but otherwise will receive placebo. This trial may provide information to answer questions regarding treatment of anemia in a population at high risk of cardiovascular events.

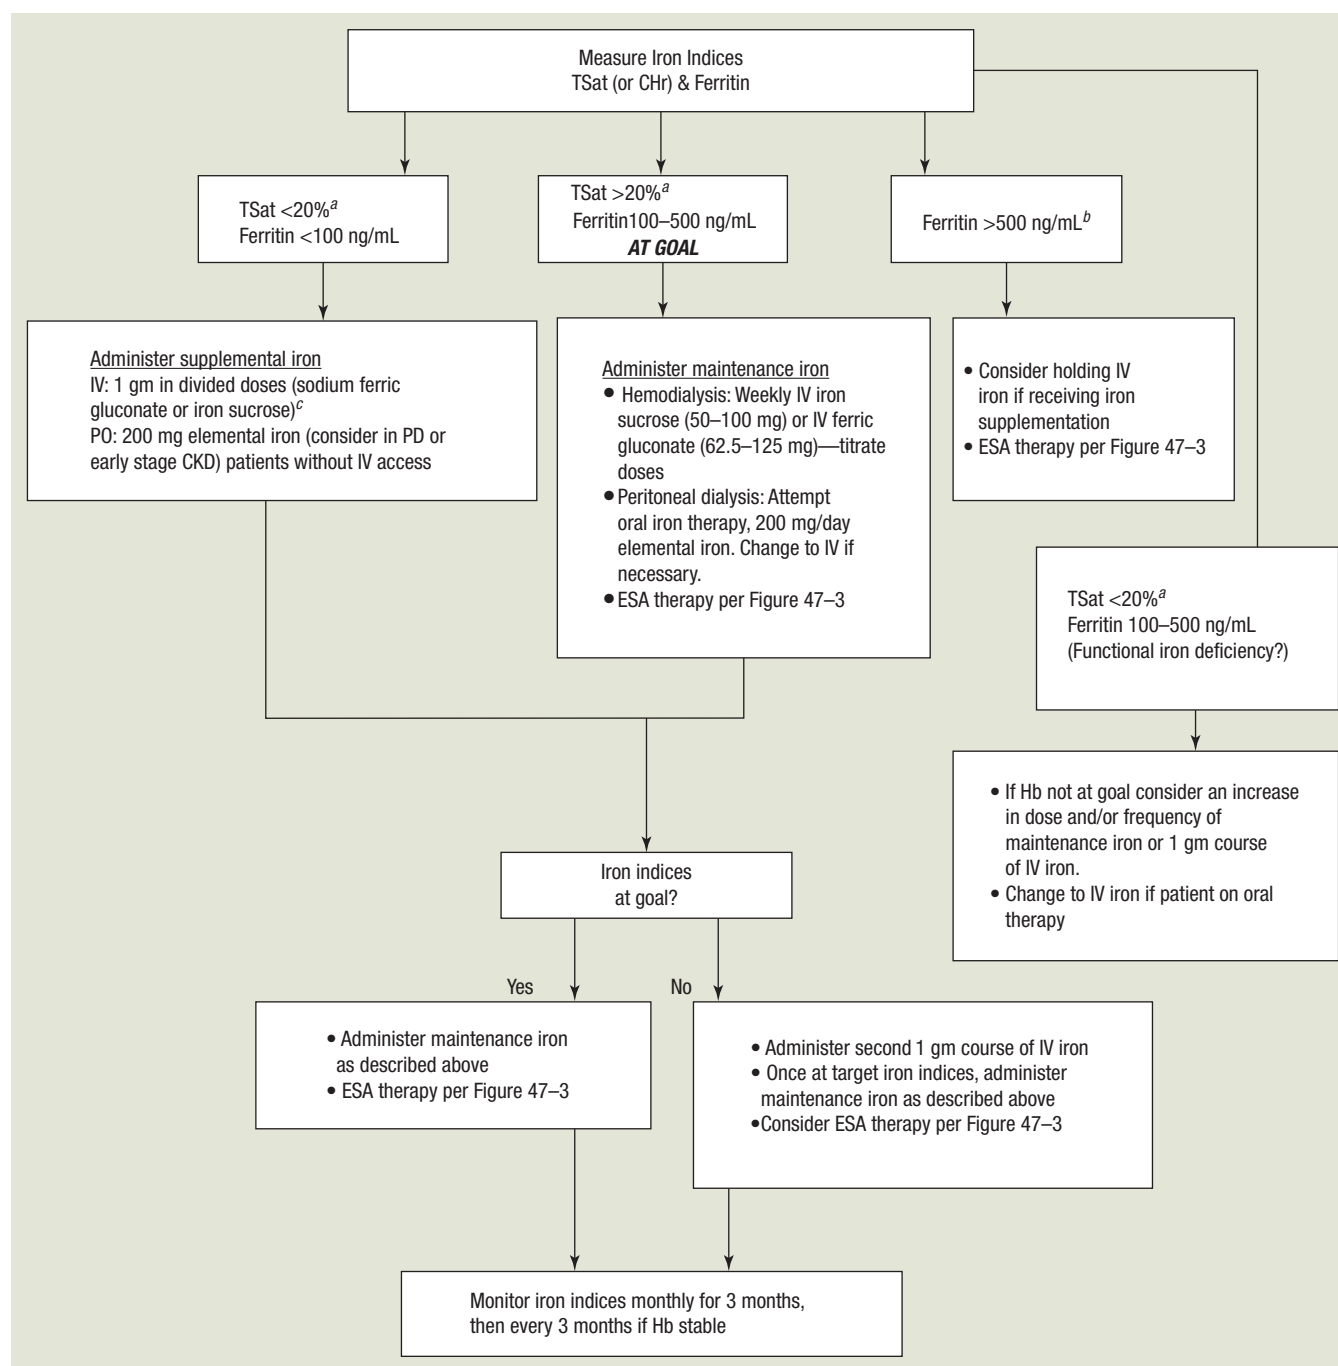

Iron Status Iron indices that should be monitored include the TSat, an indicator of iron immediately available for delivery to the bone marrow, and serum ferritin, an indirect measure of storage iron. Transferrin is the carrier protein for iron and, as a protein, may be affected by nutritional status. Serum ferritin is an acute-phase reactant, meaning it may be elevated under certain inflammatory conditions and give a false indication of storage iron. The content of hemoglobin in reticulocytes also is reliable in assessing iron status in hemodialysis patients and is recommended in the K/DOQI guidelines as an alternative to TSat to assess iron deficiency in this population.^{21,35} Table 47–2 lists the recommended target iron indices to achieve prior to initiation of ESA therapy and to maintain during therapy.²¹ The higher acceptable level for serum ferritin of greater than 200 ng/mL in hemodialysis patients is based on the information showing improved outcomes (lower ESA doses and improved response to iron) at this level of ferritin. The current K/DOQI anemia guidelines differ from the previous guidelines which had recommended an upper level for TSat of 50% and serum ferritin of 800 ng/mL to reduce the risk of iron overload. No upper level for these iron indices has been clearly established in the current recommendations based on available safety information; however, the risk of iron overload always needs to be considered with IV iron supplementation. According to the K/DOQI recommendations there is insufficient evidence to recommend routine administration of IV iron if the patient's serum ferritin level is greater than 500 ng/mL.²¹ Since ferritin can be elevated by many conditions the interpretations of singular values is challenging. The decision of whether or not to give IV iron is thus primarily based on clinical judgements.

Nonpharmacologic Therapy

Nonpharmacologic therapy for anemia of CKD includes maintaining adequate dietary intake of iron. A relatively small amount of dietary iron, approximately 1 to 2 mg (or approximately 10%), is absorbed each day, primarily in the duodenum. Although there is some debate as to whether GI absorption of iron is significantly altered in patients with severe CKD, it is clear that oral intake from dietary sources alone is generally insufficient to meet the increased iron requirements that are necessitated by the initiation of erythropoietic therapy.²¹

Pharmacologic Therapy

8 Pharmacologic therapy for anemia of CKD includes chronic therapy with an ESA to correct erythropoietin deficiency and iron supplementation to correct and prevent iron deficiency caused by ongoing blood loss and increased iron demands associated with the initiation of erythropoietic therapy (Figs. 47–2 and 47–3). Iron

^a Or CHR <29 pg/cell in hemodialysis patients

^b Clinical judgement should be used to determine if iron supplementation should be continued when ferritin >500 ng/mL

^c IV iron regimen may be divided over 8–10 HD sessions (depending on product used) or given in larger doses over a prolonged administration time (e.g. up to 400 mg iron sucrose over 2.5 hrs) for patients on PD

FIGURE 47-2. Guidelines for iron therapy in the management of the anemia of chronic kidney disease. (CHR, content of hemoglobin in the reticulocytes; ESA, erythropoietic-stimulating agent; Hb, hemoglobin; TSat, transferrin saturation.)

therapy is first-line therapy for anemia of CKD if iron deficiency is diagnosed, and for some patients the target Hb may be achieved without concomitant ESA therapy. Coadministration of iron and an ESA is often required to effectively stimulate erythropoiesis and prevent microcytic anemia that occurs with iron deficiency.

Iron Supplementation If TSat (or content of hemoglobin in the reticulocytes) and serum ferritin are below goal indices, iron supplementation is recommended. Options for iron supplementation

include oral and IV therapy (Tables 47–3 and 47–4). Available oral iron preparations differ in their content of elemental iron. Products available for oral therapy include ferrous salts (ferrous sulfate, ferrous gluconate, and ferrous fumarate), polysaccharide iron complex, and, most recently, a heme iron polypeptide formulation. Four IV iron products are currently available in the United States (Table 47–4): two composed of iron dextran (INFeD, molecular weight [MW] 96,000; and Dexferrum, MW 267,000), sodium ferric gluconate (Ferrlecit, MW 350,000), and iron sucrose (Venofer, MW 43,000).

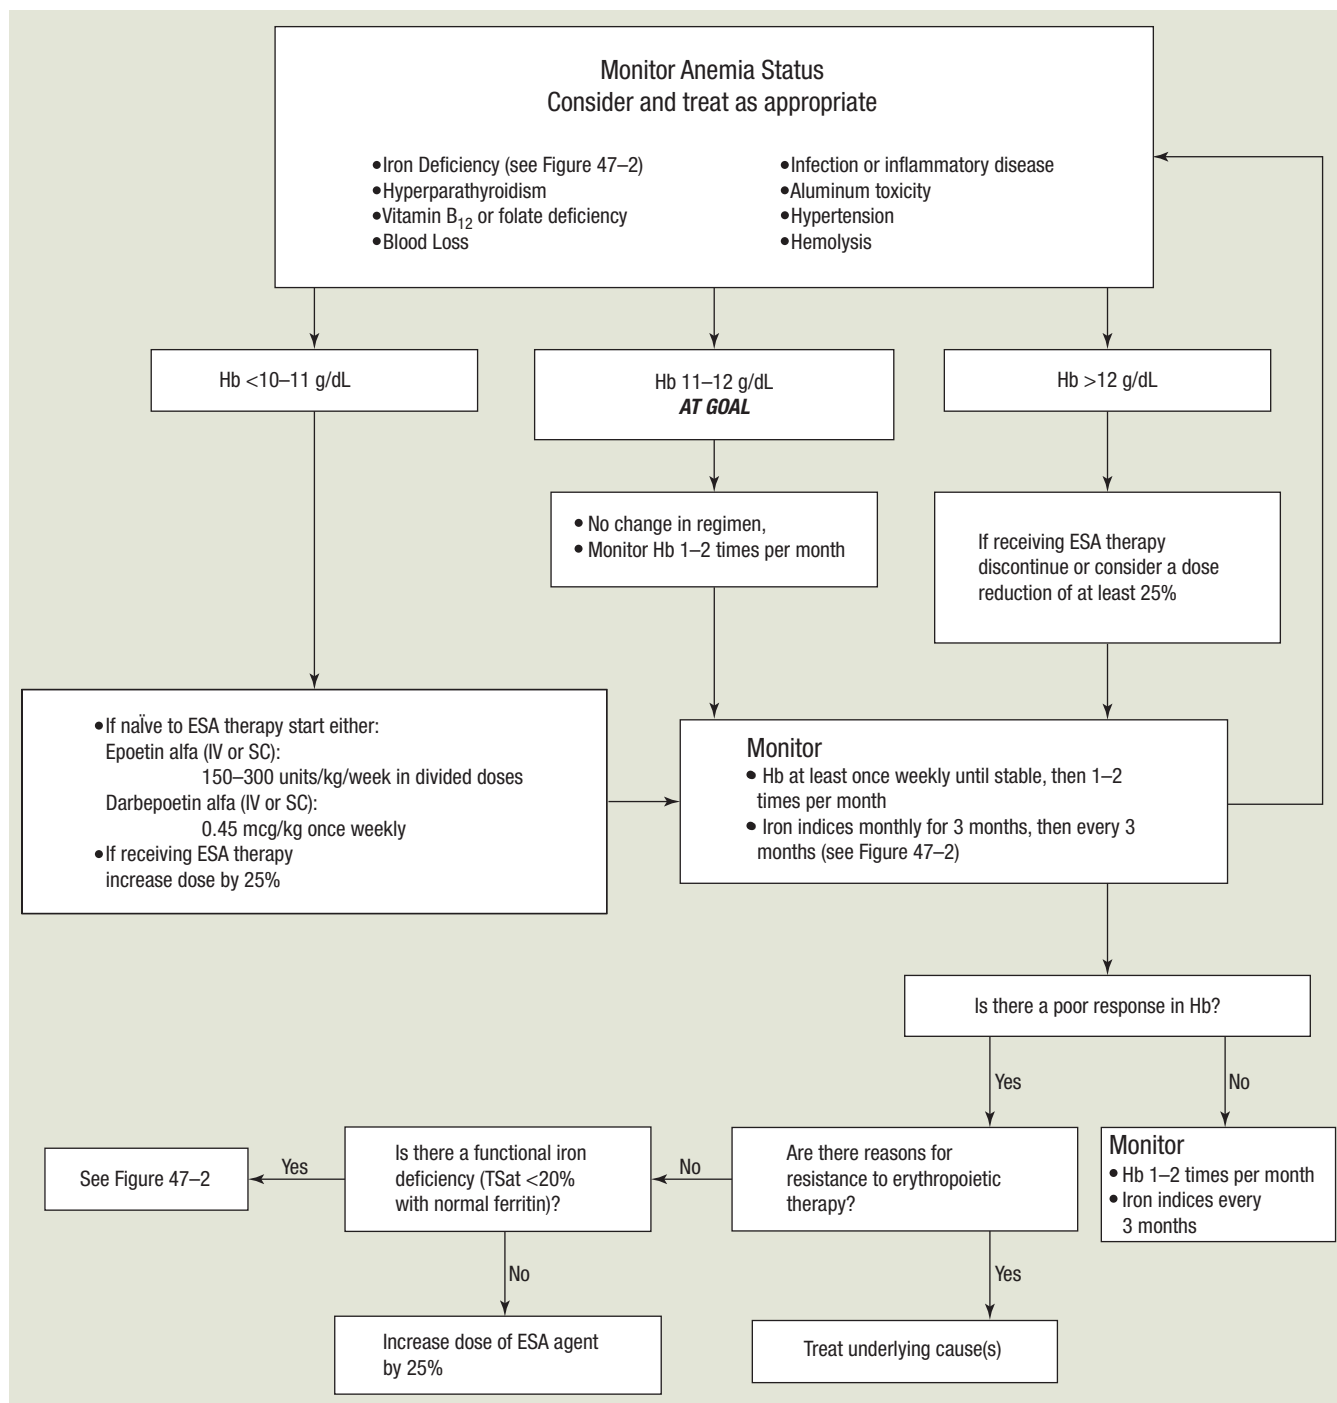

FIGURE 47-3. Guidelines for erythropoietic stimulating agent therapy in the management of the anemia of chronic kidney disease. (ESA, erythropoietic-stimulating agent; Hb, hemoglobin; SC, subcutaneous; TSat, transferrin saturation.)

Pharmacology and Mechanism of Action. Iron supplements provide the elemental iron required for production of hemoglobin and its subsequent incorporation in red blood cells, the net result of which is an increase in the transportation of oxygen to tissues. Supplementation of iron is necessary to replete iron stores and maintain adequate iron for transport to the bone marrow.

Pharmacokinetics. Approximately 10% of orally administered iron is absorbed in the duodenum and upper jejunum. Absorption of iron is decreased by food and achlorhydria. The heme form of oral iron binds to a different receptor in the GI tract than nonheme iron, is absorbed to a greater extent, and may be better tolerated.³⁶ Some oral

iron formulations also include ascorbic acid to enhance iron absorption. Although there is an association between ascorbic acid intake and oxalate formation, this association is generally not observed at doses of ascorbic acid contained in these iron formulations.

Intravenous iron preparations differ in the composition of the complex to which elemental iron is bound. These differences affect the rate of dissociation of iron from the complex to the reticuloendothelial system and subsequent storage as ferritin. The half-life of these formulations also differ: ferric gluconate (1 hour), iron sucrose (6 hours), and iron dextran (40 to 60 hours). However, there is minimal to no correlation between the pharmacokinetics of these formulations and their pharmacodynamic effects.³⁷

TABLE 47-3 Oral Iron Preparations			
Iron Product	Common Agents and Available Units	Amount of Elemental Iron Per Unit	Number of Units Per Day ^a
Ferrous sulfate	Fer-In-Sol (75 mg/0.6 mL)	75 mg	2–3
	Feosol (200 mg)	50 mg	4
	Ferrous sulfate, various preparations (325 mg)	65 mg	3–4
	Slow FE (160 mg)	50 mg	4
Ferrous fumarate	Ferrous fumarate, various preparations (300 mg)	99 mg	2
	Femiron (20 mg)	20 mg	10
	Nephro-Fer (350 mg)	115 mg	2
	Vitron-C (65–125 mg)	65 mg	3
Ferrous gluconate	Ferrous gluconate, various (325 mg)	36 mg	6
	Fergon (240 mg)	27 mg	6
Polysaccharide iron	Hytinic (150 mg)	150 mg	1–2
	Niferex (50 mg)	50 mg	4
Heme iron polypeptide	Proferrin-ES (12 mg)	12 mg	17

^aNumber of units per day depends on the amount of elemental iron per unit; 200 mg elemental iron per day is recommended.

Efficacy. Although supplementation using oral preparations may seem more practical than IV administration, oral iron therapy is limited by poor absorption and is often inadequate to achieve goal iron indices. In patients with ESRD GI absorption of iron is often inadequate to meet the increase in iron demand from ESA therapy and chronic blood loss in the hemodialysis population.²¹ Oral iron supplementation is more convenient for patients who do not have regular IV access, including patients with stages 3 and 4 CKD and those who are receiving peritoneal dialysis. Even these patients, however, are likely to require IV iron supplementation periodically to meet iron needs and correct absolute iron deficiency. Success of oral therapy is also limited by noncompliance as a result of side effects, primarily GI in nature, and the frequency of administration (up to three times per day). In 2005, over 80% of hemodialysis patients received an average monthly dose of ≥200 mg of IV iron during the first 6 months after the start of dialysis.²

Intravenous iron therapy is an effective means to prevent iron deficiency and maintain adequate iron status for erythropoiesis. Parenteral iron improves the responsiveness to ESA therapy and reduces the dose required to achieve and maintain the target Hb in hemodialysis patients.²¹ Iron administration in patients with what is

known as a functional iron deficiency is more questionable. Functional iron deficiency is characterized by a low TSat (<20%) in the presence of a normal or elevated serum ferritin. In other words, there may appear to be adequate storage iron, but iron is not being carried by transferrin to the bone marrow for red blood cell production. Under these conditions a trial of IV iron therapy may be warranted if the Hb is less than the target of 11 g/dL. A recent study conducted in ESA-treated anemic hemodialysis patients with a low TSat (<25%) and an elevated serum ferritin (>500 ng/mL) showed a significantly greater Hb response rate in patients who received a 1-g course of IV iron as sodium ferric gluconate in conjunction with a 25% increase in ESA dose than in those who only received an increase in the ESA dose.³⁸

Adverse Effects. Adverse effects of oral iron, including constipation, nausea, and abdominal cramping, increase as the dose is escalated and may be present in more than 50% of patients receiving 200 mg of elemental iron per day. These unfavorable effects often discourage patients from taking these medications on a chronic basis. Some of these GI side effects can be minimized if oral iron products are taken with food; however, food may decrease absorp-

TABLE 47-4 Intravenous Iron Preparations ^a				
Iron Compounds	FDA-Approved Indications	FDA-Approved Dosing ^{48,51,52}	Warnings	Dose Ranges ^b
Iron Dextran (INFeD, DexFerrum) ^c Ferric gluconate (Ferrlecit) ^d	Patients with iron deficiency in whom oral iron is unsatisfactory	IV push: 100 mg over 2 min (25-mg test dose required)	Black box (risk of anaphylactic reactions)	25–1,000 mg
	Adult and pediatric HD patients age 6 years and older receiving ESA therapy	IV push (adult): 125 mg over 10 min IV infusion (adult): 125 mg in 100 mL of 0.9% NaCl over 60 min IV infusion (pediatric): 1.5 mg/kg in 25 mL of 0.9% of NaCl over 60 min; maximum dose 125 mg	General	62.5–1,000 mg
Iron sucrose (Venofer) ^e	HD patients with CKD receiving ESA therapy	IV push: 100 mg over 2–5 min IV infusion: 100 mg in maximum of 100 mL of 0.9% NaCl over 15 min	General	25–1,000 mg
	Nondialysis-CKD patients receiving or not receiving ESA therapy PD patients receiving ESA therapy	IV push: 200 mg over 2–5 min on 5 different occasions within 14-day period IV infusion: 2 infusions, 14 days apart, of 300 mg in maximum 250 mL of 0.9% NaCl over 1.5 h, followed by 1 infusion, 14 days later, of 400 mg in maximum 250 mL of 0.9% NaCl over 2.5 h		

CKD, chronic kidney disease; ESA, erythropoietin-stimulating agent; HD, hemodialysis; PD, peritoneal dialysis.

^aAll products may be administered IV push (small doses only).

^bSmall dosing ranges (e.g., 25–150 mg per week) generally used for maintenance regimens. Larger doses (e.g. 1 gram) should be administered in divided doses.

^cSupplied in 2-mL single dose vials containing 50 mg of elemental iron per mL.

^dAvailable in colorless glass ampules containing 62.5 mg elemental iron (12.5 mg/mL).

^eSupplied in 5-mL single-dose vials containing 100 mg elemental iron (20 mg/mL).

tion of oral iron. Patients should initially be instructed to take oral iron on an empty stomach; however, if side effects lead to intolerance and noncompliance these agents can be administered with food or an alternative agent may be prescribed.

Adverse effects of IV iron include allergic reactions, hypotension, dizziness, dyspnea, headaches, lower back pain, arthralgia, syncope, and arthritis. Some of these reactions, in particular hypotension, can be minimized by decreasing the dose or rate of infusion of iron. The most concerning potential consequence of IV iron administration is anaphylaxis. Anaphylactoid reactions to iron dextran have been reported in up to 1.8% of patients, with serious reactions including respiratory complications and cardiovascular collapse occurring in approximately 0.6%.³⁹ Such reactions are believed to be partly a response to antibody formation to the dextran component. Adverse reactions have been reported more frequently in those receiving Dexferrum compared to INFeD; a two- to eightfold increase in the incidence was noted with Dexferrum.⁴⁰ Such differences were particularly influential in product selection prior to the availability of sodium ferric gluconate and iron sucrose. These IV iron formulations have a better safety record than either of the iron dextran products, based on their history of use in Europe over the last four decades and recent data in the United States since these products were approved.^{41,42} Sodium ferric gluconate and iron sucrose do not require a test dose prior to administration of the full dose, unlike iron dextran, which requires a 25-mg test dose to evaluate the risk of anaphylactic reactions. As a precaution with all IV preparations, patients should be observed during and immediately following administration for any adverse reactions.

Administration of IV iron also introduces a risk of iron overload. Deposition of excess iron may affect several organ systems, leading to hepatic, pancreatic, and cardiac dysfunction. Bone marrow biopsy provides the most definitive diagnosis of iron overload, but because it is an extremely invasive procedure, it is not widely employed in most clinical settings. Maintaining serum ferritin and TSat values that demonstrate efficacy in preventing iron deficiency yet are safe is the most reasonable approach to minimize the risk of iron toxicity. The challenge is in defining these upper limits, particularly for serum ferritin, which may be elevated in inflammatory conditions and not reflective of true iron stores in such situations. If symptomatic overload does occur, deferoxamine (Desferal) or phlebotomy may be necessary.

The safety and efficacy of high-dose IV iron regimens have been evaluated to determine the most cost-effective and efficacious dosing strategies. Iron dextran has been safely administered to dialysis patients in total-dose infusions ranging from 400 mg to 2 g.⁴³ Similar high-dose regimens of 500 mg have also been safely administered to patients with stages 3 and 4 CKD.⁴⁴ Although such iron dextran regimens have been safely administered, it is important to consider that with the information available today on the safety profile of sodium ferric gluconate and iron sucrose, many clinicians would consider these newer agents as first-line therapy. Sodium ferric gluconate has been safely administered at doses of 250 mg infused over 1 hour (4.2 mg/min).⁴⁵ In this same evaluation, 19 doses greater than 250 mg were administered; 1 dose of 312.5 mg, 14 doses of 375 mg, and 4 doses of 500 mg, with infusion rates varying from 1.22 mg/min to 25 mg/min. No serious adverse events were reported, although nonserious events, such as pruritus, did occur in 4 of the 144 patients who received the 250-mg dose. Doses in these higher ranges should not be adopted as standard of care until further safety data become available. If doses higher than those currently approved are used in practice, they should be administered over a prolonged time period (at least 2 hours). Iron sucrose at doses of up to 500 mg administered over 3 hours on consecutive days has been successful in maintaining iron stores without causing serious adverse events.⁴⁶ When administered over a shorter time period this same dose was

associated with dizziness, hypotension, and nausea.⁴⁷ In this same evaluation the administration of lower doses of 200 to 300 mg given over 2 hours resulted in fewer adverse events. Higher dose regimens for iron sucrose have been approved in patients with early stage CKD and peritoneal dialysis patients (see Table 47–4), populations in whom administration of higher doses are more convenient as these patients are seen less frequently by healthcare providers than the hemodialysis population.⁴⁸

Although there are conflicting reports, most clinicians believe that exposure to iron may contribute to the risk of bacterial infection because iron is used by microorganisms for metabolic functions.⁴⁹ The association of IV iron with oxidative stress, acceleration of atherosclerosis, and other cardiovascular conditions has also been suggested.⁵⁰ These potential long-term risks of IV iron therapy are not clearly defined and there are no data that unequivocally confirm that aggressive use of IV iron in CKD patients treated with ESA therapy increases patient morbidity or mortality.

Drug–Drug and Drug–Food Interactions. Drugs commonly used in the CKD population that may decrease absorption of oral iron include calcium preparations and antacids. Oral iron may also decrease the absorption of quinolone antibiotics. Medications that increase gastric pH, such as H₂-antagonists and proton pump inhibitors, may also decrease iron absorption as iron absorption in the duodenum is maximized at an acidic pH.

Dosing and Administration. Correction of absolute iron deficiency (TSat less than 20%, serum ferritin less than 100 ng/mL [less than 200 ng/mL in hemodialysis patients]) requires administration of iron. The route of administration may be oral or IV in the stage 4 CKD and peritoneal dialysis patients. If oral therapy is initiated, the recommended dose is 200 mg of elemental iron per day (see Table 47–3). The IV route of administration is preferred in hemodialysis patients. For the hemodialysis population typical repletion dosing regimens are 100 mg as iron sucrose or iron dextran over 10 dialysis sessions, or 125 mg of sodium ferric gluconate over 8 dialysis sessions (see Table 47–4).^{48,51,52} These regimens are FDA-approved and reduce the risk of adverse reactions to IV iron therapy.

Administration of 1 g of IV iron is also reasonable to initially replete hemodialysis patients with an absolute iron deficiency; however, without ongoing iron supplementation, many patients quickly become iron deficient. There is sufficient evidence to support use of maintenance doses of IV iron in hemodialysis patients (e.g., iron sucrose or iron dextran 25 to 100 mg/wk; sodium ferric gluconate 62.5 to 125 mg/wk).⁵³

Erythropoietic-Stimulating Agent Therapy

Pharmacology and Mechanism of Action. ESAs are required to stimulate differentiation of erythroid progenitor stem cells and induce the release of reticulocytes from the bone marrow to the bloodstream where they mature into erythrocytes (red blood cells). Available ESAs include epoetin alfa (distributed as Epogen by Amgen, Inc., Thousand Oaks, CA; and Procrit by Ortho Biotech, Johnson & Johnson, Raritan, NJ) and darbepoetin alfa (Aranesp by Amgen, Inc.). Epoetin beta is available from several different sources outside the United States. These agents are glycoproteins manufactured by recombinant DNA technology that have the same biologic activity as endogenous erythropoietin. Although the amino acid sequence of epoetin alfa is identical to the endogenous protein, the carbohydrate structure differs. Since 1989, epoetin alfa has been the mainstay of therapy for anemia of CKD and substantially reduced the percentage of patients dependent on transfusions for management of anemia. Darbepoetin alfa was approved for treatment of anemia of CKD in September 2001. Darbepoetin alfa differs from epoetin alfa by the addition of two N-linked carbohydrate side chains, which increases the sialic acid content of darbepoetin

compared with epoetin alfa, resulting in a higher molecular weight (~38,000 daltons for darbepoetin compared with 30,400 daltons for epoetin alfa).⁵⁴

Pharmacokinetics and Pharmacodynamics. Epoetin alfa may be administered by either the IV or subcutaneous (SC) routes. Although bioavailability with SC administration is poor (approximately 20%), the low peak serum concentrations and the prolonged half-life (approximately 24 hours as compared to 8.5 hours IV)⁵⁵ yield a Hb response that is at least as good or better than that attained with IV administration.⁵⁶ This enhanced efficacy is presumed to be caused by a more prolonged physiologic stimulation of erythroid precursors. The SC doses required to achieve and maintain the target Hb have been reported as 15% to 50% lower than doses required with IV administration.⁵³ Darbepoetin alfa has a longer half-life and extended biologic activity than does epoetin alfa (darbepoetin alfa 25.3 hours IV, 48.8 hours SC) as a consequence of the increased sialic acid content.⁵⁷ The prolonged half-life of darbepoetin offers the advantage of less-frequent dosing, starting at once-a-week or once-every-other-week dosing when given IV or SC.⁵⁸ This is of particular benefit in nondialysis CKD patients and in the peritoneal dialysis population, who are not seen by healthcare providers in the clinic as often. Prolonged dosing intervals, as infrequent as once every 4 weeks, have also been effective in maintaining target Hb in many CKD patients, including nondialysis CKD and ESRD patients.^{59,60}

The pharmacodynamics of epoetin and darbepoetin are important to consider when evaluating response to therapy. With initiation of ESA therapy or a change in dose, the Hb may begin to rise as the result of demargination of reticulocytes; however, it takes approximately 10 days before erythrocyte progenitor cells mature and are released into the circulation. The Hb continues to increase until the life span of the cells stimulated by epoetin or darbepoetin is reached (mean 2 months; range 1 to 4 months in patients with ESRD). At this point a new steady state is achieved (i.e. the rate at which red blood cells are being produced equals the rate at which they are leaving the circulation). For this reason it is important to evaluate the Hb response over several weeks as opposed to making changes in the dosing regimen prematurely.

Efficacy. Efficacy of ESA therapy is determined by the change in Hb after initiation of therapy or following a dose adjustment, with the ultimate goal of achieving the target Hb of 11 to 12 g/dL. Patients will generally respond to ESA therapy in a dose-related fashion unless there are factors present that may cause resistance to therapy. The K/DOQI guidelines define failure to respond to therapy when there has been a significant increase in the ESA dose required to maintain a target Hb or a significant decrease in Hb at a constant ESA dose, or when the Hb fails to increase to greater than 11 g/dL despite an ESA dose equivalent to epoetin greater than 500 international units/kg/wk.²¹ A number of factors and conditions may cause resistance to ESA therapy, including iron deficiency, hospitalization, catheter insertion, hypoalbuminemia, elevated C-reactive protein, chronic bleeding, aluminum toxicity, malnutrition, hyperparathyroidism, cancer and chemotherapy, AIDS, inflammation, and infection.²¹

As the most common cause of resistance, iron deficiency must be routinely evaluated for and treatment begun prior to initiation of ESAs. Inflammation (localized or systemic infection, active inflammatory disease, or surgical trauma) is associated with defective iron utilization known as *reticuloendothelial block*. Reticuloendothelial block is characterized by a reduction in iron delivery from body stores to the bone marrow, and is generally refractory to iron therapy. Erythropoietic therapy may be continued in the infected or postoperative patient, even though increased doses are often required to maintain or slow the rate of decline in Hb. Deficiencies in folate and vitamin B₁₂ should also be considered as potential

causes of resistance to ESA therapy, as both are essential for optimal erythropoiesis. Patients on hemodialysis or peritoneal dialysis should be routinely supplemented with water-soluble vitamins (including B₁₂ and folate) as these vitamins are often depleted with dialysis therapy. There is also some evidence to suggest that patients receiving ACEIs may be relatively resistant to erythropoietic therapy, although these findings have not been consistently demonstrated.⁶¹ An increase in the dosage of ESAs may be necessary in patients receiving ACEIs who do not maintain a stable Hb.

Studies have demonstrated reduced morbidity, increased exercise capacity and tolerance, and enhanced quality of life when ESA therapy was initiated, iron stores maintained, and target Hb attained.^{21,32} Data also suggest a stabilization or regression of LVH in patients with early kidney disease and in those with ESRD when anemia is successfully treated.⁶² Whether there is an optimal Hb target to prevent development of LVH remains to be determined. In a 2-year study, no difference in left ventricular mass index was observed between patients with stages 3 or 4 CKD maintained at a Hb of 9 to 10 g/dL versus 12 to 13 g/dL.⁶³ Given these observations and the recent concerns regarding the target Hb level additional prospective studies addressing this question will be needed to resolve the controversy.

Adverse Effects. Epoetin alfa and darbepoetin alfa are generally well tolerated; hypertension is the most common adverse event reported.²¹ Protocols established in some clinical settings, primarily in outpatient dialysis clinics, sometimes recommend withholding ESA therapy if blood pressure is above a defined threshold. K/DOQI guidelines for anemia do not recommend withholding ESA therapy for elevated blood pressure, but advocate more judicious use of antihypertensive agents and dialysis to control blood pressure.²¹ However, FDA approved product labeling advise that ESAs not be used in those with uncontrolled blood pressure. Although seizures have occurred in patients treated with epoetin, the incidence does not appear to be increased over the baseline levels seen in placebo control groups. Vascular access thrombosis may be more frequent during epoetin therapy, but this finding has not been supported to the extent necessary to advocate increased monitoring for this effect. The K/DOQI guidelines specifically state that vascular access occlusion, inadequate dialysis, history of seizures, or compromised nutritional status are not contraindications to ESA therapy.²¹

Neutralizing antibodies to ESAs and endogenous erythropoietin have been identified in a small number of patients treated with ESAs.⁶⁴ These patients develop antibody-mediated pure red cell aplasia (PRCA), which results in an absolute resistance to ESA therapy and intermittent blood transfusions as the primary therapeutic option. Case reports increased dramatically between 1998 and 2002 and occurred in parallel with the increase in SC administration primarily with one epoetin alfa product manufactured outside the United States, Eprex (Johnson & Johnson, Manati, Puerto Rico). Differences in this formulation that were noted at the time of the increase in PRCA cases were the substitution of human albumin with polysorbate 80 and use of uncoated rubber stoppers in the single-dose syringes, factors that in combination may increase release of organic compounds and increase immunogenicity of SC-administered epoetin alfa.²¹ Changes in packaging of these syringes with fluororesin-coated stoppers and prohibiting SC administration practices in both Europe and Canada have led to a decrease in PRCA case reports. No case of antibody-associated PRCA has been documented in patients receiving only IV administration of ESAs and few cases have been reported with other ESAs.⁶⁵

Although the case reports of antibody-associated PRCA are relatively few in number and the primary problem with the formulation addressed, clinicians should be aware of this rare phenomenon in patients resistant to ESA therapy. Further evaluation for antibody-mediated PRCA should be considered for patients receiv-

ing ESA therapy for more than 4 weeks who develop a sudden rapid decrease in Hb level (rate of 0.5 to 1.0 g/dL/wk) or require 1 to 2 red blood cell transfusions per week and who have a normal platelet and white blood cell count with an absolute reticulocyte count of less than 10,000/ μ L.²¹ Discontinuation of ESA therapy is recommended in antibody-mediated PRCA because antibodies are cross-reactive and continued exposure may lead to anaphylactic reactions. Immunosuppressive therapy has been effective for some patients, although is still considered investigative. The question remains as to whether patients who develop antierythropoietin antibodies should receive other ESAs. Although switching to another ESA has been successful in at least one case report, this practice cannot be recommended without further evidence of safety.⁶⁶

Drug-Drug Interactions. No significant drug interactions have been reported with the available ESAs.

Dosing and Administration. Recommended starting doses of epoetin alfa are 50 to 100 units/kg IV or SC three times per week for hemodialysis patients.⁶⁷ Less-frequent dosing is preferred in stage 4 CKD patients and with early stage CKD and peritoneal dialysis patients since these patients are seen in the outpatient clinic setting on a relatively infrequent basis. Studies have been done to evaluate extended dosing intervals for SC administration of epoetin alfa in early stage CKD patients.^{68–70} Improved erythropoiesis and reduced transfusion requirements were observed in patients with anemia (Hb <10 g/dL) who received once weekly SC doses of 10,000 units of epoetin alfa.⁷⁰ Monthly dosing intervals for epoetin alfa SC have also been effective in maintaining target Hb values in this population.⁶⁹

The starting dose of darbepoetin alfa in patients not previously receiving ESA therapy is 0.45 mcg/kg IV or SC administered once weekly.⁷¹ A conversion table for patients who are to be switched from epoetin alfa (units per week) to darbepoetin alfa (micrograms per week) is available in the package insert for darbepoetin.⁷¹ Frequency of dosing of darbepoetin is weekly for patients previously receiving epoetin two to three times per week and every other week for patients receiving epoetin once weekly. Extended dosing intervals of darbepoetin as infrequent as every 4 weeks have been successful in maintaining Hb levels in early stage CKD and dialysis patients.^{72,73} This extended-dosing regimen is most beneficial for stage 4 CKD patients.

The IV route of administration is preferred for most hemodialysis patients based, in part, on the risk for PRCA associated with SC administration (see Adverse Effects above) and convenient IV access for these patients during the hemodialysis procedure.²¹ Subcutaneous administration of ESAs is preferable for chronic ambulatory peritoneal dialysis patients and the nondialysis CKD population because these patients do not usually have regular IV access.

Figures 47–2 and 47–3 provide an algorithmic approach to management of anemia using ESAs and iron therapy in patients with ESRD.

Transfusions and Adjunct Therapies Red blood cell transfusions are currently a third-line treatment option for anemia of CKD. Red blood cell transfusions carry many risks and therefore should only be used in select situations, such as acute management of symptomatic anemia, following significant acute blood loss, and prior to surgical procedures that carry a high risk of blood loss, with the goal of preventing inadequate tissue oxygenation or cardiac failure. Androgen therapy was used extensively before the availability of ESAs; today, however, there is insufficient evidence to support use of androgens.²¹ The risks of liver toxicity, malignancy, virilization in females, and hypertriglyceridemia outweigh the benefits of androgen therapy. L-Carnitine supplementation and vitamin C were previously suggested as adjunctive treatments of anemia asso-

ciated with kidney disease, but are no longer recommended because of the lack of evidence supporting improved anemia management with these therapies.

Investigational Agents

Iron. Investigational agents for iron supplementation include ferumoxylol, a polysaccharide-coated iron oxide administered IV; iron oligosaccharide, elemental iron complexed with glucose; and ferric pyrophosphate, a water-soluble form of iron that may be administered via the dialysate solution used for hemodialysis and peritoneal dialysis.⁷⁴

Erythropoietic-Stimulating Agents. Continuous erythropoietin receptor activator is a new ESA that is undergoing review by the FDA and may provide another option for treatment of anemia of CKD. This agent interacts with the erythropoietin receptors to cause stimulation of erythropoiesis, but has receptor-binding characteristics that differ from native erythropoietin. The half-life of this agent is notably longer than other available ESAs, approximately 70 to 122 hours after IV and 102 to 147 hours after SC administration which translates into a longer duration of action and thus potentially less frequent dosing for CKD.^{74,75}

Hypoxia-inducible factor is a transcription factor found in erythropoietin-producing cells that activates erythropoietin during hypoxic conditions and regulates iron absorption. In conditions causing destabilization of this transcription factor erythropoietin production does not occur. An oral agent known as a hypoxia-inducible factor-stabilizing agent that prevents destabilization of hypoxia-inducible factor is being investigated and may be promising for patients with CKD.⁷⁴

A synthetic peptide-based ESA known as Hematide that has the same biologic properties as endogenous erythropoietin, but a completely different amino acid sequence has been developed for treatment of anemia associated with CKD and cancer and is currently undergoing phase II studies.⁷⁴

Pharmacoeconomic Considerations

Pharmacoeconomic considerations in the management of anemia of CKD relate primarily to the costs associated with ESAs and the increased use of IV iron to sustain erythropoiesis. Over the last decade there has been a steady rise in cost associated with the provision of ESA and IV iron for the dialysis population: the cost to Medicare has stabilized at just over \$1 billion per year during the last 2 to 3 years.² Cost advantages can be realized, however, from the benefits associated with appropriate management of anemia, including fewer days of hospitalization, decreased mortality, and increased transplant success.^{2,32} Implementation of maintenance IV iron therapy, as well as SC administration of ESAs, also has the potential to reduce Medicare cost for anemia management. Current Medicare reimbursement rates for epoetin and IV iron produce profits of 12% and 45%, respectively for most dialysis programs, and thus there is little incentive to minimize the use of either agent. In the case of iron therapy, IV iron is reimbursable by Medicare, whereas oral iron must either be paid for by the patient out-of-pocket or by secondary insurers (usually with a copayment). Capitation of payments for medications such as ESAs and IV iron therapy may force the dialysis community to change their clinical practices and thereby optimize their use. Considerations are a bit different in patients with early stage CKD as Medicare does not cover medication costs for this population. The lack of payment is a deterrent to timely implementation of therapy and likely contributes to the development of secondary complications such as anemia.

Other factors that affect the pharmacoeconomics of using ESAs include drug acquisition costs, frequency of administration, and the treatment environment (inpatient or outpatient setting).⁷⁶ Less-

frequent dosing of ESAs may be beneficial from a pharmacoeconomic perspective because cost associated with administration may be reduced. Given that both epoetin alfa and darbepoetin alfa are effective at treating anemia, cost has become the primary decision factor for drug selection. Pharmaceutical companies that distribute these products have bundled these agents with their other products and thus complicated the pharmacoeconomic evaluation picture.

CLINICAL CONTROVERSY

There is limited evidence to support routine administration of IV iron if the serum ferritin is greater than 500 ng/mL. This presents a clinical challenge in deciding if iron supplementation is warranted in anemic dialysis patients with a TSat of less than 20% (or content of hemoglobin in the reticulocytes <29 pg/cell) and an elevated serum ferritin (>500 ng/mL). The clinical judgement that must be made is whether the elevated ferritin is indicative of iron overload or a result of inflammation or reticuloendothelial iron blockade (in which case a trial of iron therapy may be rational).

Evaluation of Therapeutic Outcomes

Figures 47–2 and 47–3 depict algorithmic approaches to the evaluation of patient outcomes. Iron status should be assessed every month during initial ESA treatment, and every 3 months for those receiving a stable ESA regimen or for those hemodialysis patients not treated with an ESA.²¹ For all ESAs, the dose and subsequent adjustments of ESAs should be determined by the patient’s Hb level relative to the target Hb level, and the most recent observed rate of increase in Hb level.²¹ Hemoglobin should be monitored at least monthly in patients receiving ESA therapy, although more frequent monitoring (e.g., every 2 weeks) is warranted after initiation of an ESA or following a dose change until the Hb is stable. The response to ESA therapy should be evaluated at least over 2 to 4 weeks before a change in the dose of epoetin alfa or darbepoetin alfa is made. If the change in Hb is <1 g/dL over a 4-week time period, the dose of the ESA should be increased by 25%. If the change in Hgb is >1 g/dL over a 2-week time period, the dose of epoetin alfa or darbepoetin alfa should be reduced by 25%.^{71,77} New FDA and CMS recommendations now advise health care providers to withhold ESA therapy if the Hb is >12 g/dl; some clinicians, however, may institute a dosage reduction of ≥25% to prevent drastic shifts in Hb levels. An inadequate response to ESA therapy justifies a complete evaluation for causes of resistance (see Efficacy section above).

■ SECONDARY HYPERPARATHYROIDISM AND RENAL OSTEODYSTROPHY

Desired Outcome

The overall goal of therapy is to prevent sHPT, hyperphosphatemia, and ROD, and the detrimental consequences of these disorders, including cardiovascular and extravascular calcifications. Although clinicians are becoming more aware of such consequences, efforts to improve evaluation and management in patients prior to development of more severe disease are needed.

K/DOQI guidelines for the diagnosis and management of bone disease in CKD proposed criteria for calcium, phosphorus, Ca × P, and iPTH based on the stage of CKD (Table 47–5).⁸ The recommended corrected serum calcium for patients with stage 3 or 4 CKD is within the normal range, whereas the proposed range for patients with stage 5 CKD is slightly lower than what is considered a normal total calcium. This is based on the observation of an increased risk of soft tissue and vascular calcifications in this population and the exposure to dialysate calcium for the ESRD population. It is impor-

TABLE 47-5 Kidney Disease/Dialysis Outcomes Quality Initiative (K/DOQI) Guidelines for Calcium, Phosphorus, Calcium Phosphorus Product, and Intact Parathyroid Hormone

Parameter	Chronic Kidney Disease		
	Stage 3	Stage 4	Stage 5
Corrected calcium (mg/dL)	“Normal”	“Normal”	8.4–9.5
Phosphorus (mg/dL)	2.7–4.6	2.7–4.6	3.5–5.5
Ca × P (mg ² /dL ²)	<55	<55	<55
Intact parathyroid hormone (pg/mL)	35–70	70–110	150–300

From Eknoyan G et al.⁸

tant to note that these are calcium concentrations corrected for the degree of protein binding (i.e., corrected based on serum albumin concentration). The corrected calcium value should also be used to determine the Ca × P product. Recommended serum phosphorus concentrations are 2.7 to 4.6 mg/dL, with higher concentrations acceptable in stage 5 CKD. The proposed Ca × P of 55 mg²/dL² is much lower than the previous recommendation of 65 to 70 mg²/dL², which is still cited in some references. The iPTH recommended for patients with stage 4 or 5 CKD is above the normal range so as to prevent oversuppression of PTH and reduce the risk of adynamic bone disease. Serum aluminum levels should also be maintained below 20 mcg/L to minimize the risk of developing aluminum toxicity, a contributing factor to bone disease.⁸

10 Management of PTH, phosphorus, and calcium balance, and minimization of patient exposure to aluminum are important in preventing the development of sHPT and slowing or preventing the progression of sHPT, ROD, and cardiovascular and extravascular calcifications. Patients with ESRD usually require a combination of phosphate-binding medication, vitamin D, and calcimimetic therapy to achieve these goals. Control of serum phosphorus is paramount because hyperphosphatemia is an initiating event in the development of other metabolic disturbances. Unfortunately, hyperphosphatemia is difficult to control and hypercalcemia may develop as a result of treatment with calcium-containing phosphate binders.¹⁵ There are different considerations in management of sHPT based on the stage of CKD. Hyperphosphatemia and sHPT in patients with stage 3 or 4 CKD are often overlooked. If these patients are not evaluated early in the course of the disease, they have a higher likelihood of developing metabolic abnormalities that contribute to poor outcomes by the time they reach stage 5 CKD or ESRD. Many patients with CKD are receiving suboptimal management of their disorders of calcium, phosphorus, and PTH homeostasis.

Nonpharmacologic Therapy

Dietary Phosphorus Restriction Dietary phosphorus restriction should be a first-line intervention for management of hyperphosphatemia in patients with CKD and should be initiated for most patients with stage 3, 4, or 5 CKD. The K/DOQI guidelines recommend phosphorus restriction to 800 to 1,000 mg/day when the upper levels of phosphorus are reached (see Table 47–5).⁸ This recommendation also holds true for patients with iPTH levels above the recommended range, given the evidence that lowering phosphorus ingestion directly decreases PTH synthesis and secretion.⁷⁸ The challenge with dietary restriction of phosphorus is providing enough protein to prevent malnutrition, a common problem in the CKD population, because foods high in phosphorus are generally high in protein. Examples of foods or beverages that contain high amounts of phosphorus include meats, dairy products, dried beans, nuts, colas, peanut butter, and beer. Nutritional goals must be evaluated on an individual basis, preferably by a dietitian specializing in the care of CKD patients. Dialysis patients require a higher

protein intake (1.2 to 1.3 g/kg per day) making restriction of phosphorus even more challenging. Removal of phosphorus does occur with peritoneal dialysis and hemodialysis (approximately 2 to 3 g/wk, dependent on the dialysis prescription); however, dialysis alone usually does not adequately control hyperphosphatemia.

One of the most common obstacles to the success of dietary phosphorus restriction is patient noncompliance because of the poor palatability and inconvenience. Regular counseling by a dietitian is essential to improve patient compliance.

Parathyroidectomy Parathyroidectomy is the last therapeutic option for patients with sHPT. The K/DOQI guidelines for bone metabolism and disease recommend surgery only for those patients with persistently elevated iPTH (iPTH >800 pg/mL) associated with hypercalcemia and/or hyperphosphatemia that are refractory to medical therapy.⁸ Surgical approaches include either subtotal parathyroidectomy or total parathyroidectomy with autotransplantation of parathyroid tissue to an accessible site, such as the forearm. Postoperative hypocalcemia, hypophosphatemia, and hypomagnesemia may occur because of a marked increase in bone production in relation to bone absorption (“hungry bone syndrome”). Following surgery frequent monitoring of ionized calcium is required (every 4 to 6 hours for the first 48 to 72 hours after surgery). Ionized calcium should be maintained above 3.6 mg/dL (0.9 mmol/L), using calcium gluconate infusions if necessary. The recommended dose of calcium gluconate is 1 to 2 mg of elemental calcium per kilogram per hour, adjusted to maintain ionized calcium at 4.6 to 5.4 mg/dL (1.15 to 1.36 mmol/L). Once the ionized calcium is stable, oral therapy may be initiated with 1 to 2 g of calcium carbonate in conjunction with calcitriol in doses of up to 2 mcg per day. Adjustments in phosphate binders will also be necessary to maintain target phosphorus levels (see section on pharmacologic therapy).⁸ Treatment with supplemental calcium and vitamin D may be required for weeks or months.

Pharmacologic Therapy

As kidney function declines, dietary restriction of phosphorus alone is usually inadequate to control serum phosphorus, and phosphate-binding agents are necessary, along with vitamin D therapy and/or calcimimetic therapy, to prevent sHPT.

Phosphate-Binding Agents

Pharmacology and Mechanism of Action. Drugs that bind dietary phosphorus in the GI tract form insoluble aluminum, calcium, or magnesium phosphate which is excreted in feces, thus reducing phosphorus absorption and serum phosphorus concentrations. A variety of phosphate-binding agents are available, including calcium-, lanthanum-, aluminum-, and magnesium-containing compounds, and the nonelemental agent sevelamer hydrochloride (Table 47–6). Patients must be instructed to take these agents with meals to minimize absorption of phosphorus from dietary sources.

Efficacy. Oral calcium compounds are well established as first-line agents for control of both serum phosphorus and calcium concentrations, at least in the early stages of CKD when hypocalcemia is more common. Calcium carbonate and calcium acetate are the primary preparations used; calcium citrate is also available, but is not recommended since the citrate component increases aluminum absorption. The chloride salt is also not recommended because it is very astringent and unpalatable, and absorbed chloride may contribute to systemic acidosis. Calcium carbonate is marketed in a variety of dosage forms (see Table 47–6) and is relatively inexpensive. Unfortunately, many calcium carbonate products are considered food supplements and thus are not required by law to meet United States Pharmacopeia (USP) disintegration and dissolution requirements. In general, nationally advertised brands meet USP quality standards for disintegration and dissolution, but it is difficult to determine whether

private label or house brands conform to these standards. Variability in gastric pH may also affect disintegration or dissolution, and thus phosphate-binding efficacy. Calcium carbonate is more soluble in an acidic medium, and therefore should be administered prior to meals when stomach acidity is highest. In addition, acid-suppressing agents such as ranitidine and proton pump inhibitors may reduce the phosphate-binding activity of calcium carbonate by increasing gastric pH. Calcium acetate binds approximately twice as much phosphorus as calcium carbonate at comparable doses of elemental calcium.⁸ Increased binding potency limits GI calcium absorption; however, calcium acetate is more soluble, and therefore better absorbed than calcium carbonate in an alkaline pH, which may explain the similar incidence of hypercalcemia. Patients with a corrected calcium of less than 8.4 mg/dL should receive calcium carbonate or calcium acetate as a calcium supplement (with or without vitamin D therapy).

Although calcium-containing phosphate-binding agents continue to be used as first-line therapy, their chronic use may increase the risk for vascular and tissue calcification.¹⁵ The K/DOQI guidelines now recommend that the total dose of elemental calcium provided by calcium-containing binders not exceed 1,500 mg per day and the total daily intake from all sources not exceed 2,000 mg.⁸ This presents clinicians with a challenge for patients in whom maximum doses do not achieve the goal phosphorus. In such situations, a non-calcium-based binder alone or in combination with a calcium product may be needed. Calcium-containing binders are not recommended in dialysis patients when on two consecutive measurements the serum calcium is >10.2 mg/dL or the iPTH is <150 pg/mL.⁸

Sevelamer hydrochloride is a nonabsorbable hydrogel phosphate-binding agent that does not contain aluminum, calcium, or magnesium. The dosage needed to control serum phosphorus concentrations may be as high as 6.3 g/day.⁷⁹ Sevelamer also significantly lowers LDL cholesterol and increases HDL by a mean of 30% and 18%, respectively. This is an added beneficial effect in a population at risk for cardiovascular events. Recent evidence has shown a decreased rate of vascular calcification in hemodialysis patients receiving this agent relative to those prescribed calcium-containing binders.⁸⁰ Sevelamer is now recommended as primary therapy in dialysis patients with severe vascular or soft tissue calcifications, and may also be used as a first-line phosphate-binding agent in patients with stage 5 CKD.⁸ Sevelamer carbonate received FDA approval in October 2007 and is expected to be available in early 2008. This agent contains a carbonate buffer which may help maintain bicarbonate levels in the recommended range and reduce the potential for GI side effects.

Lanthanum carbonate is a phosphate binder recently approved for patients with ESRD.⁸¹ Short-term (6 to 28 weeks) and long-term (2 to 3 years) therapy with lanthanum has demonstrated efficacy in controlling phosphorus and maintaining PTH in the target range with less risk of hypercalcemia than calcium-containing binders.^{82,83} Initial daily doses are in the range of 750 to 1,500 mg (administered in divided doses with meals) with doses of 1,500 to 3,000 mg often being required to maintain target phosphorus in ESRD patients. The poor GI absorption, which limits systemic effects, and high binding capacity with phosphorus makes this an attractive phosphate-binding agent, particularly when options other than calcium-containing binders are needed. Lanthanum is available as a chewable tablet, which may be appealing for some patients.

Aluminum salts were widely used in the 1980s as phosphate-binding agents because of their high binding potency. They should be considered as third-line agents now and be reserved for acute treatment of severe hyperphosphatemia or used at low doses in combination with either calcium-containing binding agents or sevelamer hydrochloride in cases of hyperphosphatemia that is not responding to therapy with a single agent. The duration of aluminum therapy should be limited to 4 weeks.⁸ Magnesium-containing antacids are also effective phosphate binders and may decrease the amount of

TABLE 47-6 Phosphate-Binding Agents Used in the Treatment of Hyperphosphatemia in CKD Patients

Compound	Trade Name	Compound Content (mg)	Dose Titration ^b	Starting Doses	Comments
Calcium carbonate ^a (40% elemental calcium)	Tums	500, 750, 1,000, 1,250	Increase or decrease by 500 mg per meal (200 mg elemental calcium)	0.5–1 g (elemental calcium) three times a day with meals	First-line agent; dissolution characteristics and phosphate binding affect may vary from product to product; try to limit daily intake of elemental calcium to 1,500 mg/day Approximately 39 mg phosphorus bound per 1 g calcium carbonate
	Oscal-500	1,250			
	Caltrate 600	1,500			
	Nephro-Calci	1,500			
	LiquiCal	1,200			
	CalciChew	1,250			
Calcium acetate (25% elemental calcium)	PhosLo	667	Increase or decrease by 667 mg per meal (168 mg elemental calcium)	0.5–1 g (elemental calcium) three times a day with meals	First-line agent; comparable efficacy to calcium carbonate with half the dose of elemental calcium; do not exceed 1.5 gms of elemental calcium per day Approximately 45 mg phosphorus bound per 1 g calcium acetate By prescription only
Sevelamer hydrochloride	Renagel	400, 800	Increase or decrease by 800 mg per meal	800–1,600 mg three times a day with meals	First-line agent; lowers low-density lipoprotein cholesterol More expensive than calcium products; preferred in patients at risk for extraskeletal calcification
Sevelamer carbonate	Renvela	800	Same as HCL salt	Same as HCL salt	Same as HCL; associated with a lower risk of GI adverse events than Renagel.
Lanthanum carbonate	Fosrenol	250, 500, 750, 1,000	Increase or decrease by 250–500 mg per meal	250–500 mg three times a day with meals	First line agent Available as chewable tablets
Aluminum hydroxide	Alterna GEL	600 mg/5 mL	–	300–600 mg three times a day with meals	Third-line agents; do not use concurrently with citrate-containing products Reserve for short-term use (4 weeks) in patients with hyperphosphatemia not responding to other binders
	Amphojel	300, 600 (tablet); 320 mg/5 mL (suspension)			
Aluminum carbonate	Alu-Cap	400	–	450–500 mg three times a day with meals	Same as for aluminum hydroxide
	Basaljel	500 (tablet, capsule); 400 mg/5 mL (suspension)			
Magnesium carbonate	Mag-Carb	70 capsule	–	70 mg three times a day with meals	Third-line agent; diarrhea common; monitor serum magnesium
Magnesium hydroxide	Milk of magnesia	300, 600 (tablet); 400 mg/5 mL, 800 mg/5 mL (suspension)	–	300–400 mg three times a day with meals	Same as for magnesium carbonate
Magnesium carbonate/calcium carbonate	MagneBind 200	200	160	200 mg three times a day with meals (based on magnesium content)	Same as for calcium carbonate and magnesium carbonate

^aMultiple preparations available which are not listed.^bBased on phosphorus levels, titrate every 2 to 3 weeks until phosphorus goal reached.

calcium-containing binders necessary for control of phosphorus; however, their use may be limited by the frequent occurrence of GI side effects and the potential for magnesium accumulation.

Adverse Effects. Adverse effects of calcium-containing phosphate binders, as well as of sevelamer and lanthanum, are generally limited to GI side effects, including constipation, diarrhea, nausea, vomiting, and abdominal pain. The risk of hypercalcemia is also a concern and may necessitate restriction of calcium intake from the combination of calcium-containing binders and dietary intake. Aluminum binders can no longer be recommended as first-line therapy because of the CNS toxicity and the worsening of anemia associated with aluminum accumulation. Although an effective phosphate binder, use of magnesium is often limited by side effects that include diarrhea, abdominal cramps, hypermagnesemia, and hyperkalemia.

Drug–Drug and Drug–Food Interactions. Calcium-containing phosphate-binding agents interfere with the absorption of several other oral medications that are commonly prescribed for CKD patients, including oral iron, zinc, and quinolone antibiotics. Data regarding drug interactions with sevelamer are limited; however, in recent evaluations, no drug interactions with digoxin, warfarin,

metoprolol, enalapril, or oral iron were observed.^{84–86} Coadministration with ciprofloxacin did, however, result in a 50% decrease in bioavailability of the antibiotic.⁸⁴ There is also some information to suggest a potential interaction between sevelamer and cyclosporine (decreased bioavailability of cyclosporine) and altered phosphorus binding in the presence of agents that increase gastric pH (e.g., omeprazole).^{87,88} Consequently, it is prudent to monitor for changes in phosphorus levels following initiation of concomitant therapy with agents known to alter gastric pH. Drug interaction studies with lanthanum, although limited, have shown that coadministration with warfarin, digoxin, and metoprolol did not affect the bioavailability of those agents.⁸¹ In general, it is rational to separate the administration time of oral medications for which a reduction in bioavailability has a clinically significant effect (e.g., quinolones) from phosphate binders by at least 1 hour before or 3 hours after administration of the phosphate binder. This is a key patient-counseling recommendation as patients are often switched from one phosphate binder to another and it is easier for them to remember this general concept regarding phosphate binders and other medications. Many phosphate binders are marketed as antacids or calcium supplements and often CKD patients do not know why they have been prescribed these agents.

Regular patient counseling is essential to enhance compliance and minimize the potential for drug interactions.

Dosing and Administration. Table 47–6 lists starting doses of phosphate-binding agents and suggested dose titrations. Doses should be titrated to achieve the recommended serum phosphorus concentrations based on stage of CKD, yet avoid complications such as hypercalcemia. The daily dose of elemental calcium should not exceed 1,500 mg (2,000 mg from phosphate binders and dietary intake).⁸

Vitamin D Therapy Vitamin D compounds include ergocalciferol (vitamin D₂) and cholecalciferol (vitamin D₃) that must be converted to the active form in the kidney. Calcitriol (1,25-dihydroxyvitamin D₃) is the most active form of vitamin D and is available as an oral formulation (Rocaltrol) as well as an IV formulation (Calcijex). The currently available vitamin D analogs include paricalcitol (19-nor-1,25-dihydroxyvitamin D₂; Zemplar) and doxercalciferol (1 α -hydroxyvitamin D₂; Hectorol). Calcitriol or one of the vitamin D analogs is required for patients with severe kidney disease because these agents do not require conversion by the kidney to the biologically active form.

Pharmacology and Mechanism of Action. Active vitamin D suppresses PTH secretion by stimulating absorption of serum calcium by intestinal cells and through direct activity on the parathyroid gland to decrease PTH synthesis. As a result, the serum calcium concentration is raised and the parathyroid glands decrease the rate of secretion and formation of PTH. The set point for calcium (i.e., the calcium concentration at which PTH secretion is decreased by 50%), which is generally raised in sHPT, is lowered when active vitamin D therapy is initiated. This indicates that a lower ionized calcium concentration is effective at suppressing secretion of PTH. All of these actions are mediated by the interaction of vitamin D with vitamin D receptors, which are located in many organs, including the parathyroid gland, GI tract, and kidney.⁸⁹ Calcitriol also upregulates vitamin D receptors, which ultimately may reduce parathyroid hyperplasia. Unfortunately, the enhanced GI absorption of calcium and phosphorus with calcitriol therapy frequently leads to hypercalcemia and hyperphosphatemia. There is also evidence that hyperphosphatemia results in resistance to the PTH-suppressing effects of vitamin D analogs and directly stimulates PTH release. These actions contribute to the increase in the Ca \times P product, which can lead to soft-tissue and vascular calcification.^{14,15} Consequently, reasonable control of calcium and phosphorus must be achieved before initiation and during continued vitamin D therapy. Although this does not mean that vitamin D therapy should be withheld or discontinued in patients with a Ca \times P product greater than 55 mg²/dL², interventions, including use of agents with less risk of hypercalcemia and hyperphosphatemia, and more prudent use of phosphate binders to lower the calcium and phosphorus are necessary in such patients.

The unique interactions of vitamin D with the vitamin D receptors have been a focus of research and have led to the development of vitamin D analogs, which vary in their affinity for these receptors and thus may result in less hypercalcemia, while retaining the positive physiologic actions on bone and parathyroid tissue. Paricalcitol and doxercalciferol are D₂ compounds that effectively lower PTH in dialysis patients.^{90,91} Paricalcitol differs from calcitriol by the absence of the exocyclic carbon 19 and the fact that it is a vitamin D₂ derivative. This agent is available as an IV formulation for use in patients with stage 5 CKD and an oral form which is approved for use in those with stage 3 and 4 CKD. Doxercalciferol, in contrast to calcitriol and paricalcitol, is a prohormone that needs to be hydroxylated in the liver to its active 1,25-dihydroxyvitamin D₂ product. Doxercalciferol is also available for both IV and oral administration.

Pharmacokinetics. Calcitriol can be administered orally as well as by IV injection. Oral absorption occurs rapidly; therefore oral

and IV therapies are both reasonable options for treatment of sHPT. Although historically a topic of controversy, a review of the available literature leads to the conclusion that intermittent IV administration of calcitriol is more effective than daily oral calcitriol for sHPT.⁸ When paricalcitol is administered IV, its half-life is similar to that of calcitriol (up to 30 hours). The half-life in for oral administration of paricalcitol is 17 to 20 hours in patients with stages 3 and 4 CKD.⁹² Doxercalciferol as a prodrug has a slightly prolonged half-life of 45 hours, although this difference in half-life compared to other agents is not of clinical significance.

Efficacy. Administration of calcitriol by either the oral or IV route may be based on conventional dosing (usually 0.25 to 0.5 mcg/day) or pulse dosing (0.5 to 2 mcg two to three times per week). Logistically, IV dosing is more practical in hemodialysis patients, whereas oral therapy is more practical for those with stage 3 or 4 CKD and peritoneal dialysis patients. Conventional daily oral doses of calcitriol (0.25 mcg) may be more frequently associated with hypercalcemia and hyperphosphatemia, because vitamin D receptors are located in intestinal mucosa where direct stimulation can occur.

Although hypercalcemia is less likely with the newer analogs, elevated calcium concentrations have been observed with these agents in patients with ESRD. However, some of these cases were associated with excessive dosing of these agents and oversuppression of PTH, a condition more likely to promote hypercalcemia. When administered at doses 10 times that of calcitriol and at a dose equivalent to doxercalciferol, paricalcitol has been less frequently associated with hypercalcemia in animal studies and in human trials.^{93,94} Doxercalciferol and paricalcitol have also been evaluated in patients with stages 3 and 4 CKD. They are effective in reducing PTH to target levels; however, differences in the magnitude of elevations of calcium and phosphorus have not been directly compared in this population.^{95,96}

Although comparisons between vitamin D analogs are relatively limited there is some information comparing clinical indicators in ESRD patients receiving these agents. In one study, fewer cases of hyperphosphatemia were reported with paricalcitol than with calcitriol when administered at high doses to hemodialysis patients.⁹³ A more rapid suppression of PTH was also observed in paricalcitol-treated patients than with calcitriol, although the more clinically significant finding from this study was the decrease in incidence of hypercalcemia and elevated Ca \times P in the paricalcitol-treated patients.⁹⁷ Nontraditional effects of vitamin D, including a potential survival benefit, have also been reported.^{98–100} An improvement in 3-year survival in a large dialysis population receiving paricalcitol was observed compared with a historic cohort that received calcitriol.⁹⁸ This survival advantage was also observed for hemodialysis patients who received vitamin D (either calcitriol or paricalcitol) compared to no vitamin D and was independent of calcium, phosphorus, and PTH.⁹⁹ The relationship between all available vitamin D agents (calcitriol, doxercalciferol, and paricalcitol) and mortality was further evaluated in a retrospective analysis of more than 7,700 hemodialysis patients.¹⁰¹ After a median followup of 37 weeks, mortality (all-cause and atherosclerotic cardiovascular mortality) was similar for doxercalciferol- and paricalcitol-treated patients and similar to the calcitriol-treated patients when adjusted for laboratory values (e.g., calcium, PTH, albumin, phosphorus) and standardized mortality for the dialysis clinics included in this study. Vitamin D therapy, regardless of agent, was associated with lower mortality. Antiproteinuric effects of paricalcitol have also been reported in patients with stages 3 and 4 CKD.¹⁰⁰ These findings are of interest when considering other potential effects of vitamin D beyond suppression of PTH.

Adverse Effects. Although all agents are effective in suppressing PTH levels, they differ in the degree to which they cause other metabolic abnormalities. Adverse effects of note with vitamin D therapy in patients treated for sHPT include hypercalcemia and

hyperphosphatemia. Differences in calcitriol and vitamin D analogs have been demonstrated in animal studies and in clinical trials evaluating the effect on reduction of PTH while minimizing the risk of these adverse consequences.^{93,94}

Drug-Drug and Drug-Food Interactions. Cholestyramine may reduce the absorption of orally administered calcitriol and doxercalciferol. In vitro data suggest that paricalcitol is metabolized by the hepatic enzyme CYP3A4 and has the potential to interact with other agents that are metabolized by this enzyme.⁹² When ketoconazole, a CYP3A4 inhibitor, was given concomitantly, paricalcitol serum concentrations doubled. Caution is also advised when CYP3A4 inhibitors are given to those receiving doxercalciferol. No other significant interactions have been reported.

Dosing and Administration. Recommendations for vitamin D therapy differ based on the stage of CKD.⁸ Because changes in vitamin D metabolism can lead to deficiencies in vitamin D precursors in patients with stage 3 or 4 CKD, 25-hydroxyvitamin D levels should be measured in patients with PTH values above the upper recommended ranges of 70 pg/mL or 110 pg/mL for stages 3 and 4 CKD, respectively (see Table 47-5). If the 25-hydroxyvitamin D level is less than 30 ng/mL, a vitamin D precursor (e.g., ergocalciferol) is recommended (Table 47-7).⁸ To prevent vitamin D insufficiency, doses of 600 to 800 units per day of ergocalciferol are recommended. According to the guidelines, active vitamin D or an analog should be administered orally (e.g., as oral calcitriol, doxercalciferol, or paricalcitol) when PTH remains elevated despite adequate 25-hydroxyvitamin D levels.

Active vitamin D therapy should be initiated, when warranted, in patients with stage 3 or 4 CKD as an oral daily dose of 0.25 mcg calcitriol, 1 mcg doxercalciferol, or 1 mcg paricalcitol.¹⁰² For paricalcitol the recommended daily dose is 2 mcg if the PTH is greater than 500 pg/mL. If these agents are administered intermittently (generally three times per week), the recommended initial dose is twice the daily dose.¹⁰² Higher starting doses may be required based on the severity of sHPT. Prior to starting therapy the serum calcium and phosphorus should be well controlled (serum calcium <9.5 mg/dL and phosphorus <4.6 mg/dL) to minimize the risk of hypercalcemia and an elevated Ca × P. In patients with ESRD there is a clearly defined role for treatment with active vitamin D or a vitamin D analog because the conversion of precursors to active vitamin D is impaired. Table 47-8 lists dosing recommendations based on PTH. Serum calcium and Ca × P should be monitored regularly while the patient is receiving therapy.⁸ Dose adjustments should be made every 2 to 4 weeks based on PTH concentrations. For patients who need to be converted from calcitriol to paricalcitol, a dosing conversion ratio of 1:4 of IV calcitriol to paricalcitol has been proposed; however, some clinicians suggest a ratio of 1:3 to avoid oversuppression of PTH.⁸

TABLE 47-7 Dosing Recommendations for Vitamin D in Patients with Stages 3 and 4 Chronic Kidney Disease

Definition	Serum 25(OH)D (ng/mL)	Dose of Ergocalciferol ^a
Severe vitamin D deficiency	<5	50,000 international units/wk orally × 12 weeks, then monthly × 6 months or 500,000 international units as a single intramuscular dose
Mild vitamin D deficiency	5–15	50,000 international units/wk orally × 4 weeks, then monthly × 6 months
Vitamin D insufficiency	16–30	50,000 international units/month orally 6 months

25(OH)D, 25 hydroxyvitamin D.

^a25(OH)D levels should be measured following the 6-month course of therapy for patients with mild and severe vitamin D deficiency.

From Eknoyan G et al.⁸

TABLE 47-8 Dosing Recommendations for Vitamin D in Patients with Stage 5 Chronic Kidney Disease and Those on Hemodialysis^a

PTH (pg/mL)	IV and Oral Calcitriol Dose per HD	IV Paricalcitol Dose per HD	Oral and IV Doxercalciferol Dose per HD
300–600 ^b	0.5–1.5 mcg oral or IV	2.5–5 mcg	5 mcg oral, 2 mcg IV
600–1,000 ^b	1–4 mcg oral 1–3 mcg IV	6–10 mcg	5–10 mcg oral, 2–4 mcg IV
>1,000 ^c	3–7 mcg oral 3–5 mcg IV	10–15 mcg	10–20 mcg oral, 4–8 mcg IV

HD, hemodialysis; PTH, parathyroid hormone.

^aPeritoneal dialysis patients may be treated with oral doses of calcitriol (0.5–1.0 mcg) or doxercalciferol (2.5–5 mcg) two or three times weekly. May also use oral calcitriol at 0.25 mcg daily.

^bIf serum calcium <9.5 mg/dL, phosphorus <5.5 mg/dL, and Ca × P <55 mg²/dL².

^cIf serum calcium <10 mg/dL, phosphorus <5.5 mg/dL, and Ca × P <55 mg²/dL².

Calcimimetics

Pharmacology and Mechanism of Action. Cinacalcet hydrochloride (Sensipar) is a calcimimetic agent approved for treatment of sHPT in ESRD patients and for treatment of hypercalcemia in patients with parathyroid carcinoma. Cinacalcet is the first agent in this class to receive FDA approval. This compound acts on the calcium-sensing receptor on the surface of the chief cell of the parathyroid gland to mimic the effect of extracellular ionized calcium and increase the sensitivity of the calcium-sensing receptor to calcium, subsequently reducing PTH secretion.

Pharmacokinetics. The maximum plasma concentration of cinacalcet is achieved in approximately 2 to 6 hours following oral administration. The half-life is approximately 30 to 40 hours. Cinacalcet has a large volume of distribution (approximately 1,000 L), and is 93% to 97% bound to plasma proteins, both characteristics indicating that removal by dialysis is negligible. Cinacalcet is metabolized by the liver, specifically by the cytochrome P450 isoenzymes CYP3A4, CYP2D6, and CYP1A2.¹⁰³

Efficacy. In placebo-controlled clinical trials conducted in dialysis patients (predominantly those receiving hemodialysis) cinacalcet significantly decreased PTH and the Ca × P product within the 6-month study period, regardless of the severity of sHPT.¹⁰⁴ The starting dose of 30 mg per day was titrated every 3 or 4 weeks to a maximum dose of 180 mg per day to achieve the target PTH of ≤250 pg/mL and avoid hypocalcemia. Approximately 66% and 93% of patients in the clinical trials were receiving concurrent vitamin D and phosphate binders, respectively. If a patient experienced symptoms of hypocalcemia or had a serum calcium <8.4 mg/dL, calcium supplements and/or calcium-based phosphate binders could be increased. If ineffective, the vitamin D dose could be increased. The median dose required to achieve the desired PTH by the end of the study period was 90 mg. Cinacalcet has also been studied in patients with stage 3 and 4 CKD with sHPT and was effective in lowering PTH while maintaining the Ca and P within the target ranges.¹⁰⁵ This drug is however not approved for use in those with stage 2 CKD because of the risk of hypocalcemia. Because cinacalcet was approved after the K/DOQI guidelines on bone disease became available, the challenge to clinicians is in deciding how to most effectively use cinacalcet in conjunction with other therapies to manage hyperphosphatemia and sHPT.

Adverse Effects. The most frequently reported adverse events with cinacalcet were nausea and vomiting. Although nausea and vomiting occurred more frequently with cinacalcet, these events were generally transient, mild to moderate in nature, and infrequently led to withdrawal from clinical trials.¹⁰³

Because cinacalcet lowers serum calcium and may cause hypocalcemia, this agent should not be started if the serum calcium is less than the lower limit of normal, approximately 8.4 mg/dL. Serum calcium should be measured within 1 week after initiation or dose adjustment of cinacalcet. Once the maintenance dose is established, serum calcium should be measured approximately monthly. Potential manifestations of hypocalcemia include paresthesia, myalgia, cramping, tetany, and convulsions.

Drug–Drug and Drug–Food Interactions. Because cinacalcet is metabolized by multiple hepatic enzymes there is potential for drug interactions. Cinacalcet is also a potent inhibitor of the enzyme CYP2D6. As a result, dose adjustments of concomitant medications that are predominantly metabolized by this enzyme and have a narrow therapeutic index, such as flecainide, thioridazine, vinblastine, and most tricyclic antidepressants (i.e., amitriptyline), may be required.^{100,103}

Several agents commonly used in the CKD population have been evaluated for interactions with cinacalcet.¹⁰³ Coadministration of calcium carbonate or sevelamer did not affect the pharmacokinetics of cinacalcet. Pantoprazole did not alter the pharmacokinetics of cinacalcet HCl, an important finding since pantoprazole alters gastric pH, and the solubility of cinacalcet decreases as the gastric pH rises over 5.5. Coadministration of cinacalcet with warfarin also did not affect the pharmacokinetics of warfarin. Coadministration of cinacalcet and ketoconazole, a strong inhibitor of cytochrome P450 (CYP) 3A4, resulted in an increase in the area under the curve and maximum concentration of 2.3 and 2.2 times, respectively. Concurrent administration of cinacalcet with amitriptyline increased amitriptyline exposure and nortriptyline (active metabolite) exposure by approximately 20% in CYP2D6-extensive metabolizers.

Food has been shown to increase absorption of cinacalcet by up to 81% compared to fasting; therefore this medication should be taken with meals to achieve the maximal effect.

Dosing and Administration. The recommended starting oral dose of cinacalcet is 30 mg once daily. The dose should be titrated every 2 to 4 weeks to a maximum dose of 180 mg once daily to achieve the desired PTH levels and to maintain near-normal serum calcium concentrations. Patients with hepatic disease may require lower doses, as studies have shown a decrease in metabolism of cinacalcet in this patient population. Cinacalcet is available as a film-coated tablet containing 30, 60, or 90 mg.

Pharmacoeconomic Considerations

Pharmacoeconomic considerations in the management of sHPT and ROD include medication costs, the cost associated with laboratory procedures (e.g., monitoring of 25-hydroxyvitamin D and more frequent evaluation of iPTH in patients with stage 3 or 4 CKD), and the medical expenditures associated with the management of cardiovascular disease and bone fractures. The pattern of vitamin D product use in U.S. dialysis units has been strongly influenced by Medicare reimbursement. Currently, IV vitamin D products are separately reimbursable expenses for dialysis programs. In fact, dialysis programs often generate significant profit from the IV administration of these agents. In contrast, oral administration of vitamin D is more convenient for patients with stage 3 or 4 CKD and the peritoneal dialysis population; however, these agents are not separately reimbursable, and because they must be purchased by the patient, compliance becomes an issue.

The cost-to-benefit ratio associated with more aggressive management of metabolic disorders (e.g., hyperphosphatemia and hypercalcemia) and sHPT has not been formally evaluated. If the associated complications such as vascular and soft-tissue calcifications that may increase morbidity and hospitalizations can be significantly reduced, the additional medication costs may ultimately be of minimal consequence.

CLINICAL CONTROVERSY

Although the National Kidney Foundation's K/DOQI guidelines recommend supplementation with ergocalciferol in stage 3 and 4 CKD patients with 25-hydroxyvitamin D deficiency, there is little evidence to support this recommendation. Indeed some clinicians begin active vitamin D therapy in this clinical setting.

Evaluation of Therapeutic Outcomes

The goals for treatment with dietary phosphate restriction, phosphate-binding agents, vitamin D therapy, and/or calcimimetic therapy are to prevent sHPT and subsequent ROD without inducing adynamic bone disease from oversuppression of PTH or vascular or extravascular calcifications. Regular monitoring of serum calcium, phosphorus, $\text{Ca} \times \text{P}$, iPTH, and vitamin D status to achieve and maintain target goals is currently the most practical and effective means of achieving these outcomes.

The serum calcium, phosphorus, and iPTH levels should be measured in all patients with a GFR of less than 60 mL/min.⁸ Patients with stage 3 CKD should have followup measurements done at least every 12 months; those with stage 4 CKD should have follow up done every 3 months. More frequent monitoring is required for ESRD patients: monitor iPTH every 3 months and calcium and phosphorus every month. More frequent monitoring (monthly for iPTH and every 2 weeks for calcium and phosphorus) may be warranted following any change in the therapeutic interventions to correct these abnormalities.

■ CHRONIC METABOLIC ACIDOSIS

Desired Outcome

The goals of therapy for patients with CKD are to normalize the pH of the blood (pH of approximately 7.35 to 7.45) and maintain the serum bicarbonate within the normal range (22 to 26 mEq/L). In patients on hemodialysis, the goal of therapy is to maintain a predialysis or stabilized bicarbonate concentration at or above 22 mEq/L.¹⁹ Metabolic acidosis appears to stimulate protein catabolism, which can contribute to a negative nitrogen balance and lower albumin concentrations, as well as cause growth retardation in children. Lower serum bicarbonate levels in peritoneal dialysis patients have also been associated with a higher hospitalization rate and longer hospital stays.¹⁹ Severe acidemia (blood pH <7.1 to 7.2) suppresses myocardial contractility, predisposes patients to cardiac arrhythmias, and may lead to a decrease in total peripheral vascular resistance and blood pressure, reduced hepatic blood flow, and impaired oxygen delivery.¹⁰⁷ The prevention and treatment of severe metabolic acidosis in patients with kidney disease is also important to prevent the development of renal bone disease.

Nonpharmacologic Therapy

Therapy for metabolic acidosis requires pharmacologic intervention to correct the acidemia. Treatment of other underlying disorders that may be contributory is also warranted.

Pharmacologic Therapy

In patients with stage 4 or 5 CKD, the use of alkalinizing salts, such as sodium bicarbonate or citrate/citric acid preparations, is useful to replenish depleted body bicarbonate stores. Sodium bicarbonate tablets are manufactured in 325- and 650-mg strengths (a 650-mg tablet contains 7.6 mEq sodium and 7.6 mEq bicarbonate). Shohl's solution and Bicitra contain 1 mEq/mL of sodium and the equivalent of 1 mEq/mL of bicarbonate as sodium citrate/citric acid. Citrate is metabolized in the liver to bicarbonate, and citric acid is

metabolized to CO₂ and water. Polycitra, which contains potassium citrate, (1 mEq/mL of sodium, 1 mEq/mL of potassium, and 2 mEq/mL of bicarbonate) should not be used in patients with severe CKD as hyperkalemia may result.

The replacement dose of alkali (base) needed to restore the serum bicarbonate concentration to normal (24 mEq/L) can be approximated by multiplying the volume of distribution of bicarbonate (0.5 L/kg) by the patient's body weight (in kilograms) and the patient's base deficit (difference between the patient's serum bicarbonate value and the normal value of 24 mEq/L). The calculated amount of bicarbonate replacement therapy (in milliequivalents) should be administered over several days to prevent volume overload from excessive sodium intake. After the serum bicarbonate has normalized, a maintenance regimen of bicarbonate to neutralize daily acid production may be all that is necessary (12 to 20 mEq/day in divided doses). Doses are subsequently titrated to maintain normal plasma bicarbonate concentrations. Patients with renal tubular acidosis may require higher doses of alkalinizing agents (see Chap. 55). Fluid balance should be monitored carefully because of the sodium content of these agents. Citrate-containing solutions should not be used in combination with aluminum-containing compounds because they can enhance aluminum absorption and increase the risk of aluminum intoxication. Excessive doses of alkalinizing agents may cause metabolic alkalosis, as well as lethargy or cardiac depression secondary to a decrease in ionized serum calcium concentration. Gastrointestinal distress characterized by gastric distension and flatulence is relatively common with high doses of oral sodium bicarbonate. Patients with severe acidosis (serum bicarbonate <8 mEq/L; pH <7.2) may require IV therapy (see Chap. 55).

Metabolic acidosis in both adult and pediatric patients undergoing dialysis can often be managed with the use of higher concentrations of bicarbonate or acetate in the dialysate (>38 mEq/L bicarbonate is safe and effective). Administration of oral bicarbonate salts as described above may also be necessary for some dialysis patients.

Evaluation of Therapeutic Outcomes

Regular monitoring of arterial blood gases and serum electrolytes, particularly potassium, are necessary to determine the effectiveness of therapy. A gradual correction is appropriate to avoid overcorrection and subsequent complications such as alkalosis and other electrolyte abnormalities (see Chap. 55). Laboratory measurement of serum bicarbonate is associated with several technical problems. Blood collection techniques, transportation, and assay methodology can affect the measured concentrations. Blood samples should not have contact with air; process delays should be avoided; and consistent analytical methods should be used with serial measurements to improve accuracy.¹⁹

TREATMENT OF CARDIOVASCULAR DISEASE IN CHRONIC KIDNEY DISEASE

Specific recommendations regarding the management of cardiovascular disease in the ESRD population are included in K/DOQI guidelines. Two common risk factors for cardiovascular disease—hypertension and hyperlipidemia—are further discussed in this section.

Desired Outcome

Hypertension The goal blood pressure for cardiovascular risk reduction, in patients with early stage CKD is less than 130/80 mm Hg.¹⁰⁷ The target blood pressure in patients with ESRD is not well defined; however, the K/DOQI guidelines propose a predialysis blood pressure of less than 140/90 mm Hg and a postdialysis blood pressure of less than 130/80 mm Hg, although this recommendation

is not based on data from prospective controlled studies.¹ The targets may need to be individualized for patients who experience intradialytic hypotension. These goals can rarely be achieved using lifestyle modifications alone in CKD patients. Thus aggressive antihypertensive therapy is often required.

Hyperlipidemia Based on strong evidence of risk reduction and the benefits of lipid-lowering therapy in the general population, and the high prevalence of atherosclerotic cardiovascular disease in patients with CKD, the consensus is that CKD patients are among the highest-risk group for cardiovascular conditions (i.e., equivalent to that of patients with known coronary heart disease) and should be treated aggressively for dyslipidemia to an LDL cholesterol goal below 100 mg/dL.^{18,25} The decision to lower LDL cholesterol to less than 70 mg/dL based on more recent data in high-risk populations is a therapeutic option that is not supported by strong evidence from clinical trials. Table 47-9 lists the goals for patients with stage 5 CKD based on lipid abnormality, as well as the appropriate course of therapy.

Nonpharmacologic Therapy

Hypertension A primary intervention for management of hypertension in patients with ESRD is sodium restriction to approximately 2 to 3 g/day. Fluid intake should be restricted in patients with volume overload, particularly in patients on hemodialysis who are at risk for substantial fluid accumulation between dialysis sessions. Regular dietary counseling becomes critical to the success of nonpharmacologic interventions, given the large number of lifestyle changes typically required by CKD patients. Other lifestyle modifications, including regular exercise, weight loss, and smoking cessation, are also recommended, but difficult to implement.

In hemodialysis patients, achievement of an individual's "dry weight" is necessary to control blood pressure and may be done through dietary intervention, increased ultrafiltration, and longer dialysis sessions (see Chap. 48). Aggressive ultrafiltration in hemodialysis patients has shown beneficial effects of lowering blood pressure and decreasing left ventricular mass index. Prolonged hemodialysis also better maintains normal blood pressure, improves survival, and reduces the need for antihypertensive medications; however, the majority of hemodialysis programs in the United States use shorter dialysis sessions (3- to 4-hour sessions three times per week).¹

Hyperlipidemia In patients with elevated triglyceride levels (≥500 mg/dL) and/or LDL between 100 and 129 mg/dL, lifestyle changes

TABLE 47-9 Management of Dyslipidemia in Patients with Chronic Kidney Disease

Dyslipidemia	Goal	Initial Therapy	Modification in Therapy ^a	Alternative ^a
TG ≥500 mg/dL	TG <500 mg/dL	TLC	TLC + fibrate or niacin	Fibrate or niacin
LDL 100–129 mg/dL	LDL <100 mg/dL	TLC	TLC + low-dose statin	Bile acid sequestrant or niacin
LDL ≥130 mg/dL	LDL <100 mg/dL	TLC + low-dose statin	TLC + maximum-dose statin	Bile acid sequestrant or niacin
TG ≥200 mg/dL and non-HDL ≥130 mg/dL	Non-HDL <130 mg/dL	TLC + low-dose statin	TLC + maximum-dose statin	Fibrate or niacin

HDL, high-density lipoprotein; LDL, low-density lipoprotein; Non-HDL, total cholesterol minus HDL cholesterol; TG, triglycerides; TLC, therapeutic lifestyle changes.

^aDosing of selected agents by class: fibrate (gemfibrozil 600 mg twice a day); niacin (1.5–3 g/day of immediate-release product); statin (simvastatin 10–40 mg/day if glomerular filtration rate [GFR] <30 mL/min, 20–80 mg/day if GFR >30 mL/min); bile acid sequestrant (cholestyramine 4–16 g/day).

See Chap. 23 for more complete dosing information.

From reference 25.

without pharmacologic therapy are recommended as initial therapy (see Chap. 21). Unfortunately, most patients with CKD have already been advised to adhere to difficult dietary regimens, which may include protein, phosphorus, sodium, potassium, and fluid restrictions. Thus, although diet therapy is a reasonable first-step approach, it may not be successful in many patients with CKD because of noncompliance. A dietitian who is well versed in the management of kidney disease should be consulted.

Pharmacologic Therapy

Hypertension Most patients with hypertension and CKD require drug regimens that include three or more antihypertensive agents to achieve target blood pressure. Blood pressure reductions can be achieved with agents in all antihypertensive classes, although there is a preference for agents that inhibit the renin–angiotensin system, and choice should be guided by the individual patient's concomitant disease states.

Diuretic therapy is beneficial for management of blood pressure in patients with early CKD; however, thiazide diuretics are not generally effective in patients with a GFR of <30 mL/min. Loop diuretics can be used throughout all stages of CKD; however, patients with ESRD who have minimal to no residual kidney function will often not respond to these agents.

ACEIs or angiotensin receptor blockers are the preferred agents for patients with progressive CKD and proteinuria. They are also preferred in patients with ESRD because of their potential benefits, including regression of LVH, reduction in sympathetic nerve activity and pulse-wave velocity, improvement in endothelial function, and reduced oxidative stress.¹ Lower initial doses of these agents may be necessary because the elimination half-lives of the parent compound (captopril and lisinopril) or active metabolite (enalapril, benazepril, and ramipril) are prolonged in ESRD patients. Available angiotensin receptor blockers do not require dosage adjustment for decreased kidney function and they are not effectively removed by hemodialysis.

Calcium channel blockers that selectively lower systemic vascular resistance also appear to be effective in the treatment of hypertension in patients with ESRD and are associated with decreased total and cardiovascular mortality.¹ β -Blockers may be particularly useful in hypertensive CKD patients given the beneficial effects after myocardial infarction. Agents such as esmolol, timolol, pindolol, metoprolol, or labetalol, which are metabolized and not significantly removed by dialysis, may be easier to dose titrate than agents that are both dialyzable and extensively eliminated unchanged by the kidney (e.g., acebutolol, atenolol, bisoprolol, and nadolol). Agents requiring less-frequent dosing may be used to improve patient compliance.

Use of other antihypertensive agents in the patient with CKD should be based on recommendations in the general population (see Chap. 15). In the ESRD population, agents that act on the sympathetic nervous system, such as prazosin, terazosin, doxazosin, clonidine, guanabenz, and guanfacine, may be required in patients who are unresponsive to ACEIs, calcium channel blockers, or β -blocker therapy, and used in conjunction with adequate dialysis. Central α_2 -agonists such as clonidine appear to be the safest of these agents; however, adverse effects, such as dry mouth, may lead to extra fluid consumption in some patients. Postsynaptic α -blockers (e.g., prazosin) are associated with postural hypotension following hemodialysis. Guanethidine and methyl dopa should be avoided because of potential complications, including severe postural hypotension, severe dialysis-related hypotension, and impotence. The addition of vasodilators such as minoxidil may prove useful in patients resistant to combinations of the previously mentioned agents.

Hyperlipidemia Management of dyslipidemia in patients with CKD should be based on the report from the National Cholesterol Education Program and the K/DOQI guidelines for dyslipidemia in

patients with CKD.^{18,25} If lifestyle changes are not effective in achieving goal triglyceride and LDL levels after a few months, drug therapy is warranted (see Table 47–9). Drug therapy is also recommended for those with more extreme elevations in LDL (≥ 130 mg/dL).

Drug classes that may prove useful in treatment of lipid disorders include: 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins); the bile acid sequestrants; nicotinic acid; and fibric acids (gemfibrozil and clofibrate). Statins are the most effective drugs for lowering LDL and total cholesterol in patients with kidney disease (with or without nephrotic syndrome) and generally should be regarded as the drugs of first choice. Drug therapy for hypertriglyceridemia includes a fibrate or nicotinic acid; in general, fibrates are better tolerated. Studies evaluating statins have shown cholesterol-lowering benefits in addition to reduction in risk of nonfatal myocardial infarction and cardiac death in a relatively limited number of patients with early stage CKD.¹ In contrast results from a 4-year study evaluating the effect of atorvastatin therapy on mortality caused by cardiac events, nonfatal myocardial infarction and stroke in more than 1,200 hemodialysis patients with type 2 diabetes (a group at high risk for cardiovascular events), showed no significant benefit in the composite end point compared to the placebo group.¹⁰⁸ When evaluated individually there was a significantly greater relative risk of fatal stroke in the atorvastatin treated patients. These findings do not support initiation of statin therapy in ESRD patients with type 2 diabetes, but rather initiation at an earlier time point. It is not yet known how these results would compare with findings from a nondiabetic ESRD population.

Several potential drug interactions and/or side effects have been observed in those CKD patients receiving antilipemic therapy. The nonselective binding activity of bile acid sequestrants may reduce absorption of corticosteroids, digoxin, thiazide diuretics, warfarin, and other commonly used medications. Myositis and myalgia, along with increased serum creatine phosphokinase (CPK), may occur in ESRD patients who use clofibrate. Determining the optimal dose of clofibrate in this patient population is difficult, as plasma protein-binding changes markedly affect free concentrations of the active metabolite, clofibric acid, which has a prolonged half-life in patients with stage 5 CKD. Gemfibrozil may be a safer alternative, as the half-life is not altered with kidney dysfunction. Lower doses of 300 mg twice a day with close monitoring of CPK is recommended by some clinicians, based on an association of standard dose therapy with increases in CPK concentrations in dialysis patients.

Although HMG-CoA reductase inhibitors are remarkably free of adverse effects in otherwise healthy subjects, one should be cognizant of the potential myotoxic effects of these drugs, especially when administered with interacting agents including, but not limited to, azole antibiotics, cyclosporine, gemfibrozil, niacin, and in the presence of hepatic disease.²⁵ Patients receiving sevelamer as a phosphate binder may reap the benefits of its cholesterol-lowering effects.

Pharmacoeconomic Considerations

Hypertension Compliance and economic factors must be considered in the selection of antihypertensive therapy for CKD patients. Patients with ESRD are prescribed an average of 9 to 12 medications. Choosing agents that can be administered once or twice daily may improve patient compliance. In addition, there are now many options within some antihypertensive classes, such as calcium channel blockers, ACEIs, angiotensin receptor blockers, and β -blockers, which allow for less-frequent dosing. In most cases, no clear therapeutic advantage has been demonstrated with any particular agent within a class. Therefore, selecting the least costly agent that can be administered once or twice daily is reasonable.

As more information becomes available from studies evaluating the effects of long-term therapy of hypertension on cardiovascular events in patients with ESRD, cost benefits from potentially decreas-

ing the occurrence of such events and their comorbidities may be quantified.

Hyperlipidemia Statin therapy for treatment of dyslipidemias has been shown to be cost-effective in patients at high risk for coronary heart disease. Although this has not specifically been evaluated in patients with CKD, this population is considered in the highest-risk group for coronary heart disease and cardiovascular events. It may be reasonable at least in theory to extrapolate this information on the cost benefits of therapy to the CKD population, although findings from the atorvastatin trial in ESRD patients contradict this rationale.

CLINICAL CONTROVERSY

Currently, there is no strong consensus on whether the predialysis or postdialysis blood pressure (or an average of the two) should be used to guide therapy and assess cardiovascular risk in the hemodialysis population. This issue, along with the question of the target blood pressure in this population, mean many decisions about pharmacologic therapy are based more on clinical judgement than evidence.

Evaluation of Therapeutic Outcomes

Hypertension Blood pressure monitoring to determine the effectiveness of therapy should be done at each visit for patients with ESRD, particularly following initiation of therapy (nonpharmacologic or pharmacologic) and at home when feasible. Patients on hemodialysis should have blood pressure measured before, during, and after dialysis to determine the effect of changes in their volume status on blood pressure. Some hemodialysis patients experience a paradoxical rise in blood pressure during dialysis. In these cases, the effect of dialysis on removal of antihypertensive agents and the dosing times relative to the dialysis procedure need to be evaluated. Similarly, patients may need to adjust the time of administration of antihypertensive therapy relative to the dialysis session if intradialytic hypotension occurs. Such decisions should be based on the pharmacokinetic profile of the antihypertensive agent in patients with ESRD. In cases when antihypertensive agents need to be discontinued, they should be withdrawn slowly. Chapter 15 discusses other aspects of monitoring blood pressure and associated complications.

Hyperlipidemia Patients should have their lipid profile reassessed 2 to 3 months following a change in treatment and at least annually thereafter.²⁵ Periodic evaluations of cardiovascular performance, as described in Chapters 13 and 23, are also warranted.

■ OTHER COMPLICATIONS OF CHRONIC KIDNEY DISEASE

Pruritus

Despite advances in dialysis treatment, pruritus (itching) remains a problem for 60% to 90% of ESRD patients.¹⁰⁹ The pathogenesis of uremic pruritus is poorly understood, but has been attributed to multiple factors such as inadequate dialysis, skin dryness, secondary hyperparathyroidism, increased vitamin A and histamine plasma concentrations, and increased sensitivity to histamine. In hemodialysis patients who experienced pruritus based on responses to a questionnaire (completed by a total of 453 of 1,773 patients) more than 70% also reported difficulties with sleep during a 24-month followup period.¹¹⁰ Other factors associated with pruritus were male gender, high blood urea nitrogen and β_2 -microglobulin levels, hypercalcemia, and hyperphosphatemia. Treatment options for pruritus, beyond control of metabolic abnormalities and delivery of adequate dialysis, have been fairly limited, but include antihistamines, 5-HT₃ receptor blockers such as ondansetron, and gabapentin.^{110–112}

Nutritional Status

Protein-energy malnutrition is very common among patients with advanced CKD (stages 4 and 5) (see Chap. 147).¹⁹ Causes of malnutrition in these patients include inadequate food intake secondary to anorexia, altered taste sensation, and the unpalatability of prescribed diets. Other factors in the ESRD population, such as the effect of the dialysis procedure on removal of nutrients, hypercatabolism induced by other inflammatory conditions, and blood loss are also contributory. Protein restriction as an intervention to potentially delay progression of kidney disease in patients with stage 3 or 4 CKD may also lead to protein malnutrition by the time a patient reaches ESRD; therefore the risks versus the benefits of this intervention must be considered on an individual basis (see Chap. 46) as hypoalbuminemia and malnutrition have a strong association with mortality in chronic dialysis patients.

Patients with ESRD have increased nutritional needs relative to the general population, based on the effect of the disease state and the dialysis procedure on nutritional status. The recommended dietary protein intake in chronic hemodialysis patients is 1.2 g/kg body weight per day.¹⁹ The recommended intake for chronic peritoneal dialysis patients is at least 1.2 to 1.3 g/kg body weight per day, based on the increased protein loss that occurs with this dialysis modality. Protein requirements are higher in patients who are acutely ill (see Chap. 147). The recommended total daily energy intake in both hemodialysis and peritoneal dialysis patients is 35 kcal/kg body weight per day.¹⁹ For peritoneal dialysis patients, this includes intake from both diet and that obtained from the glucose absorbed from peritoneal dialysate. For patients older than 60 years of age this criterion differs, because increasing age is generally associated with reduced physical activity and lean body mass. Daily energy intake for these patients is 30 to 35 kcal/kg body weight per day. Nutritional support should be considered for those patients who cannot achieve these goals with oral intake alone. Another option for nutritional supplementation in patients on hemodialysis includes interdietary parenteral nutrition (see Chap. 147).

Vitamin requirements for ESRD patients receiving dialysis differ from those of a healthy person because of dietary modifications, kidney dysfunction, and dialysis therapy. The plasma concentrations of vitamins A and E are elevated in ESRD, whereas those of the water-soluble vitamins (B₁, B₂, B₆, B₁₂, niacin, pantothenic acid, folic acid, biotin, and vitamin C) tend to be low in this population, in large part because many are dialyzable. The goal for vitamin supplementation in this population should be to prevent subclinical and frank deficiency and to avoid pathology from overdosage. Special vitamin supplements have been formulated for the dialysis population, which primarily include B vitamins with C and folic acid.

Supplementation with L-carnitine has been advocated for its potential benefits in patients with ESRD including management of hypertriglyceridemia, hypercholesterolemia, and anemia.¹¹³ Although some of these benefits have been demonstrated, the evidence does not strongly support routine supplementation with L-carnitine in patients with ESRD. Cost and the addition of yet another medication to the already complex regimen prescribed for many of these patients also mitigates against the routine use of this agent.

Uremic Bleeding

Bleeding complications in patients with CKD are usually mild, but can result in major hemorrhagic events. The primary mechanisms underlying the hemostatic problem are platelet biochemical abnormalities and alterations in platelet–vessel wall interactions. Decreased platelet aggregation and adhesiveness have been shown in a number of studies in ESRD patients.¹¹⁴ Additionally, there is a decreased plasma concentration and defective binding of the large multimer of von Willebrand factor (vWF), which results in abnormal platelet–

blood vessel wall interactions. Patients on hemodialysis are at even greater risk of bleeding, not only because of the hemodialysis process itself, but from administration of other medications. Heparin is frequently administered during dialysis procedures to prevent clotting during dialysis. Patients who are at high risk for bleeding may require alternative anticoagulation procedures rather than traditional hemodialysis with systemic heparinization. In addition, dialysis patients often receive systemic anticoagulation (warfarin) or antiplatelet therapy (aspirin or clopidogrel) for prevention of access clotting or other cardiovascular disorders.

There are several nondialytic adjunctive therapies that may temporarily shorten the increased bleeding time observed in patients with kidney disease. Cryoprecipitate is rich in factor VIII, fibrinogen, and fibronectin, and shortens bleeding time. Desmopressin (1-deamino-8-D-arginine vasopressin) has minimal vasoconstrictive effects as compared to vasopressin, but effectively releases autologous factor VIII (vWF) from the endothelial lining of vessel walls. A consistent lowering of bleeding time has been observed with intravenous, subcutaneous, and intranasal routes of administration. A drawback to the use of desmopressin is tachyphylaxis with repeated doses; response may return after 3 to 4 days. This effect is felt to be caused by depletion of vWF stores following the first dose.

Administration of estrogens is also effective as an intervention to reduce bleeding time in uremic patients, a strategy based on the observation that women with von Willebrand disease improved during pregnancy.¹¹⁴ Oral conjugated estrogens and low-dose transdermal patches are also effective. Side effects, which are uncommon and usually mild, include hot flashes, nausea, vomiting, hypertension, gynecomastia, and loss of libido. An increased risk of thromboembolism may result from estrogen therapy, especially with chronic use.

CONCLUSIONS

The number of patients with and at risk for CKD is increasing, with a substantial rise in the population with stage 5 CKD expected in the next decade. Although efforts to delay progression of CKD are paramount, measures to diagnose and manage the associated secondary complications and comorbid conditions early in the course of the disease are also essential. Common complications of stages 4 and 5 CKD include anemia, secondary hyperparathyroidism, fluid and electrolyte abnormalities, metabolic acidosis, and malnutrition. Cardiovascular complications are also prevalent in the population with CKD being the leading cause of mortality in patients with stage 5 disease. Patient education plays a critical role in the appropriate management of CKD and related complications. A multidisciplinary team structure is a rationale approach to provide this education and effectively design and implement the extensive non-pharmacologic and pharmacologic interventions required.

ABBREVIATIONS

ACEI: angiotensin-converting enzyme inhibitor
 AIDS: acquired immunodeficiency syndrome
 Ca × P: calcium phosphorus product; serum calcium multiplied by serum phosphorus
 CKD: chronic kidney disease
 CPK: creatine phosphokinase
 ESAs: erythropoietic stimulating agents
 ESRD: end-stage renal disease
 FE_K: fractional excretion of potassium
 FeNa: fractional excretion of sodium

GFR: glomerular filtration rate
 Hb: hemoglobin
 HCT: hematocrit
 HDL: high-density lipoprotein
 HMG-CoA: 3-hydroxy-3-methylglutaryl coenzyme A (reductase)
 iPTH: intact parathyroid hormone
 LDL: low-density lipoprotein
 LVH: left ventricular hypertrophy
 K/DOQI: Kidney Disease Outcomes Quality Initiative
 PTH: parathyroid hormone
 ROD: renal osteodystrophy
 sHPT: secondary hyperparathyroidism
 TSat: transferrin saturation
 vWF: von Willebrand factor

EDWARD F. FOOTE AND HAROLD J. MANLEY

KEY CONCEPTS

- 1 The hemodialysis procedure involves the perfusion of blood and dialysate on opposite sides of a semipermeable membrane. Substances are removed from the blood by diffusion and convection. Excess plasma water is removed via ultrafiltration.
- 2 The native arteriovenous fistula is the preferred access for hemodialysis because of fewer complications and a longer survival rate. Venous catheters are plagued by complications such as infection and thrombosis and often deliver relatively poor blood flow rates.
- 3 Adequacy of hemodialysis can be assessed by the Kt/V and urea reduction ratio (URR). The National Kidney Foundation's Kidney Disease Outcomes Quality Initiative has set the minimum goal Kt/V at greater than 1.2 per treatment and the URR at greater than 65%. In practice, most patients on hemodialysis exceed this goal.
- 4 During hemodialysis, patients commonly experience hypotension and cramps. Other more serious complications include infection and thrombosis of the vascular access.
- 5 The peritoneal dialysis procedure involves the instillation of dialysate into the peritoneal cavity via a permanent peritoneal catheter. The peritoneal membrane lines the highly vascularized abdominal viscera and acts as the semipermeable membrane across which diffusion and ultrafiltration occur. Substances are removed from the blood across the peritoneum via diffusion and ultrafiltration. Excess plasma water is removed via ultrafiltration created by osmotic pressure generated by various dextrose or icodextrin concentrations.
- 6 Patients on peritoneal dialysis are required to instill and drain, manually or via automated systems, several liters of fresh dialysate each day. The more exchanges a patient completes each day results in greater solute removal.
- 7 Peritonitis is a common complication of peritoneal dialysis. Initial empiric therapy for peritonitis should include intraperitoneal antibiotics that are effective against both gram-positive and gram-negative organisms.
- 8 Nasal carriage of *Staphylococcus aureus* is associated with an increased risk of catheter-related infections and peritonitis. Prophylaxis with intranasal mupirocin (twice a day for 5 days every

month) or mupirocin (daily) at the exit site can effectively reduce *S. aureus* infections.

The three primary treatment options for patients with end-stage renal disease (ESRD) are hemodialysis (HD), peritoneal dialysis (PD), and kidney transplantation. The United States Renal Data System is the national system that “collects, analyzes, and distributes” data relating to the United States ESRD program.¹ According to the United States Renal Data System, at the end of 2005 (the most recent data available), there were 483,750 patients in the United States with ESRD. Of these, 314,162 and 25,895 patients were being treated with HD and PD, respectively, and 143,693 had a functioning kidney transplant. The vast majority of incident (new) dialysis patients are treated with HD. Since mid-1990, the number of prevalent PD patients has decreased. Although the number of patients who have received a kidney transplant has risen steadily, transplantation has not kept pace with the growing prevalence of ESRD in the United States.

Since 1972, the treatment of ESRD (both dialysis and kidney transplantation) has been covered by Medicare. Total spending for ESRD in 2005 was \$32 billion; approximately one-third of this was from non-Medicare payers. ESRD patients consume a disproportionate amount of healthcare dollars. Approximately 1% of the patients in the Medicare program have ESRD, yet 8.2% of the budget is consumed by the ESRD program. Although total spending for ESRD treatment continues to climb, per-patient spending (after adjusting for inflation) was fairly flat between 2004 and 2005.

There are some positive signs as it relates to public health and ESRD. Although the total number of dialysis patients is increasing in the United States, the incident rate (number of new dialysis patients per total population) has stabilized or slightly decreased from the highest value observed in 1997. The prevalent population of ESRD continues to climb, reflective of reduced mortality and enhanced patient care. The primary diagnosis for incident patients with ESRD is diabetes.¹ Chapter 46 provides a thorough discussion on the epidemiology of chronic kidney disease.

This chapter serves as a primer on the principles and practice of dialysis. The chapter focuses on HD and PD as the dialysis modalities most commonly employed for the management of ESRD (see Chap. 45 for a discussion of the role of dialysis in the management of acute renal failure). The pertinent factors which should be considered before the initiation of dialysis are described. The morbidity and mortality associated with HD and PD are compared, as these considerations may influence the dialysis method chosen by patients and clinicians. Because dialysis by either method is not a generic procedure, the variants of HD and PD are detailed. The multiple types of vascular and peritoneal access used to provide HD and PD, including various catheters and surgical techniques, are illustrated. The concept of dialysis adequacy for each modality is briefly reviewed. Finally, the clinical presentation of the common complications of both dialytic therapies is presented, along with pertinent nonpharmacologic and pharmacologic therapeutic approaches.

THOMAS D. NOLIN AND JONATHAN HIMMELFARB

KEY CONCEPTS

- 1 The initial diagnosis of drug-induced kidney disease typically involves detection of elevated serum creatinine and blood urea nitrogen, for which there is a temporal relationship between the toxicity and use of a potentially nephrotoxic drug.
- 2 Drug-induced kidney disease is best prevented by avoiding the use of potentially nephrotoxic agents in patients at increased risk for toxicity. However, when exposure to these drugs cannot be avoided, recognition of risk factors and specific techniques, such as hydration, may be used to reduce potential nephrotoxicity.
- 3 Acute tubular necrosis is the most common presentation of drug-induced kidney disease in hospitalized patients. The primary agents implicated are aminoglycosides, radiocontrast media, cisplatin, amphotericin B, foscarnet, and osmotically active agents.
- 4 Angiotensin-converting enzyme inhibitors and nonsteroidal antiinflammatory drugs are associated with hemodynamically mediated kidney injury, the pathogenesis of which is a decrease in glomerular capillary hydrostatic pressure.
- 5 Acute allergic interstitial nephritis is the underlying cause for up to 3% of all cases of acute kidney injury. Clinical manifestations of allergic interstitial nephritis typically present approximately 14 days after initiation of therapy and include fever, maculopapular rash, eosinophilia, pyuria, hematuria, proteinuria, and oliguria.

Drug-induced kidney disease or nephrotoxicity (DIN) is a relatively common complication of several diagnostic and therapeutic agents. It is seen in both inpatient and outpatient settings with variable presentations depending on the drug and clinical setting. Manifestations of DIN include acid–base abnormalities, electrolyte imbalances, urine sediment abnormalities, proteinuria, pyuria, and/or hematuria.¹ However, the most common manifestation of DIN is a decline in the glomerular filtration rate (GFR), which results in a rise in the serum creatinine (S_{cr}) and blood urea nitrogen (BUN). Initial diagnosis of DIN is often delayed as it typically involves detection of elevated S_{cr} and BUN, for which there is a temporal relationship between the toxicity and use of a

potentially nephrotoxic drug. This is consistent with the classic qualitative definition of acute renal failure (ARF) i.e., an “abrupt and sustained decrease in glomerular filtration, urine output, or both.”² Unfortunately, numerous definitions of ARF and nephrotoxicity based on various quantitative changes in the serum creatinine concentration and other clinical end points have been published.^{2,3} Consequently, it is extraordinarily difficult to ascertain the true incidence of ARF and/or DIN because broad ranges have been reported for the same agent. This may be alleviated if the recently developed new diagnostic criteria based on physiologic measurements (e.g., S_{cr} and urine output) are broadly accepted, and if the new term *acute kidney injury* (AKI) supplants the use of ARF (see Chap. 45).^{4–6}

DIN is often reversible on discontinuation of the offending agent, but may also lead to acute kidney injury and/or end-stage renal disease (ESRD). Currently, many different mechanisms are responsible for the pathogenesis of DIN and the introduction of new drugs with novel mechanisms of action provides the potential for the identification of new presentations of AKI and chronic kidney disease (CKD). This chapter reviews the epidemiology, pathophysiology, risk factors, and basic principles of prevention of DIN. Detailed discussions of these issues plus management strategies are presented for widely used agents that have been associated with a moderate to high likelihood of DIN.

EPIDEMIOLOGY

The incidence and characteristics of outpatient or community-acquired DIN are not well understood as mild toxicity is often unrecognized in this setting. However, the pharmacoepidemiology of these effects has become more important as care increasingly shifts to the outpatient setting. Up to 20% of hospital admissions, as a result of AKI, have been attributed specifically to community-acquired DIN.⁷ Conversely, DIN has been studied for years in the acute care hospital setting where it has been implicated in 8% to 60% of all cases of in-hospital AKI and as such is a recognized source of significant morbidity and mortality.⁸ In-hospital drug use may contribute to 35% of all cases of acute tubular necrosis, most cases of allergic interstitial nephritis (AIN), as well as nephrotoxicity due to alterations in renal hemodynamics and postrenal obstruction.⁹ The incidence of antibiotic-induced nephrotoxicity alone may be as high as 36%.¹ Aminoglycoside antibiotics, radiocontrast media, conventional nonselective nonsteroidal antiinflammatory drugs (NSAIDs) and selective cyclooxygenase-2 (COX-2) inhibitors, amphotericin B, and angiotensin-converting enzyme inhibitors (ACEIs) have also been frequently implicated.^{10–12} Computer-guided medication dosing for hospital inpatients may improve the safety of some of these potentially harmful drugs and minimize the occurrence of DIN in this setting.¹³

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

CLINICAL PRESENTATION

1 Because the most common manifestation of DIN is a decline in GFR leading to a rise in S_{cr} and BUN, the onset of toxicity in hospitalized, acutely ill patients is most often recognized by routine laboratory monitoring of these two chemistries. Decreased urine output may also be an early sign of toxicity, particularly with radiographic contrast media, NSAIDs, and ACEIs. In the outpatient setting, nephrotoxicity is often recognized by symptoms such as malaise, anorexia, vomiting, volume overload (shortness of breath or edema), and hypertension. S_{cr} or BUN concentrations and urine collection for creatinine clearance may subsequently be measured to quantify the degree of loss of glomerular filtration. Marked intrasubject between-day variability of S_{cr} values has been noted ($\pm 20\%$ for values within the normal range; see Chap. 44). Furthermore, they may be altered as the result of dietary changes and initiation of drug therapy, which may interfere with the assay procedure. Thus a change in S_{cr} of at least 0.5 mg/dL for subjects with a baseline $S_{cr} < 2$ mg/dL and an increase of approximately 30% for those with $S_{cr} > 2$ mg/dL, when correlated temporally with the initiation of drug therapy, is a common threshold for the identification of DIN.

CLINICAL PRESENTATION OF DRUG-INDUCED KIDNEY DISEASE

General

- The most common manifestation is a decline in GFR leading to a rise in S_{cr} and BUN.

Symptoms

- Malaise, anorexia, vomiting, shortness of breath, or edema.

Signs

- Decreased urine output may be an early sign of toxicity, particularly with radiographic contrast media, NSAIDs, and ACEIs, with progression to volume overload and hypertension.
- *Proximal tubular injury*: metabolic acidosis with bicarbonaturia; glycosuria in the absence of hyperglycemia; and reductions in serum phosphate, uric acid, potassium, and magnesium as a result of increased urinary losses.
- *Distal tubular injury*: polyuria from failure to maximally concentrate urine, metabolic acidosis from impaired urinary acidification, and hyperkalemia from impaired potassium excretion.

Laboratory Tests

- A change in S_{cr} of at least 0.5 mg/dL for subjects with a baseline $S_{cr} < 2$ mg/dL and an increase of $> 30\%$ for those with $S_{cr} > 2$ mg/dL, when correlated temporally with the initiation of drug therapy is commonly observed.^{3,10}

Other Diagnostic Tests

- Urinary excretion of *N*-acetyl- β -D-glucosaminidase, γ -glutamyl transpeptidase, glutathione *S*-transferase, and interleukin-18 are markers of proximal tubular injury and have been used for the early detection of AKI in critically ill patients.^{14,15}
- Kidney injury molecule-1 (KIM-1) is expressed in the proximal tubule and is upregulated in patients with ischemic acute tubular necrosis, appearing in the urine within 12 hours after the ischemic insult.¹⁵
- Neutrophil gelatinase-associated lipocalin (NGAL) protein may be detected in the urine within 3 hours of ischemic injury.¹⁵

TABLE 49-1 Drug-Induced Renal Structural–Functional Alterations

Tubular epithelial cell damage

- | | |
|----------------------------------|-------------------------------|
| Acute tubular necrosis | • Pentamidine |
| • Adefovir, cidofovir, tenofovir | • Radiographic contrast media |
| • Aminoglycoside antibiotics | • Zoledronate |
| • Amphotericin B | Osmotic nephrosis |
| • Cisplatin, carboplatin | • Dextran |
| • Cyclosporine, tacrolimus | • Intravenous immunoglobulin |
| • Foscarnet | • Mannitol |

Hemodynamically mediated kidney injury

- | | |
|--|---------------------------------------|
| • Angiotensin-converting enzyme inhibitors | • Cyclosporine, tacrolimus |
| • Angiotensin II receptor blockers | • Nonsteroidal antiinflammatory drugs |
| | • OKT3 |

Obstructive nephropathy

- | | |
|--------------------------|-----------------|
| Intratubular obstruction | Nephrolithiasis |
| • Acyclovir | • Indinavir |

| • Sulfonamides | |

Glomerular disease

- | | |
|-----------|--|
| • Gold | • Nonsteroidal antiinflammatory drugs, cyclooxygenase-2 inhibitors |
| • Lithium | • Pamidronate |

Tubulointerstitial disease

- | | |
|--|--|
| Acute allergic interstitial nephritis | Nephrocalcinosis |
| • Ciprofloxacin | • Oral sodium phosphate solution |
| • Loop diuretics | Papillary necrosis |
| • Nonsteroidal antiinflammatory drugs, cyclooxygenase-2 inhibitors | • Nonsteroidal antiinflammatory drugs, combined phenacetin, aspirin, and caffeine analgesics |
| • Penicillins | |
| • Proton pump inhibitors | |
| Chronic interstitial nephritis | |
| • Cyclosporine | |
| • Lithium | |
| • Aristolochic acid | |

Renal vasculitis, thrombosis, and cholesterol emboli

- | | |
|---------------------------|----------------------------|
| Vasculitis and thrombosis | • Mitomycin C |
| • Hydralazine | • Methamphetamines |
| • Propylthiouracil | • Cyclosporine, tacrolimus |
| • Allopurinol | Cholesterol emboli |
| • Penicillamine | • Warfarin |
| • Gemcitabine | • Thrombolytic agents |

Nephrotoxicity may be evidenced by alterations in renal tubular function without loss of glomerular filtration (Table 49–1). Indicators of proximal tubular injury include metabolic acidosis with bicarbonaturia; glycosuria in the absence of hyperglycemia; and reductions in serum phosphate, uric acid, potassium, and magnesium as a result of increased urinary losses. Indicators of distal tubular injury include polyuria from failure to maximally concentrate urine, metabolic acidosis from impaired urinary acidification, and hyperkalemia from impaired potassium excretion. Urinary enzymes and low-molecular-weight proteins are also used as early markers of nephrotoxicity. For example, urinary excretion of *N*-acetyl- β -D-glucosaminidase, γ -glutamyl transpeptidase, glutathione *S*-transferase, and interleukin-18 are markers of proximal tubular injury and have been used for the early detection of acute kidney damage in critically ill patients. The transmembrane protein KIM-1 is expressed in the proximal tubule and is upregulated in patients with ischemic acute tubular necrosis, appearing in the urine within 12 hours after the ischemic insult. Similarly, NGAL protein is detected in the urine within 3 hours of ischemic injury in rodent models of kidney disease. In the future, novel urinary biomarkers such as interleukin-18, KIM-1, and NGAL may facilitate the earlier diagnosis of nephrotoxicity and minimize the long-term consequences of this common drug-induced disorder.

PRINCIPLES FOR PREVENTION OF DRUG-INDUCED NEPHROPATHY

2 The primary principle for prevention of DIN is to avoid the use of potentially nephrotoxic agents in patients at increased risk for toxicity. However, because exposure to these drugs often cannot be avoided, several interventions have been proposed to reduce the potential for the development of nephrotoxicity, for example, careful and adequate hydration to establish high renal tubular urine flow rates.⁸ However, other strategies to reduce drug toxicity are still theoretical and/or investigational and relate directly to the specific nephrotoxic mechanisms of the drug. For example, adefovir is a nucleotide antiviral that is actively transported by OAT1.¹⁶ Inhibition of OAT1-mediated transport with NSAIDs minimizes accumulation of adefovir in renal proximal tubule cells and results in a reduction in DIN.¹⁷

Table 49–1 lists the several specific drug-induced renal structural–functional alterations that are responsible for the vast majority of cases of DIN. This chapter discusses the pathophysiologic mechanisms responsible for the development of DIN with these agents in detail, along with clinical presentation, prevention strategies, therapeutic management approaches, and relevant monitoring plans.

TUBULAR EPITHELIAL CELL DAMAGE

3 Renal tubular epithelial cell damage may be caused by either direct toxic or ischemic effects of drugs. Damage is most often localized in the proximal and distal tubular epithelia, and when observed as cellular degeneration and sloughing from proximal and distal tubular basement membranes is termed acute tubular necrosis.¹⁸ Swelling and vacuolization of proximal tubular cells may also be noted in those with osmotic nephrosis.¹² Acute tubular necrosis is the most common presentation of DIN in the inpatient setting. The primary agents implicated in renal tubular epithelial cell damage are aminoglycosides, radiocontrast media, cisplatin, amphotericin B, foscarnet, and osmotically active agents such as immunoglobulins, dextrans, and mannitol.^{1,12}

ACUTE TUBULAR NECROSIS

Aminoglycoside Nephrotoxicity

Incidence Although nephrotoxicity has been reported in up to 58% of patients who are receiving aminoglycoside therapy, most recent reviews suggest rates of 5% to 15%.^{19,20} The large variance is in part a result of the use of different definitions of toxicity, variability between agents in the class, and the risk factors present in the study population.

Clinical Presentation A gradual progressive rise in the serum creatinine concentration and decrease in creatinine clearance after 6 to 10 days of therapy are the initial clinical manifestations of toxicity. Patients typically present with nonoliguria, maintaining urine volumes greater than 500 mL/day. Although renal magnesium wasting can occur, that is, daily excretion of more than 10 to 30 mg, the risk of hypomagnesemia is generally low. Severe kidney injury does not usually develop if aminoglycoside therapy is stopped promptly upon notation of a significant rise in serum creatinine, but occasionally it may, and for these individuals dialysis therapy may be required (see Chap. 48). Aminoglycoside-associated nephropathy must be evaluated carefully because not all AKI during a course of therapy is caused by the aminoglycoside. Dehydration, sepsis, ischemia, and other nephrotoxic drugs frequently contribute to and complicate the identification of the causative agent or condition.

Pathogenesis The reduction of GFR in patients receiving aminoglycosides is predominantly the result of proximal tubular epithelial cell damage leading to obstruction of the tubular lumen and back leakage of the glomerular filtrate across the damaged tubular epithelium.²¹ Toxicity may be related to cationic charge, which facilitates binding of filtered aminoglycosides to renal tubular epithelial cell luminal membranes, followed by intracellular transport and concentration in lysosomes.^{1,21,22} Cellular dysfunction and death may result from release of lysosomal enzymes into the cytosol, generation of reactive oxygen species, altered cellular metabolism, and alterations in cell membrane fluidity, leading to reduced activity of membrane-bound enzymes, including Na⁺-K⁺-adenosine triphosphatase, dipeptidyl peptidase IV, and neutral aminopeptidase.

Risk Factors Multiple risk factors for aminoglycoside nephrotoxicity have been identified. These relate to the aggressiveness of aminoglycoside dosing, synergistic toxicity as the result of combination drug therapy, and preexisting clinical conditions of the patient (Table 49–2).²¹

Prevention Aminoglycoside-induced nephrotoxicity may be prevented by more discriminating selection of patients in whom the drugs are used. Moreover, alternative antibiotics should be used whenever possible and as soon as microbial sensitivities are known. Commonly used alternatives include fluoroquinolones (e.g., ciprofloxacin or levofloxacin) and third- or fourth-generation cephalosporins (e.g., ceftazidime or cefepime). When aminoglycosides are necessary, the specific drug used does not appear to significantly affect the risk of nephrotoxicity, and therapy should be selected to optimize antimicrobial efficacy. Furthermore, it is imperative to avoid volume depletion, limit the total aminoglycoside dose administered, and avoid concomitant therapy with other nephrotoxic drugs. Future therapeutic alternatives may include nonnephrotoxic aminoglycoside congeners, which are in development, that retain the desired bactericidal activity and yet are devoid of nephrotoxicity.²³

Prospective, individualized pharmacokinetic monitoring has been used for more than 25 years. Although many have reported a decrease in the incidence of aminoglycoside-induced nephrotoxicity, the studies are often small and statistically underpowered. High intermittent dosing of aminoglycosides, termed *once-daily dosing*, used in combina-

TABLE 49-2 Risk Factors for Aminoglycoside Nephrotoxicity

A. Related to aminoglycoside dosing:
Large total cumulative dose
Prolonged therapy
Trough concentration exceeding 2 mg/L
Recent previous aminoglycoside therapy
B. Related to synergistic nephrotoxicity. Aminoglycosides in combination with:
Amphotericin B
Cyclosporine
Diuretics
Vancomycin
C. Related to predisposing conditions in the patient:
Dehydration
Gram-negative bacteremia
Hypoalbuminemia
Increased age
Liver disease
Obstructive jaundice
Preexisting kidney disease
Poor nutrition
Potassium or magnesium deficiencies
Shock

tion with other antibiotics, has been intensively investigated as a practical cost-effective method to maintain antimicrobial efficacy while reducing nephro-, vestibular, and ototoxicity.^{24,25} Nephrotoxicity may be reduced because proximal tubular aminoglycoside uptake appears to be limited during the transient, high-peak serum concentrations, and because low aminoglycoside concentrations for a greater proportion of the dosing interval facilitate excretion of the aminoglycoside. Although greater clinical efficacy and reduced nephrotoxicity may be realized with once-daily compared to standard dosing, seriously ill, immunocompromised, and elderly patients, as well as patients with preexisting kidney disease, are not ideal candidates for this approach because of altered aminoglycoside clearance in these patients.²⁵

Management Serum creatinine concentrations should be measured frequently (every 2 to 4 days) during therapy. Aminoglycoside use should be discontinued or the dosage regimen revised if a S_{cr} increase of 0.5 mg/dL or more is noted that is not attributable to another cause. Other nephrotoxic drugs should be discontinued if possible, and the patient should be maintained adequately hydrated and hemodynamically stable. Short-term dialysis may be necessary, but ESRD has rarely been reported to be solely the result of aminoglycoside toxicity.

Radiographic Contrast Media Nephrotoxicity

Incidence Nephrotoxicity associated with radiographic contrast media administration is the third leading cause of hospital-acquired AKI.^{26,27} The incidence rises from <2% in patients with a low risk of AKI to 40% to 50% in patients with a high risk, such as those with CKD or diabetes mellitus.^{26,28,29} The risk of contrast-induced nephrotoxicity increases as the number of risk factors increases, and diabetic patients with CKD have the greatest risk.^{28,30}

Clinical Presentation Contrast nephrotoxicity presents most commonly as nonoliguric, transient tubular enzymuria. However, irreversible oliguric (urine volume <500 mL/day) kidney injury requiring dialysis has been reported in high-risk patients. Kidney injury typically manifests within the first 12 to 24 hours after the administration of contrast. The serum creatinine concentration usually peaks between 2 and 5 days after exposure, with recovery after 4 to 10 days. Urinalysis typically reveals only hyaline and granular casts, but may also be completely bland.³⁰ The urine sodium concentration and fractional excretion of sodium are frequently low. Although toxicity has generally been considered to be mild and reversible, an in-hospital mortality rate of 35% has been reported in patients with severe contrast media-induced AKI requiring dialysis, compared to 7% in those with contrast nephrotoxicity not requiring dialysis.²⁸

Pathogenesis Contrast nephrotoxicity appears to be caused by direct tubular toxicity and/or renal ischemia.^{28,29} Direct tubular toxicity is suggested by the frequent presence of renal tubular enzymuria and biopsy findings of proximal tubular epithelial cell vacuolization and acute tubular necrosis. In contrast to these findings, the frequent finding of a low urine sodium concentration and low fractional excretion of sodium suggests that renal tubular function is preserved. Renal ischemia may result from systemic hypotension associated with contrast injection, as well as renal vasoconstriction mediated by an imbalance of humoral agents, including prostaglandins, adenosine, atrial natriuretic peptide, nitric oxide, and endothelin.^{28,30} Renal ischemia may also result from dehydration as the result of osmotic diuresis associated with the use of hyperosmolar agents (900 to 1,780 mOsm/kg) and increased blood viscosity caused by red blood cell crenation and aggregation.²⁸

Risk Factors Preexisting kidney disease, particularly in diabetic patients, is the major risk factor.^{28,30} Conditions associated with

decreased renal blood flow, including congestive heart failure and dehydration, also confer risk. The presence of multiple myeloma has been considered a relative contraindication for contrast use, but the risk appears to be associated with concomitant dehydration, kidney disease, or hypercalcemia rather than the diagnosis itself. Both larger doses of contrast and use of hyperosmolar contrast agents have been associated with an increased risk in susceptible patients.²⁸

Prevention Because contrast nephrotoxicity can be anticipated in the majority of patients who are at risk, the use of preventative procedures is justified for most patients. Table 49–3 lists the recommended interventions for prevention of contrast nephrotoxicity. All patients scheduled to receive radiocontrast media should be assessed for risk factors, and the risk-to-benefit ratio should be considered.^{27–32} High-risk patients can be identified by evaluating medical history and indication for the contrast study, along with their most recent serum creatinine concentrations. Nephrotoxicity is best prevented in high-risk patients by using alternative imaging procedures (e.g., ultrasound, magnetic resonance imaging, and nuclear medicine scans). However, if contrast media must be used, the smallest adequate dose should be administered. Dose reduction proportional to the level of kidney function may be protective, but may limit the adequacy of imaging.³³

Low-osmolality nonionic (iohexol and iopamidol) and ionic (ioxaglate) contrast agents may be used to prevent nephrotoxicity. Standard contrast media are not reabsorbed in the kidney and cause osmotic diuresis, which contributes to the renal toxicity observed with these agents. The second generation of contrast agents have half the osmolality of standard agents and are associated with less toxicity, especially when used in patients with preexisting kidney disease.³⁰ The incidence of contrast nephrotoxicity in nondiabetic

TABLE 49-3 Recommended Interventions for Prevention of Contrast Nephrotoxicity

Intervention	Recommendation	Recommendation Grade ^a
Contrast	• Minimize contrast volume/dose	A-1
	• Use noniodinated contrast studies	A-2
	• Use low- or isoosmolar contrast agents	A-2
Medications	• Avoid concurrent use of potentially nephrotoxic drugs (e.g., nonsteroidal antiinflammatory drugs, aminoglycosides)	A-2
Normal (0.9%) saline	• Initiate infusion at least 3 hours prior to contrast exposure and continue 8–24 hours postexposure	A-1
	• Infuse at 1 mL/kg/hr up to 150 mL/h, adjusting postexposure as clinically indicated	
Sodium bicarbonate 154 mEq/L	• Initiate infusion at 3 mL/kg/h, beginning 1 hour prior to contrast exposure, then continue at 1 mL/kg/h for 6 hours postexposure	B-2
N-acetylcysteine	• Administer 600 mg orally, every 12 hours × 4 doses beginning prior to contrast exposure (i.e., one dose prior to exposure and 3 doses postexposure)	B-1

^aStrength of recommendations: A, B, C, good, moderate, and poor evidence to support recommendation, respectively. Quality of evidence: 1, Evidence from more than one properly randomized, controlled trial. 2, Evidence from more than one well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple time series; or dramatic results from uncontrolled experiments. 3, Evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

Derived from data in references 27, 28, 31, 32.

patients with underlying kidney disease is more than twofold higher in those receiving standard contrast agents than in those receiving low-osmolar agents.²⁶ However, use of low-osmolar agents does not preclude the development of nephrotoxicity and preventive measures should be considered.

CLINICAL CONTROVERSY

Some clinicians believe that low-osmolar contrast agents should be used in virtually all patients who are at risk for toxicity. Others believe that the cost-to-benefit ratio of using low-osmolar contrast agents to prevent nephrotoxicity is questionable except in patients at high risk, because low-osmolar agents are considerably (three to five times) more expensive than standard higher osmolar ionic agents.

Dehydration should be corrected before contrast administration, other nephrotoxic drugs discontinued if possible, and subsequent contrast studies appropriately timed to minimize cumulative toxicity.^{27,28} Hydration with isotonic saline before and after contrast administration reduces the incidence of toxicity, particularly in high-risk patients, and is currently the most widely accepted preventative intervention.²⁸ In addition to the correction of dehydration, saline administration may result in dilution of contrast media, prevention of renal vasoconstriction leading to ischemia, and avoidance of tubular obstruction. The results of one recent study suggest that hydration with sodium bicarbonate provides more protection than saline, perhaps by reducing the formation of pH-dependent oxygen free radicals.³⁴ *N*-acetylcysteine is a thiol-containing antioxidant that may effectively reduce the risk of developing contrast nephrotoxicity in patients with preexisting kidney disease, although a therapeutic benefit has not been consistently demonstrated.^{28,35} Nevertheless, its use should be considered, along with hydration, in all patients who are at risk of toxicity.^{28,29,31,35–37} The recommended *N*-acetylcysteine dosing regimen for prevention of contrast nephrotoxicity is 600 mg orally every 12 hours \times 4 doses, with the first dose administered prior to contrast exposure (see Table 49–3).

CLINICAL CONTROVERSY

Some clinicians believe that insufficient evidence exists to justify use of acetylcysteine for the prevention of contrast nephrotoxicity, whereas others feel that its safety profile, ease of use, low cost, and potential for benefit are adequate justification for use in all patients.

Continuous venovenous hemofiltration may also be an effective means of preventing contrast nephrotoxicity and was associated with improved outcomes in one study of patients with CKD.³⁸ However, because of the logistical issues (e.g., technical difficulty) and high cost of hemofiltration, this approach is not widely used.^{28,36} Use of mannitol and furosemide to prevent toxicity remains controversial,²⁹ and recent evidence indicates that the dopamine₁-receptor agonist fenoldopam may not prevent contrast-induced nephropathy in CKD patients.^{27,36} Consequently, these approaches are generally not recommended for the prevention of contrast nephrotoxicity.

Management Currently there is no specific therapy available for managing established contrast nephrotoxicity. Care is supportive as described in Chap. 45. Renal function (e.g., S_{cr} , urine output) and volume status should be closely monitored, and dialysis used as needed in patients with the most severe kidney injury.

Cisplatin and Carboplatin Nephrotoxicity

Incidence Platin-containing compounds are important chemotherapeutic agents that frequently cause renal tubular damage.^{39–41} The incidence of cisplatin nephrotoxicity was 50% to 100% in the 1980s. Subsequently, the incidence of toxicity has decreased to 6% to 13%, primarily as the result of limiting the total drug dose and reducing the rate of administration. However, when used in combination with other nephrotoxins, high-dose cisplatin continues to contribute to DIN. A 20% to 40% decline in GFR is frequently observed in patients treated with cisplatin.³⁹ Carboplatin, a second-generation platinum analog, is associated with a much lower incidence of nephrotoxicity than cisplatin and thus is the preferred agent in high-risk patients.⁴⁰

Clinical Presentation Peak serum creatinine concentrations occur approximately 10 to 12 days after initiation of therapy, with recovery by 21 days. However, kidney damage is dose related and cumulative with subsequent cycles of therapy, so the serum creatinine concentration may continue to rise. Irreversible kidney injury may result. Renal magnesium wasting is common and can be accompanied by hypocalcemia and hypokalemia. Hypomagnesemia may be severe, and associated with seizures, neuromuscular irritability, or personality changes, and persist long after chemotherapy has ended. Hypomagnesemia results primarily from increased urinary losses as a result of renal tubular damage as well as saline hydration and diuretic therapy to prevent toxicity. Anorexia and diarrhea also contribute, because of decreased intake and increased loss of magnesium, respectively.

Pathogenesis Proximal tubular damage appears acutely after administration of platin-containing compounds, as the result of impairment of cell energy production, possibly by binding to proximal tubular cellular proteins and sulfhydryl groups with disruption of cell enzyme activity and uncoupling of oxidative phosphorylation.⁴¹ The initial proximal tubular damage is followed by a progressive loss of glomerular filtration and impaired distal tubular function.³⁹ Renal biopsies generally show sparing of glomeruli with necrosis of proximal and distal tubules and collecting ducts.

Risk Factors Risk factors include increased age, dehydration, renal irradiation, concurrent use of aminoglycoside antibiotics, and alcohol abuse.³⁹

Prevention Toxicity is best prevented by prospective dose reduction and decreased frequency of administration, which usually requires using the platin compounds in combination with other chemotherapeutic agents, and avoiding concurrent use of other nephrotoxic drugs. Vigorous hydration with isotonic saline is important and should be used in all patients with a goal of maintaining at least 100 mL/h of urine output during and after cisplatin treatment. Hydration is initiated up to 24 hours prior to, and continued during and for 4 to 8 hours after, cisplatin administration; saline doses range from a total of 1 to 4 L administered at rates as high as 250 mL/h immediately prior to cisplatin treatment, to as high as 3 L/m² for high-dose carboplatin.³⁹ Hydration is continued during and after cisplatin administration at rates of 150 to 250 mL/h as tolerated. Although protective roles for furosemide or mannitol-induced diuresis are less clear,²⁸ their use is often necessary to maintain volume homeostasis, particularly when saline infusion rates of 250 mL/h are used. Furosemide 20 mg to 40 mg is commonly administered 30 minutes prior to cisplatin, or mannitol 12.5 g up to 50 g is administered with cisplatin to maintain \geq 100 mL/h of urine output.

Amifostine, an organic thiophosphate that is converted to an active metabolite, chelates cisplatin in normal cells and reduces the nephrotoxicity, neurotoxicity, ototoxicity, and myelosuppression

associated with cisplatin and carboplatin therapy.⁴² The renoprotective effect of amifostine administration has been demonstrated in patients receiving cisplatin/ifosfamide-based chemotherapy.⁴³ Amifostine fully preserved GFR in patients with solid tumors after administration of two cycles of chemotherapy compared to a 30% reduction in GFR in controls. In addition, although hypomagnesemia and tubular damage were still observed in the amifostine group they were markedly less severe. Pretreatment with amifostine should be considered in patients who are at risk for kidney injury, particularly patients who are elderly, volume depleted, have CKD, or are receiving other nephrotoxic drugs concurrently.

Promising investigational techniques include the use of hypertonic saline (e.g., administration of each dose in 250 mL of 3% saline) to reduce tubular cisplatin uptake,⁴⁴ *N*-acetylcysteine to reduce oxidative damage by acting as a sulfhydryl donor, and disulfiram metabolite diethyldithiocarbamate to reduce cytochrome P450 2E1-mediated generation of hydroxyl radicals.^{39,45} Recently, the protective effect of melatonin,⁴⁶ and the ability of cisplatin-incorporated polymeric micelles to maintain antitumor activity while reducing nephrotoxicity were demonstrated.⁴⁷ Finally, reduced renal exposure can be achieved with the use of localized intraperitoneal administration in conjunction with systemic administration of sodium thiosulfate for those with peritoneal tumors.

Management Acute kidney injury caused by cisplatin therapy is usually partially reversible with time and supportive care, including dialysis. Renal function indices should be closely followed, with S_{cr} and BUN concentrations checked daily. Serum magnesium, potassium, and calcium concentrations should be monitored daily and corrected as needed. Hypocalcemia and hypokalemia may be difficult to reverse until hypomagnesemia is corrected. Progressive kidney disease caused by cumulative nephrotoxicity may be irreversible and in some cases may require chronic dialysis support.

Amphotericin B Nephrotoxicity

Incidence Amphotericin B toxicity may be seen with cumulative doses as low as 300 to 400 mg, and reaches an incidence of 80% when cumulative doses approach 4 g.^{48,49} Although numerous studies demonstrate lower rates of nephrotoxicity with liposomal formulations compared to conventional amphotericin B, it is difficult to compare rates of toxicity between products and studies because of the variability in the study populations, doses administered, and inconsistent definitions of nephrotoxicity and methods of assessment.⁵⁰

Clinical Presentation Toxicity relates to cumulative dosage and usually manifests after administration of 2 to 3 g as renal tubular potassium, sodium, and magnesium wasting, impaired urine concentrating ability, and distal renal tubular acidosis as a consequence of a leak of hydrogen ions out of the tubular lumen.⁴⁹ Renal blood flow and GFR decreases are common, resulting in a rise in S_{cr} and BUN concentrations, and potassium and magnesium replacement may be necessary.⁴⁸ Consequently, renal function indices should be closely followed, with S_{cr} and BUN concentrations checked daily, and serum magnesium, potassium, and calcium concentrations monitored every other day and corrected as needed.

Pathogenesis The mechanisms of kidney injury include direct tubular epithelial cell toxicity with increased tubular permeability and necrosis, as well as arterial vasoconstriction and ischemic injury.⁴⁸ Overall, the combined effects of increased cell energy and oxygen requirements because of greater cell membrane permeability, and reduced cellular oxygen delivery because of renal vasocon-

striction, result in renal medullary tubular epithelial cell necrosis and kidney injury.

Risk Factors Risk factors include CKD, higher average daily doses, volume depletion, and concomitant administration of diuretics and other nephrotoxins (cyclosporine in particular).^{49,51} Rapid infusions of amphotericin B have the potential to increase toxicity. A recent comparison of 24-hour continuous infusions with conventional 4-hour infusions revealed a significant reduction of toxicity, attributed to decreased “pretubular” effects (e.g., effects on renal blood flow and GFR).⁵²

Prevention Several liposomal amphotericin B formulations are now available and should be used in most high-risk patients as they have been reported to reduce nephrotoxicity by enhancing drug delivery to sites of infection, thereby reducing exposure of mammalian cell membranes.^{49,51,53} Nephrotoxicity can also be minimized by limiting the cumulative dose and avoiding concomitant administration of other nephrotoxins, particularly cyclosporine.⁵⁴ Additionally, providing hydration with 1 L intravenous 0.9% sodium chloride daily during the course of therapy appears to reduce toxicity. Mannitol infusion to induce an osmotic diuresis, however, has not been shown to be protective.⁵¹

CLINICAL CONTROVERSY

Many clinicians recommend using liposomal formulations of amphotericin B in all patients with CKD and those at risk for developing nephrotoxicity, whereas others maintain that the safety and efficacy of liposomal formulations are not yet established enough to warrant their use in all patients.

Management Amphotericin nephrotoxicity is best treated by discontinuation of therapy and substitution of alternative antifungal therapy, if possible. Renal tubular dysfunction and glomerular filtration will improve gradually to some degree in most patients, but damage may be irreversible. Renal function indices should be closely followed, with S_{cr} and BUN concentrations checked daily, and serum magnesium, potassium, and calcium concentrations should be monitored daily and corrected as needed.

OSMOTIC NEPHROSIS

Several drugs, including mannitol, low-molecular-weight dextran, and radiographic contrast media, or drug vehicles, such as sucrose and propylene glycol, are associated with vacuolization, swelling, and, ultimately, necrosis of proximal tubular epithelial cells with a decline in renal function.¹² The decline in renal function may be a result of the hypertonic and osmotically active nature of these agents. Intravenous immunoglobulin solutions contain hyperosmolar sucrose and may cause osmotic nephrosis and acute kidney injury, which is usually reversible shortly after discontinuing therapy.⁵⁵ Toxicity may be prevented by diluting the solution and reducing the rate of infusion. Hydroxyethyl starch, used as a plasma volume expander, has also been implicated in the development of osmotic nephrosis.¹²

Mannitol may rarely cause oligoanuric kidney injury with proximal tubular cell vacuolization on biopsy.¹ It can also cause direct renal vasoconstriction or induce an osmotic diuresis with increased solute delivery to the macula densa and subsequent tubuloglomerular feedback, leading to vasoconstriction of the glomerular afferent arteriole and decreased renal blood flow. Risk factors for mannitol toxicity include excessive doses, preexisting kidney disease, and concomitant diuretic or cyclosporine therapy. Nephrotoxicity may

be prevented by limiting the dose and avoiding dehydration and concomitant diuretic therapy. Patients usually recover normal renal function when elevated mannitol concentrations decrease following drug withdrawal or hemodialysis.

HEMODYNAMICALLY MEDIATED KIDNEY INJURY

4 The kidneys constitute only 0.4% of body weight, but receive approximately 25% of resting cardiac output.¹ This enhances the kidney's exposure to circulating drugs. Within each nephron, blood flow and pressure are regulated by glomerular afferent and efferent arterioles to maintain intraglomerular capillary hydrostatic pressure, glomerular filtration, and urine output. Afferent and efferent arteriolar vasoconstriction are primarily mediated by angiotensin II, whereas afferent vasodilation is primarily mediated by prostaglandins (Fig. 49–1). This specialized blood flow is precisely regulated by interrelations between arachidonic acid metabolites, natriuretic factors, nitric oxide, the sympathetic nervous system, the renin-angiotensin system, and the macula densa response to distal tubular solute delivery. Hemodynamically mediated kidney injury results from a decrease in intraglomerular pressure. Mechanisms commonly include a decrease in renal blood flow, vasoconstriction of glomerular afferent arterioles, and vasodilation of glomerular efferent arterioles.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS AND ANGIOTENSIN II RECEPTOR BLOCKERS

Incidence

The incidence of ACEI- or angiotensin II receptor blocker (ARB)-mediated kidney injury has not been established. However, hospitalized patients with congestive heart failure, and those with CKD, including diabetic nephropathy, are most likely to experience a significant decline in renal function when therapy with one of these agents is initiated. Although ACEI-induced AKI has accounted for 9% of all cases of AKI requiring hospitalization,⁵⁶ reductions in GFR have been reported primarily in patients with severe atherosclerotic renal artery stenosis.⁵⁷ The rise is often minimal in renovascular disease if only one renal artery is stenotic, but is more apparent in patients with a single kidney, congestive heart failure, volume

depletion, or bilateral renal small vessel disease. Up to one-third of patients with bilateral renal artery stenosis demonstrate a rise in serum creatinine >30% after starting ACEI therapy.⁵⁶

Clinical Presentation

Therapy with ACEIs and ARBs will acutely reduce GFR, so a moderate rise in serum creatinine of 0.1 to 0.3 mg/dL should be anticipated.⁵⁸ Importantly, a distinction must be made between a potentially detrimental reduction in GFR and a normal, predictable rise in serum creatinine. A rise in S_{cr} of 0.5 mg/dL or more in the course of 1 to 2 weeks may necessitate discontinuance of the offending drug. Dose-related elevations in serum creatinine should be anticipated in most patients prescribed ACEIs, based on their pathophysiologic effects.⁵⁹ An increase in serum creatinine of up to 30% within 2 to 5 days of initiating therapy is an indication that the drug has begun to exert its desired pharmacologic effect. The increase in creatinine usually stabilizes within 2 to 3 weeks and is usually reversible upon stopping the drug. Furthermore, an association exists between acute increases in serum creatinine of $\leq 30\%$ from baseline that stabilize within the first 2 months of initiating therapy and preservation of renal function.

Pathogenesis

The kidney normally attempts to maintain GFR by dilating the afferent arteriole and constricting the efferent arteriole in response to a decrease in renal blood flow. During states of reduced blood flow, the juxtaglomerular apparatus increases renin secretion. Plasma renin converts angiotensinogen to angiotensin I, and ultimately angiotensin II by angiotensin-converting enzyme. Angiotensin II constricts the afferent and efferent arterioles resulting in a net increase in intraglomerular pressure. Additionally, renal prostaglandins, prostaglandin E_2 in particular, are released and induce a net dilation of the afferent arteriole, thereby improving blood flow into the glomerulus. Together these processes maintain GFR and urine output (Fig. 49–2).

ACEI- or ARB-mediated kidney injury is the result of a decrease in glomerular capillary hydrostatic pressure sufficient to reduce glomerular ultrafiltration.¹² When ACEI therapy (e.g., enalapril or ramipril) is initiated, the synthesis of angiotensin II is decreased, thereby preferentially dilating the efferent arteriole. This reduces outflow resistance from the glomerulus and decreases hydrostatic pressure in the glomerular capillaries, which alters Starling forces across the glomerular capillaries to decrease intraglomerular pres-

FIGURE 49-1. Normal glomerular autoregulation serves to maintain intraglomerular capillary hydrostatic pressure, glomerular filtration rate (GFR), and, ultimately, urine output. (A II, angiotensin II; PGE_2 , prostaglandin E_2 ; RBF, renal blood flow.)

FIGURE 49-2. Glomerular autoregulation during "prerenal" states (i.e., reduced blood flow). (A II, angiotensin II; GFR, glomerular filtration rate; PGE_2 , prostaglandin E_2 ; RBF, renal blood flow.)

FIGURE 49-3. Pathogenesis of angiotensin-converting enzyme inhibitor (ACEI) nephropathy. (A II, angiotensin II; GFR, glomerular filtration rate; PGE_2 , prostaglandin E_2 ; RBF, renal blood flow.)

sure, GFR, and then often leads to nephrotoxicity, particularly in the setting of reduced renal blood flow or effective arterial blood volume (Fig. 49–3), that is, “prerenal” settings in which glomerular afferent arteriolar blood flow is reduced and the efferent arteriole is vasoconstricted to maintain sufficient glomerular capillary hydrostatic pressure for ultrafiltration.

Risk Factors

Patients at greatest risk are those dependent on angiotensin II to maintain blood pressure and renal efferent arteriolar constriction. These include patients with hemodynamically significant renal artery stenosis, particularly bilateral stenosis, and those with decreased effective arterial blood volume (i.e., prerenal states), especially those with congestive heart failure, volume depletion from excess diuresis or gastrointestinal fluid loss, hepatic cirrhosis with ascites, and the nephrotic syndrome.^{12,58}

Prevention

Hemodynamically mediated AKI caused by ACEIs or ARBs is frequently preventable by recognizing the presence of preexisting kidney disease or decreased effective renal blood flow as a result of volume depletion, heart failure, or liver disease.⁵⁸ A common strategy for at-risk patients is to initiate therapy with very low doses of a short-acting ACEI (e.g., captopril 6.25 mg to 12.5 mg), then gradually titrate the dose upward and convert to a longer-acting agent after patient tolerance has been demonstrated. Outpatients may be started on low doses of long-acting ACEIs (e.g., enalapril 2.5 mg) with gradual dose titration every 2 to 4 weeks until the maximum dose or desired response is achieved. Renal function indices and serum potassium concentrations must be monitored carefully, daily for hospitalized patients and every 2 to 3 days for outpatients. Monitoring may need to be more frequent during outpatient initiation of ACEI or ARB therapy for patients with preexisting kidney disease, congestive heart failure, or suspected renovascular disease. Use of concurrent hypotensive agents and other drugs that affect renal hemodynamics (e.g., NSAIDs, diuretics) should be discouraged and dehydration avoided.

Management

Acute decreases in renal function and the development of hyperkalemia usually resolve over several days after ACEI or ARB therapy is discontinued. Occasionally patients will require management of severe hyperkalemia, usually with sodium polystyrene sulfonate

suspension (see Chap. 54). ACEI or ARB therapy may frequently be reinitiated, particularly for patients with congestive heart failure, after intravascular volume depletion has been corrected or diuretic doses reduced. Slight reductions in renal function (maintenance of a serum creatinine concentration of 2 to 3 mg/dL) may be an acceptable trade-off for hemodynamic improvement in certain patients with severe congestive heart failure or renovascular disease not amenable to revascularization.⁵⁷

NONSTEROIDAL ANTIINFLAMMATORY DRUGS AND SELECTIVE CYCLOOXYGENASE-2 INHIBITORS

Incidence

NSAIDs have an overall favorable safety profile resulting in nonprescription availability in the United States of ibuprofen, naproxen, and ketoprofen for short-term therapy. Although potential adverse renal effects from nonprescription NSAIDs have been a concern, conventional nonselective NSAIDs and selective COX-2 inhibitors are unlikely to impair renal function in the absence of renal ischemia or excess renal vasoconstrictor activity. Nevertheless, given the fact that 50 million U.S. citizens report NSAID use, it has been estimated that 500,000 to 2.5 million people will develop NSAID nephrotoxicity in the United States annually.⁶⁰

Clinical Presentation

Kidney injury can occur within days of initiating therapy, particularly with a short-acting NSAID such as ibuprofen.⁶⁰ Patients typically present with complaints of diminished urine output, weight gain, and/or edema. Urine volume and sodium concentration are usually low, and BUN, S_{cr} , and potassium are typically elevated. The urine sediment is usually unchanged from baseline, but may show granular casts. Hemodynamically mediated kidney injury associated with COX-2 inhibitors presents similarly.¹²

Pathogenesis

NSAIDs inhibit COX-catalyzed prostaglandin production and impair renal function by decreasing synthesis of vasodilatory prostaglandins from arachidonic acid.⁶⁰ Renal prostaglandins are synthesized in the renal cortex and medulla by vascular endothelial and glomerular mesangial cells. Their effects are primarily local and result in renal vasodilation (particularly prostacyclin and prostaglandin E_2). They have limited activity in states of normal renal blood flow, but in states of decreased renal blood flow their synthesis is increased and they protect against renal ischemia and hypoxia by antagonizing renal vasoconstriction due to angiotensin II, norepinephrine, endothelin, and vasopressin. Administration of NSAIDs in the setting of renal ischemia and compensatory increased prostaglandin activity may thus alter the balance of activity between renal vasoconstrictors and vasodilators. This leaves the activity of renal vasoconstrictors unopposed and promotes renal ischemia with loss of glomerular filtration. This hemodynamically mediated AKI is the most common adverse renal effect of NSAIDs.^{1,12}

Risk Factors

Persons at greatest risk for nephrotoxicity have CKD, hepatic disease with ascites, decompensated congestive heart failure, intravascular volume depletion, or systemic lupus erythematosus.¹² Additional risk factors include atherosclerotic cardiovascular disease and concurrent diuretic therapy. The elderly are also at higher risk because of interaction of prevalent medical problems, multiple-drug therapies, and reduced renal hemodynamics. NSAID use in

patients older than 65 years of age may increase the risk of AKI by up to 58%.⁶¹ Combined NSAID or COX-2 inhibitor and ACEI or ARB therapy is also a concern and should be avoided in high-risk patients.

Prevention

NSAID- and COX-2 inhibitor-induced AKI can be prevented by recognizing high-risk patients and using analgesics with less prostaglandin inhibition, such as acetaminophen, nonacetylated salicylates, aspirin, and possibly nabumetone. Nonnarcotic analgesics (e.g., tramadol) may also be useful, but do not provide antiinflammatory activity.⁶⁰ When NSAID therapy is essential for high-risk patients, the minimal effective dose should be used for the shortest duration possible, along with optimal management of predisposing medical problems and frequent renal function monitoring. Moreover, use of concurrent hypotensive agents and other drugs which affect renal hemodynamics (e.g., ACEIs, ARBs, diuretics) should be discouraged in high-risk patients and dehydration avoided.

Traditional, nonselective NSAIDs inhibit COX-1 and COX-2, whereas the selective drugs meloxicam, celecoxib, and valdecoxib preferentially inhibit COX-2. COX-2 inhibitors were anticipated to be beneficial in high-risk patients. However, recent data indicate that they affect renal function similarly to nonselective NSAIDs and thus caution is warranted with their use, particularly in high-risk patients.^{12,62}

Management

NSAID-induced AKI is treated by discontinuation of therapy and supportive care. Kidney injury is rarely severe and recovery is usually rapid. Occasionally, the hemodynamic insult is sufficiently severe to cause frank tubular necrosis, which can prolong injury.¹² The differential diagnosis of NSAID hemodynamically mediated AKI must also include NSAID-induced acute interstitial nephritis, with or without the nephrotic syndrome, because steroid therapy may benefit this type of renal injury.

CYCLOSPORINE AND TACROLIMUS

The calcineurin inhibitors cyclosporine and tacrolimus have dramatically enhanced the success of solid-organ transplantation. Nephrotoxicity, however, remains a major dose-limiting adverse effect of both drugs.⁶³ Although delayed chronic interstitial nephritis has been reported, acute hemodynamically mediated kidney injury is the primary mechanism of nephrotoxicity.^{8,12}

Incidence

Historically, reversible AKI occurred frequently in transplant recipients during the first 6 months of cyclosporine therapy. Recent data indicate that the 5-year risk of CKD after transplantation of a nonrenal organ ranges from 7% to 21%, depending on the type of organ transplanted.⁶³ In addition, the occurrence of CKD in these patients is associated with more than a fourfold increase in the risk of death.

Clinical Presentation

The clinical presentation of acute hemodynamically mediated kidney injury secondary to cyclosporine and tacrolimus is quite different than the presentation of chronic nephrotoxicity (see Chronic Interstitial Nephritis below for a discussion of the presentation). AKI may occur within days of initiating therapy. S_{cr} concentration rises and creatinine clearance decreases. Hypertension, hyperkalemia, sodium retention, and hypomagnesemia may occur. No urine sediment abnormalities are seen. Renal biopsy usually reveals thick-

ening of arterioles, mild focal glomerular sclerosis, proximal tubular epithelial cell vacuolization and atrophy, and interstitial fibrosis. Biopsy is useful to distinguish acute cyclosporine nephrotoxicity from renal allograft rejection, the latter being evidenced by cellular infiltration.⁶⁴

Pathogenesis

A dose-related hemodynamic mechanism is likely during the initial months of therapy because renal function improves rapidly following dose reduction. Reversible vasoconstriction and injury to glomerular afferent arterioles occurs, possibly as a result of increased activity of thromboxane A_2 , endothelin, and the sympathetic nervous system, or diminished activity of nitric oxide or prostacyclin.^{65,66} Vasoconstriction caused by increased renin-angiotensin system activity may also contribute. In contrast, renal arteriolar hyalinization and chronic renal ischemia, as well as increased extracellular matrix synthesis, appear to be the primary mechanisms that contribute to cyclosporine-induced CKD.^{65,66}

Risk Factors

Risk factors include age over 65 and higher initial cyclosporine dose, as well as renal graft rejection, hypotension, infection, and concomitant therapy with nephrotoxic drugs such as aminoglycosides, amphotericin B, acyclovir, NSAIDs, and radiocontrast agents, as well as drugs that inhibit cyclosporine hepatic metabolism.⁶⁴ The incidence of AKI with potential progression to chronic nephropathy has decreased since the introduction of lower-dose-therapy regimens. Unfortunately, there has been no apparent reduction in the incidence of the slow, dose-dependent decline in glomerular filtration.⁶⁶

Prevention

Because acute hemodynamically mediated kidney injury secondary to cyclosporine and tacrolimus appears to be concentration related, pharmacokinetic and pharmacodynamic monitoring is an important means of preventing toxicity. However, the persistent presence of therapeutic or low cyclosporine concentrations does not totally preclude the development of nephrotoxicity. Calcium channel blockers may antagonize the vasoconstrictor effect of cyclosporine by dilating glomerular afferent arterioles and preventing acute decreases in renal blood flow and glomerular filtration.⁶⁴ Lastly, decreased doses of cyclosporine or tacrolimus, primarily when used in combination with other nonnephrotoxic immunosuppressants, may minimize the risk of toxicity, but this may increase the risk of chronic rejection.

Management

AKI usually improves with dose reduction, and treatment of contributing illness or the discontinuation of interacting drugs. CKD is usually irreversible, but progressive toxicity may be limited by discontinuation of cyclosporine (or tacrolimus) therapy or dose reduction, with the continuation of other immunosuppressants. S_{cr} and BUN should be closely monitored (daily if possible), as should cyclosporine or tacrolimus concentrations, to ensure that serum concentrations are within the narrow therapeutic range.

OBSTRUCTIVE NEPHROPATHY

Obstructive nephropathy is the result of mechanical obstruction to urine flow following glomerular filtration, and is most commonly caused by intratubular obstruction or postrenal obstruction secondary to nephrolithiasis or prostatic hypertrophy.^{12,67}

INTRATUBULAR OBSTRUCTION

Drug-induced acute renal tubular obstruction can be caused by intratubular precipitation of tissue-degradation products or drugs and/or their metabolites. Acute uric acid nephropathy following tumor-tissue degradation as the result of chemotherapy (i.e., tumor lysis syndrome) is the most common cause of this type of kidney injury. Acute oliguric or anuric kidney injury develops rapidly. The diagnosis is supported by a urine uric acid-to-creatinine ratio greater than 1. Uric acid precipitation can be prevented by pretreatment hydration with normal saline to maintain urine output of >2.5 L/day, administration of allopurinol 300 to 600 mg daily started 2 to 3 days prior to chemotherapy, and urinary alkalinization to pH 7.0.

Drug-induced rhabdomyolysis can lead to intratubular precipitation of myoglobin, and if severe, AKI. The most common cause of drug-induced rhabdomyolysis is direct myotoxicity from β -hydroxy- β -methylglutaryl-coenzyme A reductase inhibitors, including lovastatin and simvastatin.⁶⁸ The risk of rhabdomyolysis is increased when this class of drugs is administered concurrently with gemfibrozil, niacin, or inhibitors of the CYP3A4 metabolic pathway (e.g., erythromycin and itraconazole). Rhabdomyolysis may also result from pressure necrosis as the result of stupor or coma following ingestion of CNS depressants (e.g., alcohol and narcotics), or extreme neuromuscular agitation associated with abuse of central nervous system stimulants (e.g., amphetamines, cocaine, ecstasy, and phencyclidine).⁶⁸

Intratubular precipitation of drugs or their metabolites can also cause AKI.^{12,69} Urine pH decreases to approximately 4.5 during maximal stimulation of renal tubular hydrogen ion secretion. Certain solutes can precipitate and obstruct the tubular lumen at this acid pH, particularly when urine is concentrated, such as in patients with volume depletion. For example, acyclovir is relatively insoluble at physiologic urine pH and is associated with intratubular precipitation in dehydrated oliguric patients.^{12,16,67} Sulfadiazine when used at high doses, and methotrexate may also precipitate in acidic urine and can cause oligo-anuric kidney injury. Massive administration of ascorbic acid can also result in obstruction of renal tubules with calcium oxalate crystals. Oxalate, a poorly soluble ascorbic acid metabolite, can also precipitate and worsen renal function when ascorbic acid is administered to patients with AKI or the congenital nephrotic syndrome. Low-molecular-weight dextran therapy for volume expansion and rheologic effects has also caused kidney injury, possibly by intratubular precipitation of filtered dextran. Triamterene may also precipitate in renal tubules and cause kidney injury.⁶⁹ Fosfarnet complexation with ionized calcium may result in precipitation of calcium-fosfarnet salt crystals in renal glomeruli, causing primarily a crystalline glomerulonephritis. The salt crystals may then secondarily precipitate in the renal tubules causing tubular necrosis.⁷⁰ The protease inhibitor indinavir has been associated with crystalluria, crystal nephropathy, dysuria, urinary frequency, back and flank pain, or nephrolithiasis in approximately 8% of treated patients.¹² Intratubular indinavir crystal precipitation is prevented in nearly 75% of treated patients via consumption of 2 to 3 L of fluid per day.¹²

Kidney injury caused by intratubular precipitation of most tissue-degradation products or drugs and their metabolites can be largely prevented and possibly treated by administering the drug after vigorously prehydrating the patient, maintaining a high urine volume, and urinary alkalinization.⁸

NEPHROLITHIASIS

Nephrolithiasis (formation of renal calculi or kidney stones) does not present as classic nephrotoxicity as GFR is usually not decreased. Drug-induced nephrolithiasis can be the result of abnormal crystal precipitation in the renal collecting system, potentially

causing pain, hematuria, infection, or, occasionally, urinary tract obstruction with kidney injury. The overall prevalence of drug-induced nephrolithiasis is estimated to be 1%.⁶⁷

Renal stone formation, possibly also accompanied by intratubular precipitation of crystalline material, has been a rare complication of drug therapy. Until the acquired immune deficiency syndrome (AIDS) era, triamterene had been the drug most frequently associated with renal stone formation, with a prevalence of 0.4%.⁶⁷ However, it has been unclear whether triamterene or its metabolites actually initiated stone formation, or are passively absorbed onto the organic matrix of preexisting calculi. Sulfadiazine is a poorly soluble sulfonamide that has caused symptomatic acetylsulfadiazine crystalluria with stone formation and flank or back pain, hematuria, or kidney injury in up to 29% of patients treated with the drug.⁵⁸ A high urine volume and urinary alkalinization to pH >7.15 may be protective. AKI caused by intratubular precipitation of indinavir and collecting system obstruction from nephrolithiasis have occurred.⁶⁷ Because indinavir is more water soluble at acidic pH, urine acidification could be protective but is impractical. Maintaining a high urine volume may be most protective.⁶⁷ Numerous other drugs have been implicated in the development of nephrolithiasis, including the antiviral drugs nelfinavir and fosfarnet, the antibacterial agents ciprofloxacin, amoxicillin, and nitrofurantoin, and various products containing ephedrine, norephedrine, and pseudoephedrine.⁶⁷

GLOMERULAR DISEASE

Proteinuria with or without a decline in the GFR is a hallmark sign of glomerular injury (see Chap. 50). Several different glomerular lesions may occur, mostly by immune mechanisms rather than direct cellular toxicity. Although drug-induced glomerular disease is uncommon, a variety of agents have been implicated.⁷¹

Minimal change glomerular injury with nephrotic range proteinuria (i.e., >3.5 g/day) caused by drugs is frequently accompanied by interstitial nephritis and is most common during NSAID therapy.^{60,71} Ampicillin, rifampin, phenytoin, and lithium have also been implicated. The pathogenesis is unknown, but nephrotic-range proteinuria as a consequence of NSAID therapy is frequently associated with a T-lymphocytic interstitial infiltrate, suggesting disordered cell-mediated immunity. Proteinuria usually resolves rapidly after discontinuation of the offending drug, and a 3- to 4-week course of corticosteroids may help resolve the lesion.⁷²

Focal segmental glomerulosclerosis (FSGS) is characterized by patchy areas of glomerular sclerosis with interstitial inflammation and fibrosis (see Chap. 50). FSGS has been described in the setting of chronic heroin abuse (heroin nephropathy).^{73,74} The pathogenesis is unknown but may include direct toxicity by heroin or adulterants and injury from bacterial or viral infections accompanying intravenous drug use. FSGS is also the predominant renal lesion in AIDS patients and may result from human immunodeficiency virus (HIV) infection or heroin abuse. Glomerulosclerosis caused by HIV infection may be distinguished from heroin nephropathy by tubuloreticular structures in endothelial cells on electron microscopy and the more rapid course and poorer prognosis. The bisphosphonate pamidronate, commonly used to treat malignancy-associated hypercalcemia, has also been associated with the development of collapsing FSGS. Patients receiving either high doses or prolonged therapy are at highest risk.^{75,76}

Membranous nephropathy is characterized by immune complex formation along glomerular capillary loops, and although rarely seen, has classically been associated with gold therapy, penicillamine, and NSAID use.^{12,71} The pathogenesis may involve damage to proximal tubule epithelium with antigen release, antibody formation, and glomerular immune complex deposition.

TUBULOINTERSTITIAL DISEASE

Tubulointerstitial diseases involve the renal tubules and the surrounding interstitial tissue.¹⁸ The presentation may be acute and reversible with interstitial inflammatory cell infiltrates, rapid loss of renal function, and systemic symptoms. A chronic and irreversible presentation associated with interstitial fibrosis, and minimal to no systemic symptoms have also been observed.

ACUTE ALLERGIC INTERSTITIAL NEPHRITIS

Incidence

5 AIN is the underlying cause for up to 3% of all cases of AKI.⁷² Multiple drugs have been implicated (Table 49–4). AIN usually manifests 2 weeks after exposure to a drug but may occur sooner if the patient was previously sensitized.¹¹

β -Lactams

Clinical Presentation Although methicillin-induced allergic interstitial nephritis is the prototype for AIN, it is now recognized that AIN is associated with all β -lactam antibiotics.⁷² Clinical signs present approximately 14 days after initiation of therapy and include (with their approximate incidence) fever (80%), maculopapular rash (25%), eosinophilia (80%), pyuria and hematuria (90%), low-level proteinuria (90%), and oliguria (20%). Systemic hypersensitivity findings of fever, rash, eosinophilia, and eosinophiluria suggest the diagnosis, but this constellation of findings is not consistently reliable as one or more are frequently absent. Eosinophiluria, an important marker of drug-induced AIN, is frequently absent, possibly because of fragility of eosinophils in urine and inadequate laboratory methodology. Anemia, leukocytosis, and elevated immunoglobulin E levels may occur. Tubular dysfunction may be manifested by acidosis, hyperkalemia, salt wasting, and concentrating defects.^{11,18,72}

NSAIDs

Clinical Presentation NSAID-induced AIN has a different clinical presentation than that seen with most other drugs.^{12,72} Patients are typically older than age 50 years (reflecting NSAID use for degenerative joint disease), the onset is delayed a mean of 6 months from initiation of therapy compared to 2 weeks with β -lactams, and there is a much lower incidence of fever, rash, and eosinophilia. These extrarenal symptoms are observed in only 10% of patients.^{12,72} Concomitant nephrotic syndrome (proteinuria >3.5 g/day) occurs in more than 70% of patients. Fenoprofen-allergic interstitial nephritis is considered the prototype for NSAID-induced AIN because it accounts for nearly 50% of cases.⁷² Prompt diagnosis of allergic interstitial nephritis is important as discontinuation of the offending drug may prevent irreversible renal damage.¹⁸ Renal biopsy is the most specific method for diagnosis but is usually not possible in acutely ill patients.

Pathogenesis AIN is characterized as a diffuse or focal interstitial infiltrate of lymphocytes, plasma cells, eosinophils, and occasional polymorphonuclear neutrophils.^{18,72} Granulomas and tubular epithelial cell necrosis are relatively common with drug-induced AIN. The pathogenesis is an allergic hypersensitivity response. Occasionally a humoral antibody-mediated mechanism is implicated by the presence of circulating antibody to a drug hapten–tubular basement membrane complex, low serum complement levels, and deposition of immunoglobulin G and complement in the tubular basement membrane. More commonly, a cell-mediated immune mechanism is suggested by the absence of these findings and the presence of a predominantly T-lymphocyte infiltrate with an increased helper-to-

TABLE 49-4 Drugs Associated with Allergic Interstitial Nephritis

Antimicrobials	
Acyclovir	Indinavir
Aminoglycosides	Rifampin
Amphotericin B	Sulfonamides
β -Lactams	Tetracyclines
Erythromycin	Trimethoprim-sulfamethoxazole
Ethambutol	Vancomycin
Diuretics	
Acetazolamide	Loop diuretics
Amiloride	Triamterene
Chlorthalidone	Thiazide diuretics
Neuropsychiatric	
Carbamazepine	Phenytoin
Lithium	Valproic acid
Phenobarbital	
Nonsteroidal antiinflammatory drugs	
Aspirin	Ketoprofen
Cyclooxygenase-2 inhibitors	Naproxen
Diclofenac	Phenylbutazone
Diffunisal	Piroxicam
Ibuprofen	Zomepirac
Indomethacin	
Miscellaneous	
Acetaminophen	Lansoprazole
Allopurinol	Methyldopa
Aspirin	Omeprazole
Azathioprine	<i>P</i> -aminosalicylic acid
Captopril	Phenylpropanolamine
Cimetidine	Propylthiouracil
Clofibrate	Radiographic contrast media
Cyclosporine	Ranitidine
Glyburide	Sulfinpyrazone
Gold	Warfarin
Interferon- α	

suppressor cell ratio. In particular, NSAID interstitial nephritis involves T lymphocytes, possibly in response to altered prostaglandin synthesis.^{11,18}

Risk Factors No specific risk factors have been identified because these are idiosyncratic hypersensitivity reactions. Individuals with other drug allergies may have increased risk and warrant close monitoring.

Prevention No specific preventive measures are known because of the idiosyncratic nature of these reactions. Patients must be monitored carefully to recognize the signs and symptoms, because promptly discontinuing the offending drug often leads to full recovery.¹⁸

Management Prednisone therapy has been beneficial, particularly in patients whose renal function does not improve within 1 week after stopping the offending drug, but no prospective treatment trials have been reported to date.^{18,72} Various dosage regimens have been used, but an initial dose of 1 mg/kg/day for a week, which is then tapered over 3 weeks to discontinuation, has been recommended.^{72,77} Typical renal function indices (e.g., S_{cr} , BUN) and signs and symptoms of AIN should be monitored closely for improvement.

CHRONIC INTERSTITIAL NEPHRITIS

Lithium, cyclosporine, aristolochic acid, and only a few other drugs have been reported to cause chronic interstitial nephritis, which is usually a progressive and irreversible lesion.^{1,18}

Lithium

Incidence Several renal tubular lesions are associated with lithium therapy; an impaired ability to concentrate urine (nephrogenic

diabetes insipidus) has been seen in up to 87% of patients.⁷⁸ Acute tubular necrosis and chronic tubulointerstitial nephritis are less-frequently noted, and incomplete distal renal tubular acidosis is observed in up to 50% of patients.⁷⁹ Historically, the most important question regarding lithium use was whether long-term therapy, with lithium concentrations maintained in the therapeutic range, caused chronic tubulointerstitial nephritis. It is now established that long-term lithium therapy is associated with nephrotoxicity in the absence of episodes of acute intoxication, and that the duration of therapy and the cumulative dose are the major determinants of toxicity.⁸⁰

Clinical Presentation Polydipsia (excessive thirst) and polyuria (excessive urination) are observed in 40% and 20%, respectively, of patients with nephrogenic diabetes insipidus (see Chap. 52).⁷⁹ They adapt well to their urinary-concentrating defect and these concerns are usually minimal. Acute tubular necrosis is sometimes observed in the setting of acute lithium toxicity. Urinalysis may show moderate proteinuria, a few red and white blood cells, and granular casts. Renal function usually returns to baseline values after lithium concentrations are reduced to the therapeutic range. Nephrotoxicity may develop insidiously and only be recognized by rising BUN or creatinine concentrations or the onset of hypertension.

Pathogenesis Impaired ability to concentrate urine is a result of a dose-related decrease in collecting duct response to antidiuretic hormone. This results from impaired formation of cellular cyclic adenosine monophosphate in response to antidiuretic hormone. Lithium-induced AKI occurs predominantly during episodes of acute lithium intoxication. The pathogenesis includes dehydration secondary to nephrogenic diabetes insipidus, as well as direct proximal and distal tubular cell toxicity. Chronic tubulointerstitial nephritis attributed to lithium is evidenced most commonly by biopsy findings of interstitial fibrosis, tubular atrophy, and glomerular sclerosis.^{18,80} The pathogenesis may involve cumulative direct lithium toxicity as duration of therapy correlates with the decline in the GFR. Finally, some patients may have increased susceptibility to lithium toxicity. Although the reason for this is unknown, this could explain the difficulty in characterizing the nephrotoxic effects of chronic lithium therapy.

Risk Factors The major risk factor for AKI is an elevated lithium concentration, particularly in association with dehydration. Concomitant therapy with neuroleptic agents may contribute. Chronic nephrotoxicity may result from cumulative damage caused by repeated episodes of acute renal injury.

Prevention Prevention of acute and chronic toxicity includes maintaining lithium concentrations as low as therapeutically possible, avoiding dehydration, and monitoring renal function. It is unknown whether progression to chronic kidney disease can be prevented by stopping lithium use when mild kidney injury is first recognized. This poses a dilemma as lithium is highly effective for affective disorders and the risks and potential benefits of discontinuing such a beneficial drug need to be carefully considered.⁸⁰ However, if lithium therapy is continued, renal function must be monitored and therapy discontinued if it continues to decline.

Management Symptomatic polyuria and polydipsia can be reversed by discontinuation of lithium therapy or ameliorated with amiloride 10 mg daily during continued lithium therapy (see Chap. 52).⁷⁹ If polyuria does not resolve within 7 to 10 days of therapy, then the amiloride dose should be increased to 20 mg daily.⁸¹ AKI is usually reversible with supportive care, including dialysis to reduce toxic blood lithium concentrations. Progressive chronic interstitial nephritis is treated by discontinuation of lithium therapy, adequate

hydration, and avoidance of other nephrotoxic agents. Lithium serum concentrations, as well as renal function indices, including urine output, BUN, and S_{cr} should be monitored closely for resolution of signs and symptoms of toxicity.

Cyclosporine

Delayed chronic interstitial nephritis has been reported after 6 to 12 months of therapy and can result in irreversible kidney disease. Toxicity usually manifests as a slowly rising S_{cr} concentration and decreased creatinine clearance that may not reflect the severity of histopathologic changes. Typical biopsy findings include arteriolar hyalinosis, glomerular sclerosis, and a striped pattern of tubulointerstitial fibrosis.^{64–66,79} The pathogenesis appears to involve sustained renal arteriolar endothelial cell injury which ultimately results in chronic renal ischemia because of increased release of endothelin-1, decreased production of nitric acid, and increased expression of transforming growth factor- β .⁸² Nephrotoxicity has been dose dependent in some, but not all analyses, and occurs even during low-dose therapy.⁶⁵

Aristolochic Acid (Chinese Herb Nephropathy)

Incidence In the early 1990s, a cluster of young women with rapidly progressive kidney disease leading to ESRD were reported in Brussels, Belgium.⁸³ The patients had strikingly similar pathologic findings of interstitial fibrosis with tubular atrophy on renal biopsy. Further investigation revealed that all the women were patients of the same weight-loss clinic and had received a weight-loss treatment containing Chinese herbs. Subsequent analysis of the herb-based treatment demonstrated significant amounts of *Aristolochia fangchi* (Guang fang ji), known to contain aristolochic acid, the major alkaloid of the botanical species *Aristolochia*.⁸³ The term *Chinese herb nephropathy* was established and associated with aristolochic acid exposure after confirmatory renal biopsies were obtained from additional Belgian kidney disease patients with prior exposure to the same Chinese herb-based treatment. Approximately 3% to 5% of patients who received the weight-loss regimen developed disease, and numerous additional cases of nephropathy and ESRD associated with the use of *Aristolochia* species have been reported from around the globe.⁸³

Clinical Presentation Patients with Chinese herb nephropathy typically present with mild to moderate hypertension, mild proteinuria, glucosuria, and moderately elevated S_{cr} concentrations.⁸³ Anemia and shrunken kidneys are also common on initial presentation. The overwhelming majority of cases reported to date have been in women. The main pathologic lesions observed in the kidneys are interstitial fibrosis with atrophy and destruction of tubules throughout the renal cortex; in general, the glomeruli are not affected. Perhaps the most remarkable feature of Chinese herb nephropathy is the rate at which it progresses. In most individuals, ESRD requiring dialysis or transplantation develops within 6 to 24 months of exposure. An alarming high prevalence (approximately 40%) of urothelial transitional cell carcinoma has been observed in Belgian patients who underwent renal transplantation.^{83,84}

Pathogenesis Although the precise mechanism of aristolochic acid-induced nephropathy and urothelial carcinoma is yet to be characterized, recent data indicate direct DNA damage may be the cause. The major components of aristolochic acid are metabolized to mutagenic compounds called aristolactam I and aristolactam II, respectively, which have been demonstrated to form DNA adducts in humans.⁸³

Prevention The primary means of preventing Chinese herb nephropathy appears to be the limitation of exposure to compounds

containing aristolochic acids. Several countries, including the United Kingdom, Canada, Australia, and Germany, have banned the use of *Aristolochia*-containing herbs.⁸²

NEPHROCALCINOSIS

Nephrocalcinosis is a clinical–pathologic condition characterized by extensive tubulointerstitial precipitation and deposition of calcium phosphate leading to marked tubular calcification.^{85,86} Typical risk factors for developing nephrocalcinosis include clinical conditions associated with hypercalcemia, including hyperparathyroidism, increased bone turnover, hypercalcemia of malignancy, and increased intake of calcium or vitamin D. Recently, however, several documented cases of nephrocalcinosis in patients without hypercalcemia have pointed to oral sodium phosphate solution (OSPS) used for bowel cleansing as the causative agent.^{85,86} The term acute phosphate nephropathy was coined specifically to describe OSPS-induced nephrocalcinosis, as its pathogenesis is the result of increased phosphate intake rather than hypercalcemia.⁸⁵ The incidence of acute phosphate nephropathy is unknown but rare. Patients usually present with AKI several days to months after exposure to OSPS. Patients in one cohort of 21 cases of acute phosphate nephropathy presented with AKI and a mean serum creatinine of 3.9 mg/dL at a median of 1 month after colonoscopy.⁸⁵ Low-grade proteinuria (<1.0 g/day), normocalcemia, and a bland urinary sediment are usually observed. Extensive deposition of calcium phosphate in the distal tubules and collecting ducts without glomerular or vascular injury is the hallmark of OSPS-induced nephrocalcinosis.^{85,86} Risk factors include bowel conditions associated with prolonged intestinal transit, and high sodium phosphate dosage, along with concomitant volume depletion and diuretic, NSAID, ACEI, or ARB therapy. Advanced age may also be a risk factor as most reported cases are in the elderly. OSPS should be avoided in patients with CKD.

PAPILLARY NECROSIS

Papillary necrosis is a form of chronic tubulointerstitial nephritis characterized by necrosis of the renal papillae, the regions of the kidney where the collecting ducts enter the renal pelvis.¹⁸ Analgesic use is the most common cause of papillary necrosis, accounting for a third of all cases.⁸⁷

Analgesic Nephropathy

Incidence “Classic” analgesic nephropathy is characterized by chronic tubulointerstitial nephritis with papillary necrosis.¹⁸ Chronic excessive consumption of combination analgesics, particularly those containing phenacetin, was believed to be the major cause and led to the removal of phenacetin and phenacetin mixtures from most world markets. However, contemporary analgesics, particularly aspirin, acetaminophen, and NSAIDs, alone or in combination, are also associated with the development of analgesic nephropathy. A recent review suggests that currently there is insufficient evidence to definitively associate these non-phenacetin-containing analgesics with nephropathy.⁸⁸ Analgesic nephropathy is reported as the primary cause of ESRD by as many as 9% of dialysis patients.⁸⁹

Clinical Presentation Analgesic nephropathy evolves insidiously over years. It is difficult to recognize and may be underdiagnosed as a cause of ESRD. The most sensitive and specific diagnostic criteria include (a) a history of chronic daily habitual analgesic ingestion (classically this equated to daily use for at least 5 years); (b) intravenous pyelography, renal ultrasound, or renal computed tomography imaging, which reveals decreased renal mass and bumpy renal contours; and (c) papillary calcifications.⁸⁹ Frequently, however, imaging

only demonstrates chronic pyelonephritis and small kidneys with thin renal cortices and blunted calyces. Hypertension and atherosclerotic cardiovascular disease are common. Early renal manifestations include impaired maximal urinary concentration, sterile pyuria, microscopic hematuria, and low levels of proteinuria. Urinary tract infection is common. Renal biopsy reveals nonspecific chronic interstitial inflammation and scarring.¹⁸

Pathogenesis Mechanisms of analgesic nephropathy remain unclear. The renal lesion begins in the papillary tip as a result of accumulated toxic metabolites, decreased blood flow, and impaired cellular energy production. The metabolism of phenacetin to acetaminophen, which is then oxidized to toxic free radicals that are concentrated in the papilla, appears to be the initiating factor that causes toxicity by mechanisms analogous to acetaminophen hepatotoxicity. Toxicity is prevented by availability of reduced glutathione. However, salicylates deplete renal glutathione and thereby facilitate phenacetin and acetaminophen toxicity.^{18,79}

Risk Factors The epidemiology of analgesic use and analgesic nephropathy continues to evolve.^{88,90} The classic concept persists that risk for ESRD increases with cumulative consumption of combination analgesics, phenacetin, or acetaminophen and aspirin or NSAIDs. Caffeine contained in combination analgesics may increase risk, but the role is not clear.⁸⁹ Chronic use of therapeutic doses of NSAIDs alone, but not aspirin or salicylates alone, can cause analgesic nephropathy. Case-control studies associate high-dose acetaminophen use alone with an increased risk for ESRD. However, these associations remain inconclusive as a consequence of study design flaws, as acetaminophen has been the preferentially prescribed analgesic for patients with chronic kidney disease.⁸⁸

Prevention Prevention has depended primarily on public health efforts to restrict the sale of phenacetin and combination analgesics. This has effectively reduced analgesic nephropathy in Australia and Europe. However, risk continues with continued availability of non-prescription combination analgesics containing aspirin, acetaminophen, and caffeine in the United States and throughout the world.

Individuals requiring chronic analgesic therapy may reduce risk by limiting the total dose, avoiding combined use of two or more analgesics, and maintaining good hydration to prevent renal ischemia and decrease the papillary concentration of toxic substances. Acetaminophen remains the preferred nonopioid analgesic for patients with preexisting kidney disease.

Management Treatment of established nephrotoxicity requires cessation of analgesic consumption. This can prevent progression and may improve renal function. Renal function indices, including urine output, BUN, and S_{cr} , should be monitored every several months. Patients should also be monitored for the development of transitional cell carcinoma of the renal pelvis, calyces, ureters, and bladder, which may present years after analgesic nephropathy is diagnosed.

RENAL VASCULITIS, THROMBOSIS, AND CHOLESTEROL EMBOLI

Numerous drugs are associated with the development of vasculitis.^{91,92} For example, propylthiouracil is associated with cutaneous, renal, and pulmonary vasculitis; allopurinol is associated with cutaneous, renal, and hepatic vasculitis; hydralazine is associated with cutaneous, renal, and pulmonary vasculitis; and isotretinoin is associated with cutaneous, renal, pulmonary, and gastrointestinal vasculitis.^{91,92} Systemic polyarteritis nodosa, a vasculitis with involvement of small- and medium-size renal arteries, has been described following minocycline use.⁹² Patients may present with hematuria,

proteinuria, reduced renal function, and hypertension. Hydralazine, propylthiouracil, allopurinol, and penicillamine have been implicated in the development of antineutrophil cytoplasmic antibody-positive vasculitis.⁹³ Patients exposed to these drugs who subsequently develop antineutrophil cytoplasmic antibody-positive vasculitis appear to exhibit high titers of antimyeloperoxidase antibodies. Treatment of vasculitis typically consists of withdrawing the offending drug and a tapering course of prednisone, and usually leads to resolution of symptoms within weeks to months.⁹¹

Numerous medications, including mitomycin C, oral contraceptive agents, cyclosporine, tacrolimus, muromonab-CD3, antineoplastic agents, interferon, ticlopidine, clopidogrel, and quinine can cause a thrombotic microangiopathy (hemolytic uremic syndrome or thrombotic thrombocytopenic purpura) manifested by endothelial proliferation and thrombus formation in the renal and central nervous system vasculature.^{94,95} The association with mitomycin C is notable because the pathogenesis appears to be a direct, dose-related toxic effect, rarely occurring in patients who receive doses <30 mg/m². Nephrotoxicity has occurred following chemotherapy with mitomycin C alone or with 5-fluorouracil, cisplatin, bleomycin, a vinca alkaloid, and tamoxifen. Microangiopathic hemolytic anemia and thrombocytopenia are usually present. Systemic endothelial damage with multisystem organ failure has occurred. Kidney injury can be severe and irreversible, although corticosteroids, antiplatelet agents, vincristine, plasma exchange, plasmapheresis, and high-dose intravenous immunoglobulin G have each induced clinical improvement. Gemcitabine is a pyrimidine analog used for the treatment of various solid tumors which was recently associated with the development of hemolytic uremic syndrome, with an estimated incidence of 0.015%.^{12,39}

Anticoagulants and thrombolytics, particularly warfarin, can systemically embolize cholesterol particles from aortic atherosclerotic plaques to small arteries and arterioles, including renal arterioles. These agents remove or prevent thrombus formation over ulcerative plaques, causing emboli.¹ Cholesterol emboli induce an inflammatory obliterative vascular response, causing renal ischemia. Purple discoloration of the toes and mottled skin over the legs are important clinical clues.

COSTS OF DRUG-INDUCED KIDNEY DISEASE

The pharmacoeconomics of drug-induced kidney disease are not well defined. An analysis of aminoglycoside therapy in the acute care environment for 1984 to 1985 revealed 7.3% of patients experienced nephrotoxicity. The mean additional cost for each episode of toxicity (in 1984 dollars) was \$2,501,⁹⁶ and more than \$4,500 per case in the late 1990s.²⁰ Individualized pharmacokinetic monitoring efforts were recently reported to decrease costs associated with aminoglycoside nephrotoxicity by more than \$900 per patient.¹⁹ Outpatient care costs of NSAID toxicity have also been evaluated. Costs for hospital care for NSAID-induced acute hemodynamically-mediated kidney injury and interstitial nephritis combined have been estimated at \$990 million per year.⁹⁷ The risk of ESRD stemming from immunosuppressant-induced nephrotoxicity contributes substantially to the cost of heart transplantation.⁶⁴ The estimated cost per transplantation patient was \$6,700 within 5 years, increasing to \$14,200 within 8 years after transplantation. Finally, patients who develop ESRD require dialysis, which typically costs more than \$50,000 per year.

ABBREVIATIONS

ACEI: angiotensin-converting enzyme inhibitor
AIDS: acquired immune deficiency syndrome

AIN: allergic interstitial nephritis

AKI: acute kidney injury

ARB: angiotensin II receptor blocker

ARF: acute renal failure

BUN: blood urea nitrogen

CKD: chronic kidney disease

COX: cyclooxygenase

CYP: cytochrome P450

DIN: drug-induced nephrotoxicity

ESRD: end-stage renal disease

FGS: focal segmental glomerulosclerosis

GFR: glomerular filtration rate

HIV: human immunodeficiency virus

KIM-1: kidney injury molecule-1

NGAL: neutrophil gelatinase-associated lipocalin

NSAID: nonsteroidal antiinflammatory drug

S_{cr}: serum creatinine

ALAN H. LAU

KEY CONCEPTS

- 1 Glomerulonephritis is a collection of glomerular diseases mediated by different immunologic pathogenic mechanisms, resulting in varied clinical presentation and therapeutic outcomes.
- 2 The signs and symptoms associated with glomerulonephritis can be nephritic in nature, characterized by inflammatory injury, or nephrotic in nature, characterized by proteinuria.
- 3 In the absence of specific and effective therapy for many types of glomerulonephritis, supportive treatments for edema, hypertension, hyperlipidemia, and intravascular thrombosis play important roles in reducing the complications associated with the disease.
- 4 To maximize therapeutic benefits and minimize drug-induced complications, patients have to be monitored closely to assess their therapeutic responses as well as the development of any treatment-induced toxicities.
- 5 Among all the types of glomerulonephritis, minimal-change nephropathy is most responsive to treatment. Steroids can induce good responses in most patients during initial treatment as well as relapse.
- 6 Because of the lack of consistently effective treatment for primary focal segmental glomerular sclerosis, angiotensin-converting enzyme inhibitors or angiotensin receptor blockers are commonly used for patients with mild disease to control symptoms. Steroids and immunosuppressive agents are reserved for patients with severe disease.
- 7 The optimal treatment for lupus nephritis depends on the underlying lesion and disease activity, as well as the severity and duration of the clinical presentation.
- 8 The treatment of poststreptococcal glomerulonephritis is mainly supportive and symptomatic. Antibiotic therapy does not prevent subsequent diseases but may reduce the severity.

Despite the recent advances in cell and molecular biology, the precise pathogenetic mechanisms of many glomerular diseases remain unknown and the available therapeutic regimens are still far from optimal. This chapter provides an overview of the primary causes of

glomerulonephritis with a focus on their etiology, the pathophysiologic mechanisms responsible for glomerular injury, and the clinical presentation of the eight predominant types of glomerulonephritis. Treatment options and monitoring approaches for each of these common forms of glomerulonephritis are also discussed. Although diabetes mellitus and amyloidosis are important secondary causes of glomerular diseases, a thorough discussion of the pathophysiology and management of these entities is beyond the scope of this chapter.

NORMAL GLOMERULAR ANATOMY AND FUNCTION

The glomerulus, which is enclosed within the Bowman capsule, consists of two important components: the filtration barrier and the mesangium (Fig. 50–1). The capillary wall, which serves as a filtration barrier, consists of three well-defined layers: fenestrated endothelium, glomerular basement membrane (GBM), and epithelial cells. The epithelial cells, also known as podocytes, have specialized foot processes embedded in the outer layer of the GBM. It is across this barrier that fluid flows and ultimately forms ultrafiltrate. Under normal conditions, the GBM appears to function as a compact hydrated gel of matrix proteins with a pore-like structure. The mesangium provides support for the glomerular capillaries and also modulates blood flow through the capillaries. It consists of mesangial cells embedded in an extracellular matrix.

The unique capillary bed of the glomerulus allows small nonprotein plasma constituents up to the size of inulin, which has a molecular weight of 5,200 daltons, to pass freely while excluding macromolecules equal to or larger than albumin, which has a molecular weight of 69,000 daltons. Both the size and charge of the molecules affect the ease of passage through the glomerular membrane. Fixed, negatively charged sites are found within the glomeruli in all three layers of the capillary wall: the endothelium, the epithelium, and the GBM. The movement of negatively charged molecules is thus restricted more than that of neutral or positively charged molecules. Different glomerular diseases affect this size- and charge-selective barrier to different extents; consequently, glomerulopathies present with varied clinical features and solute-excretion patterns.

Some of the glomerular cells, such as the epithelial cells, have phagocytic function that can remove macromolecules trapped within the filtration barrier. They are also capable of synthesizing the GBM. In contrast, the mesangial cells regulate glomerular hemodynamics by responding to angiotensin II and producing prostaglandins. They also synthesize and respond to various cytokines and thus play a key role in immune-mediated glomerular diseases. There are also resident phagocytes in the mesangium, removing macromolecules trapped in the basement membrane into the urinary space. These phagocytes are involved in the development of both immune and nonimmune glomerular injury.

FIGURE 50-1. Microanatomy of the glomerulus.

EPIDEMIOLOGY AND ETIOLOGY

In the United States in 2004, glomerulonephritis was the third most common cause of end-stage renal disease (ESRD), accounting for approximately 16% of all the living ESRD patients. About 8,500 patients (8.1% of all patients) develop ESRD because of glomerulonephritis each year.¹

Humoral and cellular immunologic mechanisms participate in the pathogenesis of most glomerulonephritis. Abnormalities in coagulation and metabolism, as well as hereditary and vascular diseases, also contribute to glomerular damage. The histopathologic manifestations vary substantially among the different types of glomerulonephritis. An overview of the primary pathogenetic mechanisms is presented in this section, and specific abnormalities for each of the primary types of glomerulonephritis are presented in subsequent sections.

PATHOPHYSIOLOGY

1 The glomerular lesion may be diffuse (involving all glomeruli), focal (involving some but not all glomeruli), or segmental, also known as local (involving part of the individual glomerulus). The pathologic manifestations may also be described as proliferative (overgrowth of epithelium, endothelium, or mesangium), membranous (thickening of GBM), and/or sclerotic.

The glomerular capillary wall is particularly susceptible to immune-mediated injury. Antigen and antibody tend to localize in the glomerulus, probably because of its high blood flow and capillary hydrostatic pressure. Parenchymal damage can be induced as a result of humoral- and cell-mediated immune reactions (Table 50-1). Antibodies and sensitized T lymphocytes are the primary mediators of glomerular injury.^{2,3}

Production of antibodies to endogenous or exogenous antigens that are recognized as foreign by the host is the first step in humoral immunologic damage to the glomerulus. Endogenous antigens may be intrinsic glomerular antigens, such as Heymann antigen on the epithelial cell or Goodpasture’s antigen on the GBM, or previously sequestered antigens, such as DNA or thyroglobulin. Exogenous antigens are most often viral, bacterial, parasitic, or fungal in origin. Antineutrophil cytoplasmic autoantibodies (ANCA), autoantibodies that react to the cytoplasmic components of neutrophils and mono-

cytes, are found in patients with idiopathic crescentic glomerulonephritis and also in the accompanying vasculitis.

Complexes of antigens and antibodies may be formed in the circulation and then passively entrapped in the glomerular capillary or mesangium. Alternately, experimental antibodies may combine with endogenous glomerular antigens or exogenous antigens entrapped in the glomerulus to form complexes locally, or in situ.³ The type and extent of glomerular damage are dependent on the location of the immune complex formation and the rate at which it is removed. Impaired removal facilitates the growth of the complex and thus increases the likelihood of glomerular damage.

Subsequent to antigen-antibody formation, a series of biologic events is triggered that ultimately leads to glomerular injury. Noninflammatory lesions can result from the binding of noncomplement-fixing antibody to the glomerular epithelial cell (mechanism 1), or the activation of the complement system to form the C5b-9 membrane attack complex (mechanism 2).³ Both mechanisms can damage the glomerular epithelial cell and result in capillary wall injury and proteinuria. Inflammatory lesions are induced by glomerular infiltration of circulating inflammatory cells such as neutrophils, monocytes/macrophages, and platelets (mechanism 3), or proliferation of resident glomerular mesangial cells (mechanism 4), resulting in GBM damage.³ The migration of neutrophils and monocytes to the glomerular tufts is promoted by chemoattractants such as complement fragments (C3a and C5a), platelet-activating factor, interleukin-8, and monocyte chemoattractant protein-1.⁴ Various cytokines, chemokines, and growth factors are then released to participate in the inflammatory process.²

T cells sensitized to glomerular antigen, macrophages, and resident mesangial cells are important participants in cell-mediated injury. Sensitized T cells can cause glomerular hypercellularity in the absence of antibody deposition.²⁻⁴ Cytotoxic T cells may bind with the target cells and destroy them. Alternatively, a delayed-type hypersensitivity reaction may be initiated by activated T cells through the release of lymphokines, to attract, activate, and transform monocytes into macrophages.³ These humoral and cellular mediators, in conjunction with a host of toxic molecular entities including reactive oxygen species, proteinases, eicosanoids, and procoagulants, which are secreted by neutrophils, macrophages, platelets, and resident glomerular cells can alter the permeability, blood flow, and function of the glomeruli. Vascular constriction and occlusion follow and result in the eventual destruction of the glomeruli.

Acute forms of glomerular injury may frequently lead to chronic and persistent renal dysfunction, even though the original immune factors that induce glomerular injury have resolved. Progression to ESRD may be inevitable. Experimental and clinical investigations suggest that a variety of factors may participate in the progression of renal injury. These factors include systemic and glomerular hypertension; high dietary protein intake; proteinuria; glomerular hypertrophy; hyperlipidemia; activation of the coagulation system; abnormalities of calcium and phosphorus balance; and tubulointerstitial injury. Tubulointerstitial injury is an important factor in the progression of glomerular disease. Much interest has been focused on the role of proteinuria in causing glomerular and tubulointerstitial damage. The degree of proteinuria not only is an index of the severity of glomerular disease, but also provides a measure of the rate of progression of renal injury. Heavy proteinuria is an indicator of poor prognosis in various glomerular diseases.

Proteinuria is also accompanied by an increased flux of macromolecules across the mesangium. The mesangial overload may then lead to structural damage. The passage of serum components, such as complement, across the GBM may have a pathophysiologic effect on the glomerular epithelial cells and alter the integrity of the glomerular filtration barrier. The damaging effects of macromolecules other than albumin, such as immunoglobulins, lipoproteins, transferrin, and complement, remain to be characterized.

Membranoproliferative glomerulonephritis	++	+++
Proliferative glomerulonephritis	++	+++
Acute poststreptococcal glomerulonephritis	+	++++
Crescentic glomerulonephritis ^a	+	++++

^aCan be immune complex-mediated, antiglomerular basement membrane antibody-mediated, or associated with antineutrophil cytoplasmic autoantibodies.

CLINICAL PRESENTATION

2 Although patients with glomerular disease may present with an array of signs and symptoms, they are often categorized into one of two broad classifications: nephritic or a nephrotic syndrome (Table 50–2). The unique clinical presentation characteristics of the predominant glomerulopathies are described in the individual disease sections, presented later in the chapter.

Nephritic syndrome reflects glomerular inflammation and frequently results in hematuria. White cells and cellular and granular casts are commonly found in the urine. In contrast, nephrotic syndrome reflects noninflammatory injury to the glomerular structures, and results in few cells or cellular casts in the urine. Initially, there may be limited or no reduction in renal excretory function.

Hematuria occurs when red blood cells leak through the openings of the GBM. The presence of red cell casts is highly indicative of glomerulonephritis or vasculitis. The presence of dysmorphic red blood cells in the urine is suggestive of glomerular disease. The red blood cells are damaged as they pass through the openings in the GBM or the cells may sustain osmotic injury as they travel through the different osmotic environments within the lumen of the kidney tubules.

The presence of proteinuria indicates a defect of the size- and/or charge-selective barriers within the GBM. Normal urinary protein excretion is between 40 and 80 mg/day, with a maximum of 150 mg. Fewer than 20 mg of the excreted proteins are albumin. Most of the albumin that enters the glomerular filtrate is either reabsorbed or catabolized by the tubular epithelium. The dipsticks that are commonly used to identify proteinuria detect only albumin; they become positive when protein excretion is more than 300 to 500 mg/day. They are therefore unable to detect the early stages of renal injury secondary to diabetes mellitus or hypertension, which often result in microalbuminuria with urinary albumin excretion ranges between 30 and 300 mg/day. Chemstrip Micral-Test II (Roche Diagnostics, Indianapolis, IN), a simple immunoassay on a dipstick, permits specific and semiquantitative determination of urinary albumin concentrations at five levels: 0, 10, 20, 50, and 100 mg/L. Another qualitative test, Micro-Bumintest (Bayer Diabetes Care, Mishawaka, IN), registers a positive reading when the urine albumin concentration is greater than 40 mg/L.

Hypertension is common in patients with glomerular diseases, as a result of renal salt retention causing plasma volume expansion. In contrast, increased activity of vasoconstrictors such as angiotensin II is often the cause in patients with chronic glomerular diseases. Scarring of the glomerulus resulting in regional ischemia is thought to be responsible for the hypertension. Activation of the sympathetic nervous system and the release of vasoconstrictor substances may also contribute.

NEPHRITIC SYNDROME

Glomerular bleeding resulting in hematuria is typical in nephritic syndrome. Dysmorphic red cells, especially acanthocytes, are a sensitive and specific marker of glomerular bleeding. The presence of pus and cellular and granular casts in the urine is common. The extent of proteinuria is variable. Patients with severe nephritic glomerular injury have renal function impairment because of the reduced glomerular surface area available for filtration, as a result of constriction of the capillary lumen by proliferating mesangial cells or inflammatory cells.

CLINICAL PRESENTATIONS OF NEPHRITIC AND NEPHROTIC SYNDROMES

General

- The patients are generally not in acute distress

Symptoms

- The patients may not experience any major symptoms

Nephritic Signs

- Hematuria
- Hypertension and edema as renal function declines

Nephrotic Signs

- Edema
- Weight gain
- Fatigue

Laboratory Tests

- Proteinuria (up to 3 g/day or more)
- Pus, cellular and granular casts in urine is common
- Hypoproteinemia
- Hypercoagulable state in some patients
- Proteinuria, >3.5 g/day/1.73 m²
- Hyperlipidemia
- Lipiduria

NEPHROTIC SYNDROME

Nephrotic syndrome is characterized by proteinuria greater than 3.5 g/day per 1.73 m², hypoproteinemia, edema, and hyperlipidemia. A hypercoagulable state may also be present in some patients. The syndrome may be the result of primary diseases of the glomerulus, or be associated with systemic diseases such as diabetes mellitus, lupus, amyloidosis, and preeclampsia. Hypoproteinemia, especially hypoalbuminemia, results from increased urinary loss of albumin and an increased rate of catabolism of filtered albumin by proximal tubular cells. The compensatory increase in hepatic synthesis of albumin is insufficient to replenish the protein loss, probably because of malnutrition.

Edema formation in patients with nephrotic syndrome was traditionally thought to be driven by the reduced plasma oncotic pressure secondary to hypoalbuminemia. If the oncotic pressure is low, the movement of fluid from the vascular space to the interstitial compartment results in a reduction of the plasma volume, which can trigger compensatory renal sodium and water retention through the activation of the renin–angiotensin–aldosterone axis, vasopressin, and the sympathetic nervous system (the “underfill” mechanism). However, experimental data reveal that the plasma volume is actually normal or elevated. Hypoalbuminemia may not cause edema until the serum albumin concentration is less than 2 g/dL. In addition, the transcapillary oncotic pressure gradient is not as high as previously thought because increased lymphatic flow reduces the interstitial oncotic pressure by removing protein and fluid from the interstitium, thereby reducing the transcapillary oncotic pressure gradient.⁵ Instead, fluid retention is likely mediated by a primary increase in sodium reab-

sorption at the distal nephron, which is probably caused by tubular resistance to the action of atrial natriuretic peptide (the “overflow” mechanism).⁶ It is likely that both mechanisms may contribute to nephrotic edema in different patients.⁶

Albuminuria greater than 3 g daily is associated with a significant increase in serum cholesterol concentrations in patients with primary glomerular disease.⁷ Hyperlipidemia in nephrotic syndrome is characterized by elevated serum total cholesterol and triglyceride concentrations, with increased very-low-density lipoprotein (VLDL) and low-density lipoprotein (LDL) cholesterol concentrations. Lipoprotein (a) levels may also be increased. The reduced plasma oncotic pressure as a result of hypoalbuminemia may stimulate hepatic synthesis of lipids and lipoproteins. The increased VLDL production and increased liver cholesterol synthesis, along with a decrease in LDL receptor activity, can then lead to an increase in LDL cholesterol concentrations. In addition, reduced serum albumin or the loss of a liporegulatory substance may result in reduced VLDL clearance.⁸ Nephrotic patients with hyperlipidemia, especially those with concomitant hypertension, are presumed to have an increased risk for atherosclerotic vascular disease. Hyperlipidemia also promotes the progression of glomerular injury, as evidenced by glomerulosclerosis, mesangial expansion, and hyalinosis.^{8,9}

Many patients with nephrotic syndrome have a hypercoagulable state caused by defects of several control proteins in the coagulation cascade. The concentration of the coagulation inhibitor antithrombin III is reduced because of increased loss in the urine. A reduced amount of the coagulation inhibitors proteins C and S, along with increased concentrations of factors V and VIII, increased fibrinogen concentrations, and abnormal platelet function, may also contribute to the hypercoagulable state. The net result of these alterations in coagulation is an increased risk for arterial and venous thrombosis, especially in the deep veins and renal veins. As many as 25% of patients with membranous nephropathy may have renal vein thrombosis.

DIAGNOSIS

Patients with suspected glomerular disease should have an extensive medical history obtained to identify potential systemic causes (Table 50–3). Medication, environmental, and occupational histories may also help identify possible exposure to potentially nephrotoxic agents. A carefully conducted physical examination and laboratory evaluation may reveal the presence of systemic diseases that may contribute to the development of glomerular disease (Fig. 50–2). In addition, the patient’s age, gender, and ethnic background may be helpful in

TABLE 50-3 Evaluation of Patients Suspected of Having Glomerular Disease

Medical history

To identify symptoms of medical conditions that may cause glomerular disease

- Diabetes mellitus
- Amyloidosis
- Systemic lupus erythematosus
- Other familial conditions associated with renal disease

To identify symptoms suggestive of nephrotic syndrome

- Reduced appetite
- Fatigue
- Weight gain
- Edema

Medication, environmental, and occupational histories

To identify possible exposure to potentially nephrotoxic drugs, toxins, or chemicals

Physical examination

To identify signs and symptoms associated with systemic diseases

- Hypertension
- Rash
- Arthritis
- Retinopathy
- Neuropathy
- Lymphadenopathy
- Hepatomegaly
- Malignancy

Laboratory evaluation

Urinalysis

- To determine nephrotic nature of glomerular disease
 - Proteinuria, >3 g/day
 - Lipiduria
- To determine nephritic nature of glomerular disease
 - Hematuria
 - Pyuria
 - Cellular, granular casts

Glomerular filtration rate

- To determine extent of glomerular damage

Other tests

- To identify type and etiology of glomerular disease
 - Serum complement concentration
 - Antinuclear and anti-DNA antibodies
 - Antistreptolysin antibodies
 - Circulating antiglomerular basement membrane antibodies
 - Cryoglobulins

Percutaneous renal biopsy

- To provide definitive diagnosis of glomerular disease

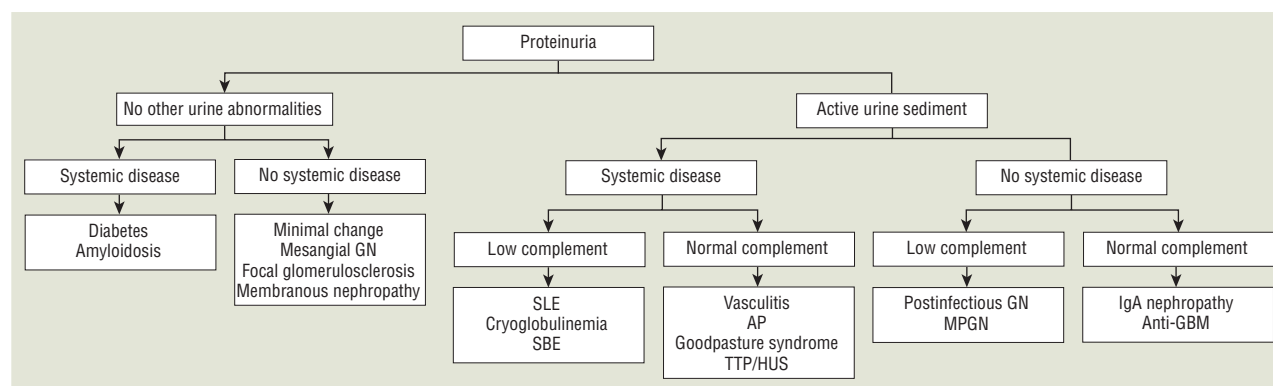

FIGURE 50-2. Clinical presentations of glomerulonephritis. (AP, anaphylactoid purpura; GBM, glomerular basement membrane; GN, glomerulonephritis; HUS, hemolytic uremic syndrome; IgA, immunoglobulin A; MPGN, membranoproliferative glomerulonephritis; SBE, subacute bacterial endocarditis; SLE, systemic lupus erythematosus; TTP, thrombotic thrombocytopenic purpura.)

pinpointing the specific type of glomerular disease. Many of the conditions are more prevalent in certain age groups, although they may occur at any age. For example, proliferative glomerulonephritis is more common in those younger than 40 years of age, whereas the incidence of membranous glomerulonephritis is dramatically higher in those older than 50 years of age.

Laboratory evaluation such as urinalysis can help differentiate the nephrotic or nephritic nature of the disease. The glomerular filtration rate (GFR) may be used to determine the extent of glomerular damage. In the early stages of the disease, the GFR may remain normal. Initial injury to the glomerulus primarily lowers the permeability coefficient (K_p) of the GBM, by reducing the surface area available for filtration and/or the unit permeability of the membrane. The reduced permeability is compensated by an elevation in the glomerular capillary hydrostatic pressure through afferent arteriolar dilation and efferent arteriolar constriction. Extensive glomerular damage may therefore be present before a substantial reduction of total GFR is evident.

Although the cause of glomerular disease may be established from clinical and laboratory evaluation, sometimes percutaneous renal biopsy may be needed to provide a definitive diagnosis.

TREATMENT

Glomerulonephritis

■ GENERAL APPROACH TO TREATMENT

The management of patients with glomerulonephritis involves specific pharmacologic therapy for the glomerular disease, and supportive measures to prevent and/or treat the pathophysiologic sequelae, namely hypertension, edema, and progression of renal disease. In patients with nephrotic syndrome, supportive therapy should also address the management of extrarenal complications of heavy proteinuria, namely hypoalbuminemia, hyperlipidemia, and thromboembolism. Because patients with significant proteinuria tend to have more rapid decline of renal function, reduction of proteinuria thus becomes critical in delaying the rate of progression toward end-stage renal disease.

Immunosuppressive agents, alone or in combination, are commonly used to alter the immune processes that are responsible for the glomerulonephritides. Corticosteroids, in addition to their immunosuppressive effect, also possess antiinflammatory activities. They reduce the production and/or release of many substances that mediate the inflammatory process, such as prostaglandins, leukotrienes, platelet-activating factors, tumor necrosis factors, and interleukin (IL)-1. Movement of leukocytes and macrophages to the site of inflammation is also inhibited. The immunosuppressive effects of corticosteroids are mediated through the inhibition of the release of IL-1 and tumor necrosis factor by activated macrophages, and IL-2 by activated T cells. In addition, the actions of migration-inhibiting factor and γ -interferon are inhibited. Processing of antigens is thus affected by the presence of corticosteroids. Cytotoxic agents, such as cyclophosphamide, chlorambucil, or azathioprine, are commonly used to treat glomerular diseases. Cyclosporine can reduce lymphokine production by activated T lymphocytes and it may decrease proteinuria by improving the permselectivity of the GBM. Mycophenolate mofetil is useful in different glomerulonephritides because of its effects on T and B cell lymphocytes.

Because many immune factors are implicated in the pathogenesis of glomerulonephritis, plasmapheresis may be used to remove these mediators. During the procedure, whole blood is removed from the body and centrifugation is used to separate the cellular elements from the plasma. The cells are then infused back to the patient after

resuspension in saline or plasma substitute. The plasma proteins, presumably including the pathogenic immune factors, are thereby removed from the patient.

Recently, many novel targets were identified and new agents are being evaluated for their usefulness to control the disease, preserve renal function, and improve patient outcome. To stay abreast of the expanding availability of treatment options, one can routinely consult one of the clinical trial registries, such as www.clinicaltrials.gov.¹⁰

■ SUPPORTIVE THERAPY

3 In patients with nephrotic syndrome, dietary measures involve restriction of sodium intake to 50 to 100 mEq/day,¹¹ protein intake of 0.8 to 1 g/day,^{11,12} and a low-lipid diet of less than 200 mg cholesterol. Total fat should account for less than 30% of daily total calories.¹¹ Sodium restriction is important not only in the control of edema, but also in the control of hypertension and proteinuria. Similarly, protein restriction not only helps to reduce proteinuria, but also has a potential role in retarding the progression of renal disease. Patients should also stop smoking because a dose-dependent increase in risk for developing ESRD was observed in men with primary inflammatory (immunoglobulin A glomerulonephritis) or noninflammatory (polycystic kidney disease) renal diseases.¹³

Edema

Management of nephrotic edema involves salt restriction, bedrest, and use of support stockings and diuretics. However, severe salt restriction is difficult to achieve and prolonged bedrest could predispose nephrotic patients to thromboembolism. Hence the use of a loop diuretic such as furosemide is frequently required. Although the delivery of diuretic to the kidney tubules is normal, the presence of large amounts of protein in the urine promotes drug binding, and thereby reduces the availability of the diuretic to the luminal receptor sites. In addition, reduced sodium delivery to the distal tubule secondary to decreased glomerular perfusion may also alter diuretic effectiveness. Large doses of the loop diuretic, such as 160 to 480 mg of furosemide, may be needed for patients with moderate edema (see Chap. 52). In some instances, a thiazide diuretic or metolazone may be added to enhance natriuresis.^{11,14} Alternatively, continuous intravenous infusion of a loop diuretic, such as furosemide 160 to 480 mg/day, may be employed.¹⁵ In patients with morbid edema, albumin infusion may be used to expand plasma volume and to increase diuretic delivery to the renal tubules, thus enhancing diuretic effect. However, it may precipitate congestive heart failure and may also reduce therapeutic response to steroid in minimal-change nephropathy. In patients with significant edema, the goal of treatment should be a daily loss of 1 to 2 lb of fluid until the patient's desired weight has been obtained.

Hypertension

Optimal control of hypertension in patients with glomerular disease is important in reducing both the progression of renal disease and the risk for cardiovascular disease¹² (see Chaps. 15 and 46). The target blood pressure to be 130/80 mm Hg in patients with chronic renal insufficiency defined by GFR <60 mL/min or albuminuria >300 mg/day is 130/80 mm Hg.¹⁶ Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin II receptor blockers (ARBs) delay the loss of renal function in patients with diabetic and nondiabetic (primarily glomerulonephritis) renal diseases.¹⁷ Nondihydropyridine calcium channel blockers (e.g., diltiazem, verapamil) reduce proteinuria and preserve renal function, and could be used as an additional agent. In contrast, the dihydropyridine calcium channel blockers (e.g., nifedipine, amlodipine, or nisoldipine) are effective in lowering blood pressure, but without the benefit of proteinuria reduction.¹⁸

Proteinuria

Dietary protein restriction reduces proteinuria and may retard renal function deterioration. Secondary analysis of the Modification of Diet in Renal Disease Study in patients with moderate renal insufficiency (GFR of 25 to 55 mL/min/1.73 m²) revealed that reduced protein intake (0.66 g/kg/day) delayed the rate of GFR deterioration in patients with severe renal insufficiency (GFR of 13 to 24 mL/min/1.73 m²).¹⁹ Consequently, modest protein restriction of 0.8 g/kg/day is reasonable for patients with moderate renal insufficiency. Decreasing dietary protein also reduces the intake of phosphorus and potassium. In many instances, the potential benefits of protein restriction have to be balanced against the need for protein intake to overcome nutritional deficiencies. For nondialyzed patients who have GFRs of less than 25 mL/min/1.73 m², dietary protein intake should be reduced to 0.6 g/kg/day.¹²

It is now recognized that proteinuria is an independent risk factor for renal function decline and cardiovascular disease.²⁰ Reducing proteinuria can retard renal function loss and delay the progression to ESRD.²¹ The antiproteinuric effect of ACEIs is associated with a fall in filtration fraction, suggesting a reduction in intraglomerular pressure. Recent studies show that ACEIs and ARBs may also have direct effects on podocytes, resulting in reduction of proteinuria and glomerular scarring.²² In addition, angiotensin-converting enzyme (ACE) inhibition may also reduce the effect of angiotensin II on renal cell proliferation, thereby reducing sclerosis. These beneficial effects on proteinuria are beyond what can be attributed by the drug's antihypertensive effects (see Chap. 46).^{23,24}

The combined use of an ACEI and an ARB reduces the rate of renal function decline more than either treatment alone.^{17,25} Such combination maximizes blockade of the renin-angiotensin system by counteracting the effects of angiotensin II produced by non-ACE pathways. In addition, with the blockade of the angiotensin II type 1 receptor, the angiotensin II produced by the non-ACE pathways may still act on the angiotensin II type 2 receptors, further facilitating vasodilation.²⁶ An angiotensin II receptor antagonist should therefore be added to the regimen for those patients who do not attain full and persistent remission of proteinuria with an ACEI alone.

Nonsteroidal antiinflammatory drugs (NSAIDs) probably reduce proteinuria through prostaglandin E₂ inhibition, resulting in a reduction of intraglomerular pressure, a decrease in GFR, and restoration of the barrier size-selectivity of the GBM.¹¹ Indomethacin and meclofenamate are the two most-evaluated NSAIDs. Their antiproteinuric effect is comparable to that attained with ACEIs, and combined treatment with an ACEI results in additional proteinuria reduction.²⁷ However, adherence to a low-sodium diet or concurrent use of a diuretic is needed to maximize the antiproteinuric effect. Because of their potential for nephrotoxicity, especially in patients with poor renal function, long-term use of an NSAID for renoprotection is not preferred.²³

Hyperlipidemia

An abnormal lipoprotein profile increases the risk of atherosclerosis and coronary heart disease in patients with nephrotic syndrome. It is therefore important to treat patients with persistent nephrotic syndrome and sustained dyslipidemia, especially those with high VLDL and LDL cholesterol levels in the presence of a normal or low high-density lipoprotein cholesterol level (see Chaps. 23 and 47). Therapy is especially needed for those with concurrent atherosclerotic cardiovascular disease, or with additional risk factors for atherosclerosis, such as smoking and hypertension.⁸

A low-fat diet is usually not sufficient to correct hyperlipoproteinemia.¹¹ β -Hydroxy- β -methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors, also known as the statins such as lovastatin, pravastatin, simvastatin, and fluvastatin, are considered the treatment of choice.¹¹ They reduce total plasma cholesterol concentra-

tion, LDL cholesterol, and total plasma triglyceride concentrations.⁸ Aside from the lipid-lowering effects, statins may confer renoprotection through different mechanisms, including reduction of cell proliferation and mesangial matrix accumulation and antiinflammatory and immunomodulatory effects.²⁸ Recent clinical studies show that they can reduce proteinuria and delay renal function loss.^{29,30} The combined use of an ACEI with a statin may offer additional benefits in controlling nephrotic hyperlipidemia.¹⁹

Anticoagulation

Renal vein thrombosis, pulmonary emboli, or other thromboembolic events, are serious and common complications of nephrotic syndrome, and are frequently seen in those with membranous nephropathy. Although patients who have documented thromboembolic episodes should be anticoagulated with warfarin until remission of nephrotic syndrome, the use of prophylactic anticoagulation is controversial. A decision analysis study suggested that prophylactic anticoagulation is beneficial in patients with membranous nephropathy.³¹ Anticoagulation should also be considered for those patients at high risk for thrombosis; e.g., those who require prolonged bedrest, those receiving high-dose intravenous steroids, post surgical patients, as well as those who are dehydrated.¹¹

■ DISEASE PROGRESSION AND TREATMENT CONSIDERATIONS

The course and prognosis of the different glomerular diseases are extremely variable and depend on the underlying etiology. In glomerular diseases with a secondary cause, such as poststreptococcal glomerulonephritis, after the initiating factor is removed, the prognosis of the renal disease is often good. In contrast, the rates of renal function deterioration among the primary glomerulonephritides vary according to the form of glomerulonephritis. The majority of patients with minimal-change disease, IgA nephropathy, and membranous nephropathy have a fairly good prognosis. However, those with focal segmental glomerulosclerosis who are resistant to therapy, as well as those with rapidly progressive glomerulonephritis who are untreated, are likely to experience rapid loss of renal function. In some instances, half of the renal function may be lost within a 3-month period. Certain glomerulonephritides, such as minimal-change nephropathy, are very responsive to treatment. In contrast, for some other types of glomerulonephritis, such as membranous proliferative glomerulonephritis, consistently effective therapy has yet to be found.

Because of the variable courses exhibited by the different glomerulonephritides, specific treatment approaches have been developed for each disease. The natural history of the glomerulonephritis has to be well delineated before a promising regimen can be evaluated, from both therapeutic and economic perspectives. Otherwise patients will be exposed to unnecessary treatment-related toxicities if they have a type of glomerulonephritis that is likely to undergo spontaneous remission. The potential therapeutic benefits of treatment regimens should always be weighed against the risks to which the patients are being exposed. It is therefore imperative to identify patients who are most likely to benefit from treatment, especially those who have other risk factors that may contribute to the deterioration of their renal function. In those instances in which satisfactory regimens are not available to treat the primary disease, appropriate supportive measures should be employed. Optimization of systemic and glomerular pressure, reducing proteinuria, and possibly controlling hyperlipidemia may all improve the long-term outcome as well as the quality of life of these patients.

Evaluation of Therapeutic Outcomes

4 Patients should be monitored closely for therapeutic response as well as the development of treatment-related toxicities. Although

the rate of renal function deterioration is an important indicator of the long-term success of treatment, resolution of nephrotic and nephritic signs and symptoms associated with the glomerulopathies is an important short-term therapeutic target.

Serum creatinine concentration as well as creatinine clearance should be evaluated prior to and during treatment; 24-hour urine outflow should be collected to determine the extent of proteinuria. Alternatively, the daily urine protein excretion may be estimated by the urinary total protein-to-creatinine concentration ratio. After establishing the correlation between the 24-hour urinary protein excretion and the protein-to-creatinine ratio, single, random urine specimens may be used in place of a 24-hour urine collection. Blood pressure should be monitored periodically to assess the need for, and the adequacy of, antihypertensive therapy. The pressures should also be evaluated in conjunction with clinical signs and symptoms of edema and fluid overload to gauge the need for volume control as well as diuretic use. For patients with nephrotic syndrome, serum lipid concentrations should be monitored. If the patient has hematuria, urinalysis and a complete blood count should be obtained. The clinician should also be aware of the patient's appetite and energy level, because these are indicators of the patient's overall state of well-being. At times, renal biopsy is needed to assess response to treatment and disease progression, to determine future treatment strategy, and to confirm the initial diagnosis.

Patients receiving cytotoxic drug treatment should be evaluated for drug-related toxicities every week during the initial treatment period. After 1 month of treatment, the frequency of monitoring may be reduced. When the patient is on long-term steroid treatment, monthly visits are often required for assessment of both efficacy and toxicities. If a favorable response is obtained after a course of treatment, the patient may be evaluated every 3 to 4 months. The patient's renal function, proteinuria, urinalysis, blood pressure, lipid profile, and the overall state of health should be assessed during these regular followup visits.

INDIVIDUAL GLOMERULOPATHIES

MINIMAL-CHANGE NEPHROPATHY

Epidemiology and Etiology

Minimal-change nephropathy (also termed *minimal-change disease*) is commonly found in children, accounting for more than 90% of all cases of nephrotic syndrome in children between 1 and 4 years of age. The percentage drops gradually to less than 50% after age 10 years, and accounts for less than 20% of all cases of idiopathic nephrotic syndrome in adults. Secondary causes of minimal-change nephropathy include NSAIDs, lupus, and various T-cell-related disorders, such as Hodgkin disease and leukemias.

Pathophysiology

Minimal-change disease is also known as “nil” disease, primarily because of the absence of definitive pathologic changes observed under light and immunofluorescence microscopy. The characteristic lesion in patients with minimal-change disease, as visualized under electron microscopy, is the spreading and fusion of the foot processes of epithelial cells over an unchanged GBM. *Lipoid nephrosis* is another term that has been used to describe this type of glomerular disease because lipids, as well as renal tubular cells, are found in the urine. The pathogenesis of minimal-change disease is unknown. Altered cell-mediated immunologic response, specifically T-cell dysfunction or changes in the T-cell subpopulations, may be responsible. The activated lymphocytes are thought to secrete lymphokines that reduce the production of anions in the GBM. The

permeability of the GBM to plasma albumin is increased through a reduction of electrostatic repulsion. The loss of anionic charges also results in fusion of the epithelial cell foot processes. Other vascular permeability factors, such as hemopexin, IL-4, and vascular endothelial growth factor, also have been suggested to be responsible.

Clinical Presentation

Most patients present initially with edema, frequently acute in onset, following a nonspecific upper respiratory tract infection, allergic reaction, or vaccinations, which might have activated the T lymphocytes. Nephrotic syndrome with massive proteinuria (substantially more than 40 mg/m² per hour for children and 3 g/day for adults), edema, hypoalbuminemia, and hyperlipidemia is common. The patient's weight may increase dramatically because of sodium and fluid retention. Nephrotic features, such as gross hematuria, are uncommon. Hypertension and decreased renal function are uncommon in children but are more common in older adults.³² In some patients, volume depletion may result in mild to moderate azotemia.

TREATMENT

Minimal-Change Nephropathy

■ PHARMACOLOGIC THERAPY

Steroids

5 Minimal-change disease is most responsive to initial treatment with corticosteroids. In children, steroid therapy is expected to reduce proteinuria in approximately 90% of the patients, with >95% 10-year renal survival.³³ Because of the excellent response to initial therapy with steroids and the prevalence of this glomerular disease in children, reduction of proteinuria secondary to steroid treatment is considered diagnostic for minimal-change disease without the need for biopsy. Prednisone is commonly administered at 60 mg/m² per day initially for 4 to 6 weeks. The dose is then reduced to 40 mg/m² per day every other day for another 4 to 6 weeks, with or without tapering afterwards (Fig. 50–3).³⁴ Proteinuria will disappear in 50% of patients after 1 week and in 90% of patients after 4 weeks of treatment. Different versions of the steroid regimen are available as there is no consensus on the optimal dose and duration. Studies are being conducted to identify to best strategy to induce remission, reduce disease recurrence, and minimize adverse effects of the therapy. Commonly, the initial episode is treated with an extended course (months) of therapy, followed by shorter treatment (weeks) for relapses.³⁵

Initial therapy For adults, prednisone 1 mg/kg per day is given initially for 4 weeks with a reduction to 0.75 mg/kg every other day for the next 4 weeks. Proteinuria will disappear in 50% to 60% of patients after 8 weeks of treatment, and complete remission will be attained in 80% of patients after 28 weeks of therapy.³²

Relapse As many as 85% of the patients who respond to initial steroid therapy (steroid sensitive) will experience a relapse of proteinuria, mostly within 6 to 12 months after disease onset. The risk of relapse is affected by the duration of initial steroid therapy.^{11,34} Children who were asymptomatic with proteinuria diagnosed during routine urine screening tend to have less-frequent relapses and a more favorable clinical course. In those who relapse, 50% to 65% may have steroid-responsive relapse episodes over the subsequent 3- to 5-year period. The dose and duration of steroid treatment for the relapse do not influence the subsequent rate of relapse.^{11,34} Commonly, 60 mg/m² per day of prednisone is given until the urine is free of protein for 3 days, to be followed by 4 weeks of alternate-day prednisone at 40 mg/m² per dose.³⁴

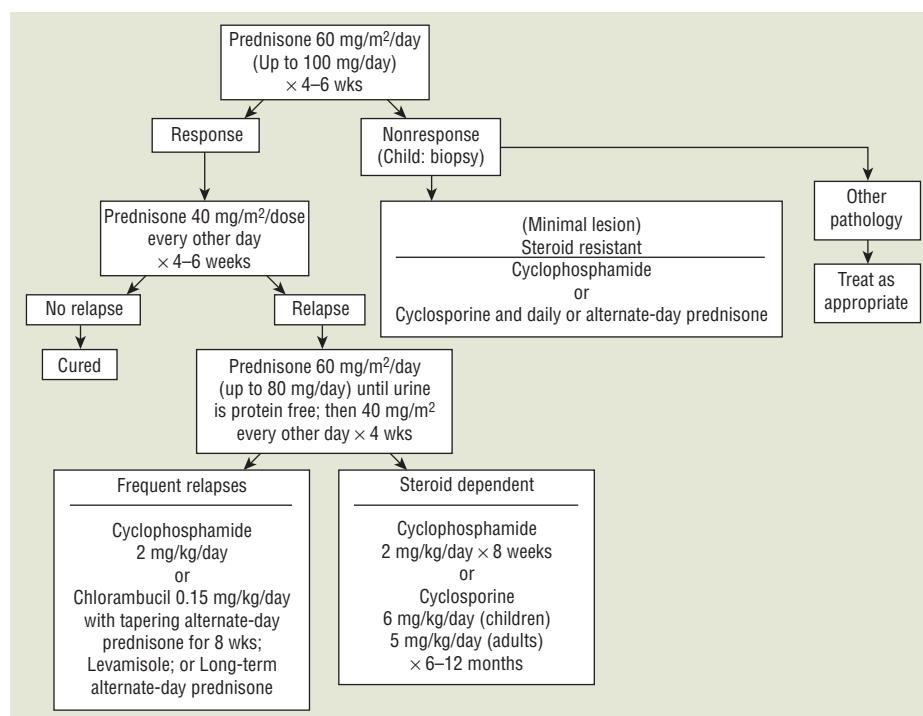

FIGURE 50-3. Treatment algorithm for minimal-change nephropathy. (Modified from reference 34.)

Frequent Relapse Approximately 10% to 20% of children will experience three or four relapses that are responsive to steroid. Half of them will then relapse frequently and become steroid dependent, requiring continuous low-dose alternate-day prednisone to maintain an extended relapse-free period.³⁴ A small number of patients eventually develop resistance to steroids, and a biopsy done at that time often reveals another pathology such as focal segmental glomerulosclerosis. It is controversial whether minimal-change disease progresses into focal segmental glomerulosclerosis or whether the glomerulosclerosis that was present at the time of initial diagnosis was inadvertently diagnosed as minimal-change nephropathy because of tissue-sampling error during the renal biopsy.

Cytotoxic Agents

Cytotoxic agents are often considered for patients who are steroid resistant, as well as for those who require large doses of steroids to sustain remission (steroid dependent). These agents are also beneficial for pediatric patients who experience growth inhibition secondary to chronic use of steroid.¹¹ Cytotoxic agents are effective in inducing remission and the duration of remission tends to be longer than that induced by steroid. In those patients who relapse after cytotoxic therapy, they may respond to steroid better than before.

Cyclophosphamide at 2 mg/kg per day for 10 to 12 weeks given alone or with prednisone (50 to 75 mg/m²) is very effective in inducing remission and restoring steroid responsiveness in patients who were previously steroid dependent and then became steroid resistant. Alternatively, chlorambucil at 0.1 to 0.2 mg/kg per day may be used. This agent, however, is associated with more adverse effects than cyclophosphamide. Azathioprine has also been used; however, treatment for 6 to 12 months is often needed before any favorable response is apparent.

The immunosuppressive effect of cytotoxic agents, with or without the concurrent use of steroids, can result in serious infections, which are the primary cause of death in patients with minimal-change nephropathy. Other toxicities associated with cyclophosphamide include gonadal fibrosis, which results in sterility, hemorrhagic cystitis, alopecia, and a potential to develop malignancy in those on long-term treatment.

Cyclosporine

Cyclosporine decreases lymphokine production by activated T lymphocytes and thereby reduces proteinuria by reversing the lymphokine-induced alterations in the anionic charge and permeability of the GBM to albumin. In patients with steroid-sensitive or steroid-dependent disease, cyclosporine induces remission in 80% to 85% of patients. However, the disease-free period is not often sustained, and relapse, which is usually not as responsive to cyclosporine retreatment, may occur as soon as the drug is tapered or discontinued.³⁶ The steroid-sparing effect of cyclosporine is also useful for steroid-dependent patients, especially those who have experienced significant adverse effects.

The usual starting dose of cyclosporine for remission induction is 5 mg/kg per day for adults and 100 to 150 mg/m² per day for children. Similar dosages are used to maintain remission long-term. The optimal cyclosporine blood concentrations, as well as the need to monitor them, are controversial. No correlation has been found between the severity of the cyclosporine-induced tubulointerstitial lesions and the mean dose or trough drug concentration. However, monitoring of the area under the serum concentration-time curve has been suggested and target exposures have been proposed. Testing the in vitro sensitivity of peripheral blood lymphocytes to cyclosporine in the presence of a T-cell mitogen may offer a novel method to predict response and individualize therapy.³⁷

Because of the risk of toxicities associated with long-term therapy, cyclosporine should not be given for more than 4 months in the absence of any beneficial effect.³⁶ Consequently, it is indicated for patients (a) who relapse frequently or are steroid dependent, after failing to respond to a course of cyclophosphamide; (b) for whom cyclophosphamide is contraindicated or when gonadal toxicity is a concern; (c) who are steroid dependent when a “steroid holiday” is needed for catch-up growth and puberty; or (d) who have steroid-resistant disease.³⁴

Levamisole

Levamisole, an immunostimulant, can promote the maturation of young T cells and restore the function of T cells and phagocytes

when the immune system is depressed. It may also inhibit the production of an immunosuppressive lymphokine. Levamisole was found to have a steroid-sparing effect and was capable of maintaining remission in children who had frequent relapse steroid-dependent nephrotic syndrome.³⁸ In addition, it is as effective as cyclophosphamide in reducing relapse rate and steroid dosages.³⁹ The most serious adverse effect of levamisole is neutropenia, which is generally reversible. At present the drug is no longer available in the United States; however, it is still used elsewhere in the world for selected steroid-dependent patients.

Mycophenolate Mofetil

Mycophenolate mofetil is an immunosuppressant that can suppress T- and B-cell lymphocyte proliferation, B-lymphocyte antibody production, and expression of adhesion molecules. It is reported to have steroid-sparing effects and to be useful in steroid-dependent patients, as well as in those who fail cytotoxic therapy.^{40,41}

Therapeutic Outcomes

The long-term prognosis of most patients with minimal-change disease is good. The majority of pediatric patients will not experience any relapse of the disease 10 years after the initial onset, and most will be free of the proteinuria after puberty. In adults, an 85% to 90% survival rate is seen 10 years after disease onset. Although this condition may spontaneously remit in up to 70% of untreated adults, life-threatening complications may be associated with untreated nephrotic syndrome. Significant deterioration in renal function is uncommon in both adult and pediatric patients and is observed only in those who are steroid resistant or steroid dependent. Because of the overall favorable outcome of the disease and the relatively uncommon progression into chronic renal failure, aggressive use of cytotoxic agents is not indicated even in most patients with frequent relapses. Toxicities associated with aggressive therapy do not justify the need to induce remission in those patients who fail to respond to steroids and the nonaggressive use of cytotoxic agents. Symptomatic therapy with diuretics to control edema, in conjunction with a low-salt diet and albumin infusion as needed for acute development of anasarca, is often a more rewarding therapeutic approach. NSAIDs and ACEIs may also be used to reduce the proteinuria.

FOCAL SEGMENTAL GLOMERULOSCLEROSIS

Etiology and Epidemiology

Focal segmental glomerulosclerosis (FSGS) is a clinicopathologic condition that can be idiopathic (primary) or secondary to a variety of causes. FSGS accounts for less than 15% of the cases of idiopathic nephrotic syndrome in children, and approximately 15% to 20% in adults; however, it may account for 36% to 80% of the cases in African Americans.⁴² The incidence of FSGS has been rapidly increasing, so that it now is the most common glomerular disease causing ESRD. Conditions such as sickle cell disease, cyanotic congenital heart disease, and morbid obesity can induce hemodynamic stress on an initially normal nephron population and result in FSGS. Severe glomerular injury can also be seen in patients with nephropathy associated with heroin abuse, human immunodeficiency virus (HIV) infection, and genetic mutations involving the podocin and WT1 genes.⁴² The primary and secondary sclerotic lesions may be morphologically similar, but they represent diseases with different courses and responses to therapy.

Pathophysiology

Sclerotic lesions are characteristically found in some of the glomeruli (focal) and usually involve only a portion of the glomeruli (segmen-

tal).⁴³ Similar to minimal-change disease, fusion of foot processes is commonly seen in those glomeruli that are not sclerotic. It is thought that both minimal-change disease and FSGS share similar pathogenetic mechanisms, with FSGS resulting in severe injury to the glomerular epithelial cells. During the early stage of FSGS, only a small number of glomeruli may have the segmental sclerotic lesion and the disease may be confined to the juxtamedullary region. If an inadequate number of glomeruli are sampled during renal biopsy, the diagnosis of FSGS may be missed, or the patient may be thought to have minimal-change disease. Resistance to steroid therapy may thus be one of the first clues that the patient, indeed, has FSGS rather than minimal-change disease. Alternatively, a patient may have the steroid-sensitive minimal-change disease initially, which subsequently progresses to steroid-resistant FSGS.

Clinical Presentation

Almost all the patients present with proteinuria, and many of them have all the features of nephrotic syndrome. The proteinuria is nonselective, containing albumin and other higher-molecular-weight proteins, and is usually less severe when compared to patients who have minimal-change disease. Hypertension, microscopic hematuria, and renal dysfunction may be seen in up to half of the patients. Reduced renal function becomes more prevalent as the disease progresses.

The presenting clinical features in nephrotic adults with minimal-change nephropathy can be indistinguishable from that of FSGS, and renal biopsy is therefore critical in the treatment of adults with nephrotic syndrome. African Americans have a four-time higher risk of developing FSGS than white or Asian patients. They tend to develop the disease earlier and present with nephrotic range proteinuria more often. They are less responsive to steroids and are more likely to experience a rapid decline in renal function, resulting in ESRD.

TREATMENT

Focal Segmental Glomerulosclerosis

■ PHARMACOLOGIC THERAPY

Steroids

⑥ The treatment of FSGS is controversial because of the lack of data from randomized, prospective, controlled trials. A course of prednisone (1 to 2 mg/kg per day) with tapering after 3 to 4 months of treatment is first used for nephrotic patients.^{42,43} Urinary protein excretion and serum albumin concentration should be monitored to assess efficacy. The median time to induce complete remission is 3 to 4 months, although 5 to 9 months may be needed in some patients.⁴² In general, 30% to 40% of all patients can be expected to attain complete remission; for those who are not responding, treatment should be continued for 6 months before they are considered steroid resistant.⁴⁴

If the patient develops a relapse after an adequate response to the initial treatment, a second course of steroids is generally sufficient.⁴² However, if relapse occurs frequently, cytotoxic agents or cyclosporine would be indicated.

For patients who are not nephrotic, their relatively favorable prognosis does not support using steroids or other immunosuppressive agents. However, close followup and good blood pressure control with ACEIs are necessary to minimize disease progression.⁴³

Most of the studies conducted thus far include mostly white patients. In a recent retrospective review of 72 patients that included 65 African American patients, steroid use was not found to associate

with renal survival or the induction of proteinuria remission.⁴⁵ The initial creatinine level, blood pressure, and severity of renal lesion are significant factors for renal survival. About one third of the patients who received steroids developed complications such as diabetes and significant weight gain.

Cytotoxic Agents

When used with steroids during initial therapy, cytotoxic agents were not found to offer any additional beneficial effect.⁴² In those patients who are not responding to steroids during initial therapy, cytotoxic agents such as cyclophosphamide (2 mg/kg/day) and chlorambucil (0.1 to 0.2 mg/kg/day) have been used with pulse methylprednisolone to induce remission. Response rates as high as 66% have been reported in uncontrolled trials, although such favorable responses have not been universally observed.⁴²

Cyclosporine

In steroid-resistant patients, cyclosporine therapy has produced a complete or partial remission in 70% of patients, with a relapse rate of 47%.⁴⁶ Encouraging results have also been reported with the concurrent use of cyclosporine and steroid.⁴² Adverse effects of cyclosporine commonly include gingival hyperplasia, hypertrichosis, hypertension, and renal insufficiency. In an attempt to minimize the long-term side effects, a regimen that included periodic cyclosporine dose reduction when given with steroid, cyclophosphamide, and mycophenolate mofetil was developed and favorable effects were observed.⁴⁷

Mycophenolate Mofetil

Mycophenolate mofetil has been reported by several small studies to have favorable effects in patients who were steroid resistant, many of whom had failed to respond to other cytotoxic agents and cyclosporine.⁴⁸ Forty-four percent of the patients had reduced proteinuria and the improvement was sustained in 50% for up to 1 year. Deterioration of renal function was not observed. Other investigators have reported similar experiences. Further studies are needed to define the role of this agent among the various treatment options.

Symptomatic Therapy

Because of the lack of a consistently effective regimen for primary FSGS, many patients with mild disease are treated conservatively. ACEIs and ARBs are effective in reducing proteinuria and in stabilizing renal function in many patients with primary or secondary FSGS.⁴² For patients who have nephrotic range proteinuria, elevated serum creatinine concentration and interstitial scarring on biopsy, corticosteroids with or without immunosuppressive agents are often used.

THERAPEUTIC OUTCOMES

ESRD develops within 10 years in 10% or less of the 30% to 50% of adults and children who had attained complete remission.^{46,49} For those patients who are resistant to therapy, the rate of renal function deterioration to ESRD may be rapid, within 1 year, or slow, over as long as 10 to 20 years; approximately 50% develop ESRD within 10 years.⁴⁹ Those patients with severe proteinuria (>10 to 15 g/day), high serum creatinine concentration at diagnosis, initial steroid resistance, or interstitial fibrosis on renal biopsy are likely to have a more rapid decline in renal function.⁴³ African American patients may also have a higher risk. Kidney transplantation is often indicated for those patients who develop ESRD; however, FSGS has recurred in 20% to 50% of the renal allografts soon after transplantation. Children and those with severe disease or rapid progression to ESRD prior to

transplantation are more likely to experience a recurrence. The proteinuria may reappear within hours after transplantation and graft failure may occur in one third to one half of the patients. The median time to recurrence was reported to be 14 days in one study. Although cyclosporine is ineffective in preventing the recurrence of nephrotic syndrome after transplantation, a high dose of the agent (up to 35 mg/kg per day) induces a remission of the recurrent disease. ACEIs and plasmapheresis are also used to prolong graft survival. The effectiveness of these therapies and the rapid recurrence of the disease in the transplanted kidney substantiate the possibility that a circulating humoral mediator is responsible for the nephropathy.

MEMBRANOUS NEPHROPATHY

Etiology and Epidemiology

Membranous nephropathy is the most common disorder responsible for idiopathic nephrotic syndrome in adults, accounting for about 20% to 25% of cases. It is also a frequent cause of renal failure secondary to glomerulonephritis. The hallmark histologic features of membranous nephropathy are glomerular capillary wall thickening with subepithelial deposits under light and electron microscopy. Most cases are idiopathic, but approximately 25% of adults and 80% of children have secondary causes.^{50,51} In the United States, the most common etiologies are autoimmune diseases (e.g., lupus), infection (e.g., hepatitis B and C), syphilis, neoplasm (e.g., carcinoma of the lung, breast, gastrointestinal tract, or kidney), and medications (e.g., gold, penicillamine, or captopril). Malaria and schistosomiasis are common causes in other parts of the world. De novo membranous nephropathy can also occur in the allografts of renal transplant patients. Because the response to therapy as well as the prognosis for idiopathic and secondary membranous nephropathy are different, it is important to identify any potential underlying causes for the nephropathy prior to treatment. Although this glomerular disease can occur at any age, the peak incidence is between ages 30 and 50 years and is especially likely in patients older than age 50 years who present with nephrotic syndrome.⁵⁰

Pathophysiology

Examination of kidney tissue under light microscopy reveals normal mesangium and normocellularity. The glomerular capillary wall may be thickened in well-developed lesions. In the advanced stage, the capillary wall is markedly thickened and intramembranous deposits are found. Progressive changes in capillary lumen patency parallel those in the GBM, resulting in glomerulosclerosis with capillary collapse and tubular atrophy in end-stage membranous nephropathy. Immunofluorescence microscopy shows strong capillary wall staining of IgG and C3 on the epithelial side of the basement membrane. Antibody-mediated immune injury appears to be the main pathogenetic mechanism. The immune complex can be formed in situ or deposited from circulating immune complexes.

Clinical Presentation

Most patients with membranous nephropathy present with heavy proteinuria (exceeding 3.5 g/day). Those patients excreting large amounts of IgG and α_1 -microglobulin, indicating more significant tubulointerstitial damage, have a lower remission rate and are more likely to progress toward renal failure.⁵⁰

The signs and symptoms are usually insidious in onset and may consist of anorexia, malaise, edema, anasarca, or ascites, and pericardial and pleural effusions may also be present. As a result of a hypercoagulable state, pulmonary embolism may develop, but rarely results in death. The incidence of renal vein thrombosis varies from 5% to 62%,⁵¹ and membranous nephropathy should be suspected when there is a sudden onset of hematuria; loin pain; pulmonary

embolus; fluctuating or worsening proteinuria or glomerular filtration rate; renal tubular acidosis; or an increase in leg edema. Hypertension is found in approximately 30% of patients and is more common with renal insufficiency or in advanced disease.

In addition to heavy proteinuria, urinalysis often reveals lipiduria and oval fat bodies. Microhematuria is seen in fewer than 25% of patients, and gross hematuria and red cell casts are rare. In idiopathic membranous nephropathy, the serum complement concentrations are normal. Low levels of complement should alert one to search for secondary causes, such as lupus, hepatitis B infection, or an alternative diagnosis. Similarly, antinuclear antibodies, anti-DNA antibodies, rheumatoid factor, hepatitis B serologies, and serum cryoglobulins are generally negative in idiopathic membranous nephropathy. Occult malignancy has been found in as many as 10% of elderly patients with membranous nephropathy.

The natural course of idiopathic membranous nephropathy is variable. Up to 30% of the patients experience spontaneous remission, commonly within 2 years of disease onset. Half of the remaining patients have persistent proteinuria with long-term preservation of renal function, while the other half has gradual loss of renal function.⁵⁰ Heavy proteinuria (>10 g/day); male gender; elevated serum creatinine concentration at the time of presentation; poorly controlled hypertension; advanced age at onset of disease; non-Asian race; certain human leukocyte antigen phenotypes; and tubulointerstitial fibrosis on initial renal biopsy are associated with progressive renal disease.^{50,51} A predictive algorithm, incorporating the level of proteinuria, initial creatinine clearance, as well as the slope of renal function decline over 6 months, has been developed to determine the risk for disease progression.⁵⁰

In general, patients with idiopathic membranous nephropathy have a relatively benign course with mean 10-year survival of approximately 70%. Those who present with persistent nonnephrotic proteinuria seldom develop renal insufficiency and have a normal life expectancy. Fewer than 10% of patients develop a remitting and relapsing course.⁵¹ The prognosis for secondary membranous nephropathy depends on the underlying cause. Remission occurs when the infection resolves or when the causative medication is withdrawn.

TREATMENT

Membranous Nephropathy

The treatment of idiopathic membranous nephropathy is controversial and ranges from supportive therapy to immunosuppression.

Conservative management of patients with mild disease includes edema control with salt restriction and diuretics⁵ and reduction of proteinuria with protein restriction and ACEIs (Fig. 50–4).⁵¹ Management of hypertension and hyperlipidemia is required for most patients, whereas prophylactic anticoagulation, despite having benefits shown to outweigh the risks, is usually given only for patients with renal vein thrombosis or documented pulmonary embolus.^{31,51}

■ PHARMACOLOGIC THERAPY

Steroids

Remission of proteinuria, whether spontaneously or treatment related, may confer a good prognosis. Corticosteroids alone were ineffective in improving proteinuria remission rate in all controlled trials and in preventing progression in all but one study.⁵¹ The result of a meta-analysis also confirmed the lack of efficacy of steroids when used alone.

Cytotoxic Agents

Cytotoxic agents, when used in conjunction with corticosteroids, are effective in increasing the remission rate of proteinuria and preserving renal function. Ponticelli and colleagues devised such a regimen by combining intravenous methylprednisolone (1 g) for 3 days followed by oral methylprednisolone (0.4 mg/kg) for the subsequent 27 days of months 1, 3, and 5. Oral chlorambucil (0.2 mg/kg) is to be given daily in months 2, 4, and 6.⁵² The 10-year renal survival was increased to 92% when compared with 60% in the control group. They later substituted cyclophosphamide (2.5 mg/kg per day) for chlorambucil, which resulted in similar rates of proteinuria remission and relapse, but with fewer serious side effects in those who received cyclophosphamide.⁵³

Results from a recent meta-analysis of randomized, controlled trials affirmed that cytotoxic agents, but not steroids, are effective in reducing nephrotic-range proteinuria, with cyclophosphamide having fewer adverse effects than chlorambucil.⁵⁴

Cyclosporine

A controlled trial found that cyclosporine, given at a dose of 3 to 4 mg/kg/day for 6 months, was effective in patients with medium risk for disease progression.⁵⁰ For patients with severe nephrotic syndrome and deteriorating renal function who do not respond to cytotoxic therapy, cyclosporine may offer some benefits; however, the risk for cyclosporine nephrotoxicity is of concern, especially

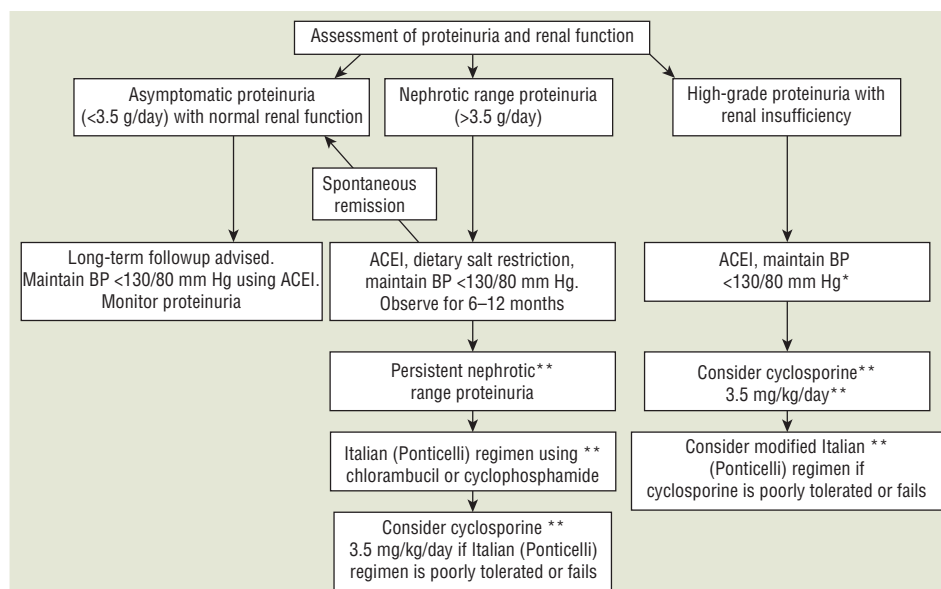

FIGURE 50-4. Treatment algorithm for idiopathic membranous nephropathy. Patients may change from one category to another during the course of followup. *, Supported by evidence from controlled trials; **, introduction of risk reduction strategies for both secondary effects of disease and adverse effects of immunotherapy; (ACEI, angiotensin-converting enzyme inhibitor; BP, blood pressure.) (Modified from reference 51.)

during long-term therapy. A 12-month course of cyclosporine (mean dose: 3.8 mg/kg/day) was found to reduce proteinuria as well as the rate of renal deterioration.⁵⁵ In a recent study of 41 patients who received cyclosporine, many with concurrent steroid and ACE inhibitor therapy, the median treatment time to complete remission was 225 days among the 34% of patients who attained complete remission.⁵⁶ During such long-term treatment, hypertension may be exacerbated and the serum creatinine concentration may be increased because of nephrotoxicity. When the renal function declines, the dose of cyclosporine should be reduced.

Alternative Therapeutic Options

Because spontaneous remission is common and only approximately 25% of patients with new-onset idiopathic membranous nephropathy ultimately develop ESRD in 20 to 30 years, it is prudent not to aggressively treat all patients at the onset of the disease. Patients who have a low risk for renal disease progression can be managed with observation and symptomatic therapy. Normalizing the blood pressure and reducing proteinuria with ACEIs and/or ARBs are important as both hypertension and proteinuria are independent risk factors for the progression of renal failure.⁵⁰ Patients with low risk for renal disease progression include children 2 to 16 years of age, adult males with proteinuria less than 2 g/day, or adult females with proteinuria less than 5 g/day and normal renal function. In contrast, patients who have a high risk of developing renal failure, including those with proteinuria greater than 10 g/day with or without impaired renal function, and patients with symptomatic nephrotic syndrome with a plasma albumin of less than 2 g/dL, should be aggressively treated to induce remission. An alkylating agent such as cyclophosphamide or chlorambucil, combined with steroids, should be given to induce remission. Recently, mycophenolate mofetil, rituximab, and eculizumab were shown separately to be effective in treating a small number of patients.^{57–59} A synthetic analog of adrenocorticotrophic hormone, tetracosactide, has also been shown in small studies to offer results superior to the cytotoxic–steroid combination regimen.⁶⁰

The cytotoxic–steroid combination regimen may be effective in inducing remission in the 30% to 40% of the medium-risk patients who relapse within 2 years after treatment discontinuation. Alternatively, cyclosporine may be used with similar effectiveness.⁵⁰ The cyclophosphamide–steroid combination should also be used for relapse in high-risk patients.

In patients with a transplanted kidney, both de novo and recurrent membranous nephropathy may occur. Patients with primary membranous nephropathy are more at risk. Recurrence is typically associated with nephrotic syndrome and a high risk of allograft failure from disease and/or rejection.

MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS

Etiology, Epidemiology, and Pathophysiology

Membranoproliferative glomerulonephritis (MPGN) is one of the least-common renal morphologic entities that occurs in older children and adults. For some unclear reason, the incidence of MPGN has been decreasing over the past few decades in the United States and Europe. However, in Africa and Asia, idiopathic MPGN is still common, perhaps secondary to exposure to unrecognized infectious and parasitic agents.

The several types of MPGN are classified according to the pathologic features. Type I MPGN, also known as mesangiocapillary glomerulonephritis, is characterized by diffuse thickening of glomerular capillary walls and mesangial hypercellularity. Immune complexes are presumed to have a major role in the pathogenesis of type I MPGN, which is the most common type of primary, idiopathic MPGN.

Type II MPGN is also known as dense-deposit disease because of the presence of dense deposits of C3 within the glomerular basement membrane, which gives rise to a ribbon-like appearance. Other variants of the disease include type III MPGN, which is seen rarely and consists of subendothelial and subepithelial deposits with lamination and disruption of the lamina densa of the GBM.

Type I MPGN is a slowly progressive disease that accounts for 80% of all MPGN, but only 5% to 15% of all cases of nephrotic syndrome seen in pediatric and adult patients. It occurs most frequently in patients between 5 and 30 years of age, and because remissions are rare, many patients eventually develop ESRD. The renal survival is 60% to 65% at 10 years, and the presence of nephrotic syndrome, interstitial disease, and hypertension are poor prognostic indicators.⁶¹ Type II MPGN is a more aggressive disease that constitutes approximately 15% of all patients with MPGN. Only 20% of patients remain stable for more than a few years and the median time before the development of ESRD is 7 years.

Clinical Presentation

Nephrotic syndrome is the most common presenting condition although some patients may also have a nephritic component (hematuria), hypertension, and renal insufficiency. Hypocomplementemia is commonly seen.

TREATMENT

Membranoproliferative Glomerulonephritis

■ STEROIDS

The efficacy of corticosteroids, cyclophosphamide, antiplatelet drugs, and anticoagulants has been evaluated for the treatment of MPGN. In children, prednisone 40 mg/m² given on alternate days is effective, when compared with placebo, in reducing the decline in GFR.⁶² This observation was confirmed by other uncontrolled studies.⁶¹ Consequently, prednisone should be given for 6 to 12 months to children with MPGN, proteinuria (more than 3 g/day), and/or impaired renal function.⁶¹ Other studies suggest that this regimen may also be beneficial in children with mild proteinuria.

Although the effect of steroids has not been proven in adults, antiplatelet drugs, such as dipyridamole and aspirin, as well as warfarin, were found in randomized controlled trials to reduce proteinuria, but had no effect on GFR.⁶¹ Subcutaneous heparin has also been used in a small number of patients with favorable results.⁶³ Adult patients with idiopathic MPGN, heavy proteinuria, and/or impaired renal function should be given dipyridamole or aspirin. Unfortunately, no controlled study comparing the effect of steroids with antiplatelet agents is yet available.

■ CYTOTOXIC AGENTS

Cyclophosphamide and azathioprine were found to have no beneficial effect. Cyclosporine was evaluated in a limited number of patients with MPGN with some beneficial effect; however, the trials were not controlled or randomized.⁶⁴ In addition, the risks for developing adverse effects were high. Figure 50–5 presents an algorithm for treatment and followup of MPGN.

■ ANTIPLATELET AGENTS

Although several studies have shown dipyridamole and aspirin to reduce proteinuria, reduction of GFR decline was not generally observed.⁶¹ Consequently, antiplatelet therapy should be considered

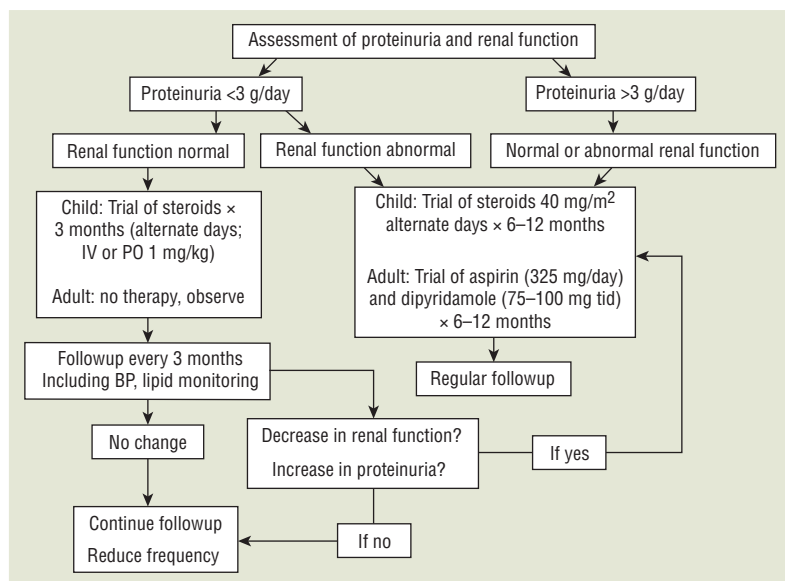

FIGURE 50-5. Treatment algorithm for membranoproliferative glomerulonephritis. (BP, blood pressure.) (Modified from reference 61.)

as a viable option only for those patients with significant proteinuria. There should be periodic followup of patients to assess proteinuria and renal function.

It is difficult to conduct large-scale controlled trials for MPGN because of the low incidence of the disease. Based on the available studies, many of the drugs evaluated do not have any consistent, beneficial effect on renal function and proteinuria. Renal transplantation is an alternative; however, the recurrence rate is close to 100% for type II MPGN and is approximately 20% to 30% for type I MPGN. Half of the allografts ultimately fail.⁶³

IMMUNOGLOBULIN A NEPHROPATHY

Etiology and Epidemiology

IgA nephropathy, also known as Berger disease, was first described in France in 1968. It now is the most common primary glomerulonephritis in the world, and accounts for 10% of patients with ESRD in many countries. The prevalence among patients with glomerulonephritis or patients who had kidney biopsy varies from as high as 50% in Japan and East Asia to 10% to 30% in Europe. In the United States, the overall prevalence is approximately 10% to 15%, but is as high as 35% among Native Americans living in New Mexico.⁶⁵ These differences in prevalence may reflect variations in genetic predisposition, as well as the criteria used for urinary screening and kidney biopsy.

IgA nephropathy is more frequently seen in younger adults and is two to six times more common in males than in females. It is uncommon in blacks, both in the United States and in Africa.⁶⁵ IgA nephropathy was once thought to be a benign disease presenting with asymptomatic hematuria; however, its ability to present with any clinical syndrome associated with glomerular disease is now recognized. Some patients will develop ESRD over variable periods of time.

Pathophysiology

Primary IgA nephropathy is an immune-complex-mediated disease in which IgA deposits and other pathologic lesions are found in kidney tissues. In contrast, Henoch-Schönlein purpura, a systemic disease that is believed to be closely linked to IgA nephropathy, shares similar immunohistologic findings in the kidneys. Both typically have vasculitis affecting the joints, skin, and gastrointestinal tract, which may result from the same pathologic process of IgA nephropathy. The diagnosis of IgA nephropathy is established by the presence of mesangial IgA deposits upon immunofluorescence examination of the kidney biopsy. The IgA immune complex, composed of IgA

antibody bound with an environmental antigen, such as a virus, bacteria, or food substances, is presumed to be deposited from the systemic circulation. Alternately, the complex may be formed in situ, with the IgA antibody bound with an endogenous antigen in the mesangium. In the mesangium, IgA can bind with receptors on the mesangial cells to induce proliferation and cytokine production. In addition, it can activate complement through the alternate pathway to induce glomerular damage.⁶⁶ The extent of the injury depends on the characteristics of the IgA that favor mesangial deposition, the susceptibility of the mesangium toward deposition, the ability to mount an inflammatory response to the deposits, and the response of the kidney to the injury in a way that favors progressive renal damage.⁶⁷

Clinical Presentation

IgA nephropathy commonly presents in the second and third decades of life, but it can occur at any age. Many patients have microscopic hematuria and proteinuria for years, persistently or intermittently, during the early stages of the disease. About half of the patients present with gross hematuria concurrent with an infection, commonly in the upper respiratory tract.⁶⁵ The hematuria may occur 1 to 2 days after the onset of infection symptoms, which is different from the 10- to 14-day delay seen after the pharyngitis in poststreptococcal glomerulonephritis. Proteinuria is common and nephrotic range often indicates advanced disease. Hypertension and edema are infrequent but are common in poststreptococcal glomerulonephritis.

Renal dysfunction is uncommon at the initial presentation; however, approximately 10% to 20% of the patients develop ESRD within 10 years, and 30% develop it after 20 years.⁶⁸ Hypertension, severe proteinuria, renal function impairment, old age, and the severity of histologic lesions are all predictive factors for poor long-term outcome.^{66–68}

TREATMENT

Immunoglobulin A Nephropathy

Spontaneous remission is seen in only 10% to 25% of children and 5% to 7.5% of adults. Unfortunately, no therapy is known to be consistently effective for the treatment of IgA nephropathy. Because of the slow progression of the disease to ESRD, it is very difficult to conduct trials to evaluate the long-term effectiveness of specific treatments. The lack of understanding of the pathogenetic mecha-

nisms and the unavailability of appropriate animal models severely limit the development of rational treatment regimens.

■ NONPHARMACOLOGIC THERAPY: LOW-GLUTEN DIET AND TONSILLECTOMY

Restriction of dietary gluten is effective in patients with celiac disease, but not in patients with no identifiable nephritogenic antigens.⁶⁹ Removal of the tonsils, which produce IgA₁ and may contribute to IgA nephropathy, may reduce proteinuria and hematuria. This is especially helpful in patients who developed recurrent macroscopic hematuria as provoked by bacterial tonsillitis. There are limited studies to show the long-term renoprotective effects of tonsillectomy; however, larger studies with longer followup are needed to affirm such beneficial effect.⁶⁷

■ PHENYTOIN

Phenytoin was evaluated because of its ability to reduce the amount of polymeric IgA in the circulation.⁶⁹ Although it reduced serum IgA concentrations and frequency of macroscopic hematuria, the glomerular lesions deteriorated in some of the patients and the drug is not generally used nowadays.

■ CORTICOSTEROIDS

Corticosteroids with or without immunosuppressive agents have been used to treat IgA nephropathy for many years. A recent meta-analysis of available trials showed that steroid therapy is associated with reduction in proteinuria, risk for progression to ESRD, as well as the rate of renal function deterioration.⁷⁰ Low-dose, short-term (<3 months) steroid therapy is not expected to yield favorable results. In contrast, larger doses of steroids (IV methylprednisolone 1g/day for 3 days at months 1, 3, and 5, and oral prednisone 0.5 mg/kg every other day for 6 months) were able to reduce proteinuria and renal function deterioration.⁷¹ However, the dose of the steroids and the risk for toxicity might be considered high by many.⁶⁷ Patients with nephrotic range proteinuria and impaired renal function are likely candidates for steroid therapy; however, the responses to such treatment are not favorable.

■ CYTOTOXIC AGENTS

Several studies have evaluated the efficacy of azathioprine and cyclophosphamide. In some of the studies, cyclophosphamide was used in conjunction with dipyridamole, heparin and warfarin. It is difficult to assess which of these agents contributed to the limited favorable effects observed. In addition, in many of these studies, blood pressure control and ACE inhibition were not always optimal. At present, there is no clear evidence to support the use of these cytotoxic agents for IgA nephropathy, except perhaps for those patients with advanced rapidly progressive disease.⁶⁷

■ FISH OIL

The third approach is to reduce glomerular inflammation and glomerulosclerosis induced by IgA deposits. Antiinflammatory agents, antiplatelet drugs, and anticoagulants have been tried without success to decrease the production or action of mediators responsible for IgA immune complex-induced glomerular damage. However, the *n*-3 fatty acids in fish oil reduce the production or action of prostaglandins and leukotrienes, thus limiting the renal damage caused by inflammation, platelet aggregation, and vasoconstriction.²⁴ In a controlled trial on patients with heavy proteinuria and mildly impaired renal function, daily use of fish oil delayed the progression of renal failure with modest reduction in proteinuria.⁷² A meta-analysis of five controlled studies indicated that a minor,

but not statistically significant, beneficial effect on renal function may be observed.⁷³ Results from several recent studies failed to confirm the beneficial effects reported earlier and further studies are needed to confirm the role as well as the optimal dose. In many of the studies, 4 to 12 g/day was given for 2 or more years. Some of the fish oil preparations are rich in cholesterol; thus it is appropriate to monitor the LDL cholesterol levels in patients receiving therapy.

■ ANGIOTENSIN-CONVERTING ENZYME INHIBITION

Because hypertension is a negative prognostic indicator of IgA nephropathy and many of these patients already have left ventricular diastolic malfunction despite being normotensive, early antihypertensive intervention with ACEIs or ARBs is important.^{65,66} If a single agent is insufficient to reduce proteinuria and maintain blood pressure at 125/75 mm Hg, combined use of ACEI and ARB should be instituted.⁶⁷

■ ALTERNATIVE THERAPEUTIC APPROACHES

Patients with IgA nephropathy have abnormal production of IgA and several different immunoglobulins. Immunoglobulins, administered intravenously initially and then intramuscularly, may have beneficial effects through immunomodulation, increased catabolism of autoantibodies, and blockade of receptors.⁷⁴ The doses in this experimental trial, which has not been independently replicated, were very high: 1 g/kg/day \times 2 days IV every month \times 3, then 0.35 mL/kg IM every 15 days \times 6 months. Plasmapheresis with albumin replacement was performed before the 2- to 12-hour IV infusions to avoid serum sickness. Reduction in proteinuria, hematuria, GFR decline, and histologic activity index were observed in 11 patients with a progressive course of the disease. Renal survival was prolonged in eight of these patients who were followed for 3 to 10 years.⁷⁵ Larger, randomized, controlled trials are needed before one can recommend this regimen with confidence.

Urokinase, danazol, dapsone, sodium cromoglycate, and plasma exchange have also been evaluated, but none is consistently effective nor shown to affect renal function.^{68,74} Cyclosporine treatment was found in a limited number of studies to reduce proteinuria; however, renal function decreased during treatment. Consequently, its use is limited by the potential for nephrotoxicity.^{24,74}

The HMG-CoA reductase inhibitor fluvastatin was reported to reduce urinary protein excretion in moderately proteinuric (0.6 to 1.6 g/day) patients who had IgA nephropathy with normal renal function.⁷⁶ Creatinine clearance remained stable during the 6-month study. Although longer-term evaluation in a larger patient population is needed to confirm this beneficial effect, statin use is an obvious choice for hyperlipidemic patients with IgA.

Antiplatelet agents are commonly used in Japan and rarely outside of Asia for IgA nephropathy.⁷⁷ A recent meta-analysis of seven trials (four in Japan and three in Hong Kong) revealed that these agents reduced proteinuria and stabilized renal function.⁷⁸ Mycophenolate mofetil and several new strategies are being evaluated as experimental treatments for IgA nephropathy on the premise that they may reduce IgA synthesis and mesangial uptake and/or suppress the effects of proinflammatory or profibrogenic mediators.⁷⁸

■ TREATMENT ALGORITHM

Normotensive patients with normal renal function, isolated microhematuria, and proteinuria less than 1 g/day should be observed closely without specific treatment.⁶⁶ It has been suggested that patients with minimal proteinuria of 0.5 to 1 g/day receive fish oil and an ACE inhibitor (ACEI) or ARB (Fig. 50–6).²⁴ Because corticosteroids reduce proteinuria, a course of alternate-day prednisone

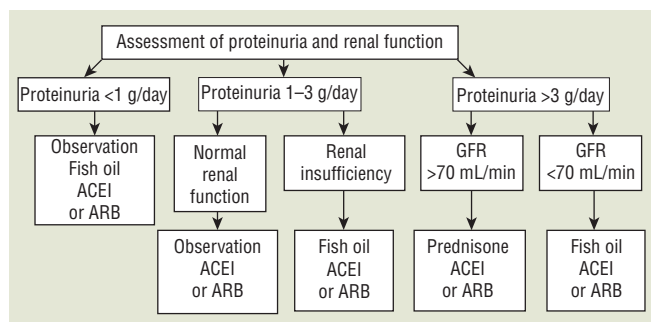

FIGURE 50-6. Treatment algorithm for biopsy-proven IgA nephropathy. (ACE, angiotensin-converting enzyme; GFR, glomerular filtration rate.) (Modified from reference 68.)

(1 mg/kg/day) with subsequent tapering is indicated for patients with proteinuria greater than 3 g/day who have good renal function (>70 mL/min).⁶⁸ A more aggressive IV or oral steroid regimen may be considered, even though its efficacy has not been definitively established. For patients with a slow progressive decline in creatinine clearance (<70 mL/min), fish oil should be given. Azathioprine, cyclophosphamide, mycophenolate mofetil, or dipyridamole/warfarin therapy may also be used, although the efficacy of these agents has not been established. If the patient experiences rapid GFR decline of more than 2 mL/min per month, immunoglobulin therapy may be considered despite the fact that only limited data are available. Other therapies that may be considered for these patients include pulse steroids, a cyclophosphamide-steroid combination, mycophenolate mofetil, and plasmapheresis.^{24,66,68,79}

■ THERAPEUTIC OUTCOMES

Urinary protein excretion and the mean arterial blood pressure at followup correlate well with the progression of disease. The risk of developing ESRD is proportional to the amount of proteinuria, under the influence of ACEI and ARB therapy, after 1 year of followup.⁸⁰ For those patients who develop end-stage renal failure, transplantation is appropriate, especially for young adults. Recurrence of IgA mesangial deposits in the renal allograft may occur in up to 50% of patients in 5 years and be universally present at 10 years or more posttransplant, but the recurrence of clinical disease is only approximately 10% to 15%.^{65,66} There is also no correlation between the aggressiveness of the primary disease and the rate of recurrence.⁶⁵ Immunosuppression using corticosteroids, azathioprine, and/or cyclosporine is not expected to prevent the recurrent nephropathy.

LUPUS NEPHRITIS

Etiology and Epidemiology

Glomerulonephritis is one of the most serious complications of systemic lupus erythematosus (SLE) and accounts for much of the morbidity and mortality of patients afflicted with the disease. SLE predominantly affects young women between 15 and 40 years of age, with an incidence of 1 in 2,000 women in the United States. African Americans are more susceptible; they develop the disease at a younger age, have nephritis earlier in the course and are more likely to progress to end-stage kidney disease.

The renal manifestations of lupus nephritis are variable and encompass a wide spectrum of histopathologic lesions.⁸¹ The underlying histopathology is associated with different prognoses and responses to therapy, which cannot be predicted solely based on clinical manifestations. Thus, a renal biopsy is required to assess the severity of the disease and to predict the short-term and long-term outcomes associated with therapy. Drugs, such as hydralazine and

procainamide, are known to precipitate a lupus syndrome; however, they are unlikely to cause disease that affects the kidney.

Pathophysiology

Immune complex deposits, whether formed in the circulation or in situ, can be found in various regions of the glomerulus, as well as the peritubular interstitium and vasculature outside the glomerulus. Based on light, immunofluorescence, and electron microscopy findings, lupus nephritis can be categorized into six World Health Organization (WHO) classes: I—normal; II—mesangial; III—focal proliferative; IV—diffuse proliferative; V—membranous; and VI—advanced sclerosing.⁸² In an attempt to enhance the predictive values of the histologic findings, semiquantitative assessments of active lesions and sclerotic changes are used to determine activity index and chronicity index, respectively. In 2003, the ISN/RPS (International Society of Nephrology/Renal Pathology Society) classification was developed to reduce interobserver reproducibility and provide a practical and standardized approach to biopsy interpretation so that outcome data can be compared worldwide.⁸³

The hallmark feature in the pathogenesis of SLE is B-cell hyperactivity and the dysregulated production of autoantibodies against multiple antigens in the body, including DNA and various ribonucleoproteins.^{81,84} The size and location of the immune complexes in the glomerulus correlate with the nature and severity of renal injury. Deposition of small numbers of stable immune complexes of intermediate size in the mesangium tends to produce less-severe inflammation in the glomerulus. The sequestration of the immune complexes in the mesangium prevents them from activating inflammatory mediators. Hence, the lesion is noninflammatory in nature. In contrast, large numbers of intermediate-sized or large immune complexes result in infiltration of inflammatory cells and release of necrotizing enzymes.

Clinical Presentation

Females have a higher risk for developing lupus, especially in the adult years. Nephritis is commonly seen within the first 4 years of diagnosis of SLE, but may also be the first manifestation of the disease. The clinical presentation ranges from minimal hematuria and proteinuria to severe, rapidly progressive diffuse glomerulonephritis. Proteinuria is very common and nephrotic syndrome is seen in most patients with membranous lesions. Microscopic hematuria is almost always present, whereas macroscopic hematuria, which commonly indicates severe renal involvement, is rare.⁸² Active urinary sediments (red cell casts, dysmorphic red cells, and hematuria) are suggestive of the diffuse proliferative lesion.⁸¹ Hypertension is present in 25% to 45% of patients, and is associated with a worse prognosis. Other conditions found to be associated with poor prognosis include elevated serum creatinine concentration, heavy proteinuria, anemia (hematocrit $<26\%$), black race, and disease onset during childhood or in those >60 years of age. Most patients have hypocomplementemia and increased antibody titers for anti-double-stranded DNA, particularly those with focal or diffuse proliferative lesions. Serum creatinine concentration at the time of diagnosis is most predictive of short-term outcome.

TREATMENT

Lupus Nephritis

7 The choice of therapy depends on the underlying lesion and the activity, as well as the chronicity indices. Acute life-threatening disease involving multiple organs requires induction treatment that can suppress the disease promptly. In contrast, long-term management of chronic indolent disease requires therapy with more acceptable side-effect profiles. Corticosteroids are the cornerstone of

therapy. However, for severe lupus nephritis, primarily the diffuse proliferative type, alkylating agents may be needed to reduce or prevent the progression to ESRD. Newer alternatives with fewer side effects are now available.

Optimal blood pressure control is important. ACE inhibitor or ARB has been shown to reduce proteinuria. Patients with normal renal function and less than 2 g of proteinuria usually do not require therapy, except for the management of extrarenal lupus manifestations. The prognosis of these patients is generally good and renal biopsy can be delayed. However, close followup of renal function and urinalysis is required.

■ ACUTE INDUCTION TREATMENT

Steroids and Cytotoxic Agents

Patients with more than 2 g of proteinuria, deteriorating renal function, and/or active urinary sediments require a renal biopsy to define the underlying lesion and determine the activity and chronicity of disease. Patients with proliferative lesions, class IV and class III with subendothelial deposits and signs of severe disease activity, should be treated with pulse intravenous methylprednisolone followed by low-dose oral steroids. Cyclophosphamide is used concurrently because it is a powerful B-cell inhibitor and can suppress the resynthesis of autoantibodies to normal levels.⁸² Combined use of intravenous cyclophosphamide and methylprednisolone is more effective than either agent alone in inducing remission.^{84,85} Cyclophosphamide is given orally in some of the regimens.⁸⁶ Azathioprine has also been used in conjunction with cyclophosphamide. The risk for adverse events, such as infection, gonadal damage, amenorrhea, and cervical dysplasia, and malignancy is increased with the cytotoxic regimens.⁸⁴ Studies show that cyclophosphamide toxicities may be related to the cumulative doses rather than the route of administration.⁸⁶ Because oral doses of cyclophosphamide tend to accrue easily, it is prudent to use it only for those who are high risk and had failed other therapies.

Mycophenolate Mofetil

Several trials have found that mycophenolate mofetil with concurrent steroid therapy is an effective agent for induction therapy. It was as effective as cyclophosphamide in inducing remission but with fewer side effects. Many of these trials were conducted in Asia and may not reflect the American patient population. However, two recent trials that included African Americans, who are at risk for poorer prognosis, also show that mycophenolate mofetil was more efficacious than intravenous cyclophosphamide and resulted in fewer adverse effects.^{84,87} Based on the recently available data, mycophenolate mofetil seems to be a viable alternative to cyclophosphamide; however, the duration of followup in these trials was not as long as the trials that were conducted to establish the efficacy of cyclophosphamide-based regimens. The ability of mycophenolate mofetil to sustain the remission long-term is still unclear (Fig. 50–7).

■ CHRONIC MAINTENANCE TREATMENT

Steroids and Cytotoxic Agents

Oral steroid is most frequently used for maintenance treatment (prednisolone 5 to 15 mg/day or equivalent).⁸² Alternate-day regimens, although not evaluated, are often used in children to minimize growth retardation. Monthly pulse IV steroids in conjunction with cyclophosphamide resulted in more sustained remission, fewer relapses, and no significant increase in side effects.⁸⁸ Meta-analysis shows this combination to be more beneficial than steroid or cyclophosphamide alone. Cyclophosphamide, because of its bladder and gonadal toxicity, has been given as monthly and then bimonthly

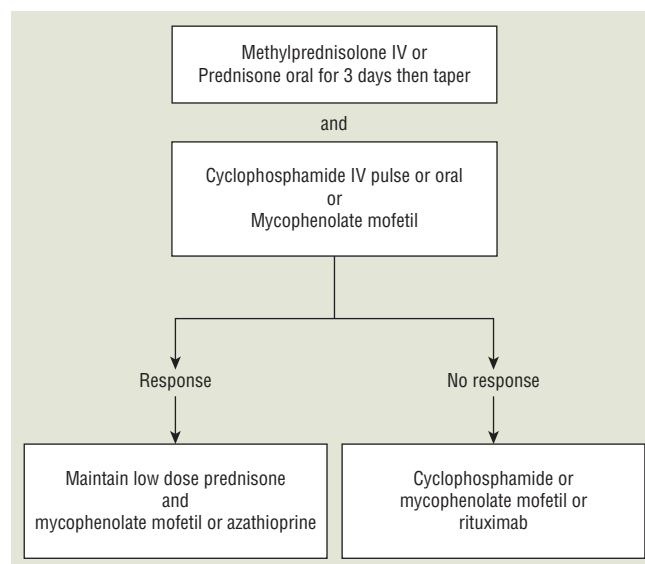

FIGURE 50-7. Treatment algorithm for proliferative lupus nephritis.

intravenous injection, instead of daily administration, for 2 or more years. However, toxicity is still a concern. A study conducted in Europe showed that after initial lower pulse doses of IV cyclophosphamide, oral azathioprine was able to attain remission rates similar to those of higher initial pulse doses of cyclophosphamide with quarterly followup doses.⁸⁹ Recently, daily doses of mycophenolate mofetil or azathioprine for 2 years have been shown to be more effective than intravenous pulses of cyclophosphamide in reducing relapse while being less toxic.⁹⁰

Cyclosporine

Cyclosporine may reduce proteinuria and lupus activity, stabilize renal function, and improve kidney morphology. However, flares of disease activity may occur when the drug is discontinued or the dosage tapered. Nephrotoxicity is also a concern after prolonged use.

■ ALTERNATIVE THERAPEUTIC AGENTS

Many new agents have been developed to target the various pathways, costimulatory molecules, and immune mediators responsible for the pathologic autoantibody production.

LJP-394 (Riquent, abetimus sodium), composed of four double-stranded oligodeoxynucleotides, render specific B lymphocytes unresponsive to immunogen by cross-linking with the surface immunoglobulin receptors, thereby reducing anti-DNA antibody production. It may reduce renal and systemic SLE flares in a subgroup of patients whose anti-DNA antibodies are bound avidly to the compound.⁹¹ However, a subsequent study did not reveal such a beneficial effect when compared with placebo.⁸⁴

Rituximab is a monoclonal antibody directed against CD20, which is a membrane-associated glycoprotein on B lymphocytes. It causes B-lymphocyte depletion without affecting plasma cells, which do not have CD20. In patients, the B-cell depletion correlates with clinical response. However, the studies available are uncontrolled and different regimens were used in heterogeneous groups of patients.⁸⁴ Results from ongoing randomized trials are needed to confirm its efficacy. Studies are also underway to evaluate epratuzumab (anti-CD22).

Disruption of communication between B and T cells can result in reduced autoimmune response. Different anti-CD40 ligand monoclonal antibodies, such as BG9588 (ruplizumab) and IDEC-131, have been evaluated; however, they were not found to be useful because of life-threatening thromboembolic complications.⁹²

TREATMENT OUTCOME

The prognosis of patients with class II disease is generally good and often no specific treatment is needed. In patients with class V disease, steroids alone commonly induce partial or complete remission. Immunosuppressive agents can be used for those who are not responsive to steroids. The survival of patients with classes III and IV disease has improved during the last two to three decades to approximately 74% to 80% at 10 years.⁸¹ With the recent use of mycophenolate mofetil, better understanding of the optimal cytotoxic regimens, the use of lower steroid dosages, and better management of complications such as hypertension, infections, hyperlipidemia, and other metabolic complications of the disease, the long-term outcome has become more favorable. Lupus patients with end-stage kidney disease on dialysis fare as well as those with non-lupus-related renal disease. In those patients who received a renal transplant, the allograft outcome of patients with lupus nephritis is favorable. Recurrence of lupus in the renal allograft can occur, but is usually of minor clinical importance.

RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

Etiology and Epidemiology

Rapidly progressive glomerulonephritis (RPGN) describes a clinicopathologic syndrome of rapid loss of renal function—usually a greater than 50% decrement of the glomerular filtration rate within 3 months. The predominant histologic finding of RPGN is extensive crescent formation, usually in more than 50% of the glomeruli. Hence, it is also known as crescentic glomerulonephritis. RPGN accounts for 2% to 7% of all renal biopsy findings, and is responsible for up to 5% of patients with end-stage kidney disease. The age ranges of susceptible patients vary with the type of RPGN. For example, types I and II RPGN are more common in younger patients, whereas type III is seen more frequently in older individuals.

RPGN is not a single disease entity. A variety of glomerulonephritides with or without systemic diseases may present as RPGN, including anti-GBM glomerulonephritis, Goodpasture's syndrome, lupus nephritis, poststreptococcal glomerulonephritis, membranoproliferative glomerulonephritis, IgA nephropathy, polyarteritis nodosa, Wegener's granulomatosis, and idiopathic crescentic glomerulonephritis.

Primary RPGN is categorized according to the immunofluorescence microscopic findings, indicating different immunopathogenesis, therapeutic approaches, and clinical outcome. Type I is characterized by the linear localization of immunoglobulins, mainly IgG, along the GBM, signifying anti-GBM antibody-induced injury. Type II is defined by the coarse granular deposition of immunoglobulins and complement within the capillary walls and mesangium, indicating immune-complex-mediated injury. Type III is characterized by scanty or complete lack of immune complex deposits; consequently, it is also known as pauci-immune RPGN. Circulating ANCA are often detected in type III RPGN.

Pathophysiology

Different etiologic factors are implicated as the cause of RPGN: toxins, drugs, viral and bacterial infections, neoplasms, autoimmune mechanisms, and various immunogenetic factors.⁹³ Regardless of the etiology and type of RPGN, damage in the glomerular capillary wall by both humoral and cellular pathways of inflammation is common. Activation of the terminal C5b-9 (membrane-attacking complex) of the complement system produces severe capillary wall injury. Proteinases and reactive oxygen species released by neutrophils and macrophages may result in severe glomerular injury. Platelets and the coagulation system are activated and result in capillary thrombosis. The ruptured capillaries release fibrinogen and procoagulants which may come into contact with

thrombogenic tissue debris and lead to fibrinoid changes. In anti-GBM glomerulonephritis, the direct attack of the anti-GBM antibody on the GBM is responsible for the capillary wall injury.⁹³ In patients with ANCA-associated disease, the interaction of ANCAs with neutrophils and monocytes, which have been primed by concurrent infections or inflammatory processes, can lead to activation of these leukocytes and release of toxic oxygen species and lytic enzymes, resulting in vascular injury.

The disruption of the capillary wall allows movement of macrophages and other plasma constituents into Bowman's space and stimulates the formation of crescents, which are composed mainly of parietal epithelial cells, as well as macrophages and fibroblasts. Crescent formation indicates the severity of the glomerular capillary disease but not its pathogenesis.

Clinical Presentation

Among the crescentic glomerulonephritides, the pauci-immune RPGN (type III) is the most frequent, accounting for more than 50% of cases, whereas the anti-GBM antibody-mediated RPGN (type I) is the least frequent, occurring in roughly 10% to 20% of patients. Of patients with type I RPGN, 60% to 70% may have concurrent pulmonary hemorrhage and Goodpasture's syndrome, which is caused by antibodies directed against the pulmonary alveolar basement membrane. Most patients with immune-complex-mediated RPGN (type II) have collagen vascular disease, systemic infections, or a severe form of primary glomerular disease. Approximately 70% of patients with type III RPGN also present with evidence of systemic vasculitis, such as Wegener's granulomatosis and polyarteritis nodosa. Some patients have only renal manifestations, and are said to have idiopathic crescentic glomerulonephritis or renal vasculitis.

The clinical presentation is dominated by progressive renal insufficiency with complaints of tea-colored urine, malaise, anorexia, low-grade fever, and migratory polyarthropathy. Type I RPGN is more common in younger patients, whereas patients with ANCA-mediated disease tend to be older.⁹⁶ Urinalysis commonly shows nephritic sediments with hematuria, erythrocyte casts, and proteinuria. However, overt nephrotic syndrome is rare.

Serologic analysis is very useful in distinguishing the different types of RPGN. The detection of serum anti-GBM antibodies with the appropriate clinical presentation confirms the diagnosis of anti-GBM glomerulonephritis. More than 80% of patients with pauci-immune or idiopathic crescentic glomerulonephritis have circulating ANCAs. ANCAs are autoantibodies specific for the cytoplasmic constituents of neutrophil granules and monocyte lysosomes. Patients with ANCA-associated disease limited to renal involvement often have P-ANCA (perinuclear staining), whereas patients with Wegener's granulomatosis tend to have C-ANCA (cytoplasmic staining). Both the anti-GBM antibody and the ANCAs are absent in patients with type II RPGN. Measurements of circulating immune complexes are not useful for making a specific diagnosis, but detection of specific serum antibodies known to mediate immune complex-associated nephritis is helpful, using anti-DNA antibody as a marker for lupus nephritis and elevated antistreptolysin O titers for poststreptococcal glomerulonephritis.

TREATMENT

Rapidly Progressive Glomerulonephritis

Early aggressive therapy has improved the renal prognosis of patients with crescentic glomerulonephritis. The rapid deterioration of renal function and the paucity of a large number of patients make randomized controlled studies very difficult to conduct. Based on the available data, immunosuppressive therapy alone appears to be

ineffective for type I RPGN, while types II and III RPGN respond well to high-dose steroid therapy.^{93,94} Regardless of the type of RPGN, poor response to therapy and an ominous renal survival are expected if the patient presents with oliguria, has a serum creatinine concentration greater than 6 or 7 mg/dL, is dialysis dependent, or has a renal biopsy showing advanced chronic parenchymal disease.⁹⁵ Because of the differences in response, the therapeutic approaches for each type of RPGN are presented separately below:

■ ANTIGLOMERULAR BASEMENT MEMBRANE GLOMERULONEPHRITIS (TYPE I)

Steroids and cyclophosphamide, in conjunction with plasma exchange, have been used effectively to control the disease. Plasma exchanges remove the pathogenic anti-GBM antibodies in circulation and are conducted for 2 weeks or until the antibodies disappear. Steroids (prednisolone 1 mg/kg/day, tapered over 6 months) and cyclophosphamide (2 to 3 mg/kg/day for 3 months) are then given to prevent new antibody production.^{94,96} Patients with mild disease generally respond well to plasma exchange alone or immunosuppression (steroid and/or cytotoxic agents). In patients with severe disease (poor renal function and extensive crescent formation), most are expected to respond to the combination of plasma exchange and steroid/cytotoxic drug therapy. Pulse intravenous administration of corticosteroids (methylprednisolone 30 mg/kg/day for 3 days) has been used successfully to alleviate pulmonary hemorrhage, but the results are not as convincing for glomerulonephritis.^{93,94} Because of the rapid decline in renal function, diagnosis should be established early so that therapy can proceed without delay. When the serum creatinine concentration is 6 mg/dL or above, or the patient is oliguric or requires dialysis, the response to therapy is usually poor and the patient should be treated conservatively.^{94,96} Poor response should also be expected when crescents are found in more than 85% of the glomeruli.

■ IMMUNE-COMPLEX-MEDIATED GLOMERULONEPHRITIS (TYPE II)

Patients with postinfectious RPGN generally have a favorable prognosis even without treatment. Complete spontaneous recovery occurs in 50% of cases, whereas chronic renal failure develops in 32%.⁹³ Pulse doses of methylprednisolone (30 mg/kg/day, every other day \times 3), followed by oral prednisone (1 mg/kg/day, tapered over several months) and then tapering, are beneficial in type II RPGN, with a response rate of 85% in patients with acute disease and 70% in those with more chronic disease.^{93,94} Plasmapheresis does not appear to provide any additional benefit.⁹⁴

■ ANTINEUTROPHIL CYTOPLASMIC AUTOANTIBODY-ASSOCIATED GLOMERULONEPHRITIS (TYPE III)

Combined use of high-dose corticosteroids and cyclophosphamide induces remission in more than 90% of patients.⁹⁵ Cyclophosphamide, if given intravenously, is associated with fewer infectious complications while being as effective as the oral route in inducing remission; however, the risk of relapse may be higher.⁹⁷ Because approximately 30% of the patients may relapse, cyclophosphamide also has been used for maintenance therapy. Mycophenolate mofetil and methotrexate are now being used and they have been shown in limited studies to be effective.^{95,97} Plasmapheresis is not expected to have any additional benefits for patients with mild to moderate disease who are receiving immunosuppressive therapy. However, as an adjunct to immunosuppressive therapy, it may be beneficial for patients with severe disease presenting with acute renal failure, especially those with pulmonary hemorrhage.⁹⁷

■ RENAL TRANSPLANTATION

Anti-GBM nephritis may recur in up to 55% of patients who received a renal transplant. However, only 25% of these patients showed clinical disease activity, with rare allograft failure. Because the frequency of recurrence and its severity are related to the presence of circulating anti-GBM antibody, it is recommended that transplantation should not be performed until the anti-GBM antibody is undetectable for at least 6 to 12 months. The recurrence rate of ANCA-associated nephritis is 17%, with the average time to relapse from transplantation of 31 months.⁹⁸

POSTSTREPTOCOCCAL GLOMERULONEPHRITIS

Etiology and Epidemiology

Poststreptococcal glomerulonephritis (PSGN) and glomerulonephritis caused by other infectious agents, such as bacteria, viruses, and parasites, were once common. Improved sanitation, personal hygiene, medical care, and public health measures helped to decrease the incidence of group A streptococcal infection both in the United States and in other developed countries, resulting in a decline of PSGN. In contrast, glomerulonephritis secondary to other infectious agents, such as hepatitis C and HIV, is seen with increasing frequency.

PSGN is now the most common form of glomerulonephritis in children, but is less common than the other types of glomerulonephritis in adults. PSGN is seen mostly in children aged between 5 and 15 years and is uncommon in children younger than 2 years of age and in adults older than 50 years of age. It normally follows pharyngeal or skin infection caused by the nephritogenic strains of group A streptococci; however, other strains of streptococci, such as groups C and G, have also been reported to cause PSGN. Streptococcal pharyngitis is more common in winter and early spring, whereas skin infection is frequently found in the summer. The risk for developing acute glomerulonephritis secondary to the nephritogenic strains of bacteria is approximately 10% to 15% in infected patients. However, three to four times more patients may experience a subclinical form of the disease.

Pathophysiology

Streptococcal antigens may induce changes in the glomerular components rendering them immunogenic or autologous IgG may be altered to become antigenic. Alternately, the streptococcal antigens may induce antibodies that react with glomerular antigens. In situ immune complexes are then formed and result in a complement-mediated inflammatory response. The kinin and coagulation cascades are activated and chemotactic factors are released to recruit neutrophils and monocytes, resulting in acute glomerular lesions.

Examination of the acute PSGN kidneys reveals hypercellular glomeruli with proliferation of mesangial and endothelial cells. Infiltration of neutrophils, monocytes, and eosinophils is apparent within the capillary lumen and also in the mesangial areas. Crescent formation may be seen in patients with severe disease, and if found in more than 30% of the glomeruli, RPGN may be present concurrently.⁹⁹ The prognosis is generally poor for these patients and complete recovery is unlikely. Immunofluorescence examination reveals diffuse granular deposits of IgG and C3 along the glomerular basement membrane and also in the mesangium.

Clinical Presentation

The nephritis is preceded by a latent period following a streptococcal infection. The latent period is commonly 7 to 14 days for pharyngitis and 14 to 28 days for skin infection. An acute nephritic syndrome then develops, commonly with hematuria and edema.

Gross hematuria is seen in 70% of patients, and microscopic hematuria can be found in all patients. Hypertension is usually mild to moderate and results from sodium and water retention. Many patients have signs and symptoms associated with volume overload, which include dyspnea, orthopnea, and cough. Urinalysis of patients with PSGN reveals hematuria, dysmorphic red blood cells, and red cell casts. Proteinuria is common, but often not in the nephrotic range. Renal function is frequently mildly impaired.

Throat or skin culture may be positive for group A streptococci, despite the latent period following the initial infection. However, antibiotic therapy may render the culture result negative. Serologic measurements of antibodies to different streptococcal antigens can confirm recent exposure to the infection. Titers that can be measured include antistreptolysin O (ASO), antistreptokinase, antihyaluronidase (AHase), antideoxyribonuclease B (ADNase B), and antinicotyladenine dinucleotidase (NADase).¹⁰⁰ In most patients with streptococcal pharyngitis, the ASO titers begin to rise about 10 to 14 days later, peak at 3 to 4 weeks, and persist for several months before decreasing. The rise in ASO titers can be reduced by antibiotic treatment and may not be seen in patients with streptococcal skin infection in whom the streptolysin may be bound to skin lipids. ADNase B and AHase titers should be used instead because they are specific and are positive in the majority of patients. The streptozyme test is a combined assay for ASO, ADNase B, NADase, and AHase. Antibodies to other antigens such as zymogen, streptococcal cationic proteinase exotoxin B (SPEB), and plasmin receptor (Plr), were evaluated recently.¹⁰¹

Serum complement levels are often decreased in patients with PSGN. If the C3 level is depressed for more than 6 to 8 weeks, MPGN, lupus nephritis, or glomerulonephritis related to endocarditis or occult visceral abscess should be suspected. Renal biopsy is not normally indicated unless the patient has prolonged hematuria, proteinuria, or depressed C3 level. Renal biopsy is needed to detect other types of glomerulonephritis such as lupus, RPGN, or MPGN.

TREATMENT

Poststreptococcal Glomerulonephritis

8 The treatment of PSGN is mainly supportive and symptomatic. Early antibiotic therapy does not prevent subsequent PSGN, but it may reduce the severity of the disease. It can, however, prevent the spread of the streptococcal infection to other family members. Antibiotic prophylaxis is not recommended because infected patients will develop long-lasting, often lifelong immunity against the strain of streptococci. Exposure to another nephritogenic strain of streptococci is possible, but unlikely.

Supportive measures, as discussed earlier in this chapter, should be used to control fluid volume and blood pressure. Because the hypertension is of the low-renin type, ACEIs and β -blockers are not expected to be useful. If the patient has crescentic disease, use of pulse steroids and/or immunosuppressive agents can be considered; however, the efficacy and safety of these agents have not been established for this condition.

The acute manifestations of PSGN are normally self-limited, and for more than 95% of patients renal function has returned to baseline within 3 to 6 weeks. Diuresis usually begins 7 to 10 days after onset of the acute episode, whereas hypertension and azotemia resolve in 1 to 2 weeks. Gross hematuria lasts for 1 to 2 weeks and proteinuria usually resolves within 6 months in more than 90% of children. However, microscopic hematuria may persist for up to 2 years. In general, children have more rapid recovery than adults. Prognosis is often better when PSGN occurs during an epidemic than in cases found sporadically. Most of the children will recover

fully and be free from chronic complications of PSGN if they have no preexisting renal disorder, heavy proteinuria, or crescentic glomerular lesions, or did not require hospitalization during the acute episode. In contrast, adult patients have a less-favorable long-term outcome. As many as 50% of the patients may develop persistent proteinuria, hypertension, and renal insufficiency, with some resulting in end-stage renal failure.

PHARMACOECONOMIC CONSIDERATIONS

Prospective, randomized, controlled comparative trials need to be conducted in a sizable patient population before the efficacy and economic implications of a new regimen can be established. This type of large-scale study is potentially feasible for the more common forms of glomerulonephritis, such as minimal-change disease, IgA nephropathy, and membranous nephropathy. In contrast, prospective controlled trials are difficult to conduct for the relatively uncommon glomerulonephritides such as membranous proliferative glomerulonephritis. After defining the natural history and the optimal drug regimen for each glomerulonephritis, in conjunction with the incidence of drug-induced complications, the economic implications of the individual treatment approach can be assessed. However, the optimal approaches for treating most types of glomerulonephritis have not been identified and the economic implications of the individual treatment regimens thus remain to be established.

CONCLUSIONS

A better understanding of the pathogenetic mechanisms leading to glomerular injury has improved the treatment of glomerulonephritis. However, the glomerulopathies are a heterogeneous group of immune disorders with different clinical courses, prognoses, and responses to current immunologic and nonimmunologic therapies. The clinician should understand the natural history and prognosis of each subgroup of glomerulonephritis, the efficacy of different immunomodulating regimens in inducing disease remission and preserving renal function, and the characteristics of at-risk patients who warrant aggressive therapy. Judicious use of immunosuppressive agents with careful monitoring of their adverse effects cannot be overemphasized. In addition, treatment of the disease complications and control of factors that lead to progression of renal disease are important in reducing the morbidity and mortality of patients with glomerulonephritis.

ABBREVIATIONS

ACE:	angiotensin-converting enzyme
ADNase B:	antideoxyribonuclease B
AHase:	antihyaluronidase

Drug Therapy Individualization for Patients with Renal Insufficiency

GARY R. MATZKE AND REGINALD F. FRYE

KEY CONCEPTS

- 1 Chronic kidney disease has been demonstrated to result in minimal alterations in the absorption or bioavailability of only a few drugs.
- 2 The volume of distribution of many drugs is increased in the presence of acute and chronic kidney disease as a consequence of volume expansion and reduced protein binding.
- 3 In addition to the expected decrement in renal clearance, non-renal clearance (i.e., gastrointestinal and hepatic drug metabolism) of several drugs is also reduced in patients with chronic kidney disease.
- 4 Individualization of a drug dosage regimen for a patient with reduced kidney function (RKF) is based on the pharmacodynamic/pharmacokinetic characteristics of the drug and the patient's degree of residual renal function.
- 5 The drug dosing guidelines for patients with RKF in many drug information resources is highly variable and thus many are ill suited for clinical use.
- 6 The effect of hemodialysis or peritoneal dialysis on drug elimination is dependent on the characteristics of the drug and the dialysis prescription.
- 7 The application of dialysis clearance data to guide drug dosage regimen design for hemodialysis patients is limited and prospective monitoring of serum concentrations is warranted.

Patients with chronic kidney disease (CKD) are commonly encountered in clinical practice. Indeed, it is estimated that nearly 15 million people in the United States have serum creatinine values of 1.5 mg/dL or greater.¹ In children, renal function does not mature to reach adult values until one year of age.² In older adults, age-related declines in renal function combine with an increased use of medications to make this patient group particularly susceptible to adverse effects secondary to the lack of appropriate pharmacotherapy individualization.^{3,4} The presence of reduced kidney function (RKF) in any patient necessitates that the clinician know how and why drug disposition is altered in the presence of CKD and the appropriate methods to individualize drug therapy to maximize therapeutic outcomes.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

CKD is often accompanied by the development of anemia, hyperparathyroidism, bleeding abnormalities, hyperlipidemia, hypertension, and changes in gastrointestinal tract integrity (see Chaps. 46 and 47). Thus CKD patients are often prescribed an extensive array of medications. There are now many reports that document changes in the disposition of some drugs in patients with CKD as the result of changes in bioavailability,^{5,6} distribution volume,^{7,8} and metabolic activity.⁹ Thus some degree of drug therapy individualization is warranted for most patients with CKD. In the simplest situation, a drug that is almost entirely renally eliminated unchanged, a dosage regimen adjustment may be calculated on the basis of the patient's residual creatinine clearance.¹⁰ However, for medications that are extensively metabolized or for which dramatic changes in protein binding and/or distribution volume have been noted, a more complex adjustment strategy may need to be employed.^{8,11} Furthermore, because of the physiologic and biochemical changes associated with progressive CKD, patients may respond to a given dose or serum concentration of a drug differently than patients with normal renal function.⁵

Knowledge of basic pharmacokinetic principles combined with the drug disposition properties of a particular compound and the degree and type of pathophysiologic alterations associated with RKF makes it possible for the clinician to design individualized therapeutic regimens to optimize therapeutic outcomes and minimize adverse events. This chapter describes the influence of CKD on drug absorption, distribution, metabolism, and elimination. The array of drug information resources for the adjustment of the dosage regimens for patients with RKF is critiqued. A practical framework for drug dosage individualization for patients with RKF based on continuous versus categorical classifications is presented and the influences of peritoneal dialysis and hemodialysis on drug disposition are discussed. Finally drug administration strategies for those receiving hemodialysis are presented. Chapter 45 discusses drug-dosage-regimen adjustment strategies for patients with acute renal failure, including those who are receiving continuous renal replacement therapy.

EFFECT ON DRUG ABSORPTION

- 1 There is little quantitative information regarding the influence of CKD on drug absorption and bioavailability. Changes in gastrointestinal transit time and gastric pH, edema of the gastrointestinal tract, vomiting and diarrhea (frequent complications of severe renal insufficiency), and antacid administration have all been proposed as a rationale for alterations in the bioavailability of drugs in CKD patients. Evaluations of bioavailability are generally conducted in those with severe stable renal insufficiency, that is, stage 5 CKD, which is also called end-stage renal disease (ESRD). The assessment of bioavailability in this patient population is, however, complicated, because most of these patients are prescribed multiple medications (often in excess of 10 to 12 different agents), many of which cannot be discontinued during the course of a bioavailability study.

Some of the drug absorption “bioavailability” studies in ESRD patients were not designed to provide an assessment of absolute bioavailability (i.e., they did not include intravenous administration of the drug). Rather, the principal outcomes were the documentation of alterations in the peak concentration (C_{\max}), time at which the peak concentration was attained (t_{\max}), or in the fractional amount of drug recovered in the urine in a finite time period. Unfortunately, this limited information has been extrapolated by some into a general conclusion that drug absorption is slowed and/or that the extent of absorption is reduced as the result of the development of CKD.⁶

In fact the absolute bioavailability of only a few drug compounds is affected by ESRD.^{5,8} An increase in bioavailability as the result of a decrease in metabolism during the drug’s first pass through the gastrointestinal tract and liver has been noted for some β -blockers (i.e., bufuralol, oxprenolol, propranolol, and tolamolol), dextropropoxyphene, and dihydrocodeine.^{5,8} Although the bioavailability of these compounds is increased, clinical consequences (development of excessive or unexpected adverse effects) have only been demonstrated with dextropropoxyphene and dihydrocodeine. The lack of association between the altered serum concentration time profile and clinical consequences of the β -blockers may result from an alteration in the responsiveness of patients with renal disease to these agents, as has been reported with propranolol in the elderly.³

EFFECT ON DRUG DISTRIBUTION

The volume of distribution of many drugs is increased in patients with moderate to severe CKD as well as those with preexisting CKD who develop acute renal failure (Table 51-1).^{8,12,13} An increase in distribution volume may result from decreased protein binding, increased tissue binding, or pathophysiologic alterations in body composition (e.g., the fractional contribution of total-body water to total-body weight).

Generally, the plasma protein binding of acidic drugs (e.g., warfarin and phenytoin) is decreased in those with ESRD,^{7,14} whereas the binding of basic drugs (e.g., quinidine and lidocaine) is usually normal or only slightly decreased or increased (Table 51-2).^{7,15,16} The decrease in binding of acidic drugs has been attributed to qualitative

TABLE 51-1 Volume of Distribution of Selected Drugs in Patients with End-Stage Renal Disease

Drug	Normal (L/kg)	ESRD (L/kg)	Change from Normal (%)
Increased			
Amikacin	0.20	0.29	45
Azlocillin	0.21	0.28	33
Cefazolin	0.13	0.17	31
Cefoxitin	0.16	0.26	63
Cefuroxime	0.20	0.26	30
Clofibrate	0.14	0.24	71
Dicloxacillin	0.08	0.18	125
Erythromycin	0.57	1.09	91
Furosemide	0.11	0.18	64
Gentamicin	0.20	0.32	60
Isoniazid	0.6	0.8	33
Minoxidil	2.6	4.9	88
Nalmefene	7.9	14.7	86
Phenytoin	0.64	1.4	119
Trimethoprim	1.36	1.83	35
Vancomycin	0.64	0.85	33
Decreased			
Chloramphenicol	0.87	0.60	-31
Digoxin	7.3	4.0	-45
Ethambutol	3.7	1.6	-57
Pipemidic acid	2.0	0.84	-58

TABLE 51-2 Unbound Fraction of Selected Drugs in Patients with Normal Renal Function and End-Stage Renal Disease

Acidic Drugs	Normal	ESRD	Change from Normal (%)
Abecarnil	4	15	275
Azlocillin	62.5	75	20
Cefazolin	16	29	81
Cefoxitin	27	59	119
Ceftriaxone	10	20	100
Clofibrate	3	9	200
Dicloxacillin	3	9	200
Diffunisal	12	44	267
Doxycycline	12	28	133
Furosemide	4	6	50
Methotrexate	57.2	63.8	12
Metolazone	5	10	100
Moxalactam	48	64	33
Pentobarbital	34	41	21
Phenytoin	10	21.5	115
Salicylate	8	20	150
Sulfamethoxazole	34	58	71
Valproic acid	8	23	188
Warfarin	1	2	100
Basic Drugs	Normal	ESRD	Change from Normal (%)
Decreased			
Bepidil	0.3	0.1	-67
Clonidine	55.6	47.6	-14
Disopyramide	32	28	-13
Propafenone	3.4	2.4	-29
Increased			
Amphotericin B	3.5	4.1	17
Chloramphenicol	45	64	42
Clonazepam	13.9	16	15
Diazepam	2	8	300
Fluoxetine	5.5	6.5	18
Ketoconazole	1	1.5	50
Prazosin	6	10.1	68
Rosiglitazone	0.16	0.22	38
Triamterene	19	43	126

changes in the binding sites, accumulation of endogenous inhibitors of binding, and decreased concentrations of albumin. The first two of these mechanisms appear to account for most of the observed changes in binding. In addition, the high concentrations of metabolites of some compounds that accumulate in patients with ESRD may interfere with the protein binding of the parent compound.

② As a result of the decrease in protein binding, the unbound fraction of many acidic drugs increases in CKD patients. A new equilibrium is ultimately established as a result of increased drug elimination/distribution, such that the unbound concentrations remain comparable despite the fact that total concentrations are reduced. Thus the net effect of changes in protein binding is an alteration in the relationship between total drug concentration and pharmacodynamic effect. This can be illustrated with the anticonvulsant phenytoin. The protein binding of this acidic drug, which binds to albumin, is significantly reduced as a result of endogenous substances that accumulate in patients with renal failure and compete for binding, as well as by conformational changes in albumin in CKD patients.¹⁷ This change in protein binding alters the relationship between total phenytoin concentration and effect or toxicity. The resulting increase in unbound fraction, from the normal of 10% to ~20% or more, results in increased hepatic clearance and decreased total concentrations. Thus in patients with CKD, the therapeutic range based on total phenytoin concentration is shifted downward from normal values of 10 to 20 mg/L as the degree of residual renal

function declines. However, the unbound concentration therapeutic range is unchanged in the presence of RKF. Unbound concentration measurements thus provide the best means for individualizing phenytoin therapy in patients with RKF and should be used whenever they are available. Several equations have been proposed to approximate the equivalent “total” phenytoin concentration in an ESRD patient relative to an individual with normal renal function.¹⁷ Although these approaches have not been rigorously evaluated, they may be useful in some clinical settings to predict dosage requirements via a standard nonlinear approach. The principal binding protein for several basic drug compounds is α_1 -acid glycoprotein, an acute-phase reactant protein whose plasma concentrations are increased in renal transplant and hemodialysis patients.⁸ As a result of this increase, the unbound fraction of those drugs may be significantly decreased in ESRD patients.

Altered tissue binding may also affect the apparent volume of distribution of a drug. For example, the distribution volume of digoxin has been reported to be reduced by 30% to 50% from normal values in patients with stage 5 CKD, as well as in hemodialysis patients.¹⁸ This reduction in the distribution volume may be secondary to a decrease in tissue binding as a result of competitive inhibition by endogenous or exogenous substances. Multiple methods have been proposed to estimate the degree of reduction in digoxin's distribution volume.¹⁸ Acidosis or the presence of digoxin-like immunoreactive substances that bind to and inhibit membrane adenosine triphosphatase may also contribute to this phenomenon.¹⁹ In this situation, the absolute amount of digoxin bound to the receptor is reduced and the resultant serum digoxin concentration is higher than anticipated.

Knowledge of protein and tissue binding changes in patients with renal insufficiency is critically important in the interpretation of serum drug concentrations, as the unbound concentration of several drugs in plasma correlates more closely with the concentration of drug at the receptor site and, therefore, with the pharmacologic effect, than does the total concentration of drug in plasma.²⁰ Because an alteration in plasma protein or tissue binding of a drug will likely alter the total drug concentration, the usual expected relationship between total drug concentration and pharmacologic response will be perturbed, but the relationship to unbound drug should not be affected.

Thus in patients with renal insufficiency, particularly in those with ESRD, a “normal” total drug concentration may be associated with either an adverse reaction secondary to elevated unbound drug concentrations, or a subtherapeutic response because of an altered plasma-to-tissue drug concentration ratio. The monitoring of unbound drug concentrations in this patient population is warranted for those drugs that have a narrow therapeutic range, are highly protein bound (free fraction of <20%), and for which marked variability in the free fraction has been reported (e.g., phenytoin and disopyramide).

Finally, the method used to calculate the volume of distribution may be influenced by renal insufficiency. The three most commonly used volume of distribution terms are: volume of the central compartment (V_c), volume of the terminal phase (V and V_{area}), and volume of distribution at steady state (V_{ss}). The V_c for many drugs approximates extracellular fluid volume and thus may be increased or decreased by acute changes. Oliguric acute renal failure, is often accompanied by fluid overload and a resultant increased V_c for many drugs. The V_{area} or V_β represents the proportionality constant between plasma concentrations in the terminal elimination phase and the amount of drug remaining in the body. V_β is affected by both distribution characteristics, as well as by the terminal elimination rate constant. V_β and V_{ss} will often be similar in magnitude, with V_β being slightly larger. Because V_{ss} has the advantage of being independent of drug elimination, it is the most appropriate volume term to use when

one desires to compare drug distribution volumes between patients with renal insufficiency and those with normal renal function.²¹

EFFECT ON METABOLISM

3 A decrease in the renal clearance of drugs in patients with RKF is well appreciated. However, there is now good preclinical evidence that CKD may lead to alterations in nonrenal clearance in some cases as the result of changes in cytochrome P450 (CYP)-mediated metabolism in the liver and other organs.^{9,22,23} The observed clinical reductions in nonrenal clearance in CKD patients have been generally proportional to the reductions in glomerular filtration rate (GFR) (Table 51-3).⁸ However, the effect(s) of RKF on nonrenal drug clearance also appear to depend on whether the renal failure is acute or chronic in nature. The degree of reduction in those with acute renal failure does not appear to be as great as that observed in ESRD patients.¹²

In general, these studies should be interpreted with caution because concurrent drug intake, age, smoking status, and alcohol intake were often not controlled. Furthermore, the possibility of pharmacogenetic variation in drug-metabolizing enzymes (e.g., CYP enzymes) must be considered. Prediction of the effect of renal insufficiency on the metabolism of a particular drug is thus difficult and there is currently no quantitative strategy to factor these changes into an individualized treatment regimen. However, some qualitative insight can be gained if one knows what enzyme is involved in the metabolism of the drug of interest and how the enzyme(s) is affected by the presence of renal insufficiency.

Investigations of the effect of chronic renal failure on hepatic enzyme activity in animals have demonstrated reductions in some, but not all, pathways of drug metabolism.^{9,22,23} The mechanism(s) by which RKF affects hepatic drug metabolism is not clearly known, but may relate to accumulation of endogenous inhibitors (e.g., uremic toxins) or to the fact that CKD patients exist in a chronic inflammatory state and have increased levels of oxidative stress,²⁴ and other factors known to downregulate CYP enzymes.²⁵ In rat models of chronic renal failure, protein expression of several CYP enzymes, including CYP3A1 and CYP3A2 (corresponding to human CYP3A4), is reduced in the liver by as much as 75%. The mechanism of this decrease in protein content and messenger ribonucleic acid expression, suggests transcriptionally mediated downregulation.²² The in vivo relevance of these findings was demonstrated in rats with chronic renal failure using enzyme-selective breath tests; the results showed

TABLE 51-3 Effect of End-Stage Renal Disease on Nonrenal Clearance of Selected Drugs

Decreased			
Acyclovir	Aztreonam	Bufuralol	Captopril
Cefmenoxime	Cefmetazole	Cefonicid	Cefotaxime
Cefotiam	Cefsulodin	Ceftizoxime	Cilastatin
Cimetidine	Ciprofloxacin	Cortisol	Encainide
Erythromycin	Imipenem	Isoniazid	Methylprednisolone
Metoclopramide	Moxalactam	Nicardipine	Nimodipine
Nitrendipine	Procainamide	Quinapril	Repaglinide
Verapamil	Zidovudine		
Unchanged			
Acetaminophen	Chloramphenicol	Clonidine	Codeine
Diffunilal	Indomethacin	Insulin	Isradipine
Lidocaine	Morphine	Metoprolol	Nisoldipine
Nortriptyline	Pentobarbital	Propafenone	Quinidine
Theophylline	Tocainide	Tolbutamide	
Increased			
Bumetanide	Cefpiramide	Fosinopril	Nifedipine
Phenytoin	Rosiglitazone	Sulfadimidine	

that CYP2C11 and CYP3A2 activity was significantly reduced (by up to 35%), while CYP1A2 activity was no different from that in control animals.²³ Consistent with these observations in animals, CYP3A activity as measured by the erythromycin breath test is 28% lower in ESRD patients as compared to healthy controls.²⁶ Although baseline CYP3A activity was lower in these patients, the increase in CYP3A activity observed following enzyme induction with rifampin was similar.²⁶ Collectively, these data indicate that CKD has a detrimental effect on some important pathways of hepatic drug metabolism in animals and man.

In addition to changes in hepatic metabolism, chronic renal failure has also been shown in animals to affect the expression and activity of CYP enzymes in the intestine.²⁷ CYP1A1 and CYP3A2 enzyme content was reduced by 43% and 71%, respectively, and corresponding messenger ribonucleic acid levels were decreased by 32% and 36%, respectively. Although this has not been evaluated in humans, it may become clinically relevant for those drugs for which intestinal metabolism is known to be important (e.g., CYP3A substrates with low bioavailability).

Thus, current data suggest a differential effect on the individual CYP enzymes with the activity of some enzymes (e.g., CYP3A4 and CYP2C9) being reduced,^{26,28} while others (e.g., CYP2E1) are not affected.²⁹ This differential effect on individual enzymes may help to explain some of the conflicting reports of whether drug metabolism is altered in the presence of RKF.

EFFECT OF RENAL INSUFFICIENCY ON METABOLITE ELIMINATION

Patients with severe renal insufficiency who are receiving chronic treatment with some agents may experience accumulation of metabolite(s) as well as parent compound. Metabolites of several drugs have been reported to have significant pharmacologic and/or toxicologic activity. However, the pharmacokinetics and pharmacology of metabolites are not often fully elucidated in humans. In a sense, the patient with severe renal impairment is being exposed to a new pharmacologic entity if the serum concentrations of the metabolite exceed those reported in patients with normal renal function.

The metabolite may have pharmacologic activity similar to that of the parent drug and thus contribute significantly to clinical response; that is true, for example, of oxypurinol. Alternatively, the metabolite may have qualitatively dissimilar pharmacologic action; for example, normeperidine has central nervous system (CNS) stimulatory activity that reportedly produces seizures, whereas meperidine has CNS depressant actions.³⁰ Because of the multiplicity of potential interactions of compounds that are primarily metabolized, the practical consequences of metabolite accumulation are difficult to predict and are most often identified in those patients at risk by trial and error.

EFFECT OF RENAL INSUFFICIENCY ON RENAL EXCRETION

Renal clearance (CL_R) of a drug is the composite of GFR, tubular secretion, and reabsorption ($CL_R = (GFR \times f_u) + CL_{\text{secretion}} - CL_{\text{reabsorption}}$), where f_u is the fraction of the drug unbound to plasma proteins. Drug elimination by filtration occurs by a diffusion process, while tubular secretion and reabsorption are bidirectional processes that involve carrier-mediated renal transport systems.³¹ Renal transport systems have been broadly classified on the basis of substrate selectivity into the anionic and cationic renal transport systems, which are responsible for the transport of a number of organic acidic and basic drugs, respectively. Renal organic anion transport is mediated by transporters, transporting polypeptides, and multidrug resistance-associated

protein transporters.³¹ Several drugs, including β -lactam antibiotics, diuretics, and nonsteroidal antiinflammatory drugs, are actively secreted by one or more of these transporter families which also have an essential role in the elimination of glucuronide metabolites. Organic cation transport systems mediate the reabsorption and excretion of endogenous cationic compounds and drugs (e.g., cimetidine, famotidine, and quinidine). The P-glycoprotein transport system in the kidney is also involved in the secretion of cationic and hydrophobic drugs (e.g., digoxin and vinca alkaloids).³¹ Other important renal transport systems include the peptide transporters, which are involved in the uptake of peptide-like drugs including β -lactam antibiotics and angiotensin-converting enzyme inhibitors, while nucleoside transporter proteins are involved in uptake of nucleosides and nucleoside analogs (e.g., zidovudine and dideoxyinosine).

Alterations in filtration, secretion, or reabsorption, secondary to CKD may have a dramatic effect on drug disposition: for drugs that are primarily filtered, a reduction in glomerular filtration rate will result in a proportional decrease in renal drug clearance. However, for drugs that are extensively renally secreted ($CL_R > 300$ mL/min), the loss of filtration clearance (up to 120 mL/min) will have less of an impact. In the absence of data delineating the contribution of tubular function to renal clearance, the clinical measurement or estimation of creatinine clearance remains the guiding factor for drug-dosage regimen design.^{8,10} Although several methods have been proposed to estimate GFR from routinely available clinical data (see Chap. 44) the usefulness of a calculated GFR to guide drug dosing has not been extensively evaluated.^{32,33}

The importance of an alteration in renal function on drug elimination depends on two factors: the fraction of drug normally eliminated by the kidney unchanged and the degree of renal insufficiency. Quantitation of the patient's renal function can be accomplished by measurement of creatinine clearance or estimation based on the stable serum creatinine concentration (see Chap. 44). Because of the time delay involved and problems in obtaining complete urine collections, measured creatinine clearance values are infrequently used for initial drug-dosage regimen design. Therefore the calculation of initial drug dosage regimens relies on the estimation of creatinine clearance (CL_{cr}) in adults and children from such routinely available clinical data as age, gender, height, weight, and serum creatinine. These relationships are most accurate for individuals of average muscle mass for their age, weight, and height. The creatinine clearance of emaciated and obese adult patients is difficult to predict, and incorrect estimates have been obtained with most methods.

Several methods are also available for estimating creatinine clearance in adults with acute renal failure using age, height, weight, serum creatinine, and time data (see Chap. 44). These methods have not been independently validated and their usefulness for approximating renal function in complex patient situations is not currently recommended.

DRUG-DOSAGE REGIMEN DESIGN FOR CHRONIC KIDNEY DISEASE PATIENTS

4 Table 51–4 lists the typical steps involved in designing a dosage regimen for a patient with CKD. The design of the optimal dosage regimen for patients with RKF is dependent on the availability of an accurate characterization of the relationship between the pharmacokinetic parameters of the drug and renal function, and an accurate assessment of the patient's renal function, CL_{cr} . Prior to 1998 there was no consensus regarding the explicit criteria for characterization of the relationship between the pharmacokinetics and pharmacodynamics of a drug and renal function. The United States Food and Drug Administration (FDA) industry guidance issued in May 1998 provided a framework to help companies decide when

TABLE 51-4 A Stepwise Approach to Adjust Drug Dosages for Patients with Renal Insufficiency

Step 1	Obtain history and relevant demographic/clinical information	Record demographic information, obtain past medical history including history of renal disease, and record current laboratory information (e.g., serum creatinine)
Step 2	Estimate creatinine clearance	Use Cockcroft-Gault equation to estimate creatinine clearance, or calculate creatinine clearance from timed urine collection
Step 3	Review current medications	Identify drugs for which individualization of the treatment regimen will be necessary
Step 4	Calculate individualized treatment regimen	Determine treatment goals (see text); calculate dosage regimen based on pharmacokinetic characteristics of the drug and the patient's renal function
Step 5	Monitor	Monitor parameters of drug response and toxicity; monitor drug levels if available/applicable
Step 6	Revise regimen	Adjust regimen based on drug response or change in patient status (including renal function) as warranted

they should conduct such a “characterization” study and proposed explicit recommendations for study design, data analysis, and assessment of the impact of the study results on drug dosing.³⁴ Thus the quality of data available to clinicians has improved dramatically in the last 10 years.

Most dosage-adjustment guidelines have proposed the use of a fixed dose or interval for patients with broad ranges of renal function.^{11,13,35–39} Indeed, normal renal function has often been ascribed to anyone who has a $CL_{cr} > 90$ mL/min even though there are many individuals who have CL_{cr} values in the range of 120 to 180 mL/min. Mild renal insufficiency encompasses the range of 60 to 89 mL/min, moderate renal insufficiency encompasses the CL_{cr} range of 30 to 59 mL/min, and severe renal insufficiency and ESRD often are defined as a creatinine clearance of 15 to 29 mL/min, and < 15 mL/min, respectively. Each of these categories encompasses at least a twofold range in renal function, and thus the calculated drug regimen may not be optimal for all patients whose renal function lies within the given range.

5 Secondary references, such as the American Hospital Formulary Service Drug Information Service,³⁵ the British National Formulary,³⁶ *Drug Prescribing in Renal Failure*,³⁷ and *Martindale: The Complete Drug Reference*,³⁸ are generally touted as excellent sources of information about a drug's pharmacokinetic characteristics in subjects with normal and impaired renal function. A recent systematic comparison of these four sources strongly suggests a need for a more consistent quantitative approach to drug dosage regimen individualization for those with CKD.⁴⁰ The authors concluded that the remarkable variation in recommendations along with the paucity of details of the methods used to generate the dosing advice, as well as the lack of reference to primary literature made these sources of drug information ill suited for clinical use. None of these sources consistently provide the explicit relationships of the kinetic parameters of interest (total body clearance, elimination rate constant, and distribution volume) with a continuous index of renal function, such as CL_{cr} . To find this information, one may need to identify the original research study that assessed the drug's disposition or a comprehensive review article on the class of drugs of interest. For many drugs one may be able to identify several of these relationships—some derived from rigorous premarketing evaluations of new drugs conducted in adequately sized studies and others from population analysis of already marketed drugs. The relationship of the most clinical value will be dependent on the similarities between the population of subjects/patients who were studied and the patient's given clinical situation. Ideally, one should be able to identify a relationship between total body clearance (CL) or elimination rate constant (k) with CL_{cr} , such

TABLE 51-5 Relationship Between Creatinine Clearance and Total-Body Clearance and Terminal Elimination Rate Constant of Selected Drugs

Drug	Elimination Rate Constant	Total Body Clearance
Acyclovir		$CL = 3.37 (CL_{cr}) + 0.41$
Amikacin	$k = (0.0024 \times CL_{cr}) + 0.01$	$CL = 0.6 (CL_{cr}) + 9.6$
Ceftazidime	$k = (0.004 \times CL_{cr}) + 0.004$	$CL = 1.15 (CL_{cr}) + 10.6$
Ciprofloxacin		$CL = 2.83 (CL_{cr}) + 363$
Digoxin		$CL = 0.88 (CL_{cr}) + 23$
Gentamicin	$k = (0.0029 \times CL_{cr}) + 0.015$	$CL = 0.983 (CL_{cr})$
Lithium		$CL = 0.20 (CL_{cr})$
Ofloxacin		$CL = 1.04 (CL_{cr}) + 38.7$
Piperacillin	$k = (0.0049 \times CL_{cr}) + 0.21$	$CL = 1.36 (CL_{cr}) + 1.50$
Tobramycin	$k = (0.0029 \times CL_{cr}) + 0.01$	$CL = 0.801 (CL_{cr})$
Vancomycin	$k = (0.00083 \times CL_{cr}) + 0.0044$	$CL = 0.69 (CL_{cr}) + 3.7$

CL , total-body clearance; CL_{cr} , creatinine clearance.

as those depicted in Table 51–5. This information, along with the patient's CL_{cr} , will enable prediction of the patient's disposition parameters and then formulation of a therapeutic regimen to attain the desired therapeutic outcome.

If specific literature recommendations and/or the relationship of kinetic parameters to CL_{cr} are not available, then one can estimate the CL or k of the patient with the method of Rowland and Tozer,¹⁰ provided the fraction of the drug that is eliminated renally unchanged (f_e) in subjects with normal renal function is known.¹³ This approach assumes that the change in CL and k are proportional to CL_{cr} , that renal disease does not alter the drug's metabolism, that the metabolites, if formed, are inactive and nontoxic, that the drug obeys first-order (linear) kinetic principles, and that it is adequately described by a one-compartment model. If these assumptions are true, then the kinetic parameter/dosage adjustment factor (Q) can be calculated as:

$$Q = 1 - [f_e(1 - KF)]$$

where KF is the ratio of the patient's CL_{cr} to the assumed normal value of 120 mL/min. Thus for a drug that is 85% eliminated renally unchanged in a patient who has a CL_{cr} of 10 mL/min, the Q factor would be:

$$\begin{aligned} Q &= 1 - [0.85(1 - (10/120))] \\ &= 1 - [0.85(0.92)] \\ &= 1 - 0.78 \\ &= 0.22 \end{aligned}$$

The estimated total body clearance for this patient can then be calculated as $CL_{PT} = CL_{norm} \times Q$, where CL_{norm} is the mean value in patients with normal renal function as reported in the literature.

After the kinetic parameters for the patient are estimated, the best method for dosage-regimen adjustment should be selected. Specifically, one must determine whether the desired goal is the maintenance of a similar peak, trough, or average steady-state drug concentration. If there is a significant relationship between peak concentration and clinical response⁴¹ (e.g., aminoglycosides) or toxicity⁴² (e.g., quinidine, phenobarbital, and phenytoin), then attainment of the specific target values is critical. If, however, no specific target values for peak or trough concentrations have been reported (e.g., antihypertensive agents, benzodiazepines, and cephalosporins), then a regimen goal of attaining the same average steady-state concentration may be appropriate.

Although several methods have been proposed to attain the desired average steady-state concentration profile, the principal choices are to decrease the dose or prolong the dosing interval. If the size of the dose is reduced while the dosing interval remains unchanged, the desired average steady-state concentration will be

FIGURE 51-1. Although the average steady-state concentrations (C_{ave}) are identical regardless of which dosage adjustment strategy one decides to implement, the concentration–time profile will be markedly different if one changes the dose and maintains the dosing interval (τ) constant (*Scenario A*), versus changing the dosing interval and maintaining the dose constant (*Scenario B*) or changing both (*Scenario C*).

similar; however, the peak will be lower and the trough higher (Fig. 51–1). Alternatively, if the dosing interval is increased and the dose size remains unchanged, the peak and trough concentrations in the patient with reduced renal function will be similar to those in the patient with normal renal function. This dosage adjustment method is often recommended because it is likely to yield significant cost savings as a result of a reduction in nursing and pharmacy time, as well as a reduction in the supplies associated with frequent drug administration. Finally, the dose and dosing interval may both need to be changed to allow the administration of a clinically feasible dose (500 mg vs. a calculated value of 487 mg) or a practical dosing interval, for example, 12 hours instead of 17 hours.

The first step in the process, if the relationship between the pharmacokinetic parameters of the drug and renal function are known, is to estimate the drug disposition parameters in the patient with renal insufficiency. The ratio (Q) of the estimated elimination rate constant or total body clearance of the patient relative to subjects with normal renal function ($CL_{\text{cr}} = 120 \text{ mL/min}$) may then be calculated. This parameter may be used to determine the dose or dosing interval alterations necessary for the patient.

For example, the following relationship between total clearance (CL) and creatinine clearance has been reported for ganciclovir⁴³:

$$CL(\text{mL/min}/1.8 \text{ m}^2) = 1.25(CL_{\text{cr}}) + 8.57$$

Thus CL for a subject with normal renal function (CL_{norm}) would be calculated as:

$$CL_{\text{norm}} = [1.25(120)] + 8.57$$

$$CL_{\text{norm}} = 158.6 \text{ mL/min per } 1.8 \text{ m}^2$$

Clearance (CL_{fail}) for a patient with a creatinine clearance of 10 mL/min would be:

$$CL_{\text{fail}} = [1.25(10)] + 8.57$$

$$CL_{\text{fail}} = 21.1 \text{ mL/min per } 1.8 \text{ m}^2$$

Ganciclovir is commonly used in solid-organ transplantation patients as prophylaxis against or treatment for cytomegalovirus

infection.⁴⁴ The inhibitory concentration of 50% (IC_{50}) of ganciclovir against most clinical isolates of cytomegalovirus is between 0.1 and 2.8 mcg/mL (approximately 0.4 to 11 $\mu\text{mol/L}$).⁴³ Consequently, trough concentrations should be maintained within this range, but caution is warranted as neutropenia is associated with the attainment of ganciclovir trough concentrations exceeding 2.6 mcg/mL (10 $\mu\text{mol/L}$).⁴⁵ If a patient with ESRD received the typical ganciclovir dose for a patient with normal renal function, the predicted trough concentrations would approach 20 $\mu\text{mol/L}$. Consequently, a dosage modification in this patient is necessary to avoid potential toxicity. The dosing regimen can be modified using the ratio of the predicted clearance values. The quotient or Q for this patient is calculated as:

$$Q = CL_{\text{fail}}/CL_{\text{norm}}$$

$$Q = 21.1/158.6$$

$$Q = 0.133$$

where CL_{norm} is the clearance in a patient with normal renal function and CL_{fail} is the clearance of the patient with impaired renal function.

The maintenance dose (D_f) for the patient or the adjusted dosing interval (τ_f) may then be calculated from the following relationships, where D_n is the normal dose and τ_n is the normal dosing interval:

$$D_f = D_n \times Q$$

$$\tau_f = \tau_n/Q$$

For this patient situation, the normal dose and dosing interval of ganciclovir would be 5 mg/kg and 12 hours, respectively. If we wanted to maintain the dosing interval at 12 hours, then D_f would be calculated as:

$$D_f = (5 \text{ mg/kg}) \times (0.133) = 0.67 \text{ mg/kg}$$

This regimen would result in decreased peak and trough concentrations compared to a patient with this degree of renal insufficiency who received a normal dosage regimen (Fig. 51–1, Scenario A). However, the peak concentrations would be lower and the trough

concentrations higher than those observed when a patient with normal renal function received a standard regimen.

If we want to maintain D_n and extend the dosing interval, τ_f would be calculated as:

$$\tau_f = \tau_n / Q = 12 / 0.133 = 90 \text{ hours}$$

This regimen would yield similar peak and trough concentrations in the renally impaired patient as in the patient with normal renal function, but there is a risk of missed doses with such an unorthodox interval (Fig. 51–1, Scenario B). In addition, the prolonged period below the steady-state drug concentration (C_{ss}) average concentration may be less than optimal.

Finally, a practical dosing interval (τ_p) may be selected and then a dose based on that interval can be calculated. If a dosage interval τ_f of 24 hours were selected, because in many institutions there is an increased risk of missed doses with longer dosing intervals, then the D_f would be calculated as follows:

$$\begin{aligned} D_f &= [D_n \times Q \times \tau_f] / \tau_p \\ &= [(5 \text{ mg/kg}) \times (0.133) \times (24)] / 12 \\ &= 1.33 \text{ mg/kg} \end{aligned}$$

This method would likely be most appropriate in this case, as prolonged subtherapeutic concentrations are avoided and troughs are reduced from the first method (Fig. 51–1, Scenario C). The selection of which dosage adjustment method to use to calculate an optimal regimen depends on the drug characteristics and the patient care situation. This dosage adjustment method assumes that the protein binding and volume of distribution of the drug are not significantly altered by renal insufficiency. Thus this approach cannot be used with accuracy for those drugs with demonstrated differences in these pharmacokinetic parameters.

If the volume of distribution (V_D) of a drug is significantly altered in patients with renal insufficiency or in whom one desires to attain a specific maximum or minimum concentration, the estimation of a dosage regimen becomes more complex. If the relationship between V_D and creatinine clearance has been characterized, then V_D may be estimated. If one assumes that a one-compartment linear model can describe the drug, the predicted V_D may then be used with the predicted elimination rate constant (k) of the drug to yield an adjusted dosing interval and intravenous or oral dose. For orally administered drugs, the τ_f can be calculated and the dose can then be approximated as:

$$\tau_f = [(-1/k_f)(\ln[C_{\min}/C_{\max}])] + t_{\text{peak}}$$

$$\text{Dose}_{\text{po}} = [FC_p^t V_D (k_a - k)] / [k_a (e^{-kt}/1 - e^{-k\tau}) (e^{-kat}/1 - e^{-ka\tau})]$$

where, F equals bioavailability, C_p^t equals the desired plasma concentration at time t , and k_a is the absorption rate constant. This approach allows for the individualization of an oral dosage regimen for attainment of specific peak and trough serum concentrations. If the drug is absorbed extremely rapidly, one can approximate the τ_f and the dose using equations originally proposed for IV dosing as:

$$\tau_f = (-1/k_f)(\ln[C_{\min}/C_{\max}])$$

$$\text{Dose}_{\text{po}} = V_D \times (C_{\max} - C_{\min})$$

Digoxin is a frequently used oral medication for which the V_D is decreased in patients with renal insufficiency, and for which one usually desires to closely control the plasma concentration time profile. The V_D and CL_{fail} of digoxin can be estimated for a 70-kg patient with a CL_{cr} of 12 mL/min per 1.73 m² as summarized by Job¹⁸:

$$\begin{aligned} V_D &= 226 + [(298(CL_{\text{cr}}))/(29.1 + CL_{\text{cr}})] \\ &= 226 + [(298(12))/(29.1 + 12)] \end{aligned}$$

$$= 226 + 87.0$$

$$= 313 \text{ L}$$

$$CL_{\text{fail}} = (0.88 \times CL_{\text{cr}}) + 23 \text{ mL/min}$$

$$= 10.6 + 23$$

$$= 33.6 \text{ mL/min}$$

$$k_f = CL_{\text{fail}} / V_D$$

$$= (33.6 \text{ mL/min} \times 1440 \text{ min/d}) / 313 \text{ L}$$

$$= (48.3 \text{ L/d}) / 313 \text{ L}$$

$$= 0.154 \text{ day}^{-1}$$

The t_{peak} is generally at 2 hours, and the k_a from the literature is about 0.76 hour⁻¹ or 18 day⁻¹.¹³ Thus one now has all the information needed to calculate the τ_f and dose for this patient:

$$\begin{aligned} \tau_f &= [(-1/k_f)(\ln[C_{\min}/C_{\max}])] + t_{\text{peak}} \\ &= [(-1/0.154)(\ln[0.8/1.4])] + 2 \text{ hours} \\ &= [(-6.49)(-0.56)] + 2 \text{ hours} \\ &= 3.6 \text{ days} + 2 \text{ hours} \\ &\approx 4 \text{ days} \end{aligned}$$

$$\begin{aligned} \text{Dose}_{\text{po}} &= [(1)(1.4)(313)(18 - 0.154)] / [18(e^{-0.154(0.083)} / 1 - e^{-0.154(4)}) - (e^{-18(0.083)} / 1 - e^{-18(4)})] \\ &= 0.226 \text{ mg or one 0.25 mg oral capsule every 4 days} \end{aligned}$$

Alternatively, the predicted volume of distribution and elimination rate constant or the total body clearance may be used to calculate a dose regimen that will maintain the desired average C_{ss} of the drug:

$$\text{Dose (mg/h)} = C_{ss} [(k_f \times V_D) \text{ or } (CL_f)]$$

Depending on how much variance above and below the average steady state one desires, the dosing interval may range from hourly to as infrequently as every 48 hours or longer. For example, if the calculated dose were 10 mg/h, the desired average steady-state concentration would be maintained with a dosing interval of 60 mg every 6 hours or 480 mg every 48 hours.

PATIENTS RECEIVING CONTINUOUS RENAL REPLACEMENT THERAPY

Continuous renal replacement therapies are used for the management of fluid overload and the removal of uremic toxins in patients with acute renal failure and other conditions.⁴⁶ The several forms of continuous renal replacement therapy in clinical use today are extensively described in Chap. 45. Which of these therapies will be optimal for a given patient is dependent on several factors, including bleeding risk, degree of hypercatabolism, acid-base balance, and experience of the healthcare provider. Chapter 45 discusses drug therapy individualization for the patient receiving any one of the most popular continuous renal replacement therapy variants.

PATIENTS RECEIVING CHRONIC PERITONEAL DIALYSIS

Although the majority of patients with ESRD receive treatment with hemodialysis, as of 2004 approximately 25,765 receive one of the multiple variants of chronic peritoneal dialysis.⁴⁷ Peritoneal dialysis, like other dialysis modalities, has the potential to affect drug disposition; however, drug therapy individualization is often less complicated in these patients as a result of the limited drug clearances achieved with the procedures (see Chap. 48).

Many of the factors that are important in determining drug dialyzability for other treatment modalities pertain to peritoneal dialysis as well.^{48,49} Peritoneal dialysis involves the instillation of 1 to 3 L of dialysis solution into the peritoneal cavity. Waste products and other substances, including drugs, move from the blood and surrounding tissues into the dialysis solution by means of diffusion and ultrafiltration. Factors that influence drug dialyzability in peritoneal dialysis include drug-specific characteristics such as molecular weight, solubility, degree of ionization, protein binding, and volume of distribution. The intrinsic properties of the peritoneal membrane that affect drug removal include blood flow, pore size, and peritoneal membrane surface area, which is approximately equal to the body surface area. There is an inverse relationship between peritoneal drug clearance and molecular weight, protein binding, and volume of distribution. Also, drug compounds that are ionized at physiologic pH will diffuse across the membrane more slowly than unionized compounds. In general, hemodialysis is more effective in removing drug substances than peritoneal dialysis such that if a drug is not removed by hemodialysis, it is unlikely to be removed by peritoneal dialysis. Detailed reviews of the disposition of other drugs in chronic peritoneal dialysis patients are reported elsewhere.^{48,50} Antiinfective agents are the most commonly studied drugs because of their primary role in the treatment of peritonitis.^{49,51} (See Chap. 48.) Most other drugs can generally be dosed based on the residual renal function of the patient because the additional clearance by peritoneal dialysis is so small.

PATIENTS RECEIVING CHRONIC HEMODIALYSIS

The number of patients with ESRD who receive chronic hemodialysis has steadily increased since the early 1970s; currently, more than 309,269 patients are being treated with this life-sustaining therapy.⁴⁷ Although many new hemodialyzers have been introduced in the past 20 years and more than 100 different ones were available in the United States in 2007, the effect of hemodialysis on drug disposition is rarely reevaluated after it is initially reported. Thus most of the literature probably represents an underestimation of the impact of hemodialysis on drug disposition.

6 The impact of hemodialysis on a patient's drug therapy is dependent on several factors, including the characteristics of each drug, the dialysis conditions, and the clinical situation for which dialysis is performed. Drug-related factors that affect dialyzability include the molecular weight or size, degree of protein binding, and distribution volume.⁸ Prior to the mid-1980s these were the primary factors that needed to be known to assess the degree of dialyzability of a given drug, because the vast majority of dialysis filters were composed of cellulose, cellulose acetate, or regenerated cellulose (cuprophane; see Chap. 48), which were generally impermeable to drugs with a molecular weight greater than 1,000 daltons, and the clearance by hemodialysis tended to decline dramatically (by up to 60%) as molecular weight increased from 100 to 500 daltons. Drugs that are small but highly protein bound also are not well dialyzed because both of the principal binding proteins, α_1 -acid glycoprotein and albumin, have a very high molecular weight. Finally, those drugs that are widely distributed throughout the body are poorly removed by hemodialysis.

The dialysis prescription for the patient can also dramatically affect the dialysis clearance. The primary factors that can vary between patients are the composition of the dialysis filter, the filter surface area, the blood and dialysate flow rates, and whether or not the dialysis unit reuses the dialysis filter. Dialysis membranes are composed of cellulose-based, semisynthetic, or synthetic materials (e.g., polysulfone, polymethylmethacrylate, or acrylonitrile). The synthetic filters are available for low-, medium-, and high-flux modes of dialysis (see Chap. 48), with the principal difference between modes being the degree of water transport which is expressed as the ultrafiltration coefficient in mL of water removal per mm Hg pressure in the

TABLE 51-6 Drug Disposition during Dialysis Depends on Dialyzer Characteristics				
Drug	Hemodialysis Clearance (mL/min)		Half-Life during Dialysis (h)	
	Conventional	High Flux	Conventional	High Flux
Ceftazidime	55–60	155 ^a	3.3	1.2 ^a

dialysate circuit (see Chap. 48). High-flux dialysis membranes have the largest pore sizes and more closely mimic the filtration characteristics of the human kidney than the filters used to deliver conventional hemodialysis. This allows the passage of most solutes, including drugs, that have a molecular weight of 20,000 daltons or less.⁵² Thus high-molecular-weight drugs such as vancomycin are extensively cleared by this mode of dialysis, although their clearance by conventional dialysis is minimal. An increase in removal has also been reported with several other drugs that have lower molecular weights (Table 51-6).⁵³ Figure 51-2 shows the plasma concentration–time profile of gentamicin in a patient receiving dialysis with a low-flux conventional (cellulose acetate [CA170]) or a high-flux (polysulfone [F80]) dialyzer. Because the clearance of gentamicin with the high-flux dialysis procedure is significantly greater than with the low-flux conventional procedure, the patient receiving high-flux dialysis will require larger doses relative to the patient receiving low-flux dialysis to maintain a similar plasma concentration–time profile.

The impact of hemodialysis on drug therapy should thus not be viewed as a generic procedure such that a certain percentage of drug

FIGURE 51-2. Clearance of gentamicin by low- and high-clearance dialyzers in a patient given the same gentamicin dose after each dialysis treatment. Concentrations in the patient receiving dialysis with a low-clearance dialyzer will experience a steady rise in the serum concentrations, whereas concentrations in the patient receiving dialysis with the high-clearance dialyzer will be maintained at the same peak and predialysis concentrations observed after the third dose.

in the body is removed with each dialysis session; neither should simple “yes–no” answers on the dialyzability of drug compounds be considered sufficient information to make therapeutic decisions. Reference materials that indicate “yes–no” status regarding the dialyzability of drug compounds provide no quantification of the impact of hemodialysis, and are thus of little value to the clinician who needs to design a dosing regimen for a patient. Compounds considered non-dialyzable with low-flux dialyzers in fact may be significantly removed by high-flux hemodialyzers. Characteristics of the dialysis procedure that was studied, such as membrane composition and surface area, and blood and dialysis flow rates, are thus critical data that should be known before one uses the hemodialysis clearance data to prospectively design a drug-dosing regimen for a hemodialysis patient.

The quantitative impact of hemodialysis on drug disposition can be calculated in several ways.⁸ The determination of the half-life during dialysis ($t_{1/2, \text{onHD}}$), has frequently been used as an index of drug removal by dialysis. Unfortunately, the $t_{1/2, \text{onHD}}$ may not be interpretable because declining plasma drug concentrations during dialysis represent elimination by the body as well as by dialysis. Furthermore, if significant rebound in drug concentrations after dialysis has been reported, the half-life of drug during dialysis procedure may be artificially low.^{54–58} An alternative and more accurate means of assessing the effect of hemodialysis is to calculate the dialyzer clearance (CL_D) of the drug.⁸ The CL_D can be calculated by several approaches. The CL_D from blood can be calculated as $CL_D^b = Q_b [(A_b - V_b)/A_b]$, where Q_b is blood flow through the dialyzer, A_b is the concentration of drug in blood going into the dialyzer, and V_b is the blood concentration of drug leaving the dialyzer. This equation is valid only if the drug concentrations are measured in whole blood and if the drug rapidly and completely distributes into red blood cells. Because drug concentrations are generally determined in plasma, the previous equation is usually modified to $CL_D^p = Q_p [(A_p - V_p)/A_p]$ where p represents plasma and Q_p is plasma flow, which equals $Q_b (1 - \text{hematocrit})$. This clearance calculation most accurately reflects dialysis drug clearance as most drugs do not significantly penetrate red blood cells or bind to formed blood elements. However, one must keep in mind that venous plasma concentrations may be artificially high and CL_D^p will be low if plasma water is removed from the blood at a faster rate than drug. This tends to occur when extensive ultrafiltration is performed simultaneously with diffusion during dialysis.

The recovery clearance approach, the benchmark for the determination of dialyzer clearance, can be calculated as⁸:

$$CL_D^r = R/AUC_{0-t}$$

where R is the total amount of drug recovered unchanged in the dialysate and AUC_{0-t} is the area under the predialysis plasma concentration–time curve during the period of time that the dialysate was collected. To determine the AUC_{0-t} , at least two, and preferably three to four, plasma concentrations should be obtained during dialysis.

The hemodialysis clearance values reported in the literature may vary significantly depending on which of these methods were used to calculate CL_D . The principal reason for this is that for most medications we do not know the degree and rapidity with which the drug crosses the red blood cell membrane. Because the CL_D^r method incorporates no assumption of the degree of red blood cell permeability, it can be reliably used as the benchmark value. The primary limitation of this calculation is that the concentrations of the drug in the dialysate may be below the sensitivity limits of the assay.

The following principles may be used to generate a drug-dosage regimen recommendation for hemodialysis patients by using a value of CL_D that is reported in the literature.^{8,53} Because clearance terms are additive, the total clearance during dialysis can be calculated as the sum of the patient’s residual renal and nonrenal

clearance during the interdialytic period (CL_{RES}) and dialyzer clearance (CL_D):

$$CL_T = CL_{\text{RES}} + CL_D$$

The half-life during the period between dialysis treatments and during dialysis can then be calculated from the following relationships using an estimate of the drug’s distribution volume (V_D), which can be obtained from the literature¹³:

$$t_{1/2, \text{offHD}} = 0.693 [V_D/CL_{\text{RES}}]$$

$$t_{1/2, \text{onHD}} = 0.693 [V_D/(CL_{\text{RES}} + CL_D)]$$

Once the key pharmacokinetic parameters have been estimated/calculated, they may be used to simulate the plasma concentration–time profile of the drug for the individual patient and then one can ascertain how much drug to administer and when. This approach to drug therapy individualization can be accomplished in a stepwise fashion assuming first-order elimination of the drug and a one-compartment model.

For example, a 34-year-old male with ESRD was admitted to a hospital from the outpatient hemodialysis unit, where he experienced shaking and chills and had a temperature of 40°C (104°F). He weighed 70 kg and was 69 inches tall, had a residual CL_{cr} of 3 mL/min, and received high-flux dialysis for 3 hours three times a week on an F80 polysulfone dialyzer. He received 140 mg of gentamicin at the end of his most recent hemodialysis treatment, which ended less than an hour prior to admission to the hospital.

The first step is to estimate this patient’s pharmacokinetic parameters of gentamicin on the basis of published population data.¹³ The volume of distribution in this patient is 23.1 L ($0.33 \text{ L/kg} \times 70 \text{ kg}$), and his residual total body clearance (CL_{RES}) estimated from the relationship between CL and creatinine clearance [$CL_{\text{RES}} = CL_{\text{cr}} \times 0.98$] is 3 mL/min or 0.176 L/h. The elimination rate constant can be approximated as:

$$\begin{aligned} k &= CL_{\text{RES}} \div V_D \\ &= 0.176 \text{ L/h} \div 23.1 \text{ L} \\ &= 0.0076 \text{ hr}^{-1} \end{aligned}$$

The hemodialysis clearance of gentamicin is dependent on the dialyzer, and a value of 116 mL/min was recently reported by Amin et al.⁵⁹

One now can predict what the plasma concentrations of gentamicin will be over the next 24 to 48 hours, assuming the infusion time for the drug (t') was 30 minutes. The concentration at the end of the 30-minute infusion (C_{max}) would be:

$$\begin{aligned} C_{\text{max}} &= \frac{(\text{Dose}/t')1 - e^{-kt'}}{CL_{\text{RES}}} \\ C_{\text{max}} &= \frac{(280 \text{ mg/h})1 - e^{-(0.0076)0.5}}{0.176 \text{ L/H}} \\ C_{\text{max}} &= (1,944 \text{ mg/L}) (0.003) = 6.0 \text{ mg/L} \end{aligned}$$

The plasma concentration prior to the next dialysis session (C_{bD}), which is 44 hours away, and the concentration after dialysis (C_{aD}) can be calculated as:

$$\begin{aligned} C_{\text{bD}} &= C_{\text{max}} \times e^{-(CL_{\text{RES}}/V_D) \times t} \\ &= 6.0 \times e^{-0.0076 \times 44} \\ &= 4.3 \text{ mg/L} \\ C_{\text{aD}} &= C_{\text{bD}} \times e^{-((CL_{\text{RES}} + CL_D)/V_D) \times t} \\ &= 4.3 \times e^{-((0.176 + 6.96)/23.1) \times 4} \end{aligned}$$

$$= 4.3 \times e^{-0.309 \times 4}$$

$$= 1.25 \text{ mg/L}$$

On the basis of these data, a second dose will likely be required at the end of the next dialysis session as one generally desires to have gentamicin concentrations fall below 2 mg/L before administering another dose.

During this interdialytic interval, however, several blood samples were collected to characterize this patient's residual gentamicin clearance, distribution volume, and the clearance of gentamicin during dialysis. Blood samples were therefore collected at the following times after the first dose:

DAY 1: 7 PM (2 hours after dose)	6.5 mg/L
DAY 2: 8 AM (39 hours after dose; just before dialysis)	4.1 mg/L
DAY 3: 12 noon (immediately after dialysis)	2.0 mg/L

The C_{\max} can be calculated by back-extrapolation to the end of the infusion as described in Chap. 5. The elimination rate during the interdialytic period (k_{ID}) and during dialysis (k_{DD}), and the V_D can be calculated as:

$$V_D = \frac{\text{Dose}/t'}{k_{\text{ID}}} \frac{1 - e^{-k_{\text{ID}}t'}}{(C_{\max} - C_{\min}e^{-k_{\text{ID}}t'})}$$

$$V_D = \frac{140/0.5}{0.0125} \frac{1 - e^{-(0.0125)0.5}}{(6.7 - 0.0e^{-(0.0125)0.5})}$$

$$V_D = \frac{134.4}{6.7} = 20 \text{ L}$$

$$k_{\text{ID}} = (\ln C_1/C_2)/\Delta t$$

$$k_{\text{ID}} = (\ln 6.5/4.1)/37 = 0.0125/\text{h}$$

$$k_{\text{DD}} = (\ln C_2/C_3)/\Delta t$$

$$k_{\text{DD}} = (\ln 4.1/2.0)/4 = 0.179/\text{h}$$

where Δt is the time in hours between the two measured concentrations and C_{\min} is the gentamicin concentration in plasma prior to the administration of this dose.

The patient's residual clearance (CL_{RES}) of gentamicin can then be calculated as:

$$\text{CL}_{\text{RES}} = V_D \times k_{\text{ID}}$$

$$\text{CL}_{\text{RES}} = 20.0 \text{ L} \times 0.0125 = 0.25 \text{ L/h or } 4.2 \text{ mL/min}$$

The dialyzer clearance (CL_D) can be calculated as follows because one knows the total clearance during dialysis (CL_T) and CL_{RES} :

$$\text{CL}_D = \text{CL}_T - \text{CL}_{\text{RES}}$$

$$\text{CL}_D = (k_{\text{DD}} \times V_D) - 4.2 \text{ mL/min}$$

$$\text{CL}_D = (0.179/\text{h} \times 20.0 \text{ L}) - 4.2 \text{ mL/min}$$

$$\text{CL}_D = (3.6 \text{ L/h or } 59.6 \text{ mL/min}) - 4.2 \text{ mL/min}$$

$$\text{CL}_D = 55.4 \text{ mL/min}$$

This case illustrates the need for individualizing drug therapy for hemodialysis patients as this patient's V_D was 13% smaller, CL_{RES} was 42% greater, and CL_D was more than 50% less than the estimates based on population parameters.

The ultimate reason for measuring the plasma concentrations of aminoglycosides and several other agents is to individualize the patient's dosage regimen to achieve a bacteriologic cure while preserving residual renal function. Thus there remains one impor-

tant step in our evaluation: the calculation of the dose this patient should receive next. The two factors that enter into this decision are the desired peak and trough concentrations and the degree of rebound in drug concentrations, after the end of dialysis. Because gentamicin concentrations have been noted to increase by approximately 25% within 1.5 to 2 hours after the end of hemodialysis, the trough concentration of this patient can be considered to be 2.5 mg/L ($2.0 \text{ mg/L} \times 1.25$). Although this value is higher than one might like to maintain in an individual with normal renal function, a prolonged period of almost 24 hours would be required just to have the concentration drop below 2.0 mg/L. It is frequently necessary in critically ill individuals with ESRD to redose the patient even though the postdialysis trough serum concentration is between 2 and 3 mg/L. Assuming the desired peak concentration was 7.0 mg/L, the postdialysis dose this patient would need can then be calculated using the simplified approach below, because the elimination half-life is extremely prolonged relative to the infusion time, and thus minimal drug is eliminated during the infusion period:

$$\text{Dose} = V_D \times (C_{\max} - C_{\min})$$

$$= 20.0 \text{ L} \times (7.0 - 2.5) = 90 \text{ mg}$$

7 It is common practice in most hemodialysis units to administer drugs after the patient has received dialysis on the premise that it is desirable to minimize the loss of drug that would result from the additional clearance during hemodialysis. Certainly, administration of antihypertensive agents and vasoactive drugs should be avoided in the hours prior to a hemodialysis session to minimize the likelihood of hypotension. However, emerging pharmacokinetic and pharmacodynamic considerations suggest that this may not be the optimal approach for several other agents, such as aminoglycosides and vancomycin.⁶⁰⁻⁶³ Two evaluations of predialysis and one of intradialytic dosing of aminoglycosides indicate that similar peak concentrations, a prime indicator of efficacy, can be obtained in these scenarios relative to those observed with postdialysis dosing.^{60,62,63} The area under the concentration-time curve during the dosing interval and the subsequent predialysis concentrations were noted to be significantly reduced and thus the risk of ototoxicity and further renal injury may be minimized. The best dosing schedule, a dose roughly twice that traditionally employed for postdialysis administration, in the 26 patients evaluated by Teigen et al., resulted in the achievement of the desired peak and area under the concentration-time curve in approximately 90% of patients.⁶² The administration of traditional doses of tobramycin (1.5 mg/kg) or vancomycin (1,000 mg) during dialysis has been associated with markedly lower areas under the concentration-time curve than those observed when the same dose was administered postdialysis; consequently, higher dosage regimens are necessary to compensate for the additional loss of drug during the dialysis procedure.^{61,63} Although these observations are intriguing, the doses proposed by Teigen et al. are only starting conditions and it is highly recommended that aminoglycoside concentrations be measured after the first dose and individualized accordingly using Bayesian methodology.

CONCLUSIONS

Subtherapeutic or supratherapeutic responses to drugs in patients with renal insufficiency are often misinterpreted and not recognized as such. The adverse outcomes associated with inappropriate drug use and dosing have not been quantified but do warrant future investigations. Sound pharmacokinetic principles, used in concert with reliable population pharmacokinetic estimates, should ultimately yield the optimal approach to drug dosage regimen design for patients with renal insufficiency. Individualization of therapy should be undertaken whenever clinical therapeutic monitoring tools are available.

The key action step is to use the knowledge we have to improve patient outcomes. The recent study of van Dijk et al. is an unfortunate reminder of how far we still have to go.⁶⁴ They observed that although dosage adjustments based on renal function were warranted in 24% of the prescriptions of the patients with CL_{cr} less than 51 mL/min, such adjustments were only performed in 59% of cases.

ABBREVIATIONS

A_b : concentration of drug in blood going into the dialyzer (arterial side)
 A_p : concentration of drug in plasma going into the dialyzer (arterial side)
 AUC_{0-t} : the area under the predialyzer plasma concentration–time curve during hemodialysis
 C_a : concentration of the drug in the plasma going into a filter
 C_{ad} : plasma concentration after dialysis
 C_{ave} : average plasma concentration
 C_{bd} : plasma concentration prior to the next dialysis session
 C_{df} : concentration of drug in the dialysis fluid
 C_{ss} : average steady-state plasma concentration
 CL : total-body clearance
 CL_D^b : dialyzer clearance from blood
 CL_{cr} : creatinine clearance
 CL_D : dialyzer clearance
 CL_{fail} : clearance of a drug in a patient with impaired renal function
 CL_{norm} : clearance of a drug in patients with normal renal function
 CL_D^p : dialyzer clearance from plasma
 CL_{PT} : estimated total body clearance for a given patient
 CL_R : net renal excretion
 $CL_{reabsorption}$: tubular reabsorption
 CL_{RES} : residual drug clearance in a dialysis patient
 $CL_{secretion}$: tubular secretion
 C_{max} : peak drug concentration
 CNS : central nervous system
 C_p^t : desired plasma concentration at time t
 CYP : cytochrome P450 enzymes
 D_f : maintenance dose for a patient with renal insufficiency
 D_n : dose for a patient with normal renal function
 $ESRD$: end-stage renal disease
 f_e : fraction of drug eliminated unchanged in the urine
 f_u : fraction of drug unbound to plasma proteins
 GFR : glomerular filtration rate
 IC_{50} : inhibitory concentration of 50%
 k_a : absorption rate constant
 k : elimination rate constant
 k_{DD} : elimination rate constant during dialysis
 KF : ratio of the patient's creatinine clearance to the assumed normal value of 120 mL/min
 k_{ID} : elimination rate constant between dialysis sessions (interdialytic)
 Q : kinetic parameter/dosage adjustment factor
 Q_b : blood flow through the dialyzer

Q_p : plasma flow through the dialyzer = Q_b (1 HCT)

R : the total amount of drug recovered unchanged in the dialysate

τ_f : dosing interval in a patient with renal failure

τ_p : practical dosing interval for a patient with renal failure

τ_n : dosing interval in a patient with normal renal function

t_{max} : time to peak drug concentration

$t_{1/2}$: half-life

$t_{1/2, onHD}$: half-life during dialysis

$t_{1/2, offHD}$: half-life off dialysis

V_{area} : volume of distribution area

V_β : volume of distribution

V_c : volume of the central compartment

V_D : volume of distribution

V_{ss} : volume of distribution at steady state

Disorders of Sodium and Water Homeostasis

JAMES D. COYLE AND MELANIE S. JOY

KEY CONCEPTS

- 1 Hypovolemic, hypotonic, hyponatremia is relatively common in patients taking thiazide diuretics. Thiazide-induced hyponatremia is usually mild and relatively asymptomatic, but it can be severe and symptomatic. Hyponatremia rarely if ever occurs with loop diuretics.
- 2 The syndrome of inappropriate secretion of antidiuretic hormone causes euvoletic, hypotonic, hyponatremia. Common causes of this syndrome include lung cancer, CNS disorders, pulmonary disorders, and a variety of drugs.
- 3 Symptoms of hyponatremia are usually neurologic in nature and symptom severity depends both on the magnitude of the decrease in serum sodium concentration and the rate at which it developed. Treatment of hyponatremia is associated with a risk of osmotic demyelination syndrome, a severe neurologic complication that can develop if the rate of serum sodium correction exceeds 8 to 12 mEq/L within 24 hours.
- 4 Asymptomatic or mildly symptomatic hyponatremic patients should generally be managed conservatively with treatment directed at the underlying cause. A 0.9% sodium chloride infusion can be cautiously used to correct the serum sodium in patients with hypovolemic, hypotonic, hyponatremia and moderate to severe symptoms. A 3% sodium chloride infusion can be cautiously used in patients with euvoletic or hypervolemic, hypotonic, hyponatremia and moderate to severe symptoms.
- 5 Hypernatremia most commonly occurs when increased water or hypotonic fluid losses are not offset by increased water intake or administration. For example, patients with diabetes insipidus excrete large volumes of dilute urine, but usually develop hypernatremia only if their water intake does not increase to offset the increased water losses.
- 6 Symptoms of hypernatremia are usually neurologic in nature, and range in severity from weakness, lethargy, restlessness, irritability, and confusion to twitching, seizures, coma, and death. The severity of symptoms depends on both the magnitude of the increase in serum sodium and the rate at which it developed.
- 7 The treatment goals in patients with hypernatremia include cautious correction of the serum sodium concentration and, when appropriate, restoration of a normal extracellular fluid volume.
- 8 Patients with central diabetes insipidus should be treated with intranasal desmopressin acetate, with goals of decreasing urine volume to less than 2 L per day while maintaining the serum sodium concentration between 137 and 142 mEq/L. Patients with nephrogenic diabetes insipidus should be treated by correcting the underlying cause when possible, and sodium chloride restriction in conjunction with a thiazide diuretic to decrease the extracellular fluid volume by approximately 1 to 1.5 L.
- 9 Edema can develop as a primary defect in renal sodium handling or as a response to a decreased effective circulating volume. It is usually first detected in the feet or pretibial areas of ambulatory patients. Pulmonary edema, evidenced by auscultatory crackles, can be life-threatening.
- 10 Diuretics are the primary pharmacologic means for achieving the desired therapeutic outcomes of minimization of edema and improving organ function. Diuretic resistance can be overcome by using an increased dose or by using a combination of a loop diuretic and a thiazide or thiazide-like diuretic.

The human body tightly regulates blood volume and plasma osmolality as both are essential for normal cellular function. Blood volume is important because it is a determinant of tissue perfusion, and effective tissue perfusion is required to deliver oxygen and nutrients to and remove metabolic waste products from tissues. Plasma osmolality is an important determinant of intracellular volume. Maintenance of normal intracellular volume is particularly critical in the brain, where alterations can result in significant neural dysfunction and potentially death.

The homeostatic mechanisms for regulating blood volume and plasma osmolality involve control of sodium and water balance.¹ Interestingly, the homeostatic mechanisms for controlling blood volume are focused on controlling sodium balance. In contrast, the homeostatic mechanisms for controlling plasma osmolality, which is largely determined by serum sodium concentration, are focused on controlling water balance. Thus, sodium and water balance are closely related and are frequently considered together. Disorders of sodium and water homeostasis are common and potentially serious. They usually result in either hypo- or hypernatremia, depending on the disorder. It is important for clinicians to understand these disorders because they can both be caused by and treated with medications. This chapter reviews the etiology, classification, clinical presentation, and therapy for disorders of sodium and water homeostasis.

TABLE 52-1 Composition of Intravenous Replacement Solutions

Solution	Dextrose (g/dL)	[Na ⁺] (mEq/L)	[Cl ⁻] (mEq/L)	Tonicity	Distribution		Free Water/L
					% ECF	% ICF	
D ₅ W	5	0	0	Hypotonic	40	60	1,000 mL
0.45% sodium chloride	0	77	77	Hypotonic	73	37	500 mL
0.9% sodium chloride	0	154	154	Isotonic	100	0	0 mL
3% sodium chloride ^a	0	513	513	Hypertonic	100	0	-2,331 mL

Cl⁻, chloride; D₅W, 5% dextrose in water; ECF, extracellular fluid; ICF, intracellular fluid; Na⁺, sodium.

^aThis solution will result in osmotic removal of water from the intracellular space.

SODIUM AND WATER HOMEOSTASIS

Hypo- and hypernatremia are syndromes of altered plasma tonicity and cell volume that reflect a change in the ratio of total exchangeable body sodium to total body water. Many factors affect tonicity and water balance and a sound understanding of the pathogenesis and evaluation approaches are of utmost importance if one is to successfully prevent and manage these syndromes.

Sixty percent of total body water is located intracellularly whereas 40% is contained in the extracellular space.¹ Sodium and its accompanying anions, chloride and bicarbonate, comprise more than 90% of the total osmolality of the extracellular fluid (ECF), whereas intracellular osmolality is primarily dependent on the concentration of potassium and its accompanying anions (mostly organic and inorganic phosphates). The differential concentrations of sodium and potassium in the intra- and extracellular fluid are maintained by the sodium-potassium-adenosine triphosphatase (Na⁺-K⁺-ATPase) pump.^{1,2} Most cell membranes are freely permeable to water, and thus the osmolality of intra- and extracellular body fluids is the same.

Solutes that cannot freely cross cell membranes, such as sodium, are referred to as effective osmoles. The concentration of effective osmoles in the ECF determines the tonicity of the ECF, which directly affects the distribution of water between the extra- and intracellular compartments.¹ Addition of an isotonic solution to the ECF will result in no change in intracellular volume because there will be no change in the effective osmolality of the ECF. Addition of a hypertonic solution to the ECF, however, will result in a decrease in cell volume, whereas addition of a hypotonic solution to the ECF will result in an increase in cell volume. Table 52-1 summarizes the composition of commonly used intravenous solutions and their respective distribution into extracellular and intracellular compartments following infusion.

The serum sodium concentration is tightly regulated, and usually varies by no more than 2% to 3%. Regulation of serum sodium concentration occurs indirectly via mechanisms that control its determinants, plasma osmolality, and blood volume.¹ The kidney regulates water excretion through a feedback mechanism with the hypothalamus, such that the serum osmolality remains relatively constant (275 to 290 mOsm/kg) despite day-to-day variations in water intake. Plasma osmolality is largely determined by the concentrations of sodium and the accompanying anions chloride and bicarbonate, and can be estimated as:

$$\text{Sosm} = (2 \times S_{\text{Na}}) + (B_{\text{glucose}}/18) + (BUN/2.8)$$

where Sosm = serum osmolality in milliosmoles per kilogram; S_{Na} = serum sodium concentration in mEq/L; B_{glucose} = glucose concentration in mg/dL; and BUN = blood urea nitrogen concentration in mg/dL.^{1,3}

Arginine vasopressin (AVP), commonly known as antidiuretic hormone (ADH), is released from the posterior pituitary when the plasma osmolality increases by 1% to 2% or more.¹ AVP binds to the vasopressin-2 (V2) receptors on the basolateral surface of renal tubular epithelial cells, resulting in the insertion of water channels

(aquaporin-2) into the apical tubular lumen surface of the cell.⁴ Water can then pass through the cell into the peritubular capillary space where it is then reabsorbed into the systemic circulation. An increase in serum osmolality sensed in the hypothalamus results not only in AVP release, but also in stimulation of thirst. The combination of an increase in water intake and a decrease in water excretion results in a decrease in the serum osmolality and inhibition of AVP secretion once the plasma osmolality is restored to normal.

Nonosmotic release of AVP occurs when a decrease in a person's effective circulating volume results in a decrease in systemic blood pressure.¹ The effective circulating volume is that part of the ECF that is located in the arterial system and is responsible for organ perfusion.¹ A decrease in the effective circulating volume (more accurately, the pressure associated with that volume) activates arterial baroreceptors in the carotid sinus and glomerular afferent arterioles, resulting in stimulation of the renin-angiotensin system and increased synthesis of angiotensin II. Angiotensin II stimulates both nonosmotic release of AVP and thirst. This volume stimulus overrides osmotic inhibition of AVP release, and conservation of water fosters restoration of effective circulating volume and blood pressure at the expense of hypo-osmolality.

Proper assessment of a patient with an abnormal serum sodium concentration requires knowledge of the fact that changes in the serum sodium concentration do not necessarily correlate with changes in ECF volume or sodium content as the sodium concentration is determined by the ratio of the ECF sodium content and ECF volume.¹ Although hyponatremia and hypernatremia can be associated with conditions of high, low, or normal ECF sodium and volume, both conditions are most commonly the result of abnormalities of water metabolism.¹

HYPONATREMIA

EPIDEMIOLOGY AND ETIOLOGY

Hyponatremia (serum sodium <135 mEq/L) is the most common electrolyte abnormality encountered in clinical practice.^{5,6} Although its prevalence is not well-established and varies with the patient population studied, it has been estimated to be as high as 28% in patients admitted to an acute care hospital, 14% in patients seen in ambulatory hospital clinics, and 7% in community clinics.⁷ Increasing age (>40 years) is clearly a risk factor for hyponatremia.⁷

Recognition of the high prevalence of hyponatremia is important because this condition is associated with significant morbidity and mortality.⁸ Transient or permanent brain dysfunction can result from either the acute effects of hypo-osmolality or from too rapid correction of hypo-osmolality in patients with symptomatic hyponatremia. Hyponatremia is predominantly the result of an excess of extracellular water relative to sodium because of impaired water excretion. The kidney normally has the capacity to excrete large volumes of dilute urine after ingestion of a water load. Nonosmotic release of AVP, however, can lead to retention of water and to a drop in serum sodium concentration, despite a fall in both serum

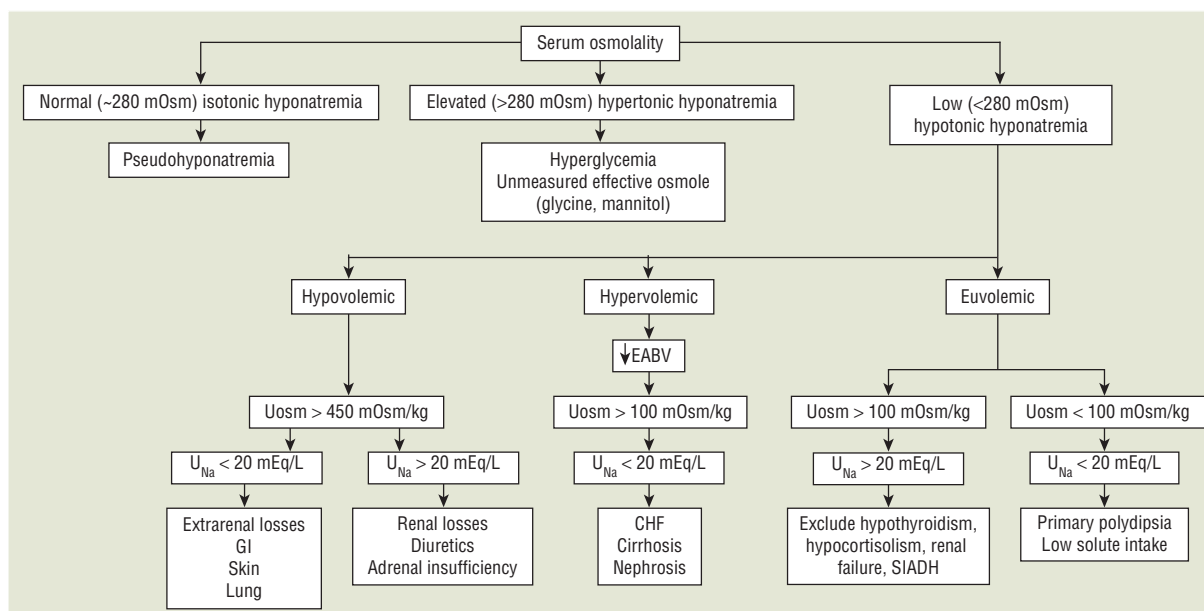

FIGURE 52-1. Diagnostic algorithm for the evaluation of hyponatremia. (CHF, congestive heart failure; SIADH, syndrome of inappropriate secretion of antidiuretic hormone; U_{Na} , urine sodium concentration; Uosm, urine osmolality.)

and intracellular osmolality. The causes of nonosmotic release of AVP include hypovolemia; decreased effective circulating volume as seen in patients with chronic heart failure (CHF), nephrosis, and cirrhosis; and the syndrome of inappropriate antidiuretic hormone secretion (SIADH). The pathophysiology, clinical features, and management of hyponatremia are detailed below.

PATHOPHYSIOLOGY

Hyponatremia can be associated with normal, increased, or decreased plasma osmolality, depending on its cause (Fig. 52-1).^{1,3} Hyponatremia in patients with normal serum osmolality can be caused by hyperlipidemia or hyperproteinemia. Historically this form of hyponatremia, termed *pseudohyponatremia*, was an artifact of the method of serum sodium concentration measurement. This laboratory artifact is uncommon today and has been overcome with the use of ion-specific electrodes to measure the serum sodium concentration. If the sodium concentration in a laboratory is still measured by flame photometry, the volume of serum is overestimated because the elevated lipids or proteins account for a greater proportion of the total volume of the sample (Fig. 52-2). Because the sodium is distributed in only the water component of serum, the measured serum sodium concentration is falsely decreased. The measurement of serum osmolality, however, is not significantly affected, leading to a discrepancy between the calculated and measured serum osmolality.

Hyponatremia associated with increased serum osmolality, termed *hypertonic hyponatremia*, suggests the presence of excess, nonsodium effective osmoles in the ECF.^{1,3} This is most frequently encountered in patients with hyperglycemia. Elevated concentrations of glucose provide effective plasma osmoles, resulting in diffusion of water from the cells into the extracellular compartment thereby expanding the ECF, which results in decrease in the serum sodium concentration. For every 100 mg/dL increase in the serum glucose concentration, the serum sodium level decreases by 1.7 mEq/L, and the serum osmolality increases by 2 mOsm/kg.³ It should be noted that this correction is only a rough estimate because the increase in serum sodium varies substantially with the degree of hyperglycemia.⁹ Other substances such as mannitol, glycine, and sorbitol that do not cross cellular membranes provide effective osmoles and can also cause hypertonic hyponatremia. The presence

of these unmeasured osmoles should be suspected in patients with hypertonic hyponatremia if there is a significant osmolal gap, the difference between the measured and calculated plasma osmolality.¹

Hyponatremia associated with decreased plasma osmolality, termed *hypotonic hyponatremia*, is the most common form of hyponatremia and has many potential causes (see Fig. 52-1).^{1,3} An important step in the diagnostic evaluation of patients with hypotonic hyponatremia is clinical assessment of the patient's extracellular fluid volume.³ Categorization of these patients into one of three groups (decreased, increased, or clinically normal ECF volume) is very helpful in identifying the pathophysiologic mechanisms responsible for the hyponatremia and an appropriate treatment regimen.

Hypovolemic Hypotonic Hyponatremia

Most patients with ECF volume contraction lose fluids that are hypotonic relative to plasma and thus can be transiently hypernatremic. This includes patients with fluid losses caused by diarrhea, excessive sweating, and diuretics. This transient hypernatremic hyperosmolality results in osmotic release of AVP and stimulation of thirst. If sodium and water losses continue, more AVP is released as

FIGURE 52-2. Elevated lipids or proteins result in a larger discrepancy between the volume of the sample and plasma water, leading to a falsely low measurement of the serum sodium concentration when using the method of flame photometry.

a result of hypovolemia. Patients who then drink water or who are given hypotonic fluids intravenously retain water and develop hyponatremia. These patients typically have a urine osmolality greater than 450 mOsm/kg, reflecting the presence of AVP and formation of a concentrated urine.¹⁰ The urine sodium concentration is <20 mEq/L when sodium losses are extrarenal, as in patients with diarrhea, and >20 mEq/L in patients with renal sodium losses, as occurs in the setting of diuretic use or adrenal insufficiency.¹⁰

① Hypotonic hyponatremia is relatively common in patients taking thiazide diuretics.¹¹ Thiazide-induced hyponatremia is usually mild, but can occasionally be severe and symptomatic.¹² It typically develops within 2 weeks of the initiation of therapy, but can occur late in therapy particularly if there has been a recent increase in the diuretic dose or other causes of hyponatremia develop.^{1,12}

The mechanism of thiazide-induced hyponatremia is likely related to the balance of its direct and indirect effects.¹ Thiazides exert their diuretic effect by blocking sodium reabsorption in the distal tubules of the renal cortex, thereby increasing sodium and water removal from the body. The resulting decrease in effective circulating volume stimulates AVP release. Increased AVP release results in increased reabsorption of free water in the collecting duct, as well as increased water intake because of stimulation of thirst. Hyponatremia results because the net result of these effects is the loss of more sodium than water.

Interestingly, hyponatremia occurs infrequently with loop diuretics.¹ This difference between thiazide and loop diuretics likely relates to their different sites of action. Loop diuretics exert their diuretic effect by blocking sodium reabsorption in the ascending limbs of the loop of Henle, many of which are located in the renal medulla. This action decreases medullary osmolality. Thus, when the loop diuretics decrease effective circulating volume and stimulate AVP release, less water reabsorption occurs in the collecting ducts than would occur if the osmolality of the renal medulla were normal. Thiazide diuretics do not alter medullary osmolality as their site of action is located in the renal cortex rather than in the medulla. In addition, most loop diuretics have a shorter half-life than the thiazides, and patients can therefore replete the urinary sodium and water losses prior to taking the next dose, thereby minimizing AVP stimulation.

Euvolemic Hypotonic Hyponatremia

② Euvolemic hypotonic hyponatremia is associated with a normal or slightly decreased ECF sodium content and increased total body water and ECF volume. The increase in ECF volume is usually not sufficient to cause peripheral or pulmonary edema, and thus patients appear clinically euvolemic. Euvolemic hyponatremia is most commonly the result of the syndrome of inappropriate ADH release (SIADH). In this syndrome, water intake exceeds the capacity of the kidneys to excrete water, either because of an increased release of AVP via nonosmotic and/or nonphysiologic processes or enhanced renal sensitivity to AVP.¹³ The urine osmolality in patients with SIADH is generally greater than 100 mOsm/kg, and the urine sodium concentration is usually greater than 20 mEq/L as a result of the ECF volume expansion.

The most common causes of SIADH include tumors such as oat cell cancer of the lung, central nervous system (CNS) disorders (e.g., head trauma, stroke, meningitis, and pituitary surgery), as well as pulmonary disease.³ A wide variety of drugs can cause SIADH by enhancing AVP release or enhancing the renal effect of AVP or by unknown mechanisms.^{3,10,14} Examples include desmopressin, oxytocin, carbamazepine, cyclophosphamide, nonsteroidal antiinflammatory drugs (NSAIDs), selective serotonin reuptake inhibitors, tricyclic antidepressants, phenothiazines, opiates, and methylenedioxymethamphetamine, a drug of abuse commonly known as “ecstasy.”^{3,10,14} Patients with renal insufficiency, adrenal insufficiency, and hypothy-

roidism can also present with euvolemic hyponatremia, and the evaluation of patients with suspected SIADH should always include exclusion of these disorders.

The differential diagnosis of euvolemic hypotonic hyponatremia also includes primary or psychogenic polydipsia. Patients with this disorder drink more water (usually >20 L/day) than the kidneys can excrete as solute-free water. Unlike SIADH, however, AVP is suppressed, resulting in a urine osmolality that is less than 100 mOsm/kg. The urine sodium is typically low (<15 mEq/L) as a result of urinary dilution.¹⁵ Hyponatremia can develop with more modest water intake in patients who are ingesting a very-low-solute diet, such as a low-sodium vegetarian diet.

Hypervolemic Hypotonic Hyponatremia

Hyponatremia associated with an increase in ECF volume occurs in conditions in which renal sodium and water excretion are impaired. Patients with cirrhosis, congestive heart failure, and nephrotic syndrome have an expanded ECF volume and edema, but a decreased effective circulating volume. This decreased volume results in renal sodium retention, and eventually ECF volume expansion and edema. At the same time, there is nonosmotic release of AVP and retention of water in excess of sodium, thus perpetuating the hyponatremia.

CLINICAL PRESENTATION

③ Patients with chronic, mild hyponatremia (serum sodium concentration greater than 125 to 130 mEq/L) are usually asymptomatic, with hyponatremia being discovered incidentally when serum electrolytes are measured for other purposes.^{1,3,16} However, recent data from a small number of carefully evaluated patients suggest that it might be more accurate to say that symptoms of mild hyponatremia are frequently unnoticed by both physician and patient.¹⁷ These data suggest that chronic, mild hyponatremia is associated with impairment of attention, posture, and gait, all of which contribute to a substantially increased risk of falls.

Patients with moderate (serum sodium concentration of 115 to 125 mEq/L) to severe (serum sodium concentration less than 110 to 115 mEq/L) or rapidly developing hypotonic hyponatremia often present with a range of neurologic symptoms resulting from hypo-osmolality-induced volume expansion of brain cells.^{1,3,16} Classic symptoms include nausea and malaise, headache, lethargy, restlessness, and disorientation, and in some seizures, coma, permanent brain damage, respiratory arrest, brainstem herniation, and death.

The presence of these symptoms and their severity depend on both the magnitude of the hyponatremia and the rate at which the hyponatremia developed.^{1,3,16} The magnitude of the hyponatremia is important because serum osmolality decreases in direct proportion to the serum sodium concentration, and water movement into brain cells increases as serum osmolality decreases. The rate of osmolality change is an important factor because brain cells are able to adjust their intracellular osmolality to minimize cellular volume changes in response to volume changes, but time is required for this adaptation to occur.^{1,18} When a decline in plasma osmolality causes movement of water into brain cells, sodium, potassium, and *organic osmolytes* move out of the cells to decrease intracellular osmolality and minimize intracellular water movement. Organic osmolytes, primarily myoinositol in humans, are osmotically active substances that contribute substantially to controlling intracellular osmolality without directly altering cellular function.¹⁸ The various components of this adaptive mechanism occur over different time frames, with sodium and potassium efflux occurring over minutes to several hours and organic osmolyte efflux occurring over hours to days.¹⁸ Maximal compensation for a decrease in plasma osmolality typically requires up to 48 hours. Thus, acute changes in plasma osmolality are not compensated for instantaneously and are more likely to be

associated with symptoms. Recent studies suggest that patients with concurrent respiratory failure and hypoxemia are at greater risk for adverse neurologic outcomes because hypoxemia diminishes the capacity of the brain to actively transport solute out of cells, leading to a higher incidence of cerebral edema.¹⁹

In addition to neurologic symptoms, patients with hypovolemic hyponatremia can present with signs and symptoms of hypovolemia including dry mucous membranes, decreased skin turgor, tachycardia, decreased jugular venous pressure, and orthostatic hypotension. These findings are helpful in identifying the type of hyponatremia.

The brain's adaption to changes in plasma osmolality is also relevant to symptoms that can develop if hyponatremia is corrected too rapidly (i.e., >12 mEq/L per day). These patients might experience an acute decrease in brain cell volume, which contributes to the pathogenesis of *osmotic demyelination syndrome*.^{20,21} Patients with this complication might develop para- or quadriplegia, pseudobulbar palsy, and locked-in syndrome 5 to 7 days after treatment because of demyelination lesions in the pons.^{21,22} Patients who have a significant degree of cerebral adaptation to hypotonic hyponatremia are at higher risk of experiencing this syndrome.²¹ This is presumably because these patients have lower intracellular osmolalities at the initiation of therapy, which results in greater decreases in intracellular volume when the plasma osmolality is raised rapidly. Brain adaptation to increases in plasma osmolality requires time, just as was true for its initial adaptation to decreases in serum sodium concentration.

CLINICAL PRESENTATION OF HYPONATREMIA

General

- Hyponatremia is asymptomatic in most patients. Symptoms directly attributable to hyponatremia include neurologic dysfunction associated with cerebral edema.

Symptoms

- The presence and severity of symptoms are related both to the magnitude and rapidity of onset of the hyponatremia. Nausea and malaise are the earliest findings, followed by headache, lethargy, restlessness, and disorientation, and eventually seizures, coma, permanent brain damage, respiratory arrest, brainstem herniation, and death if hyponatremia is severe or develops rapidly. Other symptoms that can be seen with hyponatremia are those attributable to its underlying cause, such as volume depletion in patients with hypovolemic hypotonic hypo-osmolality or volume excess in patients with hypervolemic hypotonic hyponatremia.

Signs

- General: Dry mucous membranes, decreased skin turgor, tachycardia, decreased jugular venous pressure, and postural hypotension can be present in hypovolemic patients.
- Pulmonary: Noncardiogenic pulmonary edema has been described.
- Neurologic: Depressed reflexes. Rapid correction of hyponatremia can result in an acute decrease in brain cell volume resulting in demyelinating brain injury.

Laboratory Tests

- Serum sodium values lower than 135 mEq/L are present. Plasma osmolality and urine sodium concentration can be helpful in diagnosing the cause. Tests including but not limited to serum glucose and lipids and tests to assess kidney and thyroid function should be conducted to identify or rule out potential causes.

TREATMENT

Hyponatremia

■ DESIRED OUTCOME

4 The goal of treating patients with hypovolemic hypotonic hyponatremia is to resolve the underlying cause of the sodium and ECF volume deficits, and safely correct the hyponatremia. The treatment goals for hypervolemic and euvolemic hypotonic patients depend on the underlying cause of the hyponatremia and the severity of the patient's symptoms. Patients with an acute onset of hyponatremia or severe symptoms require more aggressive therapy to correct the hypotonicity. The initial goal for these patients is to increase plasma tonicity enough to control the severe symptoms; this typically requires a relatively small increase in serum sodium concentration of ~5%.³ Once control of the severe symptoms is achieved, full correction of the serum sodium concentration should be achieved at a controlled rate. Asymptomatic patients and patients with mild to moderate symptoms do not require rapid correction of the serum sodium, and the treatment is dictated by the underlying etiology. In all cases the goal is to avoid an increase in the serum sodium concentration greater than 12 mEq/L in 24 hours.^{1,3,23} Some recommend that the maximal rate of correction not exceed 8 mEq/L in 24 hours.¹⁶

■ GENERAL APPROACH TO TREATMENT

The following principles serve as general guidelines for the treatment of patients with hyponatremia^{1,3,10,16,23}: (1) It is important for both the short- and long-term management of the patient to treat the underlying cause of hyponatremia. (2) Appropriate treatment of patients with hypotonic hyponatremia requires balancing the risks of the hyponatremia versus the risk of osmotic demyelination syndrome. In general, patients who acutely developed moderate to severe hyponatremia and/or patients who have severe symptoms are at greatest risk and potentially benefit most from more rapid correction of their hyponatremia. (3) Active correction of hypovolemic hypotonic hyponatremia is usually best accomplished with 0.9% sodium chloride solution as these patients have both sodium and water deficits, and 100% of the water stays in the ECF compartment. (4) Active correction of euvolemic and hypervolemic hypotonic hyponatremia in patients who do not require rapid correction is usually best accomplished by water restriction. Demeclocycline, vasopressin V2 receptor antagonists, or sodium chloride plus a loop diuretic, can be used if the initial response is not adequate. In patients with severe symptoms, 3% sodium chloride solution (possibly combined with furosemide) should initially be used to more rapidly correct the hyponatremia. Furosemide can be administered concurrently to enhance the serum sodium correction by increasing the excretion of water. (5) Long-term management is required for patients in whom the underlying cause of hyponatremia cannot be corrected. This can include water restriction, increasing sodium intake, and/or the use of an AVP antagonist. Application of these principles to the treatment of patients with various forms of hypotonic hyponatremia is discussed in the following sections.

ACUTE OR SEVERELY SYMPTOMATIC HYPOTONIC HYPONATREMIA

A patient who has or is at high risk of experiencing severe symptoms caused by hyponatremia should receive either 3% or 0.9% sodium chloride solution until severe symptoms resolve.^{1,3,10,16,23} Resolution of severe symptoms frequently requires only a small, 5% increase in serum sodium, although some suggest that the initial target should be to increase serum sodium to approximately 120 mEq/L.^{3,24} Choice of

infusion solution's sodium chloride concentration depends on the cause of hyponatremia. The relative concentrations of urine sodium and potassium (osmotically effective urine cations) must be compared with those of the infusate in planning a treatment regimen for patients with hypotonic hyponatremia. For the serum sodium to increase after infusion of a solution of sodium chloride, the concentration of sodium in the infusate must exceed the sum of the sodium and potassium concentration in the urine to effect net-free water excretion.

Patients with SIADH often have urinary concentrations of osmotically effective urine cations that exceed the sodium concentration of 0.9% sodium chloride (154 mEq/L), and thus these patients should be preferentially treated with 3% sodium chloride (513 mEq/L). In this case use of isotonic sodium chloride carries the potential hazard of actually worsening hyponatremia.^{1,24} The relatively high concentration of urinary sodium in patients with SIADH stems from the fact that the ECF is expanded, thus minimizing reabsorption of sodium along the nephron. When the urine osmolality exceeds 300 mOsm/kg, it is generally advisable to add an intravenous loop diuretic, not only to increase the excretion of solute-free water, but also to prevent volume overload, which can result from infusion of hypertonic sodium chloride. Intravenous furosemide, initially at a dose of 40 mg every 6 hours, is generally sufficient to prevent volume overload and to decrease the concentration of osmotically active urine cations to less than 150 mEq/L.

Patients with hypovolemic hypotonic hyponatremia, conversely, can be treated with 0.9% sodium chloride solution. In contrast to patients with SIADH, patients with this condition avidly reabsorb sodium throughout the nephron when the effective circulating blood volume is decreased. Thus the urine osmolality is primarily comprised of urea, and the concentration of urine sodium is often less than 20 mEq/L, which is substantially less than the sodium concentration in 0.9% sodium chloride solution. Use of 3% sodium chloride solution will also effectively correct hyponatremia in these patients, but its use should be reserved for situations requiring very rapid correction of the hyponatremia.

Hypervolemic hypotonic hyponatremic patients are particularly problematic to manage acutely because the sodium and volume required to minimize the risk of cerebral edema or seizures can worsen their already compensated hepatic, cardiac, or renal function. It is generally agreed that these patients should be treated with hypertonic sodium chloride and prompt initiation of fluid restriction. Loop diuretic therapy will also likely be required to facilitate urinary excretion of free water.

■ DETERMINATION OF SODIUM CHLORIDE INFUSION REGIMEN

Several methods for determining the correct sodium chloride solution infusion regimen for a hyponatremic patient have been proposed.^{1,3,25–29} It is important to recognize that usual approaches provide only a rough estimate of the correct infusion regimen as their use involves known but yet incorrect assumptions. More accurate equations have recently been derived, but the benefits of this more complex approach relative to the approach outlined below remains to be determined.^{26,27}

One commonly used approach is based on estimation of the change in plasma sodium resulting from the infusion of one liter of 3% or 0.9% sodium chloride solution as follows^{3,25}:

Change in S_{Na} with 1 liter of infusate

$$= [IV_{Na} - S^1_{Na}] \div (BW + IV_{vol})$$

where S^1_{Na} = initial patient serum sodium concentration; IV_{Na} = sodium concentration of infusate (154 mEq/L for 0.9% sodium chloride or 513 mEq/L for 3% sodium chloride); IV_{vol} = 1 L of

infusate; and BW = total body water (in liters), which can be estimated as a fraction of body weight (kilograms) as follows³⁰:

$0.6 \times \text{body weight for children and men } <70 \text{ years old}$

$0.5 \times \text{body weight for men } \geq 70 \text{ years old and females } <70 \text{ years old}$

$0.45 \times \text{body weight for women } \geq 70 \text{ years old}$

The appropriate infusion volume for a given patient can then be estimated based on the proportion of the estimated change that would result from a 1-liter infusion that is actually desired in that patient. Finally, an appropriate infusion rate can be calculated for this infusion volume to control the rate of increase in the serum sodium concentration.

For example, consider the case of a 170 centimeter (5 feet 7 inch), 60 kilogram (132 pound), 66-year-old woman who presents with nausea, vertigo, and disorientation that have developed over the past several days. She was started on carbamazepine 10 days ago for the treatment of trigeminal neuralgia. Her serum sodium is currently 108 mEq/L. Assuming this woman has carbamazepine-induced SIADH, an initial approach to treatment might include discontinuing her carbamazepine and partially correcting her hyponatremia by raising her serum sodium to approximately 120 mEq/L over the first 24 hours of hospitalization. This should be an adequate response to alleviate her current symptoms, decrease the risk of more severe symptoms, and minimize the risk of osmotic demyelination syndrome. Assuming that use of 3% sodium chloride solution is appropriate, the infusion regimen required to increase her serum sodium to 120 mEq/L over the next 24 hours can be calculated as follows:

$$\begin{aligned} &\text{Change in } S^1_{Na} \text{ with 1 L of infusate} = \\ &(513 \text{ mEq/L} - 108 \text{ mEq/L}) \div [(0.5 \text{ L/kg} \times 60 \text{ kg}) + 1.0 \text{ L}] \\ &= 13.1 \text{ mEq/L or } 1.31 \text{ mEq/100 mL} \end{aligned}$$

Because infusion of 1 L of 3% sodium chloride solution would produce a 13.1 mEq/L rise in the serum sodium, and we desire only a 12 mEq/L increase, the appropriate infusion volume is 916 mL $[(12 \text{ mEq/L} \div 13.1 \text{ mEq/L}) \times 1,000 \text{ mL}]$. In the presence of symptoms, the serum sodium should be increased by approximately 1.5 mEq/L per hour over the first 2 to 4 hours (for a total of 3 to 6 mEq/L) or until the symptoms have resolved. Thus an initial infusion rate of 114 mL/h $[1.5 \text{ mEq/L per hour} \div 1.31 \text{ mEq/L per 100 mL}]$ for the first 2 to 4 hours, followed by an infusion rate of approximately 23 to 31 mL/h for the next 20 to 22 hours, respectively, would be a reasonable initial treatment plan. The approach to this calculation would be similar if 0.9% sodium chloride solution were used, except that the expected increase in serum sodium concentration would be only 1.5 mEq/L per liter infused, and an infusion volume of approximately 8 liters would be required to achieve the targeted serum sodium concentration.

CLINICAL CONTROVERSY

Clinicians often disagree whether or not to administer 3% sodium chloride to patients with symptomatic hypotonicity. Advantages of 3% sodium chloride include more rapid correction of serum sodium concentration and smaller infusion volumes. In addition, 3% sodium chloride solution is required in conditions characterized by high urine osmolality caused by high sodium and potassium content (e.g., SIADH). The disadvantage of 3% sodium chloride is a higher risk of exceeding maximum recommended rates of correction and causing osmotic demyelination syndrome. The clinician must carefully consider the cause of the patient's hyponatremia as well as the relative risk of slower correction of the hyponatremia versus the development of osmotic demyelination syndrome.

■ EVALUATION OF THERAPEUTIC OUTCOMES

Patients with severely symptomatic hyponatremic hyponatremia should be admitted to the intensive care unit or to a highly monitored setting for close monitoring of neurologic and volume status. Serial physical examinations of the heart, lungs, and neurologic status should be performed several times over the initial 12 hours of hospitalization. The serum sodium concentration should be measured every 2 to 4 hours, and the urine osmolality, sodium, and potassium should be measured every 4 to 6 hours over the first day of therapy. The rate of administration of the infusate should then be adjusted to avoid exceeding a rise in the serum sodium greater than 12 mEq/L per day.

NONEMERGENT HYPOVOLEMIC HYPOTONIC HYPONATREMIA

Most patients with hypovolemic hyponatremic hyponatremia do not require rapid correction of their hyponatremia because they are either asymptomatic or have only mild-to-moderate symptoms. Many of these patients are at higher risk of developing osmotic demyelination syndrome if serum sodium correction occurs too rapidly because they have chronic hyponatremia that has been maximally compensated for by the brain's osmotic adaptation. The combination of the adaptive decrease in intracellular osmolality and rapid increase in serum osmolality results in excessive movement of water out of the brain cells, intracellular volume depletion, and thereby increased risk of osmotic demyelination syndrome. Treatment of these patients should include correction of the underlying condition, if possible. When direct treatment of the hyponatremia is justified, a 0.9% solution of sodium chloride should be used.¹ This solution effectively replaces both the sodium and water deficits that characterize these patients and presents a lower risk of an excessive rate of correction than 3% sodium chloride solution.

A patient's ECF volume deficit (ECFVd) can be estimated based on sex, change in body weight, and age. For example, consider the case of a 56-year-old woman who was started on hydrochlorothiazide 10 days ago for the treatment of hypertension. She is 172.7 centimeters (5 feet 8 inches) tall and weighed 62 kilograms (136.7 pounds) at that time. Today she presents with complaints of mild nausea and "feeling dizzy" when she stands up. Her weight is 55.3 kilograms (122 pounds). Physical examination reveals dry mucous membranes and orthostatic hypotension. Her serum sodium is 125 mEq/L. The patient's ECFVd could be estimated as follows³¹:

$$\begin{aligned}\text{ECFVd} &= \text{ECFV}_{\text{norm}} - \text{ECFV}_{\text{current}} \\ \text{ECFVd} &= [\text{TBW}_{\text{norm}} \times 0.5 \text{ L/kg} \times 0.33] - [\text{TBW}_{\text{current}} \times 0.5 \text{ L/kg} \times 0.33] \\ \text{ECFVd} &= [62 \text{ kg} \times 0.5 \text{ L/kg} \times 0.33] - [55.3 \text{ kg} \times 0.5 \text{ L/kg} \times 0.33] \\ \text{ECFVd} &= 1.1 \text{ L}\end{aligned}$$

If the patient's previous weight were not known, it could be roughly estimated based on clinical signs and symptoms. The presence of hyponatremia suggests an ECFVd of 5% or more, whereas the presence of orthostatic hypotension suggests an ECFVd of at least 10% to 15%. A 0.9% solution of sodium chloride is considered to be isotonic and thus is optimal to correct the volume deficit because it will remain in the ECF space (see Table 52-1).

The expected increase in the serum sodium concentration following infusion of 1 liter 0.9% sodium chloride (154 mEq/L) can be estimated as:

$$\begin{aligned}\text{Change in } S_{\text{Na}} \text{ with 1 liter of infusate} &= [\text{IV}_{\text{Na}} - S_{\text{Na}}^1] \div (\text{BW} + \text{IV}_{\text{vol}}) \\ &= [154 \text{ mEq/L} - 125 \text{ mEq/L}] \div [(0.5 \text{ L/kg} \times 55.3 \text{ kg}) + 1.0 \text{ L}] \\ &= 1.0 \text{ mEq/L}\end{aligned}$$

Thus the infusion of 1.1 L of 0.9% sodium chloride will result in an increase of serum sodium of 1.1 mEq/L ($1.1 \text{ L} \times 1.0 \text{ mEq/L}$). The patient's sodium serum concentration can thus be predicted to be 126 mEq/L ($125 \text{ mEq/L} + 1.1 \text{ mEq/L}$) following the infusion.

Because the overriding initial treatment goal is to restore effective circulating volume, it might be necessary to infuse 0.9% sodium chloride at 200 to 400 mL/h until symptoms of hypovolemia moderate. The infusion rate can then be decreased to 100 to 150 mL/h so the serum sodium level increases no more than 12 mEq/L over the initial 24 hours. Infusion of 0.9% sodium chloride at rates greater than 250 mL/h should be used cautiously in patients with a history of left ventricular dysfunction or renal insufficiency. It is important to recognize that the rate of increase in the serum sodium concentration can substantially increase once hypovolemia has been corrected if infusion rates are not decreased.¹ Once the ECF volume is restored, AVP secretion will cease, and a rapid water diuresis can ensue, which can potentially result in an increase in the serum sodium at a rate greater than 12 mEq/L per day. Ideally, the potential for this increase in correction rate is recognized prospectively, and infusion rates are appropriately adjusted. Estimation of the patient's ECFVd at the initiation of therapy can help in this regard. If the serum sodium is observed to be increasing at a rate greater than 12 mEq/L per day the infusate should be changed to 0.45% sodium chloride, and the infusion rate set to one that approximates urine output (approximately 1.5 to 2 mL/kg per hour is a reasonable initial rate), to slow the rate of increase in the serum sodium concentration.³

■ EVALUATION OF THERAPEUTIC OUTCOMES

Patients presenting with evidence of volume depletion should be reexamined frequently during the initial few hours of therapy. The serum sodium concentration should be measured every 2 to 4 hours to allow timely adjustment of the rate and composition of intravenous fluids to avoid an increase in the serum sodium greater than 12 mEq/L per day. Intravenous 0.9% sodium chloride should be administered judiciously in patients with a history of congestive heart failure or renal insufficiency, with frequent assessments of the cardiopulmonary examination so the infusion rate can be appropriately decreased at the earliest sign of pulmonary congestion.

NONEMERGENT EUVOLEMIC HYPOTONIC HYPONATREMIA

The treatment of SIADH always involves water restriction and correction of the underlying cause, if possible. Drugs that could be contributing should be identified and discontinued. The goal is to induce negative water balance by restricting water intake to less than 1,000 to 1,200 mL/day, such that water losses from insensible sources (skin and lung) and from obligate urine and fecal losses exceed intake. Daily insensible water losses via skin and lungs are approximately 900 mL/day, whereas approximately 200 mL and a minimum of 500 mL/day is lost in stool and in urine output, respectively. Because approximately 850 mL of water per day is ingested in food, and an additional 350 mL are generated from oxidative processes, the water intake reduction should result in a negative water balance of several hundred milliliters per day.¹ Other goals include maintenance of the serum sodium level above 125 mEq/L to prevent symptoms of hyponatremia, and avoidance of iatrogenic hypo- or hypervolemia.

Patients with chronic SIADH who are unable to restrict water sufficiently to maintain the serum sodium greater than 120 to 125 mEq/L can be treated by increasing solute intake with sodium chloride and/or loop diuretics.³ Sodium chloride or urea tablets

increase the obligatory daily solute excretion, which augments the capacity for renal water excretion. The goal is to increase the daily solute intake and excretion to approximately 900 mOsm per day. Because an average diet contains approximately 600 mOsm, 9 grams of sodium chloride would be required to increase the osmolar excretion to 900 mOsm/day (each 1-gram sodium chloride tablet contains 17 mmol of sodium and 17 mmol of chloride). Because extracellular volume expansion is an expected adverse effect, a loop diuretic should be administered concurrently to avoid pulmonary congestion and peripheral edema. Loop diuretics also enhance water excretion by limiting the formation of the medullary concentration gradient.³²

Demeclocycline is another treatment option for patients who are not adequately controlled by fluid restriction alone. Demeclocycline inhibits tubular AVP activity, resulting in increased water excretion.^{1,33} The usual dose of demeclocycline is 300 mg two to four times daily. Because of its delayed onset of action (3 to 6 days), this agent has no role in the acute management of severe hyponatremia, and dosage changes should be made no more frequently than every 3 to 4 days during its use.^{1,33} Demeclocycline should not be used in patients with liver disease or compromised fluid intake, who are at high risk for demeclocycline-induced renal tubular toxicity and acute renal failure, or in children because it can interfere with bone development.^{1,34}

There is substantial interest in the use of a new class of drugs called vasopressin receptor antagonists to treat SIADH, as well as other causes of euvolemic and hypervolemic hypotonic hyponatremia.^{35–37} These agents competitively bind to the vasopressin V2 receptor on the basolateral surface of epithelial cells in the collecting duct. Blockade of AVP binding to the V2 receptor prevents aquaporin-2 water channel transport to the apical surface, thereby decreasing AVP-dependent water reabsorption in the collecting duct. These agents have been called “aquaretics” because they increase the excretion of water without significantly increasing the excretion of electrolytes.³⁵ Several V2 antagonists are under investigation and show promise for the treatment of chronic hypo-osmolal syndromes such as chronic SIADH.^{35,36} One agent, conivaptan, has been recently approved by the FDA for treatment of euvolemic hyponatremia in hospitalized patients. Unlike the other vasopressin receptor antagonists being developed, conivaptan is a mixed vasopressin V1a and V2 receptor antagonist. Because it is available only for administration by intravenous infusion, its use for treatment of chronic SIADH is not practical. Other vasopressin receptor antagonists currently under development are oral medications that can play a substantial role in the management of chronic SIADH in the future.³⁷ The use of intravenous conivaptan in the management of SIADH in hospitalized patients is appealing, but its role relative to 3% sodium chloride solution remains to be established. It is important to recognize that vasopressin receptor antagonists are contraindicated in hypovolemic patients as their use would worsen the hypovolemia.

■ EVALUATION OF THERAPEUTIC OUTCOMES

The serum sodium level should be measured every 24 to 48 hours after the water restriction is initiated until it stabilizes at a concentration of greater than 125 mEq/L. A continued decline in the serum sodium level would indicate either nonadherence to the prescribed restriction or the need for a more stringent restriction. Once the serum sodium level has stabilized above 125 mEq/L, patients should then be seen every 2 to 4 weeks to assess neurologic status and to obtain serum and urine for sodium, potassium, and osmolality. Again, attention should be given to volume status (i.e., blood pressure, mucous membranes, skin turgor, and heart and lung examination), particularly in patients who are being treated with sodium chloride tablets and loop diuretics.

NONEMERGENT HYPERVOLEMIC HYPOTONIC HYPONATREMIA

The initial treatment goals for patients with asymptomatic or minimally symptomatic hypotonic hyponatremia and an expanded ECF volume include achieving a negative water balance while minimizing rapid changes in cell volume until the serum sodium is greater than 125 mEq/L. This entails correction of the underlying cause when possible, as well as restriction of water intake to a volume less than 1,000 to 1,200 mL/day. Dietary intake of sodium should be restricted to 1,000 to 2,000 mg/day, depending on the degree of ECF volume expansion and edema.

Patients with hypervolemic hypotonic hyponatremia caused by congestive heart failure should be treated with measures that can potentially improve cardiac contractility and improve the effective circulating volume, thereby limiting the nonosmotic release of AVP. Therapeutic options include digitalis or afterload reduction with angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin II receptor blockers (ARBs). Of these, only ACEIs have been shown in clinical trials to be of benefit in partially correcting hyponatremia in patients with congestive heart failure.³⁸ No specific ACE inhibitor offers any particular advantage for this indication, and the dose should be titrated to keep the systolic blood pressure in the 110 to 130 mm Hg range. Dose-limiting adverse effects include hyperkalemia (serum potassium >5.5 mEq/L), as well as a decline in renal function. The benefits and risks of continuing ACE inhibition must be weighed carefully in each case, but a decrease in glomerular filtration rate (GFR) of less than 30% that stabilizes within 2 months of therapy initiation generally does not require dosage reduction or discontinuation of the ACE inhibitor.³⁹

CLINICAL CONTROVERSY

Some clinicians regard any increase in serum creatinine in patients on ACEIs as a reason to decrease dosage or discontinue the medication. ACEIs selectively dilate the afferent arteriole, causing a decrease in intraglomerular pressure and reduced GFR. Although this might be viewed negatively, many experts suggest that the decrease in pressure is likely renoprotective, and that one does not need to reduce the dosage or discontinue therapy unless the resulting decrease in GFR is greater than 30% and does not stabilize within 2 months.

Other potentially treatable causes of asymptomatic hyponatremia associated with an expanded ECF volume include nephrotic syndrome and cirrhosis. ACEIs can be used to decrease proteinuria in patients with nephrotic syndrome, leading to partial correction of hypoalbuminemia and to a decrease in nonosmotic AVP release. Patients with advanced cirrhosis can benefit from placement of a transjugular intrahepatic portosystemic shunt, which can increase the effective circulating volume and thus reduce the nonosmotic release of AVP. This procedure can potentially exacerbate or precipitate hepatic encephalopathy, and should be avoided in patients with a history of encephalopathy. V2 receptor antagonists also show promise for treating hyponatremia in the setting of cirrhosis.⁴⁰

Vasopressin receptor antagonists have also been proposed for the treatment of hypervolemic hypotonic hyponatremia in patients with congestive heart failure and cirrhosis.^{35–37} The role of these agents in the management of these conditions, particularly congestive heart failure, is currently under intense investigation with promising early results.^{37,41–43} Vasopressin receptor antagonists are expected to play a major role in the acute and chronic management of hyponatremia in these patients in the future.

EVALUATION OF TREATMENT OUTCOMES

Patients should initially be evaluated on a daily basis for lung congestion, ascites, peripheral edema, and signs or symptoms of hyponatremia. The serum sodium concentration should be measured daily until it stabilizes above 125 mEq/L following initiation of water restriction. Patients should then be assessed 1 week following discharge, and then every 2 to 4 weeks to assess compliance with the water restriction and other treatment measures, volume status, and hyponatremia-related symptoms.

HYPERNATREMIA

EPIDEMIOLOGY AND ETIOLOGY

5 Hyponatremia (serum sodium >145 mEq/L) is always associated with hypertonicity and results from a deficit of water relative to ECF sodium content.¹ Hyperosmolar states are a potent stimulus for thirst, and therefore hyponatremia is most commonly observed in patients with an impaired thirst response or in those without access to water. Infants and comatose patients, as well as elderly or disabled patients with an impaired sensorium or functional status are therefore at highest risk for this disorder.⁴⁴ The incidence of hyponatremia in general medical-surgical hospital patients and intensive care unit patients has been estimated to be at least 1% and 7.9% respectively.^{45,46} Outcome generally depends on the rapidity with which the hyponatremia developed. Mortality from acute hyponatremia in children, which develops in less than 72 hours, ranges from 10% to 70%. In contrast, chronic hyponatremia in children, defined as that which develops over 3 or more days, has a mortality rate of 10%.⁴⁷ An acute increase in serum sodium in adults to greater than 160 mEq/L is associated with a 75% mortality rate.²⁸ Adults in whom the hyponatremia developed at a slower rate have a lower but still high mortality rate of approximately 60%. Hyponatremia in adults is often associated with a serious underlying illness, which likely contributes to the high mortality rate.

PATHOPHYSIOLOGY

Hyponatremia can result from either loss of water or hypotonic fluids, or less commonly from administration of hypertonic fluids or ingestion of sodium. Patients develop hypovolemic, hypervolemic, or isovolemic hyponatremia depending on the relative magnitude of sodium and water loss or gain caused by the underlying condition (Fig. 52–3).

Water loss commonly occurs as a result of insensible losses (evaporative losses of water through the skin and lungs) in patients deprived of water. Hospitalized patients who are febrile or receiving mechanical ventilation are often treated with intravenous fluids containing insufficient free water to replace insensible losses. Hyponatremia can be observed in patients with hypotonic gastrointestinal losses (diarrhea or vomiting) or in patients who have

	Demeclocycline

CNS, central nervous system; DI, diabetes insipidus.

been exposed to high temperatures who suffer large water losses from both sweat and insensible losses.

Diabetes insipidus (DI) is a condition characterized by decreased AVP secretion or decreased renal response to AVP.^{1,48,49} Patients excrete large volumes (3 to 20 L/day) of dilute urine, resulting in large urinary losses of water. DI is classified as either central (decreased AVP secretion) or nephrogenic (decreased renal response to AVP). Table 52–2 summarizes the causes of DI. Patients with central DI often present with sudden onset of polyuria, whereas patients with nephrogenic DI develop polyuria more gradually.

Administration of hypertonic sodium chloride can result in hyponatremia and an expanded ECF volume. This is typically iatrogenic, and can follow administration of sodium bicarbonate, use of hypertonic sodium chloride enemas, or intrauterine injection of hypertonic sodium chloride. Rarely, patients with hyperaldosteronism spontaneously present with an expanded ECF and mild hyponatremia.⁴⁴

CLINICAL PRESENTATION

6 The symptoms of hyponatremia are primarily caused by a decrease in neuronal cell volume and can include weakness, lethargy, restlessness, irritability, and confusion.^{1,44} Symptoms of more severe or rapidly developing hyponatremia include twitching, seizures, coma, and death. Hyponatremia results in movement of water from the intracellular space to the extracellular fluid. As discussed above, neurons can adapt to ECF tonicity changes by adjusting intracellular osmolality, including decreasing or increasing the concentration of organic osmolytes. In the case of hyponatremia, ECF hypertonicity results in generation of intracellular organic osmolytes within 24 hours of onset. This increase in intracellular fluid tonicity then draws water into the neurons, thus limiting the decrease in cell volume. Patients with chronic hyponatremia are therefore less likely to present with symptoms caused by this cerebral adaptation than patients with acute hyponatremia.

Hyponatremia is often associated with serious underlying illness, and signs and symptoms related to that illness can also be present. Patients with a history of severe diarrhea or vomiting can present with ECF volume depletion. Elderly patients deprived of water after sustaining a stroke or hip fracture often present with mental status changes and signs of ECF volume depletion. Clinically detectable extracellular fluid volume depletion, however, might not be evident until the serum sodium concentration exceeds 160 mEq/L, because these patients primarily have water loss, two-thirds of which is derived from the intracellular space. The urine is concentrated, osmolality often exceeds 450 mOsm/kg, as a result of both osmotic and nonosmotic release of AVP. The first step in evaluating patients with hyponatremia is the clinical assessment of the ECF volume, urine volume, and urine osmolality (Fig. 52–4).

Patients with a contracted ECF volume and a low urine output include those who have sustained insensible water losses that exceed intake, as well as those with extrarenal losses of hypotonic fluids. On physical examination, one should search for postural hypotension,

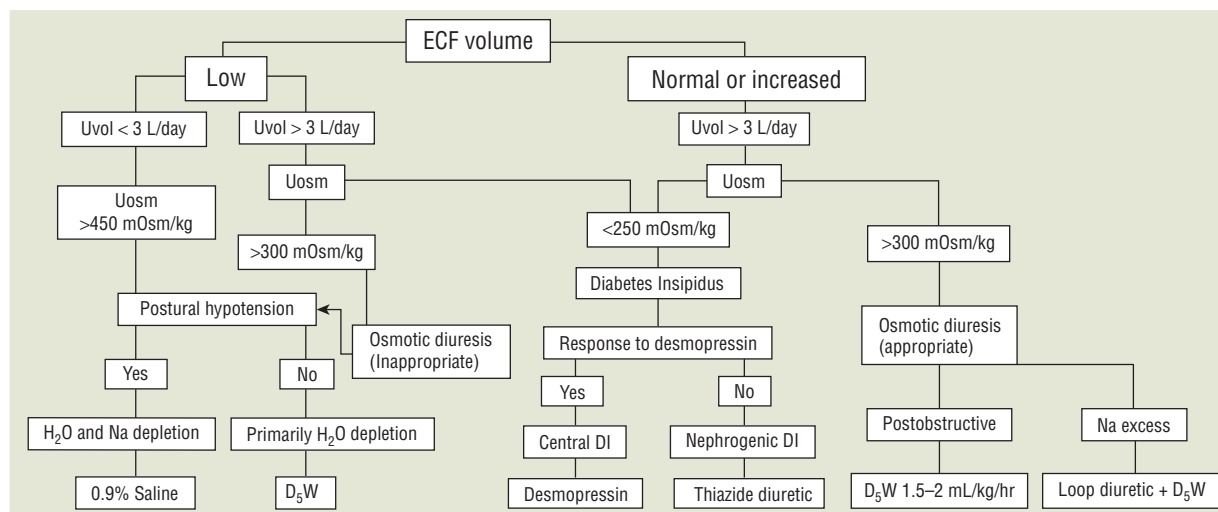

FIGURE 52-4. Diagnostic and treatment algorithm for hypernatremia. (D₅W, 5% dextrose in water; ECF, extracellular fluid; H₂O, water; Na, sodium; Uosm, urine osmolality; Uvol, daily urine volume.) See text for guidelines regarding calculations of infusion rates for intravenous solutions.

diminished skin turgor, and delayed capillary refill. The daily urine output is typically less than 1 liter.

A recent multicenter, case-control study examined the clinical presentation of hypernatremia in 150 elderly patients in geriatric care facilities.⁵⁰ Low blood pressure, tachycardia, dry oral mucosa, decreased skin turgor, and recent changes in consciousness were all more common in hypernatremic patients than in controls. Perhaps not surprisingly in this mixed patient population, the presence of signs of dehydration was variable, with orthostatic hypotension and decreased subclavicular and forearm skin turgor present in at least 60% of patients. Abnormal subclavicular and thigh skin turgor, dry oral mucosa, and recent change in consciousness were significantly and independently associated with hypernatremia.

CLINICAL PRESENTATION OF HYPERNATREMIA

General

- The rise in the plasma sodium concentration and osmolality causes acute water movement from the intracellular to the extracellular fluid. In the brain this decrease in volume can cause rupture of the cerebral veins, leading to focal intracerebral and subarachnoid hemorrhages and possible irreversible neurologic damage.

Symptoms

- The clinical manifestations of this disorder begin with lethargy, weakness, confusion, restlessness, and irritability, and can progress to twitching, seizures, coma, and death. Severe symptoms usually require an acute elevation in the plasma sodium concentration to above 160 mEq/L. Values above 180 mEq/L are associated with a high mortality rate.

Signs

- Signs of hypernatremia can include postural hypotension, tachycardia, dry oral mucosa, diminished skin turgor, and reduced or increased output of dilute or concentrated urine, depending on cause.
- Signs associated with chronic hypernatremia are often difficult to detect because most affected adults have underlying neurologic disease.

Laboratory Tests

- Serum sodium levels are generally higher than 145 mEq/L. Measurement of urine volume and osmolality may be helpful in diagnosing the cause.

Osmotic Diuresis Patients undergoing an osmotic diuresis generally have urine volumes greater than 3 L/day. Excessive urinary excretion of glucose, sodium, urea, or an exogenously administered solute such as mannitol, are identified either by history or by direct measurement of serum and urinary concentrations of the suspected solute. Patients with postobstructive diuresis, such as those with bladder outlet obstruction caused by prostatic hypertrophy, are usually volume expanded as a result of retained excess solute because of a decline in the GFR.¹ The osmotic diuresis that follows alleviation of the obstruction is appropriate in that it promotes excretion of the excess retained solute. Patients with severe hyperglycemia, conversely, present with signs of volume depletion, and the diuresis is therefore inappropriate, further exacerbating the degree of ECF volume contraction.

Diabetes Insipidus Patients with DI tend to maintain a normal ECF volume as long as they are conscious and have free access to water. Patients typically have only a slight elevation in the serum sodium concentration (usually in the 141 to 145 mEq/L range), and a daily urine volume greater than 3 liters.⁵¹ A water deprivation test is sometimes recommended to aid in the differential diagnosis between central and nephrogenic DI.²³ This consists of depriving patients of water for 8 to 12 hours. Urine osmolality, urine volume, and body weight, are then measured before and after subcutaneous administration of 5 mcg of desmopressin acetate. Patients with central DI will show a prompt increase in urine osmolality to approximately 600 mOsm/kg and a decrease in urine volume after desmopressin administration. Those with nephrogenic DI will be unable to increase the urine osmolality above 300 mOsm/kg.¹ The direct measurement of vasopressin levels after infusion of 5% sodium chloride at a rate of 0.05 mL/kg/min for no more than 2 hours improves the accuracy of diagnosis, but carries a high risk of ECF volume overload.⁵²

The value of performing a water deprivation test in patients with polyuria and hypernatremia, such as patients with DI, has recently been questioned.⁵³ Because hypernatremia provides a maximal stimulus for AVP secretion, discriminating between nephrogenic and central DI can be based on plasma vasopressin concentration and urinary response to desmopressin without the need for water deprivation. The water deprivation test is thus likely to only be of diagnostic value in patients with polyuria and a normal serum sodium concentration.

Sodium Overload Patients who have ingested large amounts of sodium (>4 tablespoons [1,400 mEq Na⁺] of sodium chloride) or

who have received greater than 5 liters of hypertonic fluids are volume expanded, although this may not always be clinically evident as edema. This results in an osmotic diuresis, polyuria, and a urine osmolality greater than 300 mOsm/kg. The excess sodium will be excreted in the urine in patients with normal renal function.

TREATMENT

Hypernatremia

■ DESIRED OUTCOME

7 The desired goals for patients with hypernatremia include correction of the serum sodium concentration at a rate that restores and maintains cell volume as close to normal as possible, as well as normalizing the ECF volume in states of ECF volume depletion or expansion. Adequate treatment should result in the resolution of symptoms associated with hypovolemia. Careful titration of fluids and medications should minimize the adverse effects from too rapid correction. Rapid correction can result in movement of excessive water into the brain cells, resulting in cerebral edema, seizures, neurologic damage, and potentially death.¹ Modulation of dietary sodium intake and sodium replacement can be necessary to prevent recurrence of hypernatremia.

■ PHARMACOLOGIC THERAPY

Hypovolemic Hypernatremia

Hypovolemic hypernatremia (postural hypotension, tachycardia, and decreased skin turgor) should initially be treated with 0.9% sodium chloride until hemodynamic stability is restored. An initial infusion rate of 200 to 300 mL/h will likely be appropriate for many patients. Once intravascular volume is restored, 0.45% sodium chloride or 5% dextrose in water (D5W) can then be infused to correct the water deficit,³¹ the volume of which can be estimated as:

$$\text{Water Deficit} = \text{Present TBW} \times [(S^1_{\text{Na}} / 140) - 1]$$

where TBW = total body water; S^1_{Na} = initial patient serum sodium concentration (in mEq/L); and 140 = normal or goal S_{Na} (in mEq/L).

The rate of correction depends on the rapidity with which the hypernatremia developed. Hypernatremia that has developed over a few hours can be corrected at a rate of approximately 1 mEq/L per hour, whereas a rate of 0.5 mEq/L per hour should be used when it has developed more slowly.^{16,44} The rate of correction should generally be limited to no more than 10 mEq/L per day.^{23,44}

Treatment of hyperglycemia-induced osmotic diuresis consists of correcting the hyperglycemia with insulin, as well as administering 0.9% sodium chloride until signs of ECF volume depletion resolve. Once hemodynamic stability is restored, the water deficit should be corrected in a manner analogous to that described for patients with hypovolemic hypernatremia above. The corrected serum sodium level should be calculated by adding 1.7 mEq/L for every 100-mg/dL increase in the serum glucose concentration before estimating the water deficit.³

Hypernatremia in patients undergoing a postobstructive diuresis should be treated with infusion of hypotonic fluids such as 0.45% sodium chloride at maintenance rates of approximately 1.5 mL/kg per hour. It is important to avoid the temptation to administer fluids to replace urine output on a 1:1 volume basis, because this tends to perpetuate the diuresis.

The serum sodium concentration and fluid status should be monitored every 2 to 3 hours over the first 24 hours of admission in patients with symptomatic hypernatremia to permit appropriate adjustment in the rate of infusion of hypotonic fluids. After symptoms resolve and the serum sodium is less than 148 mEq/L, serum

sodium determinations every 6 to 12 hours and fluid status assessment every 8 to 24 hours are generally sufficient to follow the course of therapy.

Central Diabetes Insipidus

8 Patients with central DI should generally receive AVP replacement therapy with desmopressin, an AVP analog.^{1,16} Because of variable absorption of oral desmopressin, DI is best treated with the intranasal formulation 1-desamino-8-D-arginine vasopressin (DDAVP); however, oral tablets are available and can be useful in some patients. The beginning intranasal dose should be 10 mcg once daily. Ultimately the dose may need to be titrated up to 10 mcg twice daily for most adults. Each insufflation of intranasal DDAVP delivers 10 mcg of desmopressin acetate at a concentration of 100 mcg/mL. Several medications with antidiuretic properties have been used successfully in the management of central and nephrogenic DI (Table 52-3). They can be used as an alternative to DDAVP or adjunctively.

The desmopressin dose should be adjusted to achieve adequate urinary concentration during sleep to prevent nocturia, to result in a daily urine volume of approximately 1.5 to 2 L, and to maintain the serum sodium concentration in the 137 to 142 mEq/L range. The serum sodium concentration should be measured every 3 to 4 days during the initial dose titration period, and then every 2 to 4 months. Administration of desmopressin results in nonsuppressible AVP activity and presents a risk of water intoxication caused by excess water retention.¹ Patients using desmopressin should therefore be monitored for signs and symptoms of hyponatremia and hypervolemia. It has been suggested that patients using desmopressin who experience water intoxication can minimize the risk of a second episode by delaying a dose of desmopressin each week until polyuria and thirst develop, thus demonstrating the need for additional desmopressin doses.¹⁶

Nephrogenic Diabetes Insipidus

Hypercalcemia and hypokalemia should be corrected, and medications that contribute to the pathogenesis should be discontinued. One key goal in treating nephrogenic DI is to induce a mild ECFVD (1 to 1.5 L) with a thiazide diuretic and dietary sodium restriction (85 mEq Na^+ or 2,000 mg sodium chloride per day), which often can decrease urine volume by as much as 50% (see Table 52-3). This will increase proximal water reabsorption, decrease the volume of filtrate delivered to the distal nephron, and decrease urine volume. NSAIDs such as indomethacin at a dose of 50 mg three times a day can potentiate the activity of AVP and can be used as adjunctive therapy.^{1,54} Patients with lithium-induced nephrogenic DI can derive particular benefit from amiloride at a dose of 5 to 10 mg

TABLE 52-3 Drugs Used to Manage Central and Nephrogenic Diabetes Insipidus

Drug	Indication	Dose
Desmopressin acetate	Central and nephrogenic	5–20 mcg intranasally every 12–24 hours
Chlorpropamide	Central	125–250 mg orally daily
Carbamazepine	Central	100–300 mg orally twice a day
Clofibrate	Central	500 mg orally four times a day
Hydrochlorothiazide	Central and nephrogenic	25 mg orally every 12–24 hours
Amiloride	Lithium-related nephrogenic	5–10 mg orally daily
Indomethacin	Central and nephrogenic	50 mg orally every 8–12 hours

daily; amiloride directly inhibits uptake of lithium from the tubular lumen into principal cells in the cortical collecting duct.^{1,55}

CLINICAL CONTROVERSY

The relative merits of the various drug treatment options, including NSAIDs and amiloride, for nephrogenic DI have not been well studied. Choice of agents is therefore subject to clinician variability. It is unclear if there is a significant difference among these agents in the risk of clinically important decreases in GFR when they are used to produce mild ECF volume decreases.

EVALUATION OF TREATMENT OUTCOMES

Physical examination with attention to volume status and measurement of serum and urine sodium concentration and osmolality should be assessed every 2 to 3 months during chronic therapy. A 24-hour urine collection to measure urine volume and sodium excretion will help guide therapy with diuretics and determine adherence to sodium restriction.

Sodium Overload

Treatment of sodium overload consists of administration of loop diuretics to facilitate excretion of the excess sodium, as well as intravenous D₅W. The latter should be infused at a rate that will decrease the serum sodium at approximately 0.5 mEq/L per hour, or 1 mEq/L per hour in cases in which the hyponatremia developed rapidly over several hours.⁴⁴ The volume of infusate may be estimated as described previously. Furosemide should be administered at a dose of 20 to 40 mg intravenously every 6 hours.

The serum sodium should initially be measured every 2 to 4 hours, and the diuretic continued until signs of ECF volume overload (pulmonary congestion and edema) resolve. The serum sodium concentration can be determined every 6 to 12 hours once the serum sodium level is less than 148 mEq/L and symptoms of hypertonicity resolve.

EDEMA

The body closely monitors blood volume to help ensure adequate tissue perfusion. A decline in the effective circulating volume (actually the blood pressure resulting from that volume) results in decreased sodium and water excretion by the kidney.¹ Under these conditions, the kidneys retain all of the water and sodium ingested until the effective circulating volume is restored to normal. An increase in dietary sodium is accompanied by an increase in water intake caused by the initial increase in serum osmolality and stimulation of thirst. The resultant increase in ECF volume augments renal perfusion, effecting a transient increase in GFR which leads to enhanced sodium filtration and excretion.⁵⁶ These homeostatic mechanisms are crucial in maintaining sodium balance, as retention of just a few milliequivalents of sodium per day can eventually lead to an expanded ECF volume and edema formation.

PATHOPHYSIOLOGY

9 Edema may be defined as a clinically detectable increase in interstitial fluid volume. Clinical detectability in adults generally requires an interstitial volume increase of at least 2.5 to 3 L.¹ Edema develops when excess sodium is retained either as a primary defect in renal sodium excretion, or as a response to a decrease in the effective circulating volume despite an already normal or expanded ECF volume. An increase in the capillary hydrostatic pressure

because of an expansion of the ECF volume, or an increase in central venous pressure may lead to edema formation. Edema may also occur when there is an alteration in Starling forces within the capillary.⁵⁷ The Starling equation denotes the relationship between factors affecting the movement of fluid between the capillary and interstitium and is discussed in detail in Chap. 26.

Edema may develop rapidly as in the setting of acute decompensation in myocardial contractility which leads to an elevation in pulmonary venous pressure that is transmitted back to the pulmonary capillaries resulting in acute pulmonary edema. Edema may also develop insidiously as in the case of renal sodium and water retention due to diminished effective circulating volume which leads to a rise in the ECF volume and edema formation in both peripheral and pulmonary interstitial tissues.

Edema formation in patients with nephrotic syndrome is primarily related to renal sodium and water retention. A decrease in capillary oncotic pressure does not appear to play a major role until the serum albumin concentration falls to less than 2 g/dL. This is explained by the fact that both capillary and interstitial oncotic pressure decrease proportionately above a serum albumin concentration of 2 g/dL, and thus the transcapillary oncotic gradient is not significantly altered.⁵⁸

Patients with cirrhosis initially develop ascites as a result of an increase in the pressure in the portal circulation proximal to the diseased liver. Sequestration of fluid in the abdominal cavity (ascites) and peripheral vasodilation as a consequence of increased levels of circulating cytokines, result in a decrease in the effective circulating volume, activation of the sympathetic nervous system, and secondary hyperaldosteronism. Therefore, renal sodium retention leads to worsened ascites and edema.

CLINICAL PRESENTATION

Edema is usually first detected in the feet or pretibial area of ambulatory patients and in the presacral area of bed-bound individuals. Edema is described as “pitting” when a depression created by exerting pressure for several seconds over a bony prominence such as the tibia does not rapidly refill. The severity of the edema should be rated on a semi-quantitative scale of 1+ to 4+ depending on the depth of the pit (1+ = 2 mm, 2+ = 4 mm, 3+ = 6 mm, and 4+ = 8 mm).

The extent of the edema should also be quantified according to the area of involvement. Pretibial edema, for example, should be quantified according to how far it extends up the lower leg (e.g., one-third up the lower leg). Pulmonary edema, an increase in lung interstitial and alveolar water, is often evidenced by crackles (also called rales) upon auscultation. It should be quantified according to how far the crackles extend from the dependent portion of the lung(s). So, for example, edema limited to the ankles and feet would indicate less severe edema than edema that extends halfway up the lower legs, and crackles limited to the base of both lungs in an upright person would indicate less severe pulmonary edema than crackles throughout both lung fields.

TREATMENT

Edema

GENERAL APPROACH TO TREATMENT

10 The goals of diuretic therapy are to minimize tissue edema and thus improve organ function, as well as to relieve symptoms of edema such as dyspnea in patients with congestive heart failure (CHF) or abdominal distention in patients with ascites. It is important to emphasize that the presence of edema does not always dictate the need for instituting pharmacologic (diuretic) therapy. Only pulmo-

TABLE 52-4 Maximal Effective Dose and Dosing Interval for Edema Management with Loop Diuretics

Diuretic	Dosing Interval	Normal	Cirrhosis	CHF	Nephrotic Syndrome	GFR (10–50 mL/min)	GFR (<10 mL/min)
Furosemide							
IV	6–8 hours	10–40 mg	40 mg	40–80 mg	120 mg	80 mg	200 mg
Oral	6–8 hours	20–80 mg	80 mg	80–160 mg	240 mg	160 mg	320–400 mg
Bumetanide							
IV/Oral	6–8 hours	1 mg	1 mg	2–3 mg	3 mg	2–3 mg	8–10 mg
Torsemide

CHF, congestive heart failure; GFR, glomerular filtration rate.

nary edema requires immediate pharmacologic treatment because it is life-threatening. Other forms of edema may be treated gradually, with a comprehensive approach that includes not only diuretics, but also sodium restriction and treatment of the underlying disease state. Sodium intake should generally be restricted to 1,000 to 2,000 mg/day. A slow, more judicious approach in non-life-threatening situations will help to minimize complications of diuretic therapy and excessive fluid removal. These may include impaired vital organ perfusion, azotemia, and impaired cardiac output due to a fall in the left ventricular end-diastolic filling pressure.

■ PHARMACOLOGIC THERAPY

Diuretics are the primary pharmacologic therapy for the management of edema. Patients with expanded ECF volume and edema often require therapy with diuretics when treatment of the underlying disease and daily sodium restriction are insufficient to relieve the edema. Diuretics can be categorized according to the site in the nephron where sodium reabsorption is inhibited. Loop diuretics inhibit the sodium-potassium-chloride ($\text{Na}^+/\text{K}^+-2\text{Cl}^-$) carrier in the loop of Henle. Thiazide diuretics inhibit the Na^+/Cl^- carrier in the distal tubule. Finally, potassium-sparing diuretics inhibit the sodium channel in the cortical collecting duct either directly (triamterene and amiloride), or by interfering with aldosterone activity (spironolactone and eplerenone). The efficacy of a diuretic depends on the presence of several factors, including the amount of filtered solute normally reabsorbed at the site of action, the amount of solute reabsorbed distal to the site of action, and adequate delivery of drug to the site of action in the nephron.

Loop diuretics are the most potent diuretics, as evidenced by the fact that they increase peak fractional excretion of sodium (FeNa) to 20% to 25%. Thiazide- and potassium-sparing diuretics are less potent and increase peak FeNa to 3% to 5% and 1% to 2%, respectively.¹ Although a large portion of the filtered sodium is reabsorbed in the proximal nephron, the efficacy of proximal-acting diuretics such as acetazolamide is limited by reabsorption of the excess fluid and sodium in the loop of Henle.

The effectiveness of thiazide and loop diuretics is dependent on the concentration of the drug in the tubular lumen. These diuretics are delivered to the tubular lumen of the kidney by active transport by the proximal tubular cells. Osmotic diuretics, conversely, are freely filtered into the tubular lumen in the proximal tubule, whereas spironolactone gains access to mineralocorticoid receptors in the cortical collecting duct through diffusion from the systemic circulation.

A threshold concentration of loop or thiazide diuretic must be delivered to the active site (e.g., loop of Henle or distal tubule) to achieve a natriuresis.^{1,59} Once this concentration is achieved, further increases in diuretic dose will not elicit an increase in diuretic response. Thus a ceiling dose of diuretic is recognized. Administration of 40 mg of intravenous furosemide to a normal subject will result in excretion of 200 to 250 mEq of sodium in 3 to 4 liters of urine over a 3- to 4-hour period.⁵⁹ Table 52-4 summarizes the maximal effective doses and dosing intervals for loop diuretics in patients with cirrhosis, CHF, nephrotic syndrome, as well as those with reduced renal function.

Patients with renal insufficiency often require larger doses of diuretics to achieve adequate concentrations of the drug at the active site. The natriuretic response is decreased in patients with renal insufficiency because the filtered load of sodium falls proportionately as GFR declines. This can be partially overcome by dosing diuretics more frequently, as well as by using continuous infusions in critically ill hospitalized patients.^{1,60,61} The latter will maintain more consistent levels of the diuretic above the threshold concentration. Patients who are diuretic resistant should be treated with both a loop and a thiazide-type diuretic. Patients with CHF and a normal GFR have impaired oral absorption of furosemide. An adequate diuresis is most readily sustained by increasing the frequency of diuretic administration (Fig. 52-5).

Diuretic resistance can be caused by increased uptake of sodium in the distal tubule, impaired delivery of diuretics to the site of action, or decreased intrinsic diuretic activity. Animal studies have demonstrated binding of furosemide to albumin in the tubular lumen, which decreases the availability of the drug to the active site.⁶² Human studies, however, have demonstrated that when albumin binding is inhibited by concurrent administration of sulfasoxazole, diuretic resistance persists, suggesting a decrease in intrinsic tubular sensitivity to loop diuretics.⁶³ This impaired natriuretic response can be overcome by using higher diuretic doses to increase the delivery of free drug to the secretory site in the nephron.^{60,61} Combinations of loop diuretics with distally-acting diuretics are generally necessary to promote a natriuresis that exceeds tubular sodium reabsorption (Fig. 52-6).

CLINICAL CONTROVERSY

Some clinicians advocate using combinations of diuretics in cases of diuretic resistance associated with nephrotic syndrome, while others prefer to use larger-than-average doses of single agents to overcome enhanced protein binding in the tubular lumen associated with proteinuria.

Secondary hyperaldosteronism plays a major role in the pathogenesis of edema in patients with cirrhosis. Therefore, these patients

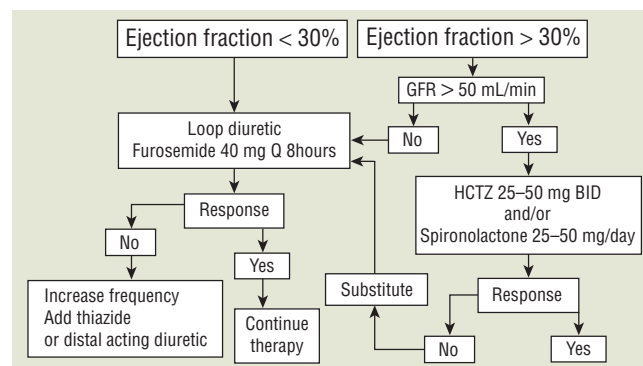

FIGURE 52-5. Therapeutic algorithm for diuretic use in patients with congestive heart failure. (GFR, glomerular filtration rate; HCTZ, hydrochlorothiazide.)

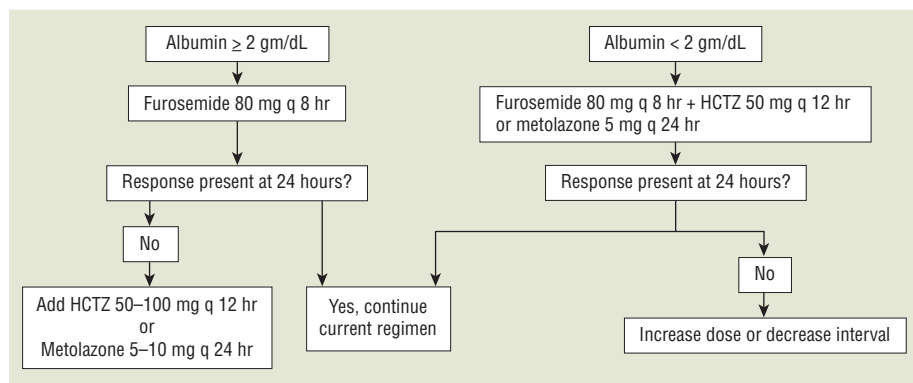

FIGURE 52-6. Therapeutic algorithm for diuretic therapy in patients with nephrotic syndrome. (HCTZ, hydrochlorothiazide.)

should initially be treated with spironolactone in the absence of impaired GFR and hyperkalemia. Thiazides can then be added for patients with a creatinine clearance >50 mL/min. For those patients who remain diuretic resistant, a loop diuretic can replace the thiazide. Patients with impaired GFR (creatinine clearance of <40 mL/min) can require a loop diuretic, with addition of a thiazide in those who do not achieve adequate diuresis.⁶¹ Care should be taken to avoid hypokalemia, which can precipitate hepatic encephalopathy by increasing ammoniogenesis (Fig. 52–7).⁶⁴

Complications of loop and thiazide diuretic therapy include hypokalemia, excess depletion of ECF volume, hyponatremia, hypomagnesemia, metabolic alkalosis, and hyperuricemia. Thiazides can also cause hypercalcemia, particularly in patients with mild subclinical hyperparathyroidism. Chronic therapy with potassium-sparing diuretics, including triamterene, amiloride, and spironolactone, can cause a mild metabolic acidosis and can precipitate hyperkalemia. Patients with moderate to severe kidney dysfunction or those receiving NSAIDs, ACEIs, or ARBs are at highest risk for this complication. In addition, spironolactone can cause reversible gynecomastia in patients receiving therapy for more than several weeks. This side effect, however, has not been associated with eplerenone, a newly available aldosterone antagonist.⁶⁵

EVALUATION OF THERAPEUTIC OUTCOMES

Patients should be monitored by careful history and intermittent physical examinations to detect signs and symptoms of edema as

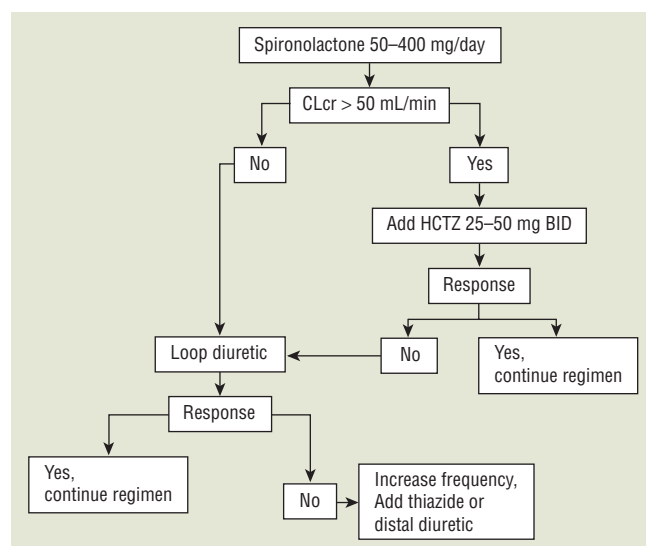

FIGURE 52-7. Therapeutic algorithm for diuretic use in patients with cirrhosis. (CL_{cr}, creatinine clearance; HCTZ, hydrochlorothiazide.)

well as adverse effects of treatment. Physical examination should include measurement of blood pressure and pulse in either supine or seated positions and after standing for 2 to 3 minutes. ECF volume can be estimated based on the height of the jugular venous pressure, extent of edema, auscultation of the heart and lungs, and skin mobility. Followup monitoring (10 to 14 days after initiation of therapy) should include determinations of serum sodium, potassium, chloride, bicarbonate, magnesium, calcium, BUN, serum creatinine, and uric acid. A new steady state will have developed over that time period and further fluctuations in ECF volume and electrolyte balance should not occur in the absence of a change in clinical status, diuretic dose, or dietary intake. Repeated blood tests are not necessary at every visit unless there is a change in the patient's clinical status.

ABBREVIATIONS

- ACEI: angiotensin-converting enzyme inhibitor
- AVP: arginine vasopressin, also known as antidiuretic hormone or ADH
- ATPase: adenosine triphosphatase
- BUN: blood urea nitrogen
- CHF: congestive heart failure
- CNS: central nervous system
- DDAVP: 1-desamino-8-D-arginine vasopressin
- D5W: 5% dextrose in water
- DI: diabetes insipidus
- ECF: extracellular fluid
- ECFVd: extracellular fluid volume deficit
- ECFV_{current}: current extracellular fluid volume
- ECFV_{norm}: normal extracellular fluid volume
- FeNa: fractional excretion of sodium
- GFR: glomerular filtration rate
- IV_{Na}: sodium concentration of infusate
- IV_{vol}: volume of infusate
- NSAID: nonsteroidal antiinflammatory drug
- S_{Na}¹: initial patient serum sodium concentration
- SIADH: syndrome of inappropriate secretion of antidiuretic hormone
- TBW: total body water
- TBW_{current}: current total body water
- TBW_{norm}: normal total body water
- V2: vasopressin-2

KEY CONCEPTS

- 1 Severe acute hypercalcemia can result in cardiac arrhythmias, whereas chronic hypercalcemia can lead to calcium deposition in soft tissues including blood vessels and the kidney.
- 2 The correction of hypercalcemia can include multiple pharmacotherapeutic modalities such as hydration, diuretics, bisphosphonates, and steroids, depending on the etiology and acuity of the hypercalcemia
- 3 Hypocalcemia is typically associated with an insidious onset, however, some drugs such as cinacalcet are associated with rapid decreases in serum calcium.
- 4 Acute treatment of hypocalcemia requires calcium supplementation whereas chronic management may require other therapies such as vitamin D to maintain serum calcium values.
- 5 Hyperphosphatemia occurs most frequently in patients with chronic kidney disease.
- 6 Treatment of nonemergent hyperphosphatemia includes the use of phosphate binders to decrease absorption of phosphorus from the gastrointestinal tract.
- 7 Hypophosphatemia is a relatively common complication among critically ill patients.
- 8 Treatment of acute hypophosphatemia usually requires intravenous supplementation of phosphorous salts.

Homeostasis of fluid and electrolytes is necessary for the body's normal physiologic functions. Disorders of calcium and phosphorus are common complications of multiple acute and chronic diseases. These disorders are frequently seen in the acute care setting; however, they are also often present in ambulatory patients albeit in a less severe state. The consequences of electrolyte disorders can range from asymptomatic to life-threatening requiring hospitalization and emergent treatment. The maintenance of fluid and electrolyte homeostasis requires adequate functioning of feedback mechanisms, hormones, and multiple organ systems.

Many common drug therapies can disturb the normal homeostatic mechanisms that maintain calcium and phosphorous balance. In addition, with some drug therapies, toxicity is enhanced when underlying electrolyte disorders are present. Drug-induced disorders

respond well to discontinuation of the offending agent(s); however, additional therapies are sometimes required to correct the disorder. This chapter reviews the etiology, classification, clinical presentation, and therapy for the most common disorders of calcium and phosphorus homeostasis.

DISORDERS OF CALCIUM HOMEOSTASIS

The maintenance of physiologic calcium concentrations in the intracellular and extracellular spaces is vital for the preservation and function of cell membranes; propagation of neuromuscular activity; regulation of endocrine and exocrine secretory functions; blood coagulation cascade; platelet adhesion process; bone metabolism; muscle cell excitation/contraction coupling; and mediation of the electrophysiologic slow-channel response in cardiac and smooth-muscle tissue.

The disorders of calcium homeostasis are related to the calcium content of the extracellular fluid, which contains less than 0.5% of the total body stores of calcium. Skeletal bone contains more than 99% of total body stores of calcium.¹ Extracellular fluid (ECF) calcium is moderately bound to plasma proteins (46%), primarily albumin.² Unbound or ionized calcium is the physiologically active form and is the fraction that is homeostatically regulated.³ Extracellular calcium, however, is most commonly measured as the total serum calcium level, which includes both bound and unbound calcium.² The normal total calcium serum concentration range is 8.5 to 10.5 mg/dL.³

Proper assessment of total serum calcium concentrations includes measurement of the patient's serum albumin concentration. Hypoalbuminemia, which can be associated with many chronic disease states, is probably the most common cause of "laboratory hypocalcemia." Patients remain asymptomatic because the unbound or ionized fraction of serum calcium remains normal (normal range 4.4 to 5.4 mg/dL). A corrected total serum calcium (S_{ca}) concentration can be calculated based on the measured total serum calcium and the difference between a patient's measured albumin concentration and the normative value of 4 g/dL by the following equation:

$$\text{Corrected } S_{ca} \text{ (mg/dL)} = \text{measured } S_{ca} \text{ (mg/dL)} + [0.8 \times (4.0 \text{ g/dL} - \text{measured albumin (g/dL)})].$$

The concentration of ionized calcium is closely regulated by the interactions of parathyroid hormone (PTH), phosphorus, vitamin D, and calcitonin (Fig. 53–1). PTH increases serum calcium concentrations by stimulating calcium release from bone, reducing renal calcium excretion, and enhancing absorption in the gastrointestinal tract secondary to increased renal production of 1,25-dihydroxyvitamin D₃. Vitamin D directly increases serum calcium, as well as phosphorus concentrations, by increasing gastrointestinal absorption. Indirectly, it can also lead to calcium release from bone and reduced renal excretion. Calcitonin inhibits osteoclastic bone resorption. Its plasma concentrations are increased when ionized calcium concentrations

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

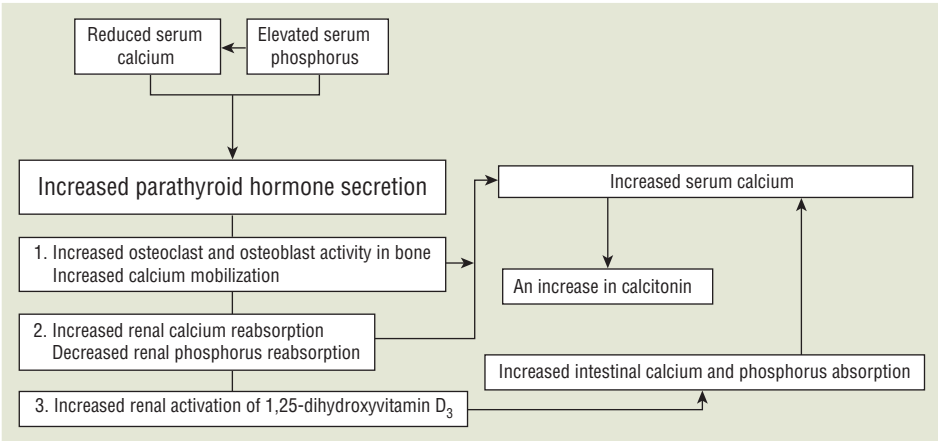

FIGURE 53-1. Homeostatic mechanisms to maintain serum calcium concentrations.

are high as the body attempts to return the calcium level to the normal range. Disruption of these homeostatic mechanisms results in the clinical manifestations of hypercalcemia or hypocalcemia.

Any factor that alters the concentration of albumin or its binding of calcium can be expected to change the unbound fraction of total serum calcium. The most significant cause of changes in calcium binding to albumin is a change in extracellular fluid pH. In the presence of metabolic alkalosis the fraction of calcium bound to albumin is increased, thus reducing the plasma concentration of ionized calcium. This can result in symptomatic hypocalcemia; that is, paresthesia, muscle cramping and spasms, memory loss, and seizures.¹ Conversely, metabolic acidosis decreases calcium binding to albumin and results in increased ionized calcium. Hypoalbuminemic states are probably the most common cause of “laboratory hypocalcemia.” When the albumin level is decreased, the ionized calcium concentration can be normal although total concentration is reduced. Each 1 g/dL drop in the serum albumin concentration below 4 g/dL will result in a decrease of total serum calcium concentration by 0.8 mg/dL.^{1,2} This approach of calculating an albumin-adjusted calcium concentration has been found to overestimate the degree of hypercalcemia and usually fails to identify hypocalcemia in critically ill patients, therefore ionized calcium values should be used to assess calcium status in these patients.^{4,5}

HYPERCALCEMIA

Hypercalcemia (total serum calcium >10.5 mg/dL) has been associated with a multitude of causes (Table 53-1). The most common causes of hypercalcemia are cancer and primary hyperparathyroidism. The reported incidence of primary hyperparathyroidism in the United States ranges from 10 to 30 cases per 100,000 people.⁶ Hypercalcemia of cancer occurs in approximately 20% to 40% of cancer patients at some time during the course of their disease.⁷ Cancer-associated hypercalcemia is predominantly encountered in hospitalized patients, whereas primary hyperparathyroidism accounts for the vast majority of cases in the outpatient setting.^{8,9}

PATHOPHYSIOLOGY

Hypercalcemia is the result of one of three primary mechanisms: increased bone resorption, increased gastrointestinal absorption, or decreased elimination by the kidneys (see Fig. 53-1). Many tumors secrete PTH-related protein, which binds to the PTH receptors in bone and renal tissues, leading to increased bone resorption and renal tubular reabsorption.¹⁰ Tumors can also secrete substances such as vitamin D, transforming growth factor, interleukins, prostaglandins, interferon, tumor necrosis factor, and granulocyte-macrophage colony stimulating factor, which are associated with the development of hypercalcemia.⁷ Hypercalcemia of malignancy is a common complication of squamous cell carcinomas of the lung,

head, and neck, hematologic malignancies such as multiple myeloma and T-cell lymphomas, and carcinomas of ovary, kidney, bladder, and breast. The most frequent types of malignancy associated with hypercalcemia are carcinomas of the lung and breast.⁹ Furthermore, up to 40% of patients with multiple myeloma can develop hypercalcemia.⁹ Primary hyperparathyroidism is the most common cause of hypercalcemia in the general population. Benign parathyroid adenomas account for 80% to 85% of these cases of hyperparathyroidism, parathyroid hyperplasia accounts for 15%, and parathyroid carcinoma is the cause in less than 1% of cases.^{7,8}

Other causes of hypercalcemia include medications, endocrine and granulomatous disorders, immobilization, high bone-turnover states (adolescence and Paget’s disease), and rhabdomyolysis. Increased gastrointestinal absorption can be the result of excessive ingestion of vitamin D analogs, calcium supplements, and lithium. Lithium and vitamin A therapy can increase bone resorption, whereas increased renal tubular reabsorption of calcium can occur with thiazide and lithium therapy. Aluminum antacids prevent calcium deposition in the bone; thereby increasing serum concentrations.¹¹ Addison’s disease, acromegaly, and thyrotoxicosis are endocrine disorders that can lead to hypercalcemia because of increased renal tubular reabsorption and increased bone resorption. Finally, the granulomatous disorders (sarcoidosis, tuberculosis, histoplasmosis, and leprosy) are

TABLE 53-1 Etiologies of Hypercalcemia

Neoplasms	Medications

Adolescence	
Rhabdomyolysis	

associated with hypercalcemia caused by an increase in gastrointestinal absorption.¹² Milk-alkali syndrome is the term applied to those situations where an individual develops hypercalcemia following the ingestion of calcium and absorbable alkali (e.g., calcium carbonate) and is an important cause of hypercalcemia in patients who are not on dialysis.^{13,14}

CLINICAL PRESENTATION

Patients with mild to moderate hypercalcemia, that is, total serum calcium concentrations of less than 13 mg/dL, can often be asymptomatic. This is usually the case in drug-induced hypercalcemia and the vast majority of patients with primary hyperparathyroidism.^{8,15,16} In fact, one study noted normocalcemia in approximately 20% of patients with a diagnosis of primary hyperparathyroidism, suggesting target tissue resistance to PTH.¹⁶ The signs and symptoms of severe hypercalcemia that are usually present if the total serum calcium concentration is >13 mg/dL may differ depending on the acuity of onset.² Hypercalcemia of malignancy usually develops quickly and is accompanied by a classic symptom complex of anorexia, nausea and vomiting, constipation, polyuria, polydipsia, and nocturia.¹⁵ Polyuria and nocturia secondary to a urinary-concentrating defect constitute some of the most frequent renal effects of hypercalcemia.¹⁵ Hypercalcemic crisis is characterized by an acute elevation of total serum calcium to a value >15 mg/dL, acute renal insufficiency, and obtundation (inability to arouse).¹⁵ If untreated, hypercalcemic crisis can progress to oliguric renal failure, coma, and life-threatening ventricular arrhythmias.¹⁵ The primary complications associated with chronic hypercalcemia (hyperparathyroidism) include metastatic calcification, nephrolithiasis, and chronic renal insufficiency.¹⁵

CLINICAL PRESENTATION OF HYPERCALCEMIA

General

- The signs and symptoms of hypercalcemia depend on severity and on the rapidity of onset.

Symptoms

- Symptoms include fatigue, weakness, anorexia, depression, anxiety, cognitive dysfunction, vague abdominal pain, and constipation. Renal symptoms can include polyuria, polydipsia, and nocturia. Rarely, severe hypercalcemia leads to acute pancreatitis.

Signs

- Renal: The most important renal manifestations which are generally the result of chronic hypercalcemia are nephrolithiasis; renal tubular dysfunction, particularly decreased concentrating ability; and acute and chronic renal insufficiency.
- Cardiovascular: Long-standing hypercalcemia can lead to the deposition of calcium in heart valves, coronary arteries, and myocardial fibers. Hypercalcemia also directly shortens the myocardial action potential, which is reflected in a shortened QT interval and coving of the ST-T wave. Spontaneous ventricular tachyarrhythmias and elevations in blood pressure have also been reported.
- Musculoskeletal: A number of rheumatologic complaints have been described in hyperparathyroidism, including gout, pseudogout, and chondrocalcinosis. The relative roles of hypercalcemia and PTH excess in these problems are not known.
- Other signs: Band keratopathy, a reflection of subepithelial calcium phosphate deposits in the cornea, is a very rare finding associated with hypercalcemia. It extends as a horizontal band across the cornea in the area that is exposed between the eyelids.

Laboratory Tests

- Serum calcium concentrations of more than 10.5 mg/dL are considered to represent hypercalcemia. Patients with values up to 13 mg/dL are generally considered to have mild or moderate hypercalcemia, whereas those with values greater than this indicate the presence of severe hypercalcemia.

Calcium and/or calcium-phosphorus complex deposition in blood vessels and multiple organs is a complication of chronic hypercalcemia and/or concomitant hyperphosphatemia and hyperparathyroidism (see Chap. 47). Calcium deposits in atherosclerotic lesions contribute to cardiac disease.¹⁷ Intracardiac and arterial calcifications have been found in patients with Paget's disease who have normal renal function. It is hypothesized that similar calcification processes occur in both bone and vascular tissue, leading to cardiovascular diseases including heart failure, systolic hypertension, and ischemic heart disease.¹⁸

The electrocardiographic changes associated with hypercalcemia include shortening of the QT interval and coving of the ST-T wave.¹⁵ Very high serum calcium concentrations can cause T-wave widening, indicating a repolarization defect that may be associated with spontaneous ventricular tachyarrhythmias.¹⁵ Hypertension and arrhythmias have occurred in the setting of hypercalcemia. The effects of digoxin on cardiac conduction including lowering of the excitation threshold, shortening of the effective refractory period and increased atrioventricular refractoriness, can be potentiated by hypercalcemia.¹⁹

Nephrolithiasis (kidney stones) and nephrocalcinosis (calcium deposits in the kidney) are the primary renal complications arising from long-standing hypercalcemia, as the result of primary hyperparathyroidism. Stone formation is dependent on a favorable milieu within the kidney or urinary tract: such as oversaturation of the urine and/or reduced concentrations of endogenous inhibitors of crystal formation (e.g., citrate or pyrophosphate). It is estimated that hyperparathyroidism accounts for 2% to 8% of all patients with calcium stones.^{20,21} Of note, in those patients with low glomerular filtration rates (GFRs), the 24-hour urinary calcium will actually diminish secondary to the reduced urine flow. However, the fractional excretion of calcium might increase.²¹ Sarcoidosis is the other hypercalcemic condition frequently associated with calcium stones.²¹ Other causes of nephrolithiasis with calcium-containing stones include hypocitraturia, renal tubular acidosis, hyperoxaluria, and hyperuricosuria.^{22,23} Stone formers who have primary hyperparathyroidism are more likely to be female, older than 50 years of age, and have a family history of multiple endocrine disorders.²⁰ High dietary sodium intake can also raise urinary calcium concentrations, perhaps due to a reduction in calcium reabsorption in the kidney, thus predisposing patients to calcium stones. Although chronic renal failure can be the ultimate result of persistent stones, it is the primary cause of renal disease in <2% of the end-stage renal disease population.

TREATMENT

Hypercalcemia

■ DESIRED OUTCOME

The indications for the treatment of acute hypercalcemia are dependent on the severity of hypercalcemia, acuity of its development, and presence or absence of symptoms requiring emergent treatment (e.g., necrotizing pancreatitis). Treatment should include interventions that reverse signs and symptoms, restore normocalcemia, treat the underlying cause of hypercalcemia, and prevent long-term consequences.

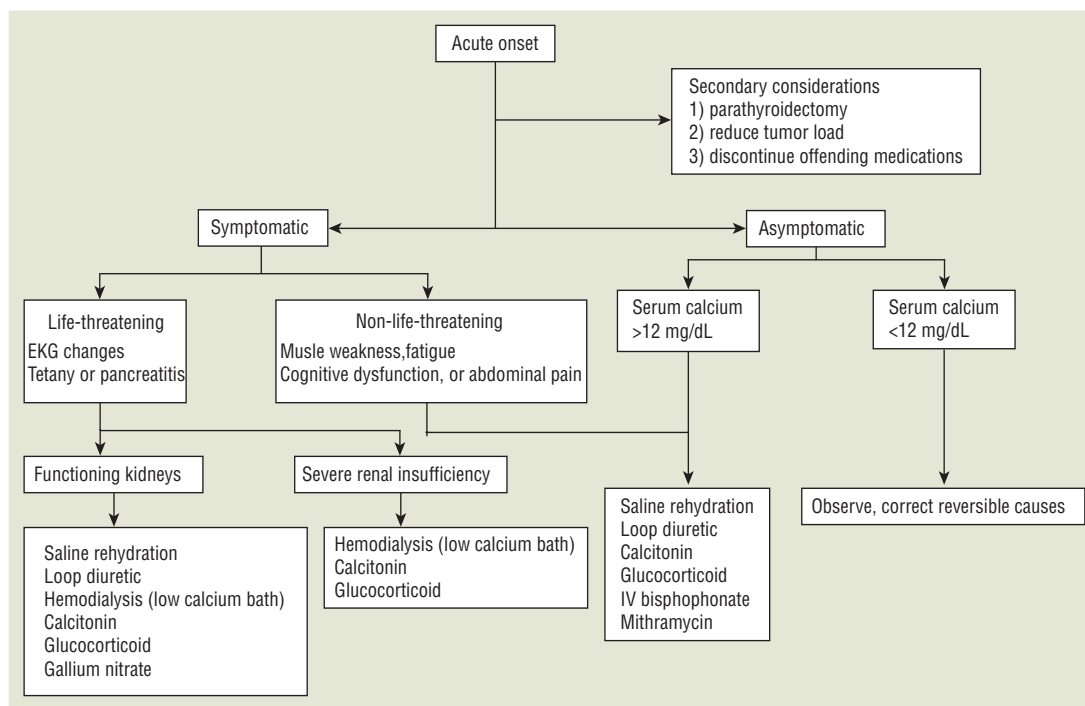

FIGURE 53-2. Pharmacotherapeutic options for the acutely hypercalcemic patient.

Chronic hypercalcemia is usually caused by an underlying medical condition or prescribed therapies. The treatment of malignancies can help mitigate acute hypercalcemic episodes. Treatment of hyperparathyroidism should reduce serum calcium concentrations as well as reduce the development of long-term complications such as vascular complications, chronic kidney disease (CKD), and kidney stones.

■ NONPHARMACOLOGIC THERAPY

Hypercalcemic crisis and acute symptomatic severe hypercalcemia should be considered medical emergencies and treated immediately (Fig. 53–2). These patients can require immediate-acting interventions to promptly reduce the serum calcium concentration if they are experiencing ECG changes, neurologic manifestations, or pancreatitis. Pharmacologic therapy consisting of volume expansion and enhancement of urinary calcium excretion with loop diuretics is usually the initial management strategy. Hemodialysis against a zero- or low-calcium dialysate solution should be considered for patients with severely impaired renal function (CKD stage 4 or 5) who cannot tolerate large fluid loads and in whom diuretics have limited efficacy.¹¹ Effective treatment of moderate to severe hypercalcemia in the absence of life-threatening symptoms begins with attention to the underlying disorder and correction of associated fluid and electrolyte abnormalities. Patients with primary hyperparathyroidism might ultimately need surgery, particularly if they have systemic manifestations. Patients with malignancy often require surgical reduction of tumor load to control the exogenous supply of cytokines and hormones that cause the hypercalcemia. In contrast, patients with drug-induced hypercalcemia generally respond to discontinuation of the offending agent.

CLINICAL CONTROVERSY

Although dialysis is the best method for rapidly reducing highly elevated serum calcium in patients with CKD, many clinicians choose a pharmacologic approach as the initial therapy.

■ PHARMACOLOGIC THERAPY

2 For those patients with normal to moderately impaired renal function (CKD stage 3 and 4), the cornerstone of initial treatment of severe hypercalcemia or hypercalcemic crisis is volume expansion to increase urinary calcium excretion (see Table 53–3). Patients with symptomatic hypercalcemia are often dehydrated secondary to vomiting and polyuria; thus rehydration with saline-containing fluids is necessary to interrupt the stimulus for sodium and calcium reabsorption in the renal tubule.²⁴ Rehydration can be accomplished by the infusion of normal saline at rates of 200 to 300 mL/h, until the patient is fluid resuscitated and serum calcium approaches the upper limit of the normal range. The precise rate depends on concomitant conditions (primarily cardiovascular and renal) and extent of hypercalcemia. The saline infusion rate can be decreased to a rate that approximates the patient's intake of oral or intravenous fluids. (See Chap. 52 for a thorough discussion of the concepts and calculations of water deficit.) Adequacy of hydration is assessed by measuring fluid intake and output or by central venous pressure monitoring.^{9,10} Loop diuretics such as furosemide (40 to 80 mg IV every 1 to 4 hours) or ethacrynic acid (for patients with sulfa allergies) can also be instituted to increase urinary calcium excretion and to minimize the development of volume overload from the administration of saline⁹ (Fig 53–2 and Table 53–2). Loop diuretics such as furosemide block calcium (and sodium) reabsorption in the thick ascending limb of the loop of Henle and augment the calciuric effect of saline alone. The importance of rehydration prior to loop diuretic use is critical because if dehydration persists or becomes worse the serum calcium can actually increase because of enhanced proximal tubule calcium reabsorption.² Potassium chloride, 10 to 20 mEq/L, should be added to the saline solution after rehydration is accomplished to maintain normokalemia in the presence of diuretic therapy. Serum magnesium levels should also be monitored, and magnesium replacement instituted if magnesium levels fall below 1.8 mg/dL. Rehydration with saline and administration of furosemide can result in a decrease of 2 to 3 mg/dL in total serum calcium within 24 to 48 hours.⁹

TABLE 53-2 Drug Therapy Used to Treat Acute Hypercalcemia

Drug	Starting Dosage	Time Frame to Initial Response	Contraindications	Adverse Effects
0.9% saline ± electrolytes	200–300 mL/h	24–48 hours	Renal insufficiency; congestive heart failure	Electrolyte abnormalities; fluid overload
Loop diuretics	40–80 mg IV every 1–4 hours	N/A	Allergy to sulfas (use ethacrynic acid)	Electrolyte abnormalities
Calcitonin	4 units/kg every 12 hours SQ/IM 10–12 units/h IV	1–2 hours	Allergy to calcitonin	Facial flushing, nausea/vomiting, allergic reaction
Pamidronate	30–90 mg IV over 2–24 hours	2 days	Renal insufficiency	Fever
Etidronate	7.5 mg/kg per day IV over 2 hours	2 days	Renal insufficiency	Fever
Zoledronate	4–8 mg IV over 15 minutes	1–2 days	Renal insufficiency	Fever, fatigue, skeletal pain
Ibandronate	2–6 mg IV bolus	2 days	Renal insufficiency	Fever, musculoskeletal pain
Gallium nitrate	200 mg/m ² per day	?	Severe renal insufficiency	Nephrotoxicity; hypophosphatemia; nausea/vomiting/diarrhea; metallic taste
Mithramycin	25 mcg/kg IV over 4–6 hours	12 hours	Decreased liver function; renal insufficiency; thrombocytopenia	Nausea/vomiting; stomatitis; thrombocytopenia; nephrotoxicity; hepatotoxicity
Glucocorticoids	40–60 mg oral prednisone equivalents	?	Serious infections; hypersensitivity	Diabetes; osteoporosis; infection

SQ, subcutaneous.

In those patients in whom saline hydration therapy is contraindicated (e.g., those with severe chronic heart failure [CHF] or moderate to severe renal dysfunction), short-term therapy with calcitonin is a viable alternative agent to initiate reduction of serum calcium levels; within 24 to 48 hours. Calcitonin has a rapid onset of action (within 1 to 2 hours); however, the degree and extent of serum calcium level reduction are often unpredictable.² Calcitonin decreases serum calcium concentrations, primarily by inhibiting bone resorption. It can also reduce renal tubular reabsorption of calcium, thus promoting calciuresis. Calcitonin from salmon sources is most commonly administered subcutaneously or intramuscularly (for larger volumes) in a starting dose of 4 units/kg every 12 hours. The side effects from intravenously administered calcitonin (facial flushing, nausea, and vomiting) limit patient acceptability. Allergic reactions, although rare, do occur; therefore a test dose (intradermal injection of 0.1 mL of a 10-units/mL solution) is recommended prior to starting therapy. If marked erythema and/or wheal formation does not occur within 15 minutes after administration, therapy can begin. Salmon calcitonin therapy is associated with tachyphylaxis caused by antibody formation to foreign proteins or molecules resembling the calcitonin polypeptide.²⁵ Tachyphylaxis has been primarily documented in patients receiving therapy for more than 4 months and thus might not be clinically significant in the acute care setting. The addition of corticosteroid therapy or conversion to human calcitonin increases effectiveness.² Finally, intravenous phosphate has been used to rapidly reduce ionized calcium concentrations through the formation of insoluble calcium-phosphate salts. However, intravenous phosphate is extremely hazardous because extraskelatal precipitation of calcium-phosphate can result in metastatic calcification, hypotension, acute renal failure, or death and thus it currently does not have a role in the management of acute hypercalcemia.²

Bisphosphonates block bone resorption very efficiently, render the hydroxyapatite crystal of bone mineral resistant to hydrolysis by phosphatases, and also inhibit osteoclast precursors from attaching to the mineralized matrix, thus blocking their transformation into mature functioning osteoclasts.^{9,15,26} The antiresorptive properties of this class of agents can provide long term control of serum calcium and are the first-line therapy for cancer-associated hypercalcemia. Pamidronate is very effective in controlling hypercalcemia associated with malignancy and slightly more effective than etidronate.⁷ The usual dose of pamidronate is 30 to 90 mg as an IV infusion given over 2 to 24 hours. Pamidronate also has the advantage of single-day therapy.⁹ Etidronate, when administered in doses of 7.5 mg/kg per day by slow intravenous infusion over at least 2 hours for 3 days, is effective in the therapy of hypercalcemia of malignancy.⁹ Zoledronate and ibandronate are the newest high-potency bisphosphonates with demonstrated effectiveness in the

treatment of hypercalcemia of malignancy. Complete response has been reported in 88.4% to 86.7% of zoledronate-versus 69.7% of pamidronate-treated patients.^{27,28} Zoledronate intravenous doses of 4 to 8 mg given over 5 minutes have resulted in normalization of serum calcium concentrations.²⁸ Intravenous infusions of 0.02 or 0.04 mg/kg diluted in 5% dextrose (given over 20 to 50 minutes) have also been effective.²⁹ A similar hypocalcemic response has been noted with ibandronate in comparison to pamidronate (76.5% versus 75.8%); however, the time period to a relapse of hypercalcemia was longer with ibandronate (14 days versus 4 days), suggesting a therapeutic advantage.³⁰ In contrast to other bisphosphonates, ibandronate can be administered by bolus injection. Single doses of 4 to 6 mg when administered every 3 to 4 weeks have been effective in managing hypercalcemia of malignancy.³¹ The onset of serum calcium concentration decline is slower with bisphosphonate therapy (concentrations begin to decline in 2 days and reach a nadir in 7 days); thus calcitonin therapy can be necessary if rapid serum level reduction is required.^{9,31} Duration of normocalcemia varies, but usually does not exceed 2 to 3 weeks. It appears to be dependant on the severity and treatment response of the underlying malignancy.² The duration of response has been suggested to be longer with zoledronate (4 to 5 weeks), although the data is sparse.²⁹ Fever is a common side effect of intravenous bisphosphonate therapy. Although oral bisphosphonates are useful for the treatment of bone turnover in Paget's disease, there are insufficient data to suggest their use for the initial treatment of hypercalcemia. The use of oral bisphosphonates for maintenance therapy in patients predisposed to hypercalcemia (malignancy) has been successful in some cases.³² The safety of continuous bisphosphonate therapy in patients with moderate to severe renal insufficiency is currently unknown. Renal function monitoring (serum creatinine) is advised with the use of bisphosphonates, as cases of acute tubular necrosis have been reported.^{33,34} Although there are no published guidelines for frequency of serum creatinine monitoring, it is advisable to evaluate serum creatinine within a week after the infusion and just prior to the next scheduled dose.

CLINICAL CONTROVERSY

Bisphosphonates are renally eliminated and prescribing information advises caution in patients with GFR <30 to 35 mL/min, however, emerging evidence suggests that these agents may slow the rate of cardiovascular calcification in patients with kidney disease.

Gallium nitrate is indicated for the treatment of symptomatic hypercalcemia of malignancy not responsive to hydration therapy.³⁵ How-

ever, because of its adverse side-effect profile, it is generally reserved for those who fail to respond to less toxic agents. Gallium nitrate inhibits bone resorption, and may be superior to calcitonin in inducing normocalcemia. It can provide a longer duration of normocalcemia as compared to etidronate. The initial dose is usually a continuous IV infusion of 200 mg/m² per day for 5 consecutive days. Gallium nitrate can be more effective in achieving normocalcemia in patients with epidermoid (squamous) cancers.³⁶ Because gallium nitrate is nephrotoxic, the initial dose should be conservative and the patient's renal function closely monitored if it is coadministered with other nephrotoxic drugs, including some chemotherapeutic agents, nonsteroidal antiinflammatory drugs (NSAIDs), and antibiotics (e.g., gentamicin). Other common adverse effects include hypophosphatemia, nausea, vomiting, diarrhea, hypocalcemia, and metallic taste.

Mithramycin (plicamycin) is a potent cytotoxic antibiotic that inhibits osteoclast-mediated bone resorption and thereby reduces hypercalcemia. Mithramycin can be administered at a dose of 25 mcg/kg via intravenous infusion over 4 to 6 hours in saline or 5% dextrose solutions. This therapy can be repeated daily for 3 to 4 days or on alternating days for 3 to 8 doses.^{9,37} Serum calcium levels begin to fall within 12 hours of a mithramycin dose, with the peak effect generally occurring over 48 to 96 hours.^{2,9} Single doses are usually well tolerated.³⁷ Common dose-related adverse effects of mithramycin include nausea, vomiting, stomatitis, thrombocytopenia, inhibition of platelet function, and renal and hepatotoxicity can be avoided by limiting the number of doses administered to less than four.² Mithramycin is usually limited to short-term therapy (typically one to two doses) in patients who have not responded to alternative therapies. Complete blood count, liver function, and renal function should be monitored within 1 to 2 days after administration. Mithramycin should be avoided in patients with thrombocytopenia and liver and renal insufficiency (creatinine clearance <30 mL/min).⁹

Prednisone or an equivalent agent in the corticosteroid class is usually effective in the treatment of hypercalcemia resulting from multiple myeloma, leukemia, lymphoma, sarcoidosis, and hypervitaminoses A and D.^{2,26,37} These agents are effective because they reduce gastrointesti-

nal calcium absorption, increase urinary calcium excretion, and decrease bone resorption and osteoblast proliferation.⁸ Daily doses of 40 to 60 mg of prednisone or the equivalent are effective at reducing serum calcium within 3 to 5 days followed by a reduction in urinary calcium excretion within 7 to 10 days. The disadvantages of corticosteroid therapy are its relatively slow onset of action and the potential for diabetes mellitus, osteoporosis, and increased susceptibility to infection.^{6,25}

CHRONIC HYPERCALCEMIA

Chronic, asymptomatic hypercalcemia can be treated with subcutaneous administration of salmon calcitonin; 50 to 100 international units daily or three times weekly for patients with Paget's disease. The intranasal formulation of calcitonin has been used in doses of 200 to 400 international units daily; unfortunately this has resulted in only mild decreases in serum calcium. The lack of significant efficacy of the synthetic intranasal formulation is the result of the lower potency and shorter duration of action as compared to salmon calcitonin.

Asymptomatic patients with mild hypercalcemia may be carefully observed, especially if treatment for the underlying condition (malignancy) is initiated. The calcimimetic agent cinacalcet HCl was recently approved for its calcium-lowering effect in the management of parathyroid carcinoma.^{40,41} These agents bind to the calcium-sensing receptor, albeit at a different location than calcium, and increase the sensitivity for receptor activation by extracellular calcium. This results in reduced PTH and serum calcium concentrations.^{40,41} Cinacalcet HCl administered at a starting dose of 30 mg orally twice daily has been used for the treatment of parathyroid carcinoma. The dosage is titrated every 2 to 4 weeks in 30-mg increments until the desired serum calcium level is achieved. The maximum approved dosage is 90 mg three to four times daily. Patients should have serum calcium measured within 1 week after starting or increasing the dose of this agent.^{42,43} Patients who develop nephrolithiasis from hypercalciuria are most often treated with sodium citrate to enhance stone dissolution, thiazide diuretics to decrease urinary calcium excretion, or shock wave lithotripsy (Table 53-3).

TABLE 53-3 Treatment of Nephrolithiasis Associated with Chronic Hypercalcemia and Hypercalciuria

Intervention	Indications	Comments
Extracorporeal shock wave lithotripsy Uses sound waves to break up stones which then can pass spontaneously	Obstruction of the urinary tract especially with stones >5 mm.	Consider adjunctive use of potassium citrate to inhibit aggregation of residual fragments.
Enhancement of stone dissolution <i>Alkalinizing agents</i> Potassium citrate 20 mEq twice daily Sodium citrate 20 to 30 mEq twice daily	Treatment for non emergent active stones. Can also be used for prevention.	Potassium citrate preferred over sodium citrate as it decreases urinary calcium, inhibits calcium oxalate precipitation, and increases urinary citrate more
Decrease urinary calcium excretion <i>Thiazide diuretics</i> Hydrochlorothiazide 50 mg everyday Indapamide 25 mg everyday Chlorthalidone 25 mg everyday	Prevention	Drug of choice in patients with low bone density
Binding intestinal calcium <i>Cellulose sodium phosphate (Calcibind)</i> Calcium binding ion-exchange resin that decreases gastrointestinal absorption of calcium: 5 g PO twice daily with oxalate restriction	Prevention for those with absorptive hypercalciuria	Alternative to thiazides if intolerant or ineffective, monitor bone density
Inhibition of crystal formation <i>Phyllanthus niruri plant extract</i> Inhibits calcium oxalate stone formation by incorporating glycosaminoglycans into the calculi: 2 grams daily	Prevention, after shock wave lithotripsy	Commercial preparations with <i>P. niruri</i> as the sole ingredient can be difficult to obtain
Low calcium diet <400 mg per day	Prevention	Monitor bone density prior to and periodically during treatment, limit oxalate restriction, can increase hyperoxaluria, data suggest high calcium intake may actually be more beneficial

HYPOCALCEMIA

The incidence of hypocalcemia in intensive care unit patients ranges from 70% to 90% based on total serum calcium values of less than 8.5 mg/dL, to 15% to 50% based on the observation of ionized calcium concentrations of less than 4.4 mg/dL.³ Emergent treatment of hypocalcemia is rarely warranted unless life-threatening symptoms are present (e.g., frank tetany or seizures). Hypocalcemia occurs infrequently in the outpatient setting and is most common in elderly, malnourished patients and those who have received sodium phosphate as a bowel preparation agent.

PATHOPHYSIOLOGY

Hypocalcemia is the result of alterations in the effect of PTH and vitamin D on the bone, gut, and kidney (see Fig. 53–1). The primary causes of hypocalcemia are postoperative hypoparathyroidism and vitamin D deficiency. Other causes include magnesium deficiency, thyroid surgery, medications, hypoalbuminemia, blood transfusions, peripheral blood progenitor cell harvesting, tumor lysis syndrome, and mutations in the calcium-sensing receptor.^{44–49} PTH concentrations are elevated in conditions of hypocalcemia, with the exception of hypoparathyroidism and hypomagnesemia.⁵⁰

An acute, symptomatic rapid fall in total serum calcium concentrations (to values <7 mg/dL) is common in patients who have had a parathyroidectomy or thyroidectomy. Hypocalcemia in these postsurgical patients is generally transient in nature.⁵¹ The “hungry bone syndrome” is a condition of profound hypocalcemia whereby the bone avidly incorporates calcium and phosphorus from the blood in an attempt to recalcify bone. This is common after surgical parathyroidectomy in patients who have had a prolonged state of hyperparathyroidism and/or hyperthyroidism. Serum calcium concentrations should be monitored every 6 hours during the 24 to 48 hours following such surgeries, and pharmacologic doses of calcium can be necessary to prevent or minimize the drop in serum calcium. Additionally, mild to moderate hypocalcemia can be a long-term consequence of parathyroidectomy in hemodialysis patients.⁵¹

Vitamin D and its metabolites play an important role in the maintenance of extracellular calcium concentrations and in normal skeletal structure and mineralization. Vitamin D is necessary for the optimal absorption of calcium and phosphorus. On a worldwide basis, the most common cause of chronic hypocalcemia is nutritional vitamin D deficiency. In malnourished populations, manifestations include rickets and osteomalacia. Nutritional vitamin D deficiency is uncommon in Western societies because of the fortification of milk with ergocalciferol.⁵¹ The most common cause of vitamin D deficiency in Western societies is gastrointestinal disease.¹⁵ Gastric surgery, chronic pancreatitis, small-bowel disease, intestinal resection, and bypass surgery are associated with decreased concentrations of vitamin D and its metabolites.¹⁵ Vitamin D replacement therapy might need to be administered by the intravenous route if poor oral bioavailability is noted. Decreased production of 1,25-dihydroxyvitamin D₃ can occur as a result of a hereditary defect resulting in vitamin D–dependent rickets. Recently, polymorphisms of the vitamin D receptor have been identified, and these genetic variations can contribute to increased risk of rickets associated with vitamin D and calcium deficient diets, especially in certain African and East Asian populations.⁵² It also can occur secondary to chronic renal insufficiency if there is insufficient production of the 1- α -hydroxylase enzyme for the production of the most active metabolite, 1,25-dihydroxyvitamin D₃.⁵³ Treatment of hypocalcemia associated with CKD is reviewed in Chap. 47.

Hypomagnesemia of any cause can be associated with severe symptomatic hypocalcemia that is unresponsive to calcium replacement therapy (see Chap. 54). Reduced serum magnesium concentrations can impair PTH secretion and induce resistance of target organs to the actions of PTH.⁴³ Normalization of serum calcium concentrations in these patients is thus dependent on appropriate replacement of magnesium.

Drug-induced hypocalcemia has been reported in patients receiving furosemide, calcitonin, bisphosphonates, gallium nitrate, mithramycin, cinacalcet, fluoride, ketoconazole, and pentamidine.^{43,54} Oral phosphorus therapy, commonly used to treat patients with malabsorption syndromes caused by gastrointestinal diseases, can also result in hypocalcemia. The anticonvulsants phenobarbital and phenytoin cause hypocalcemia by increasing catabolism of vitamin D and thereby impairing calcium release from bone and reducing intestinal calcium absorption.⁴³ Drugs that cause hypomagnesemia (aminoglycosides, amphotericin B, cyclosporine, diuretics, foscarnet, and cisplatin) are also associated with an increased risk of hypocalcemia. Chelating agents in blood (citrate) and in radiographic contrast media (ethylenediamine tetraacetate) can also cause transient hypocalcemia.^{44,45,55} Concentrated citrate is increasingly being used in hemodialysis catheter locks and to anticoagulate the dialysis circuit during continuous renal replacement therapy. Symptomatic hypocalcemia (ionized calcium <2.4 mg/dL) has been reported in patients exposed to citrate solutions, which appears to be related to the concentration of the citrate solution.⁵⁶ Injection of citrate solutions greater than the volume of the dead space of the catheter lumen or accidental injection of citrate catheter lock solutions that are not intended for systemic administration have been associated with serious cardiovascular problems such as hypotension or cardiac arrest.⁵⁷

CLINICAL PRESENTATION

The clinical manifestations of hypocalcemia are quite variable. The more acute the drop in ionized calcium concentration, the more likely the patient will develop symptoms.⁵⁰ Increases in plasma pH enhances the binding of calcium to albumin thus alkalosis can result in rapid decreases in ionized calcium. Concomitant hypomagnesemia, hypokalemia, hyponatremia, and additive side effects from prescribed medications also increase the likelihood of symptomatic presentation.

Hypocalcemia can manifest as neuromuscular, CNS, dermatologic, and cardiac sequelae.¹⁵ Acute hypocalcemia is more likely to manifest as neuromuscular (paresthesia, muscle cramps, tetany, and laryngeal spasm) and cardiovascular symptoms, whereas chronic hypocalcemia often presents as CNS (depression, anxiety, memory loss, confusion, hallucinations, and tonic-clonic seizures) and dermatologic symptoms (hair loss, grooved and brittle nails, and eczema).⁴³ The hallmark sign of acute hypocalcemia is tetany caused by enhanced peripheral neuromuscular irritability.¹⁵ Tetany manifests as paresthesia around the mouth and in the extremities, muscle spasms and cramps, carpopedal (hands and feet) spasms, and rarely as laryngospasm and bronchospasm.¹⁵ Chvostek's and/or Trousseau's sign can be elicited during physical examination.⁴³ Chvostek's sign is elicited as twitching of facial muscles when the facial nerve is tapped anterior to the ear. Trousseau's sign is elicited by carpal spasm when a blood pressure cuff is inflated above systolic blood pressure for 3 minutes.

The cardiovascular manifestations of hypocalcemia result in electrocardiographic changes characterized by a prolonged QT interval and symptoms of decreased myocardial contractility often associated with congestive heart failure.⁴³ Both acute and chronic hypocalcemia can result in a reversible syndrome characterized by acute myocardial failure or refractory congestive heart failure.

Other cardiovascular manifestations include arrhythmias, bradycardia, and hypotension that is unresponsive to fluid and pressor administration.⁴³

CLINICAL PRESENTATION OF HYPOCALCEMIA

General

- Hypocalcemia is caused in part by disorders of vitamin D or PTH. Acute causes of hypocalcemia result in rapid decreases in serum ionized calcium and can be associated with sepsis, alkalosis, or drugs. Parathyroidectomy or thyroidectomy are also associated with a rapid reduction in serum calcium. Malnutrition associated with vitamin D deficiency should not be overlooked as an etiology of chronic hypocalcemia.

Symptoms

- The symptoms of hypocalcemia, usually associated with an acute decrease in serum calcium, include tetany, paresthesia, muscle cramps, and laryngeal spasms. Chronic hypocalcemia is usually associated with the symptoms of depression, anxiety, memory loss, and confusion.

Signs

- Neurologic: The hallmark of acute hypocalcemia is tetany, which is characterized by neuromuscular irritability including seizure potential. Extraparathyroidal disorders, mainly parkinsonism but also dystonia, hemiballismus, choreoathetosis, and oculogyric crises, occur in 5% to 10% of patients with idiopathic hypoparathyroidism. Chvostek's and/or Trousseau's signs can be elicited during physical examination.
- Dermatologic: The skin can be dry, puffy, and coarse. Other dermatologic manifestations can include hyperpigmentation, dermatitis and eczema, and psoriasis. Hair and skin signs including coarse, brittle, and sparse hair with patchy alopecia and brittle nails can also appear.
- Ophthalmologic: Cataract development has been reported to occur with hypocalcemia.
- Dental manifestations: These are usually associated with the presence of chronic hypocalcemia in early development. Signs include dental hypoplasia, failure of tooth eruption, defective enamel and root formation, and abraded carious teeth.
- Cardiovascular: Hypotension, decreased myocardial performance, and congestive heart failure have been reported. A prolonged QT interval, arrhythmias, and bradycardia can also occur but are more common with acute or very severe hypocalcemia.
- Gastrointestinal: Steatorrhea can be associated with chronic hypocalcemia.
- Musculoskeletal: Although patients with chronic hypocalcemic disorders have skeletal abnormalities, such findings do not appear to be direct consequences of hypocalcemia. Some patients with hypocalcemia have myopathy.
- Endocrine: Hypocalcemia alone can impair insulin release. In addition, idiopathic hypoparathyroidism can be associated with polyglandular autoimmune syndromes.

Laboratory Tests

- Serum calcium levels of less than 8.5 mg/dL are considered to represent hypocalcemia. Ionized calcium values less than 4.4 mg/dL (<1.1 mmol/L), which are often measured in critically ill patients, are also indicative of hypocalcemia.

TREATMENT

Hypocalcemia

■ DESIRED OUTCOME

The goals of therapy for patients with normal renal function are the resolution of signs and symptoms of hypocalcemia, restoration of normocalcemia, management of associated electrolyte abnormalities, and treatment of the underlying cause of hypocalcemia. The goals for patients with chronic renal insufficiency are different and are discussed in detail in Chap. 47. Asymptomatic hypocalcemia associated with hypoalbuminemia requires no treatment because ionized (physiologically active) plasma calcium concentrations are normal. Treatment of hypocalcemia is dependent on identification of the pathogenesis of the underlying disorder, acuteness of onset, and presence and severity of symptoms. Acute symptomatic hypocalcemia requires parenteral administration of soluble calcium salts (Fig 53–3).

■ PHARMACOLOGIC THERAPY

The initial therapeutic intervention for patients with acute symptomatic hypocalcemia is to administer 100 to 300 mg of elemental calcium intravenously over 5 to 10 minutes.⁵⁸ This can be accomplished by the administration of 1 g of calcium chloride (27% elemental calcium) or 2 to 3 g of calcium gluconate (9% elemental calcium). Calcium gluconate is generally preferred over calcium chloride for peripheral venous administration because calcium gluconate is less irritating to veins. The use of calcium gluconate provides a less predictable and slightly smaller increase in plasma ionic calcium compared with calcium chloride. Calcium should not be infused at a rate greater than 60 mg of elemental calcium per minute because severe cardiac dysfunction, including ventricular fibrillation, can result.⁵⁸ Intravenous calcium administration should be used with caution in patients receiving digitalis glycosides because of the possibility of bradycardia or atrioventricular (A-V) block.³ The bolus dose of calcium is only effective for 1 to 2 hours and should be followed by a continuous infusion of elemental calcium at a rate of 0.5 to 2 mg/kg per hour.³ The calcium concentrations should be monitored every 4 to 6 hours during the intravenous infusions. The ionized calcium concentration usually normalizes within 4 hours, and the maintenance infusion rate of elemental calcium can then be decreased to 0.3 to 0.5 mg/kg per hour to maintain the desired calcium concentration.² Calcium should not be added to bicarbonate- or phosphate-containing solutions because of the possibility of precipitation.

Once acute hypocalcemia is corrected by parenteral administration, further treatment modalities should be individualized according to the cause of hypocalcemia. If hypomagnesemia is present, magnesium supplementation is indicated (see Chap. 54). Hypocalcemia secondary to hungry bone syndrome following parathyroidectomy has been attenuated by pretreatment with bisphosphonates.⁵⁹ Asymptomatic and chronic hypocalcemia associated with hypoparathyroidism and vitamin D–deficient states can be managed by oral calcium and vitamin D supplementation (see Tables 47–6 and 47–7). Therapy is begun with 1 to 3 g/day of elemental calcium.¹ Average maintenance doses range from 2 to 8 g of elemental calcium per day in divided doses. If serum calcium does not normalize, a vitamin D preparation might need to be added.

Treatment of hypocalcemia associated with vitamin D–deficient states should be individualized. In patients with malabsorption, vitamin D requirements vary markedly, and large doses can be required. In contrast, vitamin D deficiency associated with anticonvulsant medication can be corrected with smaller doses of vitamin D. Oral doses of 1,25-dihydroxyvitamin D₃ usually range from 0.5 to

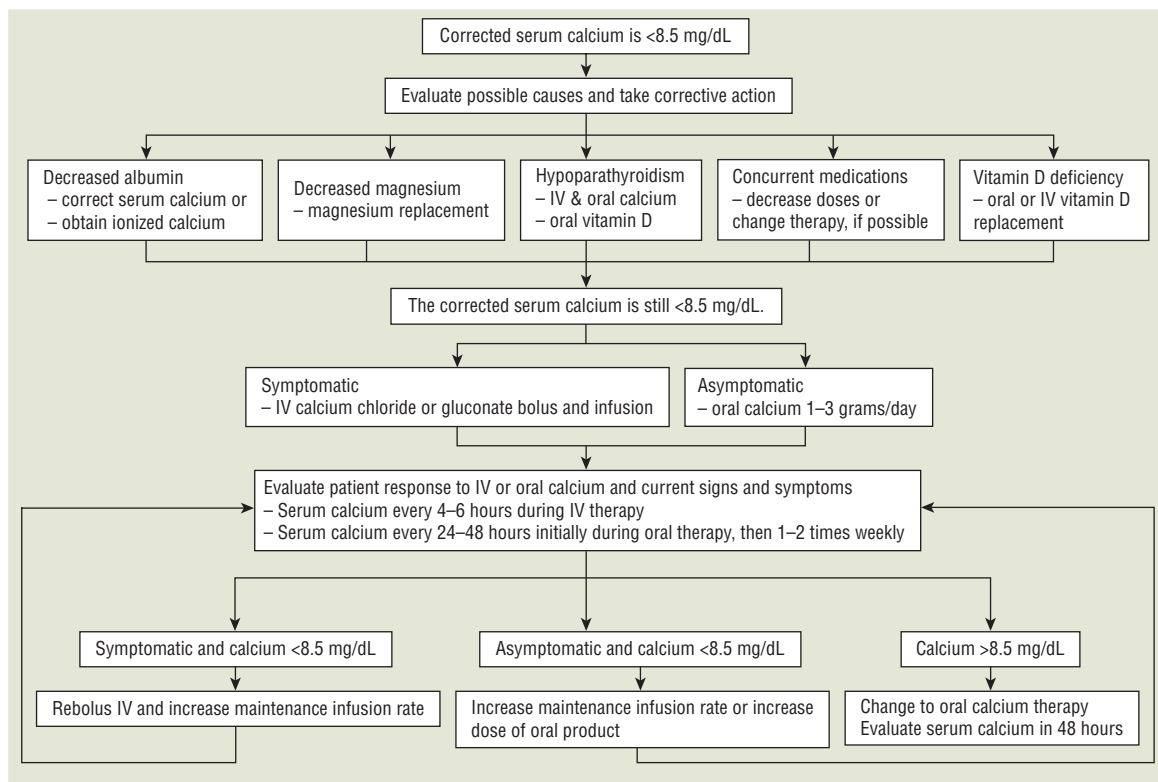

FIGURE 53-3. Hypocalcemia diagnostic and treatment algorithm.

3 mcg daily. The usual initial oral dose of ergocalciferol is 50,000 international units daily.⁵⁸ Vitamin D doses are usually adjusted approximately every 4 weeks. Vitamin D deficiency is highly prevalent especially in areas of low sun exposure and limited dietary sources of vitamin D.⁶⁰ New data suggest that current dietary recommendations are not sufficient to maintain 25-hydroxyvitamin D₃ concentrations at or above 32 mcg/L.⁶⁰ The treatment of vitamin D deficiency associated with CKD generally requires the administration of 1,25-dihydroxyvitamin D₃ or another synthetic vitamin D₂ analog, such as paricalcitol or doxercalciferol. Patients who have reduced 25-hydroxylase activity (e.g., hepatic disease) can also require treatment with calcitriol (1,25-dihydroxyvitamin D₃). The newer vitamin D₂ analogs (paricalcitol and doxercalciferol) were developed to preferentially suppress PTH secretion with less effect on serum calcium concentration and thus their efficacy for the management of hypocalcemia may be minimal. In selected cases, increasing calcium ingestion can be required if vitamin D replacement alone is ineffective in returning calcium concentrations to normal.

Adverse effects of oral calcium and vitamin D supplementation include hypercalcemia and hypercalciuria, especially in the hypoparathyroid patient, in whom the renal calcium-sparing effect of PTH is absent. Hypercalciuria can increase the risk of calcium stone formation and nephrolithiasis in susceptible patients. One maneuver to help prevent calcium stones is to maintain the urine calcium excretion below 300 mg per day. Intermittently monitoring 24-hour urine collections for total calcium excretion can help to minimize the occurrence of hypercalciuria. The addition of thiazide diuretics for patients at risk for stone formation can result in a reduction of both urinary calcium excretion and vitamin D requirements.⁵⁸

DISORDERS OF PHOSPHORUS HOMEOSTASIS

Phosphorus is an essential element in phospholipid cell membranes, nucleic acids, and phosphoproteins, which are required for mito-

chondrial function.⁶¹ Phosphorus regulates the intermediary metabolism of carbohydrates, fats, and proteins. Phosphorus also regulates enzymatic reactions including glycolysis, ammoniogenesis, and the 1-hydroxylation of 25-hydroxyvitamin D₃.⁶¹ In addition, phosphorus is required for the generation of 2,3-diphosphoglycerate (2,3-DPG) in red blood cells, which is required for normal oxygen-hemoglobin dissociation and delivery of oxygen to the tissues.⁶² Phosphorus is the source of the high-energy bonds of adenosine triphosphate (ATP), thus fueling a wide variety of physiologic processes, including muscle contractility, electrolyte transport, neurologic function, and other important biochemical reactions.⁶¹ Considering its diverse biologic importance, it is not difficult to appreciate the clinical implications of disorders of phosphorus homeostasis.

Phosphorus, the major intracellular anion, is present in living organisms mainly as organic phosphate esters such as 2,3-DPG, adenosine, guanosine triphosphate, and fructose 1,6-diphosphate.⁶¹ Only a small fraction of intracellular phosphorus exists as inorganic phosphate; however, this fraction is critical because it is the source from which ATP is resynthesized.⁶¹ The majority of inorganic phosphate is located in the extracellular space where it is the prime determinant of intracellular phosphate; thus small increments in the organic phosphate levels can profoundly alter both the extracellular and intracellular phosphate levels. Metabolic disturbances (acidosis, alkalosis, and ketoacidosis), hydrogen ion shifts, and hormones (PTH, calcitonin, cortisol, and vitamin D) all can cause transcellular shifts in phosphorus concentrations. Because of these phenomena, the serum phosphorus level does not accurately reflect total body stores.⁶²

The typical Western diet provides a daily intake of 800 to 1,600 mg of phosphorus. Approximately 60% to 80% of this is absorbed in the gastrointestinal tract by passive and active transport (vitamin D mediated). PTH, 1,25-dihydroxyvitamin D₃, and low-phosphate diets mediate increased absorption. Decreased absorption occurs under conditions of increased dietary intake of phosphorus and magnesium, glucocorticoid therapy, and hypothyroidism. The normal serum phosphorus concentration in adults is 2.5 to 4.5 mg/dL and for children younger than 12 years old it is 4 to 5.6 mg/dL. Excretion by

the kidney is the single most important regulator of steady-state serum phosphorus concentrations. Renal excretion of phosphorus is a two-step process: glomerular filtration and proximal tubular reabsorption by passive transport coupled to sodium. Under normal conditions, 85% to 90% of filtered phosphate is reabsorbed, the majority in the early proximal tubule. Renal tubular reabsorption of phosphorus is inhibited by PTH and 1,25-dihydroxyvitamin D₃.⁶¹ Conversely, phosphorus reabsorption in the renal tubule is increased by growth hormone.⁶¹ Internal phosphorus balance (transcellular phosphate distribution) is also of importance in the maintenance of normal serum phosphorus. The serum phosphorus level can vary by as much as 2 mg/dL throughout the day, primarily as the result of changes in carbohydrate intake, insulin secretion, and diurnal variation.⁶¹

HYPERPHOSPHATEMIA

Hyperphosphatemia typically results from either renal failure or endogenous intracellular phosphate release. Hyperphosphatemia occurs frequently in patients with acute renal failure and is a nearly universal finding in those with CKD. Tumor lysis syndrome is a complication of chemotherapy associated with massive lysis of cells and release of intracellular contents. The incidence of tumor lysis syndrome has been reported to be as high as 40% in patients treated for non-Hodgkin's lymphoma.⁶¹ Other causes of hyperphosphatemia include hemolysis and rhabdomyolysis.

Pathophysiology

The most common cause of hyperphosphatemia is a decrease in urinary phosphorus excretion secondary to decreased GFR.⁶³ Retention of phosphorus decreases vitamin D synthesis and induces hypocalcemia, which leads to an increase in PTH; a finding that can be seen in those with stage 2 to 3 CKD. This physiologic response inhibits further tubular reabsorption of phosphorus as the kidney attempts to correct hyperphosphatemia and normalize serum calcium concentrations. Patients with excessive exogenous phosphorus administration or who experience massive tissue breakdown or cell lysis in the setting of acute renal failure can rapidly develop moderate to severe hyperphosphatemia (serum phosphorus >6.5 mg/dL).⁶¹ Severe hyperphosphatemia (serum phosphorus >7.0 mg/dL) is commonly encountered in patients with CKD, especially those with GFRs less than 15 mL/min per 1.73 m² (see Chap. 47).

Hyperphosphatemia caused by an increase in renal tubular reabsorption associated with hypoparathyroidism is usually less severe than that observed in patients with severe renal failure or excessive exogenous or endogenous introduction of phosphorus into the ECF. Acromegaly and thyrotoxicosis can also cause hyperphosphatemia by reducing urinary phosphorus excretion.

Iatrogenic causes of hyperphosphatemia have been widely reported, and clinicians should be aware of the phosphorus content of intravenous, oral, and rectally administered products. Large doses of phosphorus administered intravenously to treat hypercalcemia can ultimately result in severe life-threatening hyperphosphatemia. Although less-well recognized, oral and rectal administration of phosphate-containing solutions such as sodium phosphate (Fleet Phospho-Soda) can also result in severe and life-threatening hyperphosphatemia, especially in patients with moderate and severe renal insufficiency.^{63,64} The risk of mortality is dependent on the amount of phosphorus absorbed from the administered product, however, fatalities have occurred at lower phosphorus concentrations.⁶³ Acute phosphate nephropathy and renal failure have also been reported with the use of oral sodium phosphate bowel preparations. Recently the FDA issued a safety warning regarding the use of these products in patients at risk (the elderly, those with CKD) or on medications known to effect renal hemodynamics (e.g., diuretics, NSAIDs or renin-angiotensin aldosterone system inhibitors).⁶⁵ Intravenous or oral vitamin D therapy can increase absorption

of phosphorus in the gastrointestinal tract by up to 50%. Bisphosphonate therapy is also associated with increased serum phosphate concentrations. Acute phosphorus poisoning as a result of ingestion of laundry detergents is a rare and often unrecognized cause of elevated phosphate concentrations.

Any disorder that results in necrosis of skeletal muscle (i.e., rhabdomyolysis) can generate the release of large amounts of intracellular phosphorus into the systemic circulation. This condition is frequently associated with acute renal failure (see Chap. 45) and thus severe hyperphosphatemia can develop because of increased endogenous phosphorus release coupled with decreased renal phosphorus excretion. Bowel infarction, malignant hyperthermia, and severe hemolysis are also conditions that can increase endogenous release of phosphorus.

Moderate hyperphosphatemia is also commonly observed in patients undergoing treatment for acute leukemia and lymphomas.⁶⁶ Chemotherapeutic treatment of acute lymphoblastic leukemia can result in the release of large amounts of phosphorus into the systemic circulation secondary to lysis of lymphoblasts. Initiation of chemotherapy for Burkitt's lymphoma results in tumor lysis syndrome, a rapid lysis of malignant cells that results in hyperphosphatemia, hyperuricemia, hyperkalemia, and hypocalcemia.⁶⁶

Lactic acidosis and diabetic ketoacidosis can trigger the transcellular shift of endogenous intracellular phosphorus into the extracellular space and thereby dramatically increase serum phosphorous concentrations. In one study, hyperphosphatemia was present in more than 90% of patients with diabetic ketoacidosis prior to the initiation of treatment.⁶⁷ After the institution of treatment, serum phosphorus levels should be checked hourly as they can decrease rapidly, and patients can ultimately develop hypophosphatemia.

Clinical Presentation

The severe acute onset of hyperphosphatemia can result in calcium and phosphorus complexation and lead to the precipitation of calcium phosphate into soft tissues, intrarenal calcification, nephrolithiasis, or obstructive uropathy. Other symptoms associated with moderate to severe hyperphosphatemia include nausea, vomiting, diarrhea, lethargy, and seizures. The major effects of long-term hyperphosphatemia are related to the development of hypocalcemia (caused by phosphate inhibition of renal 1- α -hydroxylase) and its related consequences, as well as vascular and organ damage resulting from the deposition of calcium-phosphate crystals. Extravascular calcification can result in band keratopathy, "red eye," pruritus, and periarticular calcification, especially in CKD patients. In addition, soft-tissue calcifications in the conjunctiva, skin, heart, cornea, lung, gastric mucosa, and kidney have been observed, primarily in CKD patients with chronic disordered mineral metabolism.⁶¹ Hyperphosphatemia associated with CKD can result in renal osteodystrophy because of overproduction of PTH. This condition is discussed in detail in Chap. 47.

CLINICAL PRESENTATION OF HYPERPHOSPHATEMIA

General

- As the serum phosphate concentration is primarily determined by the ability of the kidneys to excrete dietary phosphate, hyperphosphatemia is uncommon in patients with normal kidney function.

Symptoms

- Acute symptoms include GI disturbances, lethargy, obstruction of the urinary tract, and rarely seizures. Symptoms associated with chronic hyperphosphatemia are associated with deposition of calcium-phosphate crystals and include "red eye" and pruritus.

Signs

- The elevated calcium-phosphate product results in precipitation in arteries, joints, soft tissues, and the viscera. This can result in tissue ischemia, termed *calciophylaxis*.

Laboratory Tests

- Serum phosphate levels higher than 4.5 mg/dL represent hyperphosphatemia.

TREATMENT**Hyperphosphatemia****■ DESIRED OUTCOME**

Management of patients with acutely elevated serum phosphorus should be directed at avoiding gastrointestinal and neurologic symptoms and preventing deposition in the urinary tract to avoid the development of acute renal failure. The treatment of hyperphosphatemia is focused on returning serum phosphate concentrations to the normal or near normal (for those with CKD) range, with the hope that one can minimize the long-term cardiovascular consequences of calcium-phosphorus crystal deposition in the vasculature. Calcium-phosphate crystals are likely to form in vivo when the product of the serum calcium and phosphate concentrations exceeds 50 to 60 mg^2/dL^2 .³⁸ The recently published National Kidney Foundation's Dialysis Outcomes Quality Initiative guidelines for bone metabolism and disease defines the goal calcium-phosphorus product as less than 55 mg^2/dL^2 .⁶⁸ Furthermore, serum phosphorus concentrations greater than 6.5 mg/dL, have been independently associated with increased morbidity and mortality. Serum phosphorus concentrations should be maintained in the 2.7 to 4.6 mg/dL range for those with stage 3 and 4 CKD, whereas for patients in stage 5 CKD the goal is to maintain values between 3.5 and 5.5 mg/dL.⁶⁸

■ PHARMACOLOGIC THERAPY

Severe symptomatic hyperphosphatemia manifesting as hypocalcemia and tetany should be treated by the intravenous administration of calcium salts. Although this can seem counterintuitive in a patient with a phosphorus of 16 mg/dL and a calcium of 7 mg/dL (the calcium-phosphorus product is 112 mg^2/dL^2), correction of severe hypocalcemia is of primary importance because of the critical nature of this disorder. If calcium concentrations are not critically low, the initial management strategy should include limitation of all exogenous sources of phosphorus and efforts to block further absorption should be initiated. Dialysis can be initiated if the patient remains symptomatic despite these interventions.

In general, the most effective way to treat asymptomatic chronic hyperphosphatemia is to decrease phosphate absorption from the GI tract by the use of phosphate-binding agents.⁶¹ Antacids containing divalent and trivalent cations (calcium, lanthanum, magnesium, and aluminum), or sevelamer are the agents most frequently used in the prevention and treatment of hyperphosphatemia (see Table 47–6).^{69,70} Long-term treatment with aluminum hydroxide and aluminum carbonate should be discouraged because the use of these agents has been associated with anemia, CNS disorders, and bone disease.⁷¹ Short-term therapy with these agents is effective and safe. Aluminum and calcium are available in oral suspension formulations, which can aid administration in acutely ill patients with G-tubes. The most frequent adverse effect from phosphate-binding agents (especially calcium) is constipation (see Table 47–6). Calcium salts are the preferred phosphate-binding agents except when there is concomitant hypercalcemia. Therapy with the polymer agent (sevelamer) or lanthanum carbonate might avoid the detrimental effects associated with aluminum, magnesium, or calcium therapy.¹¹

CLINICAL CONTROVERSY

Emerging data suggest that noncalcium, nonaluminum phosphate binders (e.g., sevelamer) can slow progression of cardiac calcification in chronic hemodialysis patients, however there are no data to suggest that there are any benefits to using sevelamer for the management of those with normal renal function who develop acute hyperphosphatemia.

HYPOPHOSPHATEMIA

Mild to moderate hypophosphatemia is defined as a serum phosphorus concentration of 1 to 2 mg/dL, whereas severe hypophosphatemia is defined as a serum phosphorus concentration of less than 1 mg/dL.⁷² Hypophosphatemia has been observed in approximately 1% to 3% of the laboratory screening panels of patients who have been admitted to a hospital.⁶² The incidence in hospitalized critically ill patients is 18% to 28%.⁷² Unlike its severe form, mild or moderate hypophosphatemia seldom causes recognizable signs and symptoms.⁶⁶

PATHOPHYSIOLOGY

Hypophosphatemia can be the result of decreased gastrointestinal absorption, increased urinary excretion, or extracellular to intracellular redistribution.⁶¹ Although mild to moderate hypophosphatemia is common and can occur in inpatients and outpatients, severe hypophosphatemia is predominantly encountered in the acute care setting and can be associated with life-threatening symptoms, including seizures, coma, and rhabdomyolysis (Table 53–4).

Phosphate-binding substances such as sucralfate, calcium carbonate, sevelamer, lanthanum carbonate, and aluminum- or magnesium-containing antacids have the potential to bind large amounts of phosphorus in the gut, thereby preventing absorption. If phosphate-binding agents are ingested on a chronic basis in conjunction with a dietary phosphorus deficiency, hypophosphatemia can result.⁶⁶ Patients who are receiving long-term phosphate-binding agents, those with peptic ulcer disease or CKD, and those who may be predisposed to moderate hypophosphatemia (alcoholics) are at highest risk for the development of severe hypophosphatemia. Hyperparathyroidism can cause hypophosphatemia as a result of decreased gastrointestinal absorption of dietary phosphorus.

Increased renal losses of phosphorus can occur in hyperparathyroid (primary and secondary) patients with normal renal function and those with vitamin D deficiency. Elevated PTH levels lead to an increase in serum calcium concentrations and decreased serum phosphorus concentrations. Serum phosphorus is decreased as the result of a reduction in renal tubular reabsorption.⁷² Recovery from extensive third-degree burns is associated with development of an anabolic state as stress levels decrease and nutritional therapies take effect as well as a marked diuretic phase associated with an impressive renal loss of phosphate.⁶⁶ Because phosphorus is rapidly incorporated into the new cells, this can contribute to the severity of the hypophosphatemia. Drugs that cause increased renal elimination of phosphorus include diuretics (acetazolamide and osmotic diuretics), glucocorticoids, and sodium bicarbonate.

Rapid refeeding of malnourished patients with high-carbohydrate, high-calorie diets with inadequate amounts of supplemental phosphorus can result in severe symptomatic hypophosphatemia. This phenomenon is especially prevalent in patients with other underlying risk factors for the development of hypophosphatemia, such as alcoholism.⁷³ The etiology of severe hypophosphatemia associated with hyperalimentation and nutritional recovery can be separated into two phases: acute, rapid hypophosphatemia secondary to intracellular shifts of phosphorus resulting from glucose-induced insulin secretion;

TABLE 53-4 Conditions Associated with the Development of Hypophosphatemia

Decreased gastrointestinal absorption
Phosphate-binding drugs
Sucralfate
Calcium carbonate
Aluminum/magnesium antacids
Sevelamer
Lanthanum carbonate
Decreased dietary phosphorus intake
Glucocorticoids
Vitamin D deficiency/resistance
Hypoparathyroidism

Alcoholism
Respiratory alkalosis
Diabetic ketoacidosis (correction)
Dextrose solutions
Insulin
Catecholamines
Anabolic steroids
Glucagon
Calcitonin
Erythropoietin

and the gradual decrease in serum phosphorus concentration over 5 to 10 days secondary to tissue repair in the presence of phosphorus deprivation.⁷⁴ The development of severe hypophosphatemia secondary to hyperalimentation can be prevented by the administration of 12 to 15 mmol of phosphorus per liter of hyperalimentation solution or 15 mmol per 1,000 calories of dextrose.⁷⁵ Transcellular shifts in phosphorus also occur after parathyroidectomy, causing severe hypocalcemia and hypophosphatemia because of hungry bone syndrome (deposition of phosphorus and calcium in the bone).

Severe and prolonged respiratory alkalosis (a result of hyperventilation, pain, anxiety, and sepsis) can cause hypophosphatemia.⁶² Respiratory alkalosis is thought to contribute significantly to the hypophosphatemia observed during alcohol withdrawal.⁶² Although patients with diabetic ketoacidosis may present with hyperphosphatemia, the institution of therapy to correct it can cause serum phosphorus concentrations to decrease rapidly as phosphorus shifts back into the intracellular compartment. In addition, the acidosis associated with the diabetic ketoacidotic state can cause a decomposition of organic compounds inside the cell and a release of inorganic phosphorus into the plasma and subsequently into the urine.⁶¹ The combination of intracellular phosphorus breakdown and the shift of phosphorus into cells on initiation of treatment can lead to severe

hypophosphatemia. Drugs associated with transcellular shifts in phosphorus include dextrose solutions, glucagon, insulin, catecholamines, calcitonin, erythropoietic agents, and anabolic steroids.

Chronic ethanol abusers are prone to a variety of serum electrolyte disorders including hypocalcemia, hypomagnesemia, hypokalemia, and hypophosphatemia. The etiology of hypophosphatemia in the alcoholic patient is multifactorial. Malnutrition, poor dietary intake, diarrhea, vomiting, and the use of phosphate-binding antacids can all contribute to the hypophosphatemia of alcoholism.⁶¹ In addition, serum phosphorus concentrations may decrease after hospitalization in the alcoholic patient with the institution of dextrose-containing intravenous fluids, as a result of an intracellular shift of phosphorus.^{61,74} Hyperventilation associated with the alcohol withdrawal syndrome can also contribute to the development of hypophosphatemia.⁶⁶ Alcoholic patients are particularly susceptible to the complications of hypophosphatemia such as rhabdomyolysis, which is often seen during withdrawal or refeeding.^{66,74} Thus serum phosphorus concentrations should be routinely monitored in alcoholic patients.

CLINICAL PRESENTATION

The clinical manifestations of severe hypophosphatemia are diverse and can affect many organ systems. It is likely that two primary biochemical abnormalities are responsible for most of the clinical manifestations of severe hypophosphatemia.⁶¹ First, intracellular energy stores may be decreased secondary to depletion of intracellular ATP, which is dependent on inorganic intracellular phosphate. This can result in disruptions in cellular function. Second, reduced red blood cell 2,3-DPG concentrations are associated with a shift to the left of the oxyhemoglobin saturation curve. This shift is associated with a decrease in the release of oxygen to peripheral tissues (increased oxygen affinity for hemoglobin) and may result in tissue hypoxia.⁶¹ These metabolic disorders can be seen in a wide variety of organ systems.

Neurologic (CNS) manifestations of severe hypophosphatemia result in a metabolic encephalopathy syndrome. This progressive syndrome of irritability, apprehension, weakness, numbness, paresthesia, dysarthria, confusion, obtundation, seizures, and coma has been described in patients with severe hypophosphatemia.^{66,73} Neuropsychiatric disturbances include apathy, delirium, hallucinations, and paranoia. Peripheral neuropathy and symptoms resembling Guillain-Barré syndrome have also been reported.⁷³

Severe hypophosphatemia can result in significant dysfunction of skeletal muscle ranging from myalgia, bone pain, and weakness, with chronic hypophosphatemia, to potentially fatal rhabdomyolysis with severe acute hypophosphatemia.⁷³ Laboratory evaluations can help to distinguish between chronic and acute on chronic hypophosphatemia. Elevated alkaline phosphatase, normal creatine phosphokinase, and normal to low phosphorus and calcium are present in cases of chronic hypophosphatemia. In contrast, hyperkalemia, hyperuricemia, elevated blood urea nitrogen (BUN) and creatinine, hypercalcemia, and myoglobinuria are present in cases in which rhabdomyolysis complicates the acute or chronic hypophosphatemia.⁷³ Hypophosphatemia can result in acute respiratory failure secondary to respiratory muscle weakness and diaphragmatic contractile dysfunction. Thus frequent assessment of serum phosphorus concentration is indicated in patients at risk for respiratory failure. Likewise, adequate treatment of hypophosphatemia in respiratory failure can aid in successful weaning from the ventilator.⁶² Dysphagia and ileus have also been attributed to hypophosphatemia.⁶²

Cardiac muscle function has been reported to be impaired in the setting of hypophosphatemia and has resulted in congestive cardiomyopathy. This has been reported in alcoholics, and postoperative and intensive care patients. A depletion in cardiac ATP stores has

been hypothesized as the cause of this syndrome.⁷³ Arrhythmias have also been reported in patients with hypophosphatemia. Because hypophosphatemia is a potentially reversible cause of heart failure, it should be considered in patients who experience an acute deterioration in ventricular function.

Hematologic manifestations of hypophosphatemia include decreased levels of 2,3-DPG, decreased red blood cell ATP, and membrane rigidity.⁶¹ When red blood cell ATP decreases to below 15% of normal, cells become spherocytic and rigid, and are trapped and destroyed in the spleen.⁶¹ Therefore hemolysis can be a manifestation of severe hypophosphatemia. Reduction in ATP content of white blood cells can result in mobility, chemotaxis, phagocytosis, and bactericidal dysfunction.⁶⁶ These changes can contribute to an increased risk of infection in hypophosphatemic patients. Animal studies also demonstrate platelet abnormalities in the setting of hypophosphatemia.⁷³ The implications of hypophosphatemia for human platelet function, however, have not been determined.

Finally, prolonged hypophosphatemia may result in osteopenia and osteomalacia because of enhanced osteoclastic resorption of bone. Glucose intolerance from hypophosphatemia caused by tissue insensitivity to insulin has also been described.

CLINICAL PRESENTATION OF HYPOPHOSPHATEMIA

General

- The manifestations of hypophosphatemia depend on the chronicity and severity of the phosphate depletion. The major conditions associated with symptomatic hypophosphatemia are chronic alcoholism, intravenous hyperalimentation without adequate phosphate supplementation, and the chronic ingestion of antacids. Severe hypophosphatemia can also be seen during treatment of diabetic ketoacidosis and with prolonged hyperventilation.

Symptoms

- Except for the effects on mineral metabolism, the symptoms of hypophosphatemia are caused by two consequences (reduction of red cell 2,3-DPG and reduction of intracellular ATP levels), and can impact virtually all organ systems. The symptoms are predominantly neurological and can include irritability, apprehension, weakness, numbness, paresthesia, and confusion. Severe acute development of hypophosphatemia can result in seizures or coma.

Signs

- The initial response of bone to hypophosphatemia contributes to hypercalcemia and hypercalciuria. Prolonged hypophosphatemia can also result in rickets and osteomalacia.
- Neurologic: Severe hypophosphatemia can lead to a metabolic encephalopathy.
- Cardiopulmonary: Impaired myocardial contractility, respiratory failure secondary to ATP depletion, congestive heart failure, new onset or worsening of an existing condition.
- Musculoskeletal: Proximal myopathy, dysphagia, and ileus have been reported. Acute hypophosphatemia superimposed on pre-existing severe phosphate depletion can lead to rhabdomyolysis.
- Hematologic: Alterations in the hematopoietic system can also occur, resulting in hemolysis, reduction in phagocytotic and granulocyte chemotactic ability, as well as defective clot retraction and thrombocytopenia.

Laboratory Tests

- Serum phosphate levels below 2.4 mg/dL are indicative of hypophosphatemia.

TREATMENT

Hypophosphatemia

■ DESIRED OUTCOME

The goals of therapy are the reversal of signs and symptoms of hypophosphatemia, normalization of serum phosphorus concentrations, and management of underlying conditions. Awareness of the clinical situations in which hypophosphatemia is anticipated (alcoholism, diabetic ketoacidosis, and parenteral nutrition) is of vital importance in preventing iatrogenic hypophosphatemia. The routine addition of phosphorus in concentrations of 12 to 15 mmol/L to intravenous hyperalimentation solutions is of utmost importance for the prevention of severe hypophosphatemia in hospitalized patients.

■ PHARMACOLOGIC THERAPY

Severe (<1 mg/dL) or symptomatic hypophosphatemia should be treated with parenteral phosphorus replacement. Oral phosphorus supplementation is usually reserved for patients who are asymptomatic or who exhibit mild to moderate hypophosphatemia. Estimation of total body phosphorus deficit is difficult because phosphorus is an intracellular electrolyte. Dosage and infusion recommendations, as well as response to parenteral phosphorus replacement, are highly variable.⁷² The infusion of 15 mmol of phosphorus in 250 mL 5% dextrose or 0.9% sodium chloride over 3 hours is a safe and effective treatment for severe hypophosphatemia.⁷² Mean increases in serum phosphate of 0.5 to 0.8 mg/dL have been reported. Doses of 15 to 30 mmol of phosphorus can be given over 1 to 3 hours in patients without hypercalcemia (serum calcium >10.5 mg/dL).^{72,75} Other authors recommend a wider dosage range of 0.08 to 0.64 mmol/kg body weight (5 to 45 mmol in a 70-kg patient) given over 4 to 12 hours.^{65,76} Intravenous phosphate therapy produces the desired increase in serum phosphorus at 24 hours in 20% to 80% of patients. Response is dependent on the degree of phosphate depletion and replacement dose administered.⁶¹ Furthermore, the initial success is often followed in 48 to 72 hours by recurrent hypophosphatemia, necessitating close monitoring of serum phosphorus and repeated administration of phosphorus products as warranted.

CLINICAL CONTROVERSY

The recommended initial dosage of intravenous phosphorus in conditions of severe hypophosphatemia is not well established and can range from 5 to 45 mmol of phosphorus.

Parenteral phosphorus supplementation is associated with risks of hyperphosphatemia, metastatic soft tissue deposition of calcium-phosphate product, hypomagnesemia, hypocalcemia, and hyperkalemia or hyponatremia (caused by intravenous phosphorus salt) (Table 53–5). Inappropriate administration of large doses of parenteral phosphorus over relatively short time periods has resulted in symptomatic hypocalcemia and soft-tissue calcification.⁶¹ The rate of infusion and choice of initial dosage should therefore be based on severity of hypophosphatemia, presence of symptoms, and coexistent medical conditions. Patients should be closely monitored with frequent (every 6 hours) serum phosphorus determinations for 48 to 72 hours after starting intravenous therapy. It can be necessary to continue administration of intravenous phosphorus for several days in some patients, although other patients may be able to tolerate an oral maintenance regimen. Monitoring should also include assessment of serum potassium, calcium, and magnesium concentrations. Hypomagnesemia secondary to intracellular shifts occurs frequently (27% to 80%) in severely hypophosphatemic patients.⁷² Therapy with parenteral phos-

TABLE 53-5 Phosphorus Replacement Therapy

Product (Salt)	Phosphate Content	Initial Dosing Based on Serum K
Oral therapy (potassium phosphate + sodium phosphate)		
Neutra-Phos (7 mEq/packet each of Na and K)	250 mg (8 mmol)/packet	1 packet three times daily ^a
Neutra-Phos-K (14.25 mEq/packet of K)	250 mg (8 mmol)/packet	Serum K >5.5 mEq/L Not recommended
K-Phos Neutral (13 mEq/tablet Na and 1.1 mEq/tablet K)	250 mg (8 mmol)/tablet	Serum K >5.5 mEq/L 1 tablet three times daily
Uro-KP-Neutral (10.9 mEq/tablet Na and 1.27 mEq/tablet K)	250 mg (8 mmol)/tablet	Serum K >5.5 mEq/L 1 tablet three times daily
Fleets Phospho-soda (Sodium phosphate solution)	4 mmol/mL	Serum K >5.5 mEq/L 2 mL three times daily
Intravenous therapy		
Sodium PO ₄ (4.0 mEq/mL Na)	3 mmol/mL	Serum K >3.5 mEq/L 15–30 mmol IVPB
Potassium PO ₄ (4.4 mEq/mL K)	3 mmol/mL	Serum K < 3.5 mEq/L 15–30 mmol IVPB

IVPB, intravenous piggyback; K, potassium; Na, sodium; PO₄, phosphate.

^aMonitor serum K closely + intravenous piggy back.

phorus should be undertaken with great caution and at reduced dosage for patients with hypercalcemia or renal dysfunction.^{66,74}

Mild to moderate or asymptomatic hypophosphatemia can be treated by the administration of oral phosphorus salts in doses of 1.5 to 2 g (50 to 60 mmol) daily in divided doses (see Table 53–5). Phosphorus concentrations should be monitored daily, with the goal of correcting the reduced phosphorus concentration in approximately 7 to 10 days. The primary dose-limiting adverse effect associated with oral phosphorus replacement is the development of osmotic diarrhea. Patients with mild to moderate hypophosphatemia and moderate to severe renal insufficiency should receive reduced daily oral doses (i.e., 1 g or approximately 30 mmol of phosphorus) with careful monitoring of serum phosphorus concentration because they are predisposed to phosphorus retention. In addition to phosphorus supplementation for hypophosphatemia, dipyridamole can decrease renal phosphate leaking and increase serum phosphorus. Doses of 75 mg four times daily have resulted in increases in serum 1,25-dihydroxyvitamin D₃ and decreases in serum calcium and urolithiasis events.⁷⁷

CONCLUSIONS

Clinicians play an integral part in the management of fluid and electrolyte abnormalities; initially they should review the patient's medication history to determine if any of the patient's current drug therapy contributed to the existing abnormalities. They should also carefully evaluate all drug therapy options to reduce the risk of developing new electrolyte problems and to optimize the outcome of the current management plan. This proactive interventional approach will facilitate the management of mild disorders in the community and can reduce the need for hospitalization.

ABBREVIATIONS

ATP: adenosine triphosphate

BUN: blood urea nitrogen

CHF: congestive heart failure

CKD: chronic kidney disease

CNS: central nervous system

2,3-DPG: 2,3-diphosphoglycerate

NSAID: nonsteroidal antiinflammatory drug

PTH: parathyroid hormone

S_{ca}: serum calcium

Disorders of Potassium and Magnesium Homeostasis

DONALD F. BROPHY AND TODD W. B. GEHR

KEY CONCEPTS

- 1 Potassium is the primary intracellular ion in the human body.
- 2 The normal serum potassium concentration range is 3.5 to 5 mEq/L (3.5 to 5 mmol/L).
- 3 Potassium regulates many biochemical processes in the body and is a key ion for electrical action potentials across cellular membranes.
- 4 Potassium chloride is the preferred potassium supplement for the most common causes of hypokalemia.
- 5 In patients with concomitant hypokalemia and hypomagnesemia, it is imperative to correct the hypomagnesemia before the hypokalemia.
- 6 Hyperkalemia is a common occurrence in patients with acute or chronic kidney disease.
- 7 Magnesium is an important cofactor for many cellular functions.
- 8 The normal serum magnesium concentration range is 1.4 to 1.8 mEq/L (0.85 to 1.15 mmol/L).
- 9 Hypomagnesemia is commonly caused by excessive gastrointestinal or renal magnesium wasting.
- 10 Hypermagnesemia is commonly observed in patients with acute or chronic kidney disease.

Potassium and magnesium are electrolytes that are responsible for numerous metabolic activities. Disorders of these electrolytes are frequently seen in both the acute care and community ambulatory care settings. Clinicians should have a firm understanding of the etiology, pathophysiology, symptoms, pharmacotherapy, and monitoring of these disorders. This chapter describes the homeostatic mechanisms that are responsible for the maintenance of normal potassium and magnesium serum concentrations. The clinical disorders responsible for the development of hyperkalemia, hypermagnesemia, hypokalemia, and hypomagnesemia are also reviewed.

POTASSIUM

- 1 Potassium is the most abundant cation in the body, with estimated total body stores of 3,000 to 4,000 mEq.¹ Ninety-eight percent

of this amount is contained within the intracellular compartment, and the remaining 2% is distributed within the extracellular compartment. The sodium potassium adenosine triphosphatase (Na^+ - K^+ -ATPase) pump located in the cell membrane is responsible for the compartmentalization of potassium. This pump is an active transport system that maintains increased intracellular stores of potassium by transporting sodium out of the cell and potassium into the cell at a ratio of 3:2. Consequently, the pump maintains a higher concentration of potassium inside the cell.

2 The normal serum concentration range for potassium is 3.5 to 5.0 mEq/L, whereas the intracellular potassium concentration is usually approximately 150 mEq/L.² Approximately 75% of the intracellular potassium is located in skeletal muscle; the remaining 25% is located in the liver and red blood cells. Extracellular potassium is distributed throughout the serum and interstitial space. Potassium is dynamic in that it is constantly moving between the intracellular and extracellular compartments according to the body's needs. Thus the serum potassium concentration alone does not accurately reflect the total body potassium content.

3 Potassium has many physiologic functions within cells, including protein and glycogen synthesis and cellular metabolism and growth. It is also a determinant of the electrical action potential across the cell membrane.¹ The ratio of the intracellular to extracellular potassium concentration is the major determinant of the resting membrane potential across the cell membrane. Thus the resting membrane potential is greatly affected by variations in extracellular potassium concentration. Serum potassium concentrations outside the normal range can have disastrous effects on neuromuscular activity, in particular cardiac conduction. Hypo- and hyperkalemia are both associated with potentially fatal cardiac arrhythmias, along with other neuromuscular disturbances.

CONTROL OF POTASSIUM HOMEOSTASIS

Potassium homeostasis, the maintenance of serum potassium within the normal range, is affected by dietary intake, gastrointestinal and urinary excretion, hormones, acid-base balance, and body fluid tonicity.³

The recommended daily allowance for dietary potassium intake is approximately 50 mEq/day.¹ Potassium is found in abundance in fruits, vegetables, and meats. The typical American ingests approximately 50 to 150 mEq of potassium daily.³ Nearly all of this is absorbed, with only 10 to 20 mEq/day eliminated in feces. The amount eliminated in the feces increases, however, in patients with diarrhea, and in those with underlying chronic kidney disease (CKD).⁴

The kidney is the primary route of potassium elimination. Potassium is freely filtered but almost all of it is reabsorbed passively in the proximal tubule and the thick ascending limb of the loop of Henle.⁵ Therefore urinary potassium excretion is primarily determined by potassium secretion from the luminal cells of the distal tubule and collecting duct. Although the amount of potassium filtered by the

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

glomerulus approaches 700 mEq per day, only approximately 10% to 20% is actually excreted in the urine.¹ However, this amount can vary based on dietary intake, serum potassium concentration, and aldosterone activity. For example, more potassium is renally excreted in conditions that result in high aldosterone activity (e.g., dehydration) when the body is attempting to conserve sodium or when there is an increase in dietary potassium intake.

Hormones such as insulin, catecholamines, and aldosterone dramatically affect potassium homeostasis. Insulin is the most important hormonal mediator of potassium balance because it stimulates the cellular Na⁺-K⁺-ATPase pump to increase transport of potassium into liver, muscle, and adipose tissue.³ There is a complex negative feedback loop in which insulin secretion tightly regulates serum potassium concentrations: an increase of only a few tenths of a milliequivalent stimulates pancreatic insulin secretion in an attempt to prevent hyperkalemia from developing.¹ If hyperkalemia does occur, glucagon is released from the liver to protect against insulin-induced hypoglycemia. Conversely, hypokalemia inhibits insulin secretion, a finding that explains why some patients receiving diuretics develop hyperglycemia.

An elevation in circulating catecholamines such as epinephrine usually results in the intracellular movement of potassium by two mechanisms.⁶ They stimulate the β-receptor, which directly activates the Na⁺-K⁺-ATPase pump. Second, they stimulate glycogenolysis, which raises blood glucose concentrations, thereby increasing insulin secretion. This dual mechanism is often used therapeutically in patients with hyperkalemia to normalize serum potassium concentrations.

Aldosterone, a mineralocorticoid that is secreted from the adrenal glands in response to high serum potassium concentrations, promotes urinary potassium excretion. Aldosterone works in the distal tubule and collecting duct to promote the reabsorption of sodium and water in exchange for potassium. Aldosterone may also have extrarenal activity by stimulating cellular Na⁺-K⁺-ATPase pump activity.⁶

Changes in acid–base status significantly affect the serum potassium concentration. For example, the infusion of metabolic inorganic acids, such as hydrochloric acid, results in an increase in serum potassium. The body compensates for excessive hydrogen ions by moving them from the serum into the cell, in exchange for intracellular potassium, to maintain electroneutrality. The process by which this occurs is complex, and a cellular H⁺-K⁺-ATPase pump has been identified. The efflux of potassium into the serum can result in hyperkalemia. A commonly quoted approximation of the pH effect is that for every 0.1 unit decrease in pH, there is a corresponding increase in serum potassium of 0.6 to 0.8 mEq/L (with a wide range of 0.2 to 1.7).⁵ This is often referred to as *false hyperkalemia* because there is not a true excess of total body potassium. Metabolic acidosis associated with lactic acidosis and ketoacidosis, does not result in hyperkalemia, because both cations and anions enter the cell, thus maintaining electroneutrality.¹ Respiratory acidosis also does not significantly affect the serum potassium concentration.⁶

Conversely, metabolic alkalosis has been associated with hypokalemia. As a result of a net loss of hydrogen ion from the serum, intracellular hydrogen ions enter the serum to increase the acidity of the blood. To maintain electroneutrality extracellular potassium ions are shifted intracellularly. This creates a relative deficiency of potassium in the serum. Serum potassium decreases approximately 0.6 mEq/L for each 0.1 unit increase in blood pH. This is frequently termed *false hypokalemia* because there is not a true deficiency in total body potassium.

Finally, hyperosmolality can result in enhanced movement of potassium from the cell into the extracellular fluid. This occurs most likely because of the associated cell shrinkage and water loss, which increases the intracellular-to-extracellular potassium gradient.³ This is seen most commonly in conditions such as diabetic ketoacidosis. Conversely, hypo-osmolality does not seem to affect potassium distribution.

HYPOKALEMIA

Epidemiology

Hypokalemia (defined as a serum potassium concentration <3.5 mEq/L) is one of the most commonly encountered electrolyte abnormalities in clinical practice.^{7,8} Hypokalemia can be categorized as mild (serum potassium 3 to 3.5 mEq/L), moderate (serum potassium 2.5 to 3 mEq/L), or severe (<2.5 mEq/L). When hypokalemia is detected, a diagnostic workup that evaluates the patient’s comorbid disease states and concomitant medications should be initiated. Hypokalemia is virtually nonexistent in healthy adults. This is due in part to the relatively high potassium content in the typical Western diet as well as the body’s effective potassium-sparing mechanisms, which tightly regulate the serum potassium concentration. However it has been estimated that as many as 50% of patients who receive thiazide or loop diuretics have serum potassium concentrations less than 3.5 mEq/L.⁸

Etiology and Pathophysiology

Hypokalemia results when there is a total body potassium deficit, or when serum potassium is shifted into the intracellular compartment. Total body deficits occur in the setting of poor dietary intake of potassium, or when there are excessive renal and gastrointestinal losses of potassium.

Maintaining a consistent dietary intake of potassium is important because the body has no effective method for storing potassium. At steady state, potassium excretion matches potassium intake; approximately 90% of ingested potassium is renally excreted, whereas 10% is excreted in feces.⁹ This underscores the importance of eating a well-balanced diet. Elderly patients with chronic diseases and those undergoing surgery are at increased risk for developing hypokalemia because of insufficient intake or losses resulting from surgery.

Many drugs can cause hypokalemia by a variety of mechanisms including intracellular potassium shifting and increased renal or stool losses (Table 54–1). The most common cause of drug-induced hypokalemia is loop and thiazide diuretic administration as these agents inhibit renal sodium reabsorption, which results in increased sodium delivery to the distal tubule. Consequently, hypokalemia develops because the distal tubule selectively reabsorbs sodium, and excretes potassium down its concentration gradient. Second, because

TABLE 54-1 Mechanism of Drug-Induced Hypokalemia		
Transcellular Shift	Enhanced Renal Excretion	Enhanced Fecal Elimination
β₂-Receptor agonists	Diuretics	Sodium polystyrene sulfonate
Epinephrine	Acetazolamide	Phenolphthalein

Caffeine	Mineralocorticoids	
Insulin overdose	Miscellaneous	
	Aminoglycosides	
	Amphotericin B	
	Cisplatin	

diuretics result in volume contraction, aldosterone is secreted which further promotes the renal excretion of potassium. If concomitant potassium supplements are not provided to patients receiving loop and thiazide diuretics, mild to moderate hypokalemia is inevitable.

The second most common etiology of hypokalemia is excessive loss of potassium-rich GI fluid as a result of diarrhea and/or vomiting. The typical potassium loss in feces is approximately 10 mEq per day.⁷ In diarrheal states, this amount increases proportionally with the volume of stool output. Vomiting also accounts for substantial potassium losses, which have been estimated to be as high as 30 to 50 mEq per liter of vomitus.⁸ Metabolic alkalosis can also occur in cases of severe diarrhea and vomiting as a result of loss of these bicarbonate-rich fluids. This causes an intracellular shifting of potassium, which lowers the serum concentration of potassium even further. Prolonged diarrhea and vomiting can significantly affect children and elderly patients because their kidneys are unable to effectively maintain adequate fluid status.

Hypomagnesemia can also contribute to the development of hypokalemia because it reduces the intracellular potassium concentration and promotes renal potassium wasting.¹⁰ The intracellular potassium concentration decreases because hypomagnesemia impairs the function of the Na^+/K^+ -ATPase pump. The precise mechanism of the accelerated renal loss of potassium is unknown. It is unclear whether hypomagnesemia directly causes hypokalemia, because the two are often found together as a result of drugs (diuretic administration) or disease states (diarrhea). When concomitant hypokalemia and hypomagnesemia occur, the magnesium deficiency should be corrected first, otherwise full repletion of the potassium deficit is difficult.

CLINICAL PRESENTATION OF HYPOKALEMIA

General

- The signs and symptoms of hypokalemia are usually nonspecific and highly variable between patients.

Symptoms

- Symptoms are highly dependent on the degree of hypokalemia and its rapidity of onset.
- Mild hypokalemia is often asymptomatic.
- Moderate hypokalemia is associated with cramping, weakness, malaise, and myalgias.

Signs

- Cardiovascular: In severe hypokalemia, electrocardiogram (ECG) changes often include ST-segment depression or flattening, T-wave inversion, and U-wave elevation. Clinical arrhythmias include heart block, atrial flutter, paroxysmal atrial tachycardia, ventricular fibrillation, and digitalis-induced arrhythmias.
- Musculoskeletal: Cramping and impaired muscle contraction.

Laboratory Tests

- Serum potassium concentration less than 3.5 mEq/L is diagnostic. Hypomagnesemia (serum magnesium concentration <1.7 mg/dL) can also be present.

TREATMENT

Hypokalemia

■ DESIRED OUTCOME

The goals of hypokalemia management are to prevent the development of and to treat if present serious life-threatening complications, to normalize the serum potassium concentration, to identify

and correct the underlying cause of hypokalemia, and to prevent overcorrection of the serum potassium concentration.

■ GENERAL APPROACH TO THERAPY

The general approach to therapy depends on the degree and rapidity with which hypokalemia developed and the presence of symptoms. Serum potassium concentrations between 3.5 and 4 mEq/L are a sign of early potassium depletion. No pharmacologic therapy is recommended at this point; however, these patients should be encouraged to increase their dietary intake of potassium-rich foods. When the serum potassium concentration is between 3 and 3.5 mEq/L, it is debatable whether pharmacologic therapy should be initiated. Oral potassium supplementation should be initiated in patients with underlying cardiac conditions that predispose them to cardiac arrhythmias.¹¹ This includes patients receiving concomitant digoxin therapy. Patients with serum potassium concentrations below 3 mEq/L should always be treated to achieve values between 4 and 4.5 mEq/L. In asymptomatic patients, oral therapy is the preferred route of administration. Intravenous potassium can be necessary in symptomatic patients with severe depletion, or in patients who are intolerant to oral supplementation. In patients with concomitant moderate to severe hypomagnesemia, the magnesium deficit should be corrected before potassium supplementation, to prevent refractory hypokalemia.^{10,12}

■ NONPHARMACOLOGIC THERAPY

Various nonpharmacologic therapies have been used to prevent and treat hypokalemia. The best and most abundant source of potassium supplementation comes from dietary sources, in particular, fresh fruits and vegetables, fruit juices, and meats.¹² Table 54–2 lists foods that are excellent sources of potassium. Salt substitutes that contain potassium chloride are another effective, inexpensive source of potas-

TABLE 54-2 Foods That Are High in Potassium

Highest content (>1,000 mg/100 g)

Ground beef
Steak
Pork
Lamb
Veal

sium. Increased dietary intake of foods with high potassium content is not recommended long-term for many patients because it can add unwanted calories to the patient's diet. Moreover, dietary potassium is almost entirely coupled with phosphate, rather than chloride, so it is not as effective in correcting potassium loss associated with hypochloremic conditions such as vomiting, nasogastric suctioning, and diuretic therapy.¹²

■ PHARMACOLOGIC THERAPY

Guidelines for potassium supplementation were last published by the National Council on Potassium in Clinical Practice in 2000 (Table 54-3).¹² These guidelines provide a comprehensive framework for potassium prophylaxis and replacement in many distinct patient populations. When deciding on appropriate pharmacotherapy to replete potassium, five factors must be considered: (1) the patient's normal baseline potassium concentration; (2) underlying medical conditions that can affect potassium balance; (3) concomitant medications that can affect potassium balance; (4) the patient's dietary and salt intake; and (5) the patient's ability to comply with the therapeutic regimen.¹²

A general rule for potassium replacement is that for every 1-mEq/L decrease of potassium below 3.5 mEq/L, there is a corresponding total body potassium deficit of 100 to 400 mEq. Because of the wide variance in projected deficits, each patient's therapy must be individualized and adjustments made on the basis of the patient's signs, symptoms, and frequent measurements of serum potassium. In patients receiving chronic loop or thiazide diuretic therapy, 40 to 100 mEq of potassium can correct mild to moderate potassium deficits. Doses up to 120 mEq can be required in more severe deficiencies. When providing oral

potassium supplementation, the total daily dose should be divided into three to four doses to minimize the development of GI side effects. Patients receiving diuretics can become chronically hypokalemic and can benefit from combination potassium-sparing diuretic therapy.

CLINICAL CONTROVERSY

The replacement of potassium intravenously can be accomplished by IV piggyback or Buretrol administration. A pharmacist usually prepares the potassium IV piggyback, double checks the concentration and fluid, and then dispenses the final product to the medical unit. However, with Buretrol administration, essentially any clinician (e.g., nurse or physician) can prepare the solution on the medical unit, and infuse the potassium solution into the patient. The Joint Commission and the United States Pharmacopeia 797 Standards now advocate that all parenteral products be compounded in a sterile, laminar flow environment, and be double-checked by a pharmacist to assure patient safety. Many hospitals to date have not adapted these recommendations, which were developed to improve patient safety.

4 Whenever possible, potassium supplementation should be administered by mouth. Three salts are available for oral potassium supplementation: chloride, phosphate, and bicarbonate. Potassium phosphate should be used when patients are both hypokalemic and hypophosphatemic; potassium bicarbonate is most commonly used when potassium depletion occurs in the setting of metabolic acidosis. Potassium chloride, however, is the primary salt form used because it is the most effective treatment for the most common causes of potassium depletion (i.e., diuretic-induced and diarrhea-induced) as these conditions are associated with potassium and chloride losses.

Potassium chloride can be administered in either tablet or liquid formulations (Table 54-4). The liquid forms are generally less expensive; however, patient compliance can be low because of their strong, unpleasant taste.¹² Two sustained-release solid dosage forms are currently available in the United States: a wax-matrix formulation, and a microencapsulated formulation. The microencapsulated tablet is generally preferred because it disintegrates better in the stomach and is associated with less GI irritation.^{7,12}

Intravenous potassium use should be limited to: (1) severe cases of hypokalemia (serum concentration <2.5 mEq/L); (2) patients exhibiting signs and symptoms of hypokalemia such as ECG changes or muscle spasms; or (3) patients unable to tolerate oral therapy. Intravenous supplementation is more dangerous than oral therapy because it is more likely to result in hyperkalemia, phlebitis, and pain at the site of infusion.

The vehicle in which IV potassium is administered is important. Whenever possible, potassium should be prepared in saline-containing solutions (e.g., 0.9% or 0.45% sodium chloride [NaCl]). Dextrose-containing solutions stimulate insulin secretion, which can

TABLE 54-3 General Consensus Guidelines for Potassium Replacement

Guideline	Comment
Potassium replacement therapy should accompany dietary consumption of potassium-rich foods.	Potassium-rich foods often cannot completely replace potassium associated with chloride losses (vomiting, diuretics, or nasogastric suction) because it is almost entirely coupled to phosphate. Furthermore, increasing dietary intake of these foods can lead to unwanted weight gain.
Potassium replacement is recommended for patients who are sodium sensitive, and hypertensive patients.	A high-sodium diet often results in excessive urinary potassium excretion.
Potassium replacement is recommended in patients who are subject to vomiting, diarrhea, or diuretic/laxative abuse.	These conditions promote excessive renal and GI potassium loss.
Potassium supplementation is best administered orally in divided doses over several days to achieve full repletion.	
Laboratory measurement of serum potassium is convenient but not always accurate.	Clinicians should be aware of the factors that result in transcellular potassium shifts. Monitoring 24-hour urinary potassium excretion can be necessary in high-risk patients.
Patient adherence to potassium replacement can be increased with compliance-enhancing regimens.	Microencapsulated products have no bitter smell or aftertaste and have much better GI tolerance. Regimens should be made as simple as possible to follow.
A potassium dosage of 20 mEq/day is usually sufficient to prevent hypokalemia from occurring. Doses of 40–100 mEq are usually sufficient to treat hypokalemia.	

TABLE 54-4 Differentiation of Available Potassium Supplements

Supplement	Comment
Controlled-release microencapsulated tablet	Disintegrates better in GI tract; fewer GI erosions as compared to wax-matrix tablets
Encapsulated controlled-release microencapsulated particles	Fewer erosions as compared to wax-matrix tablets
Potassium chloride elixir	Inexpensive, poor taste, poor compliance, immediate effect
Potassium chloride effervescent tablets for solution	More expensive than elixir, convenient
Wax-matrix extended-release tablets	Easier to swallow; more GI erosions as compared to other therapies

cause intracellular shifting of potassium worsening the patient's hypokalemia, and should be avoided whenever possible.¹³ Generally, 10 to 20 mEq of potassium is diluted in 100 mL 0.9% NaCl for intravenous administration. These concentrations are safe when administered through a peripheral vein over 1 hour. When infusion rates exceed 10 mEq/h, ECG monitoring should be performed to detect cardiac changes. The serum potassium concentration should be evaluated following the infusion of each 30 to 40 mEq, to direct further potassium replacement requirements. Multiple doses of potassium can be repeated as needed until the serum potassium concentration normalizes. To allow adequate time for the potassium to equilibrate between the intra- and extracellular spaces, the clinician should wait at least 30 minutes from the end of each infusion before obtaining a serum concentration. Care should be taken to avoid sampling from the same line in which the potassium was infused, as this can result in a spuriously high potassium concentration.

In cases of severe potassium depletion, patients can require as much as 300 to 400 mEq/day. In this instance, it is common practice to dilute 40 to 60 mEq in 1,000 mL 0.45% NaCl and infuse at a rate not exceeding 40 mEq/h. When possible, this should be performed in an intensive care unit under continuous ECG monitoring. Because of the high potassium concentration, and the risk for burning pain and peripheral venous sclerosis, the infusion should be through a central intravenous line into a large vein (e.g., superior vena cava). Given the volume required to infuse this dose of potassium, this infusion strategy might be impractical in certain clinical situations (e.g., patients requiring fluid restriction). A reasonable alternative is to split the potassium dose between the oral and intravenous routes. For example, if a symptomatic patient requires 120 mEq of potassium, the clinician can give 60 mEq as the immediate-release potassium liquid, and the other 60 mEq can be given via the intravenous route (20 mEq/100 mL/h in three doses). When giving large potassium doses, serum monitoring should be performed following the administration of half the dose to guide the clinician as to the need for additional potassium. This can also help avoid the development of hyperkalemia.

■ ALTERNATIVE THERAPIES

Potassium-sparing diuretics are an alternative to chronic exogenous potassium supplementation, especially when patients are concomitantly receiving drugs that are known to deplete potassium (e.g., diuretics or amphotericin B). Spironolactone inhibits the effect of aldosterone in the distal convoluted tubule, thereby decreasing potassium elimination in the urine. Spironolactone is especially effective as a potassium-sparing agent in patients with primary or secondary hyperaldosteronism. Amiloride and triamterene act by an aldosterone-independent mechanism; however, the precise mechanism of their potassium sparing is unknown.

Spironolactone is available as 25-mg, 50-mg, and 100-mg tablets. The usual starting dose is 25 to 50 mg daily, and can be titrated to a maximum dose of 400 mg/day. The potassium-retaining effects generally take approximately 48 hours to occur. Important side effects include hyperkalemia, gynecomastia, breast tenderness, and impotence in men.

Triamterene is available as 50-mg and 100-mg capsules. The usual starting dose is 50 mg twice daily, which can be titrated to 100 mg twice daily. Triamterene 50 mg is available as a combination product with hydrochlorothiazide 25 mg and is commonly used for the treatment of hypertension. Common side effects include hyperkalemia, sodium depletion, and metabolic acidosis.

Amiloride is available as a 5-mg tablet. The usual starting dose is 5 mg daily; however, 10 mg can be given in those with severe hypokalemia. This is also available as a combination product with hydrochlorothiazide 50 mg. The most common side effects are hyperkalemia and metabolic acidosis.

Generally, concomitant use of potassium supplementation with potassium-sparing diuretics is not necessary. There is a significant

risk of hyperkalemia during combination therapy, especially in patients with underlying renal insufficiency or diabetes mellitus.

To date, there have been no pharmacoeconomic evaluations of the different pharmacotherapeutic alternatives to manage hypokalemia. The most economical source of chronic potassium supplementation is to increase the amount in the diet. Thus patients receiving diuretic therapy should be instructed to increase their dietary intake of potassium-rich foods. By doing so, they can often avert the need for exogenous potassium therapy.

■ EVALUATION OF THERAPEUTIC OUTCOMES

5 Serum potassium concentrations should be monitored regularly while the patient is receiving potassium supplementation. For patients receiving prophylactic potassium supplementation during diuretic therapy, the serum potassium and magnesium concentrations, as well as renal function should be monitored every 1 to 2 months in stable patients. In hospitalized patients receiving oral therapy for mild hypokalemia, the potassium concentration should be monitored every 2 to 3 days. Generally, the potassium concentration begins to increase within 72 hours. If it does not increase by at least 1 mEq/L within 96 hours, the clinician should suspect concomitant magnesium depletion. If present, correcting the magnesium deficit generally results in normalization of potassium. Patients receiving IV potassium supplementation require close ECG monitoring if the infusion rate is greater than 20 mEq/h. Doses greater than this should be administered only in the presence of continuous ECG monitoring. Additionally, the patient should have potassium concentrations obtained halfway through, and 30 minutes following completion of the total potassium dose to guide further potassium dosing. Finally, the patient should be assessed for adverse effects such as burning pain at the infusion site or phlebitis.

HYPERKALEMIA

Hyperkalemia, defined as a serum potassium concentration greater than 5.5 mEq/L, can be further classified according to its severity: mild hyperkalemia (serum potassium 5.5 to 6 mEq/L), moderate hyperkalemia (6.1 to 6.9 mEq/L), and severe hyperkalemia (>7 mEq/L).¹⁴

Epidemiology

Hyperkalemia is much less common than hypokalemia. In fact, if all patients with acute and chronic kidney disease were excluded, the true prevalence of hyperkalemia would be insignificant.¹⁴ Indeed, the incidence of hyperkalemia in hospitalized patients is highly variable, and reports have ranged from 1.4% to 10%.¹⁵ Most cases of hyperkalemia are the result of overcorrection of hypokalemia with intravenous potassium supplements. Severe hyperkalemia occurs more commonly in elderly patients with renal insufficiency who receive chronic oral potassium supplementation.^{15,16}

Etiology and Pathophysiology

Hyperkalemia develops when potassium intake exceeds excretion (true hyperkalemia) (i.e., elevated total body stores), or when the transcellular distribution of potassium is disturbed (i.e., normal total body stores). The four primary causes of hyperkalemia—(1) increased potassium intake, (2) decreased potassium excretion, (3) tubular unresponsiveness to aldosterone, and (4) redistribution of potassium into the extracellular space—are discussed below.

Hyperkalemia Associated with Increased Potassium Intake

Hyperkalemia in this setting is almost always associated with renal insufficiency. Patients with stage 4 or 5 CKD and dialysis patients who are noncompliant with dietary potassium restrictions often present with life-threatening hyperkalemia. Many of these patients

do not realize that fresh fruits and vegetables contain large amounts of potassium. Anecdotally, in many dialysis centers the incidence of hyperkalemia peaks during the summer months, when fresh garden produce is available. Another common dietary source associated with the development of hyperkalemia is potassium chloride salt substitutes. Many dialysis patients are instructed to use salt substitutes to avoid excessive sodium intake in an attempt to control volume overload. These patients unwittingly become hyperkalemic because these products contain approximately 10 to 15 mEq potassium per gram, or 200 mEq per tablespoon. Finally, many over-the-counter herbal and alternative medicine products may contain significant concentrations of potassium.¹⁷ Indeed, noni juice, a product touted for its many health benefits, has been implicated as a cause of hyperkalemia in patients with renal dysfunction.¹⁸

It is essential for patients with CKD to receive education regarding dietary sources of potassium as well as information on the potassium content of herbal products because the ingestion of these can lead to hyperkalemia.

Hyperkalemia Associated with Decreased Renal Potassium Excretion ⑥ The kidneys excrete 80% of the daily potassium intake. Therefore when the kidney is unable to excrete potassium appropriately, as in acute renal failure (ARF) and stage 4 to 5 CKD, potassium is retained and often results in hyperkalemia. Finally, many drugs can inhibit the kidney's ability to excrete potassium by inhibiting aldosterone and thus contribute to an increase in serum potassium concentrations.

Severe hyperkalemia is more common in ARF than in CKD because patients are often hypercatabolic and can have underlying disorders, such as rhabdomyolysis or tumor lysis syndrome, which result in release of potassium from injured or lysed cells.¹⁹ Severe hyperkalemia is rare in stable CKD patients, perhaps because of enhanced GI and renal potassium excretion.²⁰ Data suggest that hyperkalemia actually directly stimulates renal K^+ excretion through an effect that is independent of, and additive to, that of aldosterone.²⁰ Renal excretion of potassium is also inhibited by various endocrinologic disorders, including adrenal insufficiency, Addison's disease, and selective hypoaldosteronism. All of these disorders involve a decreased production of aldosterone, which results in the retention of potassium.

Several drugs have profound effects on the kidney's ability to regulate potassium.²¹ Four drug classes in particular have specific effects on the kidney: angiotensin-converting enzyme inhibitors (ACEIs), angiotensin-II receptor blockers (ARBs), potassium-sparing diuretics, and prostaglandin inhibitors such as nonsteroidal antiinflammatory drugs (NSAIDs). Although hyperkalemia with these drugs is typically dose-dependent, the rates of hyperkalemia have been reported to range from 5% to 10% in most clinical trials. Other commonly used drugs that can cause hyperkalemia are digoxin, cyclosporine, tacrolimus, trimethoprim-sulfamethoxazole, heparin, and pentamidine.²¹

Tubular Unresponsiveness to Aldosterone Certain medical conditions, such as sickle cell anemia, systemic lupus erythematosus, and amyloidosis, can produce a defect in tubular potassium secretion, possibly as the result of an alteration in the aldosterone-binding site. The exact mechanism of the tubular unresponsiveness is unknown.

Redistribution of Potassium into the Extracellular Space The efflux of potassium from within the cell into the extracellular fluid, which is associated with no change in total body potassium stores, is to be expected in the presence of metabolic acidosis, diabetes mellitus, chronic renal failure, or lactic acidosis. β -Blockers can also result in a transcellular potassium shift.²¹

The serum potassium concentration can also be falsely elevated in some conditions, and not reflect the actual *in vivo* potassium concentration. This is termed *pseudohyperkalemia*. Pseudohyperkalemia occurs most commonly in the setting of extravascular hemolysis of red blood cells.¹⁴ When a blood specimen is not

processed promptly and cellular destruction occurs, intracellular potassium is released into the serum. Pseudohyperkalemia can also occur in conditions of thrombocytosis or leukocytosis. If severe hyperkalemia is found in a patient who is asymptomatic with an otherwise normal laboratory report, the hyperkalemia is most likely pseudohyperkalemia, and a repeat blood sample should be evaluated. Truly elevated potassium concentrations are normally associated with other laboratory abnormalities, such as low carbon dioxide (acidosis) or elevated blood urea nitrogen and creatinine concentrations (indicating renal insufficiency).

CLINICAL PRESENTATION OF HYPERKALEMIA

General

- Related to the effects of excessive potassium on neuromuscular, cardiac, and smooth muscle cell function.

Symptoms

- Frequently asymptomatic.
- The patient might complain of heart palpitations or skipped heartbeats.

Signs

- ECG changes (see Fig. 54–1 for description).

Laboratory Tests

- Serum potassium concentration >5.5 mEq/L.

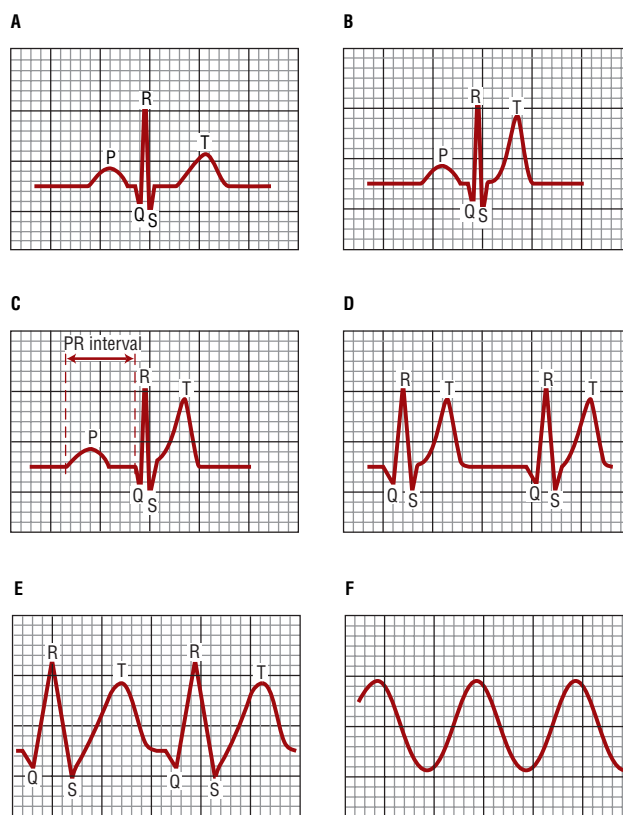

FIGURE 54-1. The earliest electrocardiographic manifestation of hyperkalemia is an increase in the rate of ventricular repolarization, which results in a peaking of the T wave at serum potassium concentrations of ~5.5 to 6 mEq/L (B), relative to the normal ECG presentation (A). Further increases in the serum potassium concentration above 6 mEq/L result in conduction delays through the His-Purkinje system, the atrial myocardium, and the ventricular myocardium. The ECG manifestations of these conduction delays and the sequence in which they occur are a widening of the PR interval (C), delay through the His-Purkinje system, a loss of the P wave (D), delay through the atrial myocardium, a widening of the QRS complex (E), and delay through the ventricular myocardium. Finally, there is a merging of the QRS complex with the T wave (F), which results in a sine-wave appearance.

TREATMENT

Hyperkalemia

■ DESIRED OUTCOME

The goals of therapy for the treatment of hyperkalemia are to antagonize adverse cardiac effects, reverse any symptoms that are present, and return the serum and total body stores of potassium to normal. Asymptomatic patients with mild hyperkalemia usually require no specific therapy other than the tincture of time, dietary education to control intake, and monitoring of serum potassium daily if an inpatient or weekly if an outpatient to assure resolution. Severe hyperkalemia (>7 mEq/L) or moderate hyperkalemia (6.1 to 6.9 mEq/L), when associated with clinical symptoms or ECG changes, requires immediate treatment. Initial treatment of severe and moderate symptomatic hyperkalemia is focused on antagonism of the cardiac membrane actions of hyperkalemia (e.g., with calcium). Secondarily, one should attempt to decrease extracellular potassium concentration by promoting its intracellular movement (e.g., with glucose, insulin, β_2 -receptor agonists, or sodium bicarbonate) or enhance its removal from the body by hemodialysis and/or the oral administration of cation-exchange resins. In any case, the underlying cause of hyperkalemia should be identified and reversed, and exogenous potassium must be withheld.

■ GENERAL APPROACH TO TREATMENT

The general treatment approach for patients with hyperkalemia is outlined in Fig. 54-2. In patients who have acute ECG changes, calcium should be administered to prevent or treat any cardiac manifestations of hyperkalemia. Once the patient is hemodynamically stabilized, the serum potassium concentration should be rapidly decreased to <5.5 mEq/L within minutes by administering drugs that cause an intracellular shift. If the patient is asymptomatic, rapid correction is not necessary. The clinician can administer an ion exchange resin (e.g., sodium polystyrene sulfonate [SPS]) that results in removal of potassium from the body over several hours to days.

■ NONPHARMACOLOGIC THERAPY

Hemodialysis patients who present with severe hyperkalemia, or with cardiac manifestations of hyperkalemia, should undergo an additional hemodialysis treatment as soon as possible. Because even in emergent situations it takes a while to arrange for a dialysis treatment, bicarbonate, epinephrine, or insulin plus glucose therapy are often administered while the patient is waiting for or in transit to the dialysis unit. Other forms of dialysis can be performed (e.g., peritoneal dialysis or continuous renal replacement therapy), although they are less effective means to acutely lower an elevated serum potassium.²²

■ PHARMACOLOGIC THERAPY

Various drug therapies have been used to lower the serum potassium concentration. The optimal regimen for a given patient is dependent on the rapidity and degree of lowering that is necessary. Table 54-5 provides an overview of the available therapies, and their respective onset and the degree of change one can expect.

In asymptomatic patients with mild to moderate hyperkalemia (serum concentration 5.5 to 6.9 mEq/L), aggressive therapy is usually not indicated. However, the clinician should have a low threshold for giving intravenous calcium in asymptomatic patients with known cardiac histories. In patients with normal renal function, or those with stage 3 or 4 CKD, loop diuretics can be administered in the short term to promote urinary potassium excretion. Furosemide 20 to 40 mg orally is a common starting dose, and this can be titrated to

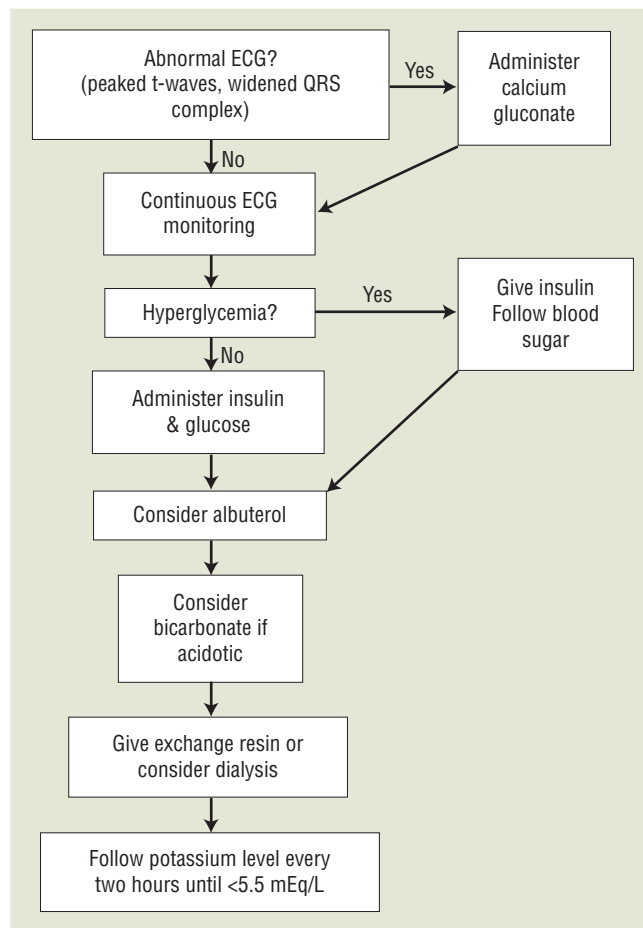

FIGURE 54-2. Treatment approach for hyperkalemia.

response. Its onset of activity is within minutes, and its duration of activity is approximately 4 to 6 hours. Close monitoring of the patient's volume status and other electrolyte concentrations is required while the patient is receiving loop diuretic therapy. Alternatively, SPS (Kayexalate), a cation-exchange resin, can be administered orally or rectally by enema. SPS is available in powder form or prepackaged as a 70% sorbitol suspension. The oral route is more effective than the enema and is better tolerated by the patient. As the resin passes through the intestines, each gram of SPS exchanges 1 mEq of sodium for 1 mEq of potassium ions, which are in a relatively higher concentration in the large intestine. The onset of action of SPS is within 1 hour, and it can be repeated every 4 hours as needed. The sorbitol component of the suspension promotes the excretion of the cationically modified potassium exchange resin by inducing diarrhea. The usual oral dose of SPS is 15 to 60 g in the 70% sorbitol suspension. A retention enema prepared by mixing 60 to 100 g SPS in 100 to 200 mL of a 30% sorbitol or 10% dextrose suspension warmed to body temperature will usually remove 0.5 mEq of potassium per gram of SPS.²³ The enema may be retained in the rectum for several hours as tolerated by the patient.

In symptomatic patients, or in those with severe hyperkalemia (serum potassium >7 mEq/L), emergency care is indicated. Initial therapy in this setting is the administration of intravenous calcium to protect the heart from life-threatening arrhythmias.^{19,22} Calcium antagonizes the cardiac membrane effect of hyperkalemia and reverses ECG changes within minutes. Its duration of action is 30 to 60 minutes, and it can be repeated as needed based on ECG findings. Intravenous calcium can be given as either the chloride or gluconate salt; each is available as a 10% solution by weight. Calcium chloride provides approximately three times more calcium than equal volumes of the gluconate salt; however, it can cause

TABLE 54-5 Therapeutic Alternatives for the Management of Hyperkalemia

Medication	Dose	Route of Administration	Onset/Duration of Action	Acuity	Mechanism of Action	Expected Result
Calcium	1 g (1 ampule)	IV over 5–10 min	1–2 min/10–30 min	Acute	Raises cardiac threshold potential	Reverses electrocardiographic effects
Furosemide	20–40 mg	IV	5–15 min/4–6 hours	Acute	Inhibits renal Na ⁺ reabsorption	Increased urinary K ⁺ loss
Regular insulin	5–10 units	IV or SC	30 min/2–6 hours	Acute	Stimulates intracellular K ⁺ uptake	Intracellular K ⁺ redistribution
Dextrose 10%	1,000 mL (100 g)	IV over 1–2 hours	30 min/2–6 hours	Acute	Stimulates insulin release	Intracellular K ⁺ redistribution
Dextrose 50%	50 mL (25 g)	IV over 5 min	30 min/2–6 hours	Acute	Stimulates insulin release	Intracellular K ⁺ redistribution
Sodium bicarbonate	50–100 mEq	IV over 2–5 min	30 min/2–6 hours	Acute	Raises serum pH	Intracellular K ⁺ redistribution
Albuterol	10–20 mg	Nebulized over 10 min	30 min/1–2 hours	Acute	Stimulates intracellular K ⁺ uptake	Intracellular K ⁺ redistribution
Hemodialysis	4 hours	N/A	Immediate/variable	Acute	Removal from serum	Increased K ⁺ elimination
Sodium polystyrene sulfonate	15–60 g	Oral or rectal	1 hour/variable	Nonacute	Resin exchanges Na ⁺ for K ⁺	Increased K ⁺ elimination

K⁺, potassium ion; Na⁺, sodium ion; SC, subcutaneous.

tissue necrosis if extravasation occurs. For this reason, calcium gluconate is more commonly administered, with the standard dose being 10-mL IV bolus over 5 to 10 minutes.

Rapid correction of hyperkalemia may necessitate the administration of drugs that result in an intracellular shift of potassium, such as insulin and dextrose, sodium bicarbonate, and the β_2 -receptor agonist albuterol. The treatment of choice depends on the underlying medical disorders accompanying hyperkalemia. For example, in patients with concomitant metabolic acidosis, a sodium bicarbonate bolus or infusion of 50 to 100 mEq is the preferred therapy (see Chap. 55 for additional information). Sodium bicarbonate helps to correct the metabolic acidosis by raising the extracellular pH, in addition to causing a rapid intracellular potassium shift. It should be noted that sodium bicarbonate is much less effective when hyperkalemia is not related to metabolic acidosis.¹⁹ Sodium bicarbonate is also less effective in patients with end-stage renal disease (ESRD), in whom a decrease in serum potassium may not be seen for as long as 4 hours.²³ Sodium bicarbonate can also lead to sodium and volume overload in patients with stage 4 or 5 CKD. Administration of insulin (5 to 10 units IV) and dextrose (10% or 50%) is an effective method of reducing potassium. Insulin increases the activity of the Na⁺-K⁺-ATPase pump, thereby intracellularly shifting potassium. Glucose should be given with insulin unless the serum glucose is greater than 250 mg/dL because hypoglycemia can develop with unopposed insulin therapy. β_2 -Adrenergic agonists, such as albuterol, have a dual mechanism for lowering serum potassium. First, they stimulate the Na⁺-K⁺-ATPase pump to promote intracellular potassium uptake. Second, they stimulate pancreatic β -receptors to increase insulin secretion. Albuterol can be administered intravenously (0.5 mg given over 15 minutes) or via nebulizer (10 to 20 mg nebulized over 10 minutes); however, it should be noted that injectable albuterol is not available in the United States. There are important limitations with albuterol therapy, most notably variable bioavailability via the inhaled route (leading to potential over- or underdosing and unpredictability of response) and second, cardiac side effects such as tachycardia can be undesirable in patients who already have abnormal ECGs.

A recent Cochrane review evaluated the emergency treatment of hyperkalemia.²⁴ Many of the reviewed studies were small, and not all intervention groups had sufficient data for meta-analysis to be performed. However, given these limitations, inhaled and nebulized β -agonists, and IV insulin-and-glucose were all deemed effective. The combination of nebulized β -agonists with IV insulin-and-glucose appeared to be more effective than either agent alone. The meta-analysis results were equivocal for IV bicarbonate, and notably, SPS was not effective by 4 hours.

A major problem with drawing conclusions from this meta-analysis is the heterogeneity of the study population. Most of the data were from nonrandomized, noncontrolled observational studies and case reports. Doses of the drugs were not standardized and followup was often lacking. Therefore, the clinician should exercise caution when extrapolating these findings to their clinical practice. For example, SPS has been used clinically with good results for many years. However, the Cochrane database found few data to support its use. This underscores the need for clinicians to be able to interpret the limitations of the published literature. Nonetheless, the Cochrane database review corroborates the approach detailed in Fig. 54–2.

■ EVALUATION OF THERAPEUTIC OUTCOMES

The evaluation of therapeutic outcomes differs based on the severity of hyperkalemia. For example, mild or moderate asymptomatic hyperkalemia is observed much more frequently compared to symptomatic, severe hyperkalemia. Many drugs such as ACEIs, ARBs, and spironolactone result in asymptomatic hyperkalemia. In patients with normal renal function, once these drugs are initiated and the dose titrated, clinicians should check the potassium concentration at least monthly. For those patients with renal dysfunction, monitoring can be more frequent, such as biweekly until the dose is stabilized. In the case where the patient has been on a stable dose for a long period of time and hyperkalemia develops, the clinician should attempt to downward titrate the dose or switch to another medication without hyperkalemia as a side effect (e.g., calcium channel blocker).

In patients who have acute symptomatic hyperkalemia (e.g., ECG changes), frequent potassium concentration and ECG monitoring is warranted. The patient should receive continuous ECG telemetry monitoring until the serum potassium concentration decreases below 5 mEq/L, and the ECG abnormalities resolve. Similarly, while the patient is receiving emergent therapy, serial serum potassium concentrations should be obtained every hour until the potassium concentration decreases below 5 mEq/L. For patients who receive insulin and dextrose therapy for hyperkalemia, blood glucose monitoring should be performed hourly, or more frequently if patients demonstrate signs and symptoms of hypoglycemia. For patients who receive large doses of sodium bicarbonate therapy for hyperkalemia, an arterial blood gas or serum chemistry profile should be obtained to assess their acid–base status. Furthermore, the patient should be evaluated for signs of fluid overload secondary to the high sodium load. Patients receiving albuterol therapy should be questioned regularly regarding the development of palpitations and tachycardia. In asymptomatic patients receiving SPS, serum potassium concentrations can be

obtained within 4 hours, and the dose repeated as necessary. The patient's medication records should be reviewed to assure the patient is not receiving drug therapy that increases the serum potassium concentration. Furthermore, the patient should be questioned regarding the occurrence of diarrheal stool output.

DISORDERS OF MAGNESIUM HOMEOSTASIS

7 Magnesium plays a central role in cellular function and is an important cofactor in more than 300 biochemical reactions in the body, especially those systems that are dependent on adenosine triphosphate.²⁵ Mitochondrial function, protein synthesis, cell membrane function, and parathyroid hormone (PTH) secretion are just a few important functions affected by magnesium. It is the fourth most abundant extracellular cation and second most abundant intracellular cation. Disorders of magnesium homeostasis are commonly encountered in clinical situations and most frequently are manifested as alterations in cardiovascular and neuromuscular function. Life-threatening conditions such as paralysis and cardiac arrhythmias can occur, making the proper recognition and treatment of these problems of paramount importance.

8 Magnesium is principally distributed in bone (67%) and muscle (20%). Because of its predominantly intracellular distribution, measurement of magnesium in the extracellular compartment may not accurately reflect the total body magnesium content. The majority of magnesium in the extracellular fluid is in the ionized form as only 20% is bound to serum proteins. The normal range for serum magnesium is 1.4 to 1.8 mEq/L, which is equivalent to 1.7 to 2.3 mg/dL or 0.85 to 1.15 mmol/L.

The maintenance of magnesium homeostasis depends on the balance between intake and output. Thirty to forty percent of ingested magnesium is absorbed in the small bowel. A small amount is present in intestinal secretions and reabsorbed in the sigmoid colon. The kidneys play a major role in maintaining magnesium balance. Renal magnesium handling is unique in that approximately 20% of the filtered magnesium is reabsorbed in the proximal tubule; the majority of reabsorption occurs in the thick ascending limb of the loop of Henle.¹ This explains why loop diuretics often cause profound urinary magnesium wasting. Unlike most other important electrolytes, there is no hormonal regulation of the distribution of magnesium between bone and circulating or intracellular magnesium pools. Because of this, both hypomagnesemia and hypermagnesemia commonly occur.

HYPOMAGNESEMIA

Epidemiology

Hypomagnesemia is a common problem in both ambulatory and hospitalized patients. Although the exact prevalence is difficult to estimate, it has been reported that up to 65% of intensive care unit patients are magnesium deficient.²⁶ Although serum magnesium concentrations are not a reliable index of total body magnesium content, they remain the primary diagnostic tool to evaluate body stores.

Etiology and Pathophysiology

9 Hypomagnesemia is usually associated with disorders of the intestinal tract or kidney. Drugs or conditions that interfere with intestinal absorption or increase renal excretion of magnesium can result in hypomagnesemia (Table 54-6). Decreased intestinal absorption as a result of small bowel disease is the most common cause of hypomagnesemia worldwide. These disorders include regional enteritis; radiation enteritis; ulcerative colitis; acute and chronic diarrhea; pancreatic insufficiency and other malabsorptive syndromes; small-bowel bypass surgery; and chronic laxative abuse.²⁷ Hypomagnesemia is commonly

TABLE 54-6 Causes of Hypomagnesemia

Gastrointestinal

Reduced intake

- Protein-calorie malnutrition
- Prolonged parenteral fluid administration without magnesium
- Alcoholism

Reduced absorption

- Primary hypomagnesemia
- Malabsorption syndromes (e.g., tropical sprue, celiac disease, radiation enteritis, or intestinal lymphectasia)
- Short-bowel syndrome (e.g., small-bowel resection or ileal bypass)
- Pancreatic insufficiency

Increased loss

- Excessive vomiting
- Prolonged nasogastric suction
- Excessive laxative use
- Intestinal and biliary fistulas
- Prolonged diarrhea (ulcerative colitis, Crohn's disease, or cancer of the colon)

Renal

Primary tubular disorders

- Primary renal magnesium wasting
- Bartter syndrome
- Renal tubular acidosis
- Diuretic phase of acute tubular necrosis
- Postobstructive diuresis
- Postrenal transplant diuresis

Glomerulonephritis

Pyelonephritis

Drug-induced renal losses

- Aminoglycosides
- Amphotericin B
- Cyclosporine
- Diuretics
- Digitalis
- Cisplatin

Hormone-induced renal losses

- Primary hyperparathyroidism
- Hyperthyroidism
- Aldosteronism
- "Hungry bone syndrome" after parathyroidectomy

Internal redistribution

- Diabetic ketoacidosis
- Glucose, amino acid, or insulin administration
- Massive blood transfusion (citrate)
- Pancreatitis with lipidemia (magnesium soap)

Other

- Excessive sweating and lactation
- Hypercalcemia and hypercalciuria
- Phosphate depletion
- Chronic alcoholism
- Extracellular fluid volume expansion

associated with alcoholism. The etiology is often multifactorial, including reduced intake, pancreatic insufficiency, chronic vomiting and diarrhea, and urinary magnesium wasting. In addition, patients who are hospitalized for acute alcohol withdrawal often receive IV glucose and can experience even greater reductions in their serum magnesium concentration. Because hypomagnesemia can contribute to the development of delirium tremens associated with alcohol withdrawal, aggressive magnesium replacement is indicated for these patients, especially those with tachyarrhythmias, hypocalcemia, or hypokalemia.

Primary renal magnesium wasting can be caused by a defect in renal tubular magnesium reabsorption, or inhibition of sodium reabsorption in those segments in which magnesium transport follows passively. The former condition is associated with hypercalciuria, nephrolithiasis, and progressive renal disease. The latter is associated with Gitelman and Bartter syndromes.²⁸ Much more common than these is renal magnesium wasting secondary to thia-

zide and loop diuretics.²⁷ Other commonly used drugs that can cause renal magnesium wasting include aminoglycosides, amphotericin B, cyclosporine, tacrolimus, cisplatin, pentamidine, and foscarnet.²⁶

Clinical Presentation

Hypomagnesemia is typically an asymptomatic condition.²⁷ However, because hypomagnesemia is often associated with a variety of other electrolyte abnormalities such as hypokalemia and hypocalcemia, it is difficult to ascribe specific clinical manifestations solely to magnesium deficiency. Hypocalcemia is one of the most prominent symptoms of hypomagnesemia. The etiology of hypocalcemia is not entirely clear, but it is probably caused by decreased secretion of PTH, low 1,25-(OH)₂ vitamin D concentrations, and skeletal resistance to PTH.²⁸ As with hypokalemia, hypocalcemia accompanied by hypomagnesemia is most effectively treated with magnesium administration.

CLINICAL PRESENTATION OF HYPOMAGNESEMIA

General

- The dominant organ systems affected by hypomagnesemia are the neuromuscular and cardiovascular systems.

Symptoms

- Neuromuscular symptoms such as tetany, twitching, and generalized convulsions are common.
- Cardiac symptoms include heart palpitations.

Signs

- Neuromuscular: Presence of Chvostek sign, Trousseau sign, tremor, and tetany.
- Cardiovascular: Cardiac arrhythmias (ventricular fibrillation, torsade de pointes, or digoxin-induced arrhythmias), sudden cardiac death, and hypertension can be present. ECG abnormalities include widened QRS complex and peaked T waves with mild hypomagnesemia; and prolonged PR interval, progressive widening of QRS complex, and flattened T waves with moderate to severe hypomagnesemia.

Laboratory Tests

- Serum magnesium concentration less than 1.4 mEq/L. Serum potassium and calcium concentrations can also be low.

TREATMENT

Hypomagnesemia

■ DESIRED OUTCOME

The treatment goals in the management of hypomagnesemia are (1) resolution of the corresponding signs and symptoms, (2) restoration of normal magnesium concentrations, (3) correction of concomitant electrolyte abnormalities, and (4) identification and correction of the underlying cause of magnesium depletion.

■ GENERAL APPROACH TO TREATMENT

Nearly all of the data regarding magnesium replacement therapy have been derived from reports in acutely ill, hospitalized patients. Magnesium supplementation can be given by the oral, IM, or IV route. Table 54-7 outlines one approach to the hypomagnesemic patient. The severity of the magnesium depletion and the presence of severe signs and symptoms should dictate the route of administration. Because IM administration is painful, it should be reserved for those patients with severe hypomagnesemia and limited venous access. IV bolus

TABLE 54-7 Guidelines for Treatment of Magnesium Deficiency in Adults

1. Serum magnesium <1 mEq/L (1.2 mg/dL) with life-threatening symptoms (seizure or arrhythmia)	
<i>Day 1</i>	2 g magnesium sulfate (1 g magnesium sulfate = 8.1 mEq Mg ²⁺) mixed with 6 mL 0.9% NaCl in 10-mL syringe and administer IV push over 1 minute
	Follow with 1.0 mEq Mg ²⁺ /kg lean body weight IV infusion over 24 hours
<i>Days 2-5</i>	0.5 mEq Mg ²⁺ /kg lean body weight per day divided in maintenance IV fluids
2. Serum magnesium <1 mEq/L (1.2 mg/dL) without life-threatening symptoms	
<i>Day 1</i>	Total of 1 mEq Mg ²⁺ /kg lean body weight per day as continuous IV infusion, or divided and given IM every 4 hours for five doses
<i>Days 2-5</i>	0.5 mEq Mg ²⁺ /kg lean body weight IV infusion per day as continuous IV infusion or divided and given IM every 6-8 hours
3. Serum magnesium >1 mEq/L (1.2 mg/dL) and <1.5 mEq/L (1.8 mg/dL) without symptoms	
As in no. 2, above, or	
Milk of magnesia 5 mL four times daily as tolerated, or	
Magnesium-containing antacid 15 mL three times daily as tolerated, or	
Magnesium oxide tablets 400 mg four times daily; increase to two tablets four times daily as tolerated	

Mg²⁺, magnesium ion; NaCl, sodium chloride.

administration is associated with flushing, sweating, and a sensation of warmth; thus bolus administration should be avoided if possible. There have been no clinical trials assessing the optimal regimen for magnesium replacement, however, most clinicians agree that 8 to 12 g of magnesium sulfate in the first 24 hours followed by 4 to 6 g per day for 3 to 5 days is adequate to replete body stores.²⁷ Even if severe magnesium depletion is present, approximately 50% of the administered dose is excreted in the urine. Consequently, magnesium replacement should be performed over 3 to 5 days, and continued supplementation should be provided for patients unable to eat and for those patients with continued magnesium wasting.

■ PHARMACOLOGIC THERAPY

Asymptomatic patients, or those patients with serum magnesium concentrations greater than 1 mEq/L (1.2 mg/dL), can be treated with oral supplements, such as magnesium-containing antacids or laxatives, or magnesium oxide tablets or capsules. The typical dose of magnesium oxide is 400 to 800 mg given three or four times daily until repleted. However, as expected, diarrhea is the most common dose-limiting side effect of oral therapy, which can greatly reduce patient compliance. Moreover many oral products contain very little magnesium, which necessitates frequent dosing.

In cases of severe magnesium depletion (serum concentrations <1 mEq/L), or if signs and symptoms are present regardless of the serum concentration, IV magnesium should be administered. A 50% solution of magnesium sulfate is available for injection in 2-mL or 10-mL ampules (4 mEq/mL). The 50% solution should be diluted to 20% before injection to prevent venous sclerosis and pain. Therapy should be continued until the signs and symptoms have completely resolved. In patients with renal insufficiency, the dose should be reduced by 50%.

■ EVALUATION OF THERAPEUTIC ENDPOINTS

In patients with acute, asymptomatic mild to moderate hypomagnesemia receiving therapy, serum magnesium concentrations should be obtained at least daily during their hospitalization. Patients receiving oral magnesium therapy should be questioned regarding GI

TABLE 54-8 Causes of Hypermagnesemia

tolerance and the occurrence of diarrhea. Patients being treated for symptomatic severe hypomagnesemia should have their serum magnesium concentration monitored hourly until the serum concentration reaches 1.5 mEq/L and the symptoms resolve. At that point the serum magnesium concentration can be monitored every 6 to 12 hours for the next 24 hours while receiving magnesium supplementation. Once the magnesium concentration is stable in the normal range, a concentration can be obtained daily. It should be reiterated that it typically takes 3 to 5 days to fully replete total body magnesium stores.

FIGURE 54-3. Clinical findings associated with hypermagnesemia.

Patients receiving oral magnesium-containing antacids or supplements should be asked regularly about the occurrence of diarrhea.

HYPERMAGNESEMIA

Epidemiology

10 Hypermagnesemia (serum magnesium >2 mEq/L) is a rare occurrence that is generally seen in patients with stage 4 or 5 CKD when magnesium intake exceeds the excretory capacity of the kidneys. Elderly patients are prone to hypermagnesemia because of their reduced glomerular filtration rate (GFR) and because of their tendency to consume magnesium-containing antacids and vitamins.

Etiology and Pathophysiology

Because absolute magnesium excretion decreases as GFR declines, serum magnesium concentrations tend to increase in patients with moderate to severe CKD. Indeed, magnesium concentrations steadily increase as the GFR decreases below 30 mL/min/1.73m². As long as the patient maintains a normal diet, the serum magnesium concentration typically stabilizes at approximately 2.5 mEq/L. If patients with stage 4 or 5 CKD are taking concomitant magnesium-containing antacids, the serum concentration can approach 6 mEq/L, a value associated with signs and symptoms of toxicity. Critically ill patients with multiorgan system failure receiving enteral or parenteral nutrition are also prone to develop hypermagnesemia. Finally, the parenteral treatment of eclampsia with magnesium sulfate can lead to hypermagnesemia. Table 54-8 lists other causes of hypermagnesemia.

Clinical Presentation

The signs and symptoms of hypermagnesemia reflect magnesium's action on the neuromuscular and cardiovascular systems.²⁷ Symptoms are rare when the serum concentration is less than 4 mEq/L (Fig. 54-3).

TREATMENT

Hypermagnesemia

■ DESIRED OUTCOME

The goals of therapy are to (1) reverse the neuromuscular and cardiovascular manifestations of hypermagnesemia, (2) decrease the magnesium concentration toward normal values, and (3) identify and treat the underlying cause of hypermagnesemia.

■ PHARMACOLOGIC THERAPY

There are three primary means of treating hypermagnesemia: (1) reduce magnesium intake, (2) enhance elimination of magnesium, and (3) antagonize the physiologic effects of magnesium. The optimal treatment regimen for the management of hypermagnesemia depends on the presence of signs and symptoms and the degree of serum concentration elevation. Intravenous calcium in doses of 100 to 200 mg of elemental calcium directly antagonizes the neuromuscular and cardiovascular effects of hypermagnesemia. Oral calcium is not used because of its relatively poor bioavailability and lack of immediate onset. The clinical effect of calcium is immediate, but the effect is transient; hence repeated intravenous doses of 100 to 200 mg of elemental calcium might need to be administered hourly until the symptoms abate and the magnesium concentration is normalized. Supportive care with cardiac pacing, vasopressors, and mechanical ventilation can be necessary in life-threatening situations. In patients with normal renal function, or those with

stage 1, 2, or 3 CKD, forced diuresis with saline and loop diuretics can promote magnesium elimination. An initial loop diuretic intravenous bolus of furosemide 40 mg or a similar equivalent can be used. Subsequent dosing can be determined based on the patient's clinical response. Patients with CKD can require long-term loop diuretic therapy to maintain adequate fluid and electrolyte balance. In dialysis patients, their hemodialysis prescription should be changed to employ magnesium-free dialysate.

■ EVALUATION OF THERAPEUTIC ENDPOINTS

Patients who are receiving intravenous calcium salts for the treatment of severe, symptomatic hypermagnesemia should have their serum magnesium concentration evaluated hourly until symptoms abate and the magnesium concentration decreases below 4 mg/dL. Furthermore the patient should be continuously monitored to detect ECG changes. In CKD patients who can produce urine, forced diuresis with saline and furosemide should reduce the serum magnesium concentration within 6 to 12 hours. Close monitoring of the urine output and physical examination for signs of volume overload are important. Emergency hemodialysis will usually correct the hypermagnesemia within 4 hours and is a reasonable option for those who are currently receiving hemodialysis. To prevent further episodes of hypermagnesemia, the patient should receive dietary education regarding foods and beverages that contain large quantities of magnesium.

In conclusion, disorders of potassium and magnesium are frequently encountered in both the acute care and community ambulatory care settings. If severe, these disorders can have catastrophic results. Clinicians should be able to identify patients at risk for these common electrolyte disorders and quickly design appropriate pharmacotherapy and monitoring regimens to optimize patient outcomes.

ABBREVIATIONS

ACEI: angiotensin-converting enzyme inhibitor

ARB: angiotensin-II receptor blocker

ARF: acute renal failure

CKD: chronic kidney disease

ECG: electrocardiogram

ESRD: end-stage renal disease

GI: gastrointestinal

NSAID: nonsteroidal antiinflammatory drug

PTH: parathyroid hormone

SPS: sodium polystyrene sulfonate

JOHN W. DEVLIN, GARY R. MATZKE, AND PAUL M. PALEVSKY

KEY CONCEPTS

- 1 The kidney plays a central role in the regulation of acid–base homeostasis through the excretion or reabsorption of filtered bicarbonate (HCO_3^-), the excretion of metabolic fixed acids and generation of new HCO_3^- .
- 2 Arterial blood gases, along with serum electrolytes, physical findings, medical and medication history, and the clinical condition of the patient, are the primary tools to determine the cause of an acid–base disorder and to design and monitor a course of therapy.
- 3 Metabolic acidosis and metabolic alkalosis are generated by a primary change in the serum bicarbonate concentration. In metabolic acidosis, bicarbonate is lost or a nonvolatile acid is gained, whereas metabolic alkalosis is characterized by a gain in bicarbonate or a loss of nonvolatile acid.
- 4 Renal tubular acidosis refers to a group of disorders characterized by impaired tubular renal acid handling despite normal or near-normal glomerular filtration rates. These patients often present with hyperchloremic metabolic acidosis.
- 5 Respiratory compensation for a primary metabolic acidosis begins rapidly (within 15 to 30 minutes) but does not reach a steady state for 12 to 24 hours after the onset of metabolic acidosis.
- 6 Primary therapy of most acid–base disorders must include treatment or elimination of the underlying cause, not just correction of the pH and electrolyte disturbances.
- 7 Potassium supplementation is always necessary for patients with chronic metabolic acidosis, as the bicarbonaturia resulting from alkali therapy increases the renal potassium wasting.
- 8 Effective treatment of the underlying cause of some organic acidoses (e.g., ketoacidosis) can result in the regeneration of bicarbonate within hours, thus mitigating the need for alkali therapy.
- 9 Loss of gastric acid from vomiting or nasogastric suctioning is often responsible for the development of a metabolic alkalosis, characterized by hypochloremia and hyperbicarbonatemia.
- 10 Aggressive diuretic therapy can produce a metabolic alkalosis, and the accompanying hypokalemia can be serious.
- 11 The patient's response to volume replacement can be predicted by the urine chloride concentration and permits the differential diagnosis of metabolic alkalosis.
- 12 Management of these disorders usually consists of treatment of the underlying cause of mineralocorticoid excess. In patients in whom the mineralocorticoid excess cannot be corrected, chronic pharmacologic therapy can be required.
- 13 In most cases of acute metabolic acidosis, such as following cardiopulmonary arrest, sodium bicarbonate therapy is not indicated and can be detrimental. Blood gas analysis should guide therapy.

Acid–base disorders are common, and often serious, disturbances that can result in significant morbidity and mortality. This chapter reviews the mechanisms responsible for the maintenance of acid–base balance and the laboratory analyses that aid clinicians in their assessment of acid–base disorders. The pathophysiology of the four primary acid–base disturbances is presented, the therapeutic options are critiqued, and guidelines for the achievement of the desired therapeutic outcomes are presented. Because many drugs affect acid–base homeostasis and many acid–base abnormalities are potentially preventable, clinicians must anticipate drug-related problems to avoid or minimize the clinical consequences, and when necessary, design appropriate treatment regimens.

ACID–BASE CHEMISTRY

An acid (in this equation, hydrochloric acid $[\text{HCl}]$) is a substance that can *donate* protons (hydrogen ion $[\text{H}^+]$):

A base (in this equation, ammonia $[\text{NH}_3]$) is a substance that can *accept* protons (hydrogen ion $[\text{H}^+]$):

The acid–base pairs commonly encountered in clinical practice are listed in Table 55–1.

The acidity of body fluids is quantified in terms of the hydrogen ion concentration. By convention, the degree of acidity is expressed as pH, or the negative logarithm (base 10) of the hydrogen ion concentration. Thus hydrogen ion concentration and pH are inversely related. Normally, the pH of blood is maintained at 7.40 ($[\text{H}^+]$ of 4×10^{-8} M) with a range of 7.35 to 7.45. A pH of less than 6.7 ($[\text{H}^+]$ of 2×10^{-7} M), representing a fivefold increase in hydrogen ion concentration, or greater than 7.7 ($[\text{H}^+]$ of 2×10^{-8} M), representing a 50% decrease in hydrogen ion concentration, are considered incompatible with life.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

TABLE 55-1 Acid–Base Pairs

Carbonic acid/bicarbonate	H ₂ CO ₃ /HCO ₃ [−]
Monobasic/dibasic phosphate	H ₂ PO ₄ /HPO ₄ [−]
Ammonium/ammonia	NH ₄ ⁺ /NH ₃
Lactic acid/lactate	H ₃ C ₃ O ₂ /H ₂ C ₃ O ₂ [−]

The hydrogen ion concentration in blood may not be indicative of that in other body compartments. For example, the pH within cells, within the cerebrospinal fluid, or on the surface of bone can all be altered without causing an alteration in blood pH.¹ Recognizing this caveat, the acid–base status of the body is usually analyzed based on measurement of blood pH. Alterations in blood pH serve as the basis for the diagnosis of acid–base disorders.

Because the dissociation of acid–base pairs is an equilibrium reaction, the relationship between hydrogen ion concentration or pH and the relative concentrations of the acid and base can be described mathematically in terms of the dissociation constant for the acid–base buffer pair. When expressed as a logarithmic relationship, where pK is the negative logarithm of the dissociation constant K, this is known as the Henderson-Hasselbalch equation:

$$pH = pK + \log([base]/[acid])$$

BUFFERS

The ability of a weak acid and its corresponding anion (base) to resist change in the pH of a solution on the addition of a strong acid or base is referred to as *buffering*. An acid–base pair is most efficient in functioning as a buffer at a pH close to its pK. The principal extracellular buffer is the carbonic acid/bicarbonate (H₂CO₃/HCO₃[−]) system. Other physiologic buffers include plasma proteins, hemoglobin, and phosphates. Because the isohydric principle requires that all buffer systems remain in chemical equilibrium, the complex buffering of biologic fluids can be analyzed based on a single buffer pair.

The carbonic acid/bicarbonate buffer system plays a unique role in acid–base homeostasis. In addition to being the most abundant extracellular buffer, the components of this buffer pair are under dynamic regulation by the body. In the presence of carbonic anhydrase, carbonic acid, [H₂CO₃] is in equilibrium with carbon dioxide (CO₂) gas. Changes in ventilation that alter the partial pressure of CO₂ (PCO₂) in the blood regulates the carbonic acid level in the blood. The bicarbonate concentration is independently regulated by the kidney. Because the pK for the carbonic acid/bicarbonate system is 6.1, the relationship between pH, carbonic acid, and bicarbonate concentrations can be described by the Henderson-Hasselbalch equation. The concentration of carbonic acid is directly proportional to the amount of CO₂ dissolved in blood, which is equal to the product of PCO₂ and its solubility in physiologic fluids, (PCO₂ × 0.03). This term can therefore be substituted into the equation below in place of [H₂CO₃].

$$pH = 6.1 + ([HCO_3^-]/[H_2CO_3])$$
$$pH = 6.1 + \log([HCO_3^-]/(PCO_2 \times 0.03))$$

Thus, hydrogen ion concentration and pH are determined not by the absolute amounts of bicarbonate and PCO₂, but by their ratio.¹ Under normal physiologic conditions, the kidneys maintain the serum bicarbonate at approximately 24 mEq/L (24 mmol/L), whereas the lungs maintain the PCO₂ at approximately 40 mm Hg. The normal physiologic pH is thus 7.4:

$$pH = 6.1 + \log[24/(0.03 \times 40)]$$
$$pH = 6.1 + 1.3 = 7.4$$

If, in response to an acid load, the serum bicarbonate concentration were to decrease to 12 mEq/L [12 mmol/L], the predicted pH would be:

$$[HCO_3^-] = 12 \text{ mEq/L (12 mmol/L)}$$
$$PCO_2 = 40 \text{ mm Hg}$$
$$pH = 6.1 + \log[12/(0.03 \times 40)]$$
$$pH = 6.1 + 1.0 = 7.1$$

However, the normal respiratory response to an acid load is hyperventilation. As a result, if the PCO₂ decreased to approximately 26 mm Hg, the change in pH would be less:

$$[HCO_3^-] = 12 \text{ mEq/L (12 mmol/L)}$$
$$PCO_2 = 26 \text{ mm Hg}$$
$$pH = 6.1 + \log[12/(0.03 \times 26)]$$
$$pH = 6.1 + 1.19 = 7.29$$

Thus, the physiologic regulation of both PCO₂ and [HCO₃[−]] permit the carbonic acid/bicarbonate system to provide more effective buffering of the extracellular fluids than could be achieved on the basis of chemical buffering alone.

REGULATION OF ACID–BASE HOMEOSTASIS

Cellular metabolism results in the production of large quantities of hydrogen that need to be excreted to maintain acid–base balance. In addition, small amounts of acid and alkali are also presented to the body through the diet. The bulk of acid production is in the form of CO₂, with the average adult producing approximately 15,000 mmol of CO₂ each day from the catabolism of carbohydrate, protein, and fat.² When respiratory function is normal, the amount of CO₂ produced metabolically is equal to the amount lost by respiration, and the blood CO₂ concentration remains constant.

Digestion of dietary substances and tissue metabolism also results in the production of nonvolatile acids. These acids are derived primarily from the sulfur-containing amino acids cysteine and methionine, as well as from ingested sulfur. In addition, phosphates are generated from the metabolism of proteins and phospholipids. Neutral substances such as glucose can also be incompletely metabolized to intermediates, such as lactic and pyruvic acid, and fatty acids can be incompletely metabolized to acetoacetic acid and β-hydroxybutyric acid. These dietary and metabolic fixed acids are excreted, primarily by the kidney, to maintain acid–base homeostasis. On average, daily fixed acid excretion is approximately 0.8 mEq/kg per day.³

Three mechanisms, each of which vary in their onset, collectively maintain acid–base balance: extracellular buffering, ventilatory regulation of carbon dioxide elimination, and renal regulation of hydrogen ion and bicarbonate excretion. Extracellular buffering occurs rapidly and is the body’s first defense against a sudden increase in hydrogen ion concentration. Hyperventilation will then result in a decrease in PCO₂, returning blood pH toward normal. Finally, the kidney will excrete the excess hydrogen ion, with the resultant return of acid–base balance to normal over a period of day(s).

EXTRACELLULAR BUFFERING

The body’s buffering system can be divided into three components: bicarbonate/carbonic acid, proteins, and phosphates. The bicarbonate buffer is the most important of the body’s buffers, because (1) there is more bicarbonate present in the extracellular fluid (ECF) than any other buffer component; (2) the supply of carbon dioxide is unlimited; and (3) the acidity of ECF can be regulated by controlling either the bicarbonate concentration or the PCO₂.

Carbonic acid represents the respiratory component of the buffer pair because its concentration is directly proportional to the PCO_2 , which is determined by ventilation. Bicarbonate represents the metabolic component because the kidney may alter its concentration by reabsorption, generating new bicarbonate, or altering elimination.⁴ The bicarbonate buffer system easily adapts to changes in acid–base status by alterations in ventilatory elimination of acid (PCO_2) and/or renal elimination of base (HCO_3^-).

The phosphate buffer system consists of serum inorganic phosphate (3.5 to 5 mg/dL [1.2 to 1.6 mmol/L]), intracellular organic phosphate, and calcium phosphate in bone. Extracellular phosphate is present only in low concentrations, so its usefulness as a buffer is limited; however, as an intracellular buffer, phosphate is more useful. Calcium phosphate in bone is relatively inaccessible as a buffer, but prolonged metabolic acidosis will result in the release of phosphate from bone.

Intracellular and extracellular proteins also act as buffering systems. The charged side chains of amino acids provide the buffering action. Because the concentration of protein is much greater intracellularly than extracellularly, protein is much more important as an intracellular buffer.

RESPIRATORY REGULATION

The second mechanism for maintenance of acid–base homeostasis is control of ventilation. Both the rate and depth of ventilation can be varied to allow for excretion of CO_2 generated by diet and tissue metabolism. Medullary chemoreceptors in the brainstem sense changes in PCO_2 and in pH and modulate the control of breathing. Increasing minute ventilation (the total amount of air exhaled over a 1-minute period), by increasing respiratory rate and/or tidal volume (the amount of air exhaled in one breath), will increase CO_2 excretion and decrease the blood PCO_2 . Conversely, decreasing minute ventilation decreases CO_2 excretion and increases blood PCO_2 . This system rapidly adjusts, within minutes, to changes in acid–base balance.²

RENAL REGULATION

1 Because bicarbonate is a small ion, it is freely filtered at the glomerulus. The bicarbonate load delivered to the nephron is approximately 4,500 mEq/day. To maintain acid–base balance, this entire filtered load must be reabsorbed. Bicarbonate reabsorption occurs primarily in the proximal tubule (Fig. 55–1). In the tubular lumen, filtered bicarbonate combines with hydrogen ion secreted by the apical sodium ion (Na^+)- H^+ -exchanger to form carbonic acid. The carbonic acid is rapidly broken down to CO_2 and water by carbonic anhydrase located on the luminal surface of the brush border membrane. The CO_2 then diffuses into the proximal tubular cell, where it reforms carbonic acid in the presence of intracellular carbonic anhydrase. The carbonic acid dissociates to form hydrogen ion, that can again be secreted into the tubular lumen, and bicarbonate that exits the cell across the basolateral membrane and enters the peritubular capillary.

Excretion of metabolic fixed acids and generation of new HCO_3^- is achieved through renal ammoniogenesis and distal tubular hydrogen ion secretion. Ammoniogenesis plays a critical role in acid–base homeostasis, with ammonium (NH_4^+) excretion comprising approximately 50% of renal net acid excretion. Ammonium is generated from the deamination of glutamine in the proximal tubule. For each ammonium ion excreted in the urine, one bicarbonate ion is regenerated and returned to the circulation.⁵

Distal tubular hydrogen ion secretion accounts for the remaining 50% of net acid excretion (Fig. 55–2). In the distal tubular cell, CO_2 combines with water in the presence of intracellular carbonic

FIGURE 55-1. Proximal tubular bicarbonate reabsorption. In the tubular lumen, filtered bicarbonate (HCO_3^-) combines with hydrogen ion (H^+) secreted by an apical sodium ion (Na^+)- H^+ -exchanger to form carbonic acid (H_2CO_3). The carbonic acid is rapidly broken down to carbon dioxide (CO_2) and water by carbonic anhydrase located on the luminal surface of the brush border membrane. The CO_2 then diffuses into the proximal tubular cell, where it reforms carbonic acid in the presence of intracellular carbonic anhydrase. The carbonic acid dissociates to form hydrogen ion, that can again be secreted into the tubular lumen, and bicarbonate that exits the cell across the basolateral membrane and enters the peritubular capillary.

anhydrase to form carbonic acid, which dissociates to H^+ and HCO_3^- . The H^+ is actively transported into the tubular lumen by a H^+ -adenosine triphosphatase (ATPase). The bicarbonate exits the cell across the basolateral membrane and enters the circulation.⁵

ACID–BASE DISTURBANCES

Alterations in blood pH are designated by the suffix “-emia”; *acidemia* is an arterial blood pH <7.35 and *alkalemia* is an arterial

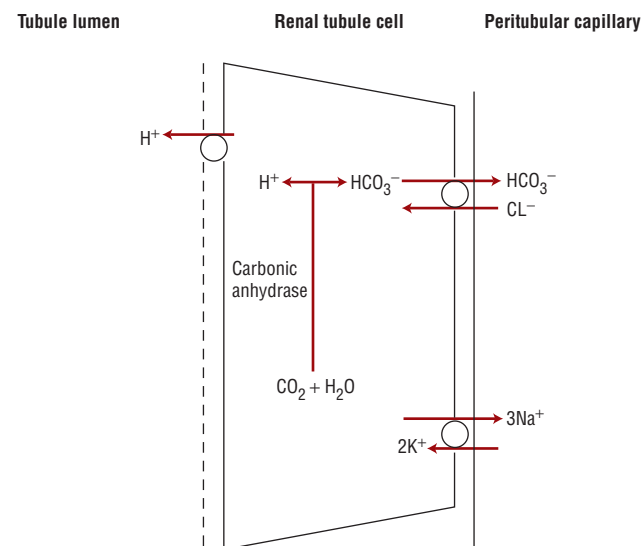

FIGURE 55-2. Collecting duct acid excretion. Hydrogen ion (H^+) and bicarbonate (HCO_3^-) are generated intracellularly from carbon dioxide (CO_2) and water, in the presence of intracellular carbonic anhydrase. The hydrogen ion is actively secreted into the tubular lumen by H^+ -adenosine triphosphatase (ATPase) located in the apical (luminal) membrane. Bicarbonate exits the cell across the basolateral membrane and enters the peritubular capillary. (Cl^- , chloride ion; Na^+ , sodium ion.)

TABLE 55-2 Interpretation of Simple Acid–Base Disorders			
Acid–Base Disorder	pH	Primary Disturbances	Compensation
Acidosis			
Respiratory	Decrease	Increase PaCO ₂	Increase HCO ₃ [−]
Metabolic	Decrease	Decrease HCO ₃ [−]	Decrease PaCO ₂
Alkalosis			
Respiratory	Increase	Decrease PaCO ₂	Decrease HCO ₃ [−]
Metabolic	Increase	Increase HCO ₃ [−]	Increase PaCO ₂

HCO₃[−], bicarbonate; PaCO₂, partial pressure of carbon dioxide from arterial blood.

blood pH >7.45. The pathophysiologic processes that result in alterations in blood pH are designated by the suffix “-osis.” These disturbances are classified as either metabolic or respiratory in origin. In metabolic acid–base disorders, the primary disturbance is in the plasma bicarbonate concentration. Metabolic acidosis is characterized by a decrease in the plasma bicarbonate concentration whereas in metabolic alkalosis the plasma bicarbonate concentration is increased. Respiratory acid–base disorders are caused by alterations in alveolar ventilation that produce corresponding changes in the partial pressure of carbon dioxide from arterial blood (PaCO₂). In respiratory acidosis, the PaCO₂ is elevated; in respiratory alkalosis it is decreased. Each disturbance has a compensatory (secondary) response that attempts to correct the [HCO₃[−]]:PaCO₂ ratio toward normal and mitigate the change in pH (Table 55–2). Although the time course of the respiratory compensatory responses to metabolic disturbances is rapid, the metabolic compensation for respiratory disturbances is slow. As a result, respiratory disturbances are characterized as acute (minutes to hours in duration), indicating that there has not been sufficient time for metabolic compensation, or chronic (days), indicating sufficient time for metabolic compensation has elapsed.

CLINICAL ASSESSMENT OF ACID–BASE STATUS

2 Blood gases are measured to determine the patient’s oxygenation and acid–base status. Under normal circumstances, there is no clinically significant difference in pH between arterial and mixed venous blood. Arterial samples are designated with the letter “a” (e.g., partial pressure of oxygen from arterial blood [PaO₂] and PaCO₂), whereas mixed venous samples are labeled with the letter “v” or not labeled (e.g., partial pressure of oxygen from venous blood [PvO₂] and partial pressure of carbon dioxide from venous blood [PvCO₂]). The normal values for arterial and venous blood gases are shown in Table 55–3. Arterial blood reflects how well the blood is being oxygenated by the lungs (an accurate measurement of PaO₂), whereas venous blood reflects how much oxygen tissues are using. Arterial blood rather than venous blood should be used whenever possible because venous blood obtained from an extremity can

TABLE 55-3 Normal Blood Gas Values		
	Arterial Blood	Mixed Venous Blood
pH	7.40 (7.35–7.45)	7.38 (7.33–7.43)
PO ₂	80–100 mm Hg	35–40 mm Hg
SAO ₂	95%	70%–75%
PCO ₂	35–45 mm Hg	45–51 mm Hg
HCO ₃ [−]	22–26 mEq/L (22–26 mmol/L)	24–28 mEq/L (24–28 mmol/L)

HCO₃[−], bicarbonate; PCO₂, partial pressure of carbon dioxide; PO₂, partial pressure of oxygen; SAO₂, saturation of arterial oxygen.

provide misleading information. If metabolism in the extremity is altered by hypoperfusion, exercise, infection, or some other cause, the difference in the amount of dissolved oxygen between arterial and venous blood can be dramatic. The venous pH and PCO₂ during cardiopulmonary resuscitation, might be significantly lower and higher, respectively, than the arterial pH and arterial PCO₂. This indicates a severe tissue acidosis from CO₂ accumulation caused by hypoperfusion.

ANALYSIS OF ARTERIAL BLOOD GAS DATA

Arterial blood gases provide an assessment of the patient’s acid–base status. Low pH values (<7.35) indicate an acidemia, whereas high pH values (>7.45) indicate an alkalemia (Fig. 55–3). In a metabolic acidosis, the pH is decreased in association with a decreased serum bicarbonate concentration and a compensatory decrease in PaCO₂. In a respiratory acidosis, the pH is decreased; the PaCO₂, however, is elevated. The serum bicarbonate concentration is variable, depending on whether it is an acute disturbance (minimal increase in serum bicarbonate) or a chronic respiratory acidosis (substantial increase in serum bicarbonate). In a metabolic alkalosis, the pH is elevated in association with an increased bicarbonate concentration and a compensatory increase in PaCO₂. In respiratory alkalosis, the pH is also elevated; the PaCO₂, however, is decreased. As with respiratory acidosis, the metabolic compensation is variable, with a minimal decrease in serum bicarbonate in acute respiratory alkalosis and a larger decrease in [HCO₃[−]] in chronic respiratory alkalosis. Although each measurement has a normal range (see Table 55–3), it is often easiest to consider the midpoint of each range as the normal value. This would correlate to a pH of 7.4, PaCO₂ of 40 mm Hg and HCO₃[−] of 24 mEq/L (24 mmol/L). Steps in acid–base interpretation are described in Table 55–4.

When arterial blood gases differ significantly from those expected on the basis of the patient’s clinical condition and previous laboratory determinations, additional venous blood samples should be drawn to assess plasma electrolyte concentrations. The bicarbonate calculated from the patient’s PaCO₂ and pH of the blood gas should be compared with the measured total CO₂ content (the amount of CO₂ gas extractable from plasma, consisting of HCO₃[−], H₂CO₃, and PCO₂). Ordinarily, the blood gas bicarbonate value is approximately

FIGURE 55-3. Analysis of arterial blood gases. (HCO₃[−], bicarbonate; PCO₂, partial pressure of carbon dioxide.)

TABLE 55-4 Steps in Acid–Base Diagnosis

1. Obtain arterial blood gases (ABGs) and electrolytes simultaneously.
2. Compare $[\text{HCO}_3^-]$ on ABG and electrolytes to verify accuracy.
3. Calculate anion gap (AG).
4. Is acidemia (pH <7.35) or alkalemia (pH >7.45) present?
5. Is the primary abnormality respiratory (alteration in PaCO_2) or metabolic (alteration in HCO_3^-)?
6. Estimate compensatory response (Table 55–7)
7. Compare change in $[\text{Cl}^-]$ with change in $[\text{Na}^+]$

$[\text{Cl}^-]$, chloride ion; $[\text{HCO}_3^-]$, bicarbonate; $[\text{Na}^+]$, sodium ion; PaCO_2 , partial pressure of carbon dioxide from arterial blood.

1 to 2 mEq/L (1 to 2 mmol/L) less than total CO_2 content.³ If these values do not correspond, the results should be interpreted with caution because the difference can reflect an error in the blood collection or storage of the sample, or in the calibration of the blood gas analyzer.

METABOLIC ACID–BASE DISORDERS

METABOLIC ACIDOSIS

Pathophysiology

Metabolic acidosis is characterized by a decrease in pH as the result of a primary decrease in serum bicarbonate concentration. This can result from the buffering (consumption of HCO_3^-) of an exogenous acid, an organic acid accumulating because of a metabolic disturbance (e.g., lactic acid or ketoacids), or the progressive accumulation of endogenous acids secondary to impaired renal function (e.g., phosphates and sulfates).⁶ The serum HCO_3^- can also be decreased as the result of a loss of bicarbonate-rich body fluids (e.g., diarrhea, biliary drainage, or pancreatic fistula) or occur secondary to the rapid administration of non-alkali-containing intravenous fluids (dilutional acidosis).

The serum anion gap (SAG), as defined below, can be used to infer whether an organic or mineral acidosis is present.

$$\text{SAG} = [\text{Na}^+] - [\text{Cl}^-] - [\text{HCO}_3^-]$$

To maintain electroneutrality, the total concentration of cations in the serum must equal the total concentration of anions.

$$[\text{Na}^+] + [\text{UCs}] = ([\text{Cl}^-] + [\text{HCO}_3^-]) + [\text{UAs}]$$

The cation concentration is equal to the sodium concentration plus that of “unmeasured” cations (UCs), predominantly magnesium, calcium, and potassium. The anion concentration is equal to the concentrations of chloride, bicarbonate, and “unmeasured” anions (UAs), including proteins, sulfates, phosphates, and organic anions. Therefore, as the result of the combination of the two equations above, the SAG can be expressed as:

$$\text{SAG} = [\text{UAs}] - [\text{UCs}]$$

The normal SAG is approximately 9 mEq/L (9 mmol/L), with a range of 3 to 11 mEq/L (3 to 11 mmol/L). This value is lower than the value of 12 mEq/L (12 mmol/L) cited in the literature in the past because of changes in the instrumentation for measurement of serum electrolytes.⁷ Increases in the anion gap to values in excess of 17 to 20 mEq/L (17 to 20 mmol/L) are indicative of the accumulation of unmeasured anions in ECF.

These unmeasured anions are generated as the result of the consumption of HCO_3^- by endogenous organic acids such as lactic acid, acetoacetic acid, or β -hydroxybutyric acid or from the ingestion of toxins such as methanol or ethylene glycol. The degree of elevation

in the SAG is dependent on the clearance of the anion, as well as the multiple factors that influence HCO_3^- concentrations. Thus the SAG is a relative rather than an absolute indication of the cause of metabolic acidosis. The SAG can also be elevated in the metabolic acidosis because of renal failure, as the result of the accumulation of various organic anions, phosphates, and sulfates.

In hyperchloremic metabolic acidosis, bicarbonate losses from the ECF are replaced by chloride, and the SAG remains normal. This decrease in bicarbonate results from losses from the gastrointestinal tract, dilution of bicarbonate in the ECF space by the addition of sodium chloride solutions, or the addition of chloride-containing acids to the ECF. Common causes of metabolic acidosis with an increased or a normal SAG are listed in Table 55–5.

Hyperchloremic Metabolic Acidosis

Hyperchloremic metabolic acidosis can result from increased gastrointestinal bicarbonate loss, renal bicarbonate wasting, impaired renal acid excretion, or exogenous acid gain. Gastrointestinal disorders such as diarrhea, biliary or pancreatic drainage through either a surgical drain or fistula can result in the loss of large volumes of bicarbonate-containing fluids. Severe diarrhea, the most common cause of hypochloremic metabolic acidosis, can lead to a daily loss of 5 to 10 L of fluid containing 100 to 140 mEq/L (100 to 140 mmol/L) of sodium, 20 to 40 mEq/L (20 to 40 mmol/L) of potassium, 80 to 100 mEq/L (80 to 100 mmol/L) of chloride, and 30 to 50 mEq/L (30 to 50 mmol/L) of bicarbonate.⁴ Patients who have undergone ureteral diversion into the sigmoid colon or isolated ileal loop can also develop a hyperchloremic metabolic acidosis. In these patients, chloride is reabsorbed, and the bicarbonate secreted by the gas-

TABLE 55-5 Common Causes of Metabolic Acidosis

Increased Serum Anion Gap	Normal Serum Anion Gap/ Hyperchloremic States
Lactic acidosis	Gastrointestinal bicarbonate loss
Diabetic ketoacidosis	Diarrhea
Lactic acidosis (see Table 55–6)	External pancreatic or small bowel drainage (fistula)
Renal failure (acute or chronic)	Ureterosigmoidostomy, ileostomy
Methanol ingestion	Drugs
Ethylene glycol ingestion	Cholestyramine (bile acid diarrhea)
Salicylate overdosage	Magnesium sulfate (diarrhea)
Starvation	Calcium chloride (acidifying agent)
	Renal tubular acidosis
	Hypokalemia
	Proximal renal tubular acidosis (type II)
	Distal renal tubular acidosis (type I)
	Carbonic anhydrase inhibitors (e.g., acetazolamide)
	Hyperkalemia
	Generalized distal nephron dysfunction (type IV)
	Mineralocorticoid deficiency or resistance
	Tubulointerstitial disease
	Drug-induced hyperkalemia
	Potassium-sparing diuretics (amiloride, spironolactone, triamterene)
	Trimethoprim
	Pentamidine
	Heparin
	Angiotensin-converting enzyme (ACE) inhibitors and receptor blockers
	Nonsteroidal antiinflammatory drugs (NSAIDs)
	Cyclosporin A
	Other
	Acid ingestion (ammonium chloride, hydrochloric acid, hyperalimentation)
	Expansion acidosis (rapid saline administration)

trointestinal epithelial cells while urine retained in the colon or bowel loop results in a net loss of bicarbonate.

Hyperchloremic metabolic acidosis caused by renal bicarbonate wasting is the defining disturbance in proximal renal tubular acidosis and is a complication of therapy with carbonic anhydrase inhibitors. During the treatment of diabetic ketoacidosis, renal loss of β -hydroxybutyrate and acetoacetate, which would otherwise be metabolized to yield bicarbonate, can contribute to the development of hyperchloremic metabolic acidosis. Impaired renal acid excretion that occurs as a result of distal tubular dysfunction in patients with distal renal tubular acidosis can also occur in patients with moderate to severe renal insufficiency from other causes. The metabolic acidosis of renal insufficiency is initially hyperchloremic but can progress to an anion-gap acidosis as the renal insufficiency worsens and sulfates, phosphates, and other anions accumulate. Hyperchloremic metabolic acidosis can also result from the exogenous administration of acid (hydrochloric acid, ammonium chloride) or the unbuffered administration of acid salts from the amino acids in total parenteral nutrition fluids.

Renal Tubular Acidosis

④ Renal tubular disorders can involve the proximal tubule, with a resultant failure to reabsorb filtered bicarbonate, or affect acid excretion in the distal tubule. The distal renal tubular acidosis (RTAs) are the most common, and are all characterized by impaired net acid excretion. The distal RTAs are subdivided into those that are associated with hypokalemia (type I) and those associated with hyperkalemia (type IV). Patients with classic distal (type I) RTA have impaired hydrogen ion secretion and are unable to excrete the daily acid load necessary to maintain acid–base balance.⁴ These patients are unable to maximally acidify their urine (i.e., attain urine pH of <5.5), even in the face of an acid challenge. Type I RTA may be the result of a primary tubular defect or develop secondary to a wide variety of disorders including hypercalcemia, multiple myeloma, systemic lupus erythematosus, Sjögren syndrome, sickle-cell disease, and renal transplant rejection, or following the administration of amphotericin B or ingestion of toluene. The primary form of this disorder usually occurs in children and can result in severe acidosis, slowed growth, nephrocalcinosis, and kidney stones.^{7,8} In adults, clinical complications include osteomalacia, nephrocalcinosis, and recurrent kidney stones. The hypokalemia associated with classic distal (type I) RTA results from secondary hypoaldosteronism associated with volume depletion. The renal potassium wasting decreases considerably if bicarbonate therapy is administered.

The hyperkalemic distal (type IV) RTAs are a heterogeneous group of disorders characterized by hypoaldosteronism or generalized distal tubule defects. The most common form of type IV RTA is hyporeninemic hypoaldosteronism. This syndrome is most commonly associated with mild renal insufficiency caused by diabetic nephropathy, but can also be seen in a variety of other disorders, including chronic interstitial nephritis, sickle-cell disease, human immunodeficiency virus (HIV) nephropathy, and obstructive uropathy. The clinical presentation of this syndrome is often exacerbated by pharmacologic therapy with agents that can interfere with the renin-angiotensin-aldosterone axis, such as β -adrenergic blockers, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and nonsteroidal antiinflammatory drugs. Heparin can induce the syndrome by inhibiting adrenal aldosterone biosynthesis. Patients with this form of RTA are able to maximally acidify their urine (urine pH <5.5).⁷ The primary defect in acid excretion is impaired ammoniogenesis caused by mild renal insufficiency. Hyperaldosteronism predisposes to the development of hyperkalemia, which results in further impairment of ammoniogenesis.

Treatment to control the hyperkalemia is usually sufficient to reverse the metabolic acidosis, and mineralocorticoid replacement is frequently unnecessary.

Hyperkalemic distal (type IV) RTA resulting from generalized distal tubule defects is less common than hyporeninemic hypoaldosteronism but is more common than classic distal (type I) RTA. Patients with this defect have impaired tubular potassium secretion in addition to impaired urinary acidification (urine pH >5.5 despite acidemia or acid loading). Urinary obstruction is the most frequent cause of this disorder, which can also be associated with sickle-cell nephropathy, systemic lupus erythematosus, HIV nephropathy, analgesic abuse nephropathy, amyloidosis, renal transplant rejection, and chronic cyclosporine nephrotoxicity.

Proximal (type II) RTA is characterized by defects in proximal tubular reabsorption of bicarbonate. Normally, more than 85% of filtered bicarbonate is reabsorbed in the proximal tubule. Defects in proximal tubular bicarbonate reabsorption result in increased delivery of bicarbonate to the distal nephron, which has a limited capacity for bicarbonate reabsorption. As a result, at a normal serum bicarbonate concentration, the filtered bicarbonate load is incompletely reabsorbed, and is lost in the urine. As the serum bicarbonate concentration decreases, the filtered load of bicarbonate is proportionately decreased. A new equilibrium is established in which the kidney is able to reabsorb the filtered bicarbonate load, albeit at a reduced serum bicarbonate concentration. Thus patients with proximal RTA present with a chronic, nonprogressive hyperchloremic metabolic acidosis. These patients are able to acidify their urine in response to an acid load, but develop bicarbonaturia at a reduced serum bicarbonate concentration following bicarbonate loading. The impaired bicarbonate reabsorption results in salt wasting and secondary hyperaldosteronism. Hypokalemia, which can be severe, usually develops as a result of the hyperaldosteronism and bicarbonaturia.^{4,7} Unlike patients with classic distal (type I) RTA, the hyperkalemia if present in proximal RTA is exacerbated by alkali replacement. Proximal RTA can develop as an isolated defect, or it can be associated with generalized proximal tubular dysfunction (Fanconi syndrome), with impaired proximal tubular glucose, phosphate, and amino acid reabsorption. Proximal RTA usually presents as an acquired disorder, secondary to a variety of diseases (amyloidosis, multiple myeloma, or nephrotic syndrome) or exposure to toxins (lead, cadmium, mercury, or outdated tetracyclines). Pharmacologic therapy with carbonic anhydrase inhibitors produces an iatrogenic form of proximal RTA.

Elevated Anion Gap Metabolic Acidosis

Metabolic acidosis with an increased SAG commonly results from increased endogenous organic acid production. In lactic acidosis, lactic acid accumulates as a by-product of anaerobic metabolism. Accumulation of the ketoacids β -hydroxybutyric acid and acetoacetic acid defines the ketoacidosis of uncontrolled diabetes mellitus, alcohol intoxication, and starvation (see Table 55–5). In advanced renal failure, accumulation of phosphate, sulfate, and organic anions is responsible for the increased SAG, which is usually less than 24 mEq/L.⁹ The severe metabolic acidosis seen in myoglobinuric acute renal failure caused by rhabdomyolysis may be caused by the metabolism of large amounts of sulfur-containing amino acids released from myoglobin.

The presence of mild elevations in the SAG cannot be automatically attributed to the presence of a high SAG metabolic acidosis. Elevations in the SAG are commonly seen in hospitalized patients, especially those who are critically ill.¹⁰ A variety of factors can contribute to this nonspecific elevation in the SAG, including the presence of alkalemia, which increases the anionic charge of albumin and other plasma proteins. The usefulness of the SAG as a marker of acid–base status is dependent on proper interpretation of a patient's

clinical status.^{8,9} Despite these limitations, when the SAG exceeds 20 to 25 mEq/L a significant organic acidosis is likely to be present.

High anion gap metabolic acidosis can develop in many clinical settings, including uncontrolled diabetes mellitus (see Chap. 77), alcohol intoxication (see Chaps. 39 and 69), and starvation (see Chap. 66). Toxic ingestions of methanol and ethylene glycol, are also associated with high anion gap metabolic acidosis and can be differentiated from other causes of SAG because of the presence of an elevated osmolar gap (see Chap. 10). The mechanisms responsible for the development of acidosis in these settings are diverse.

Lactic Acidosis Lactic acidosis is one of the most common causes of high SAG metabolic acidosis and can impact approximately 1% of hospitalized patients. Lactic acid is the end product of anaerobic metabolism of glucose (glycolysis). In normal individuals, lactic acid derived from pyruvate enters the circulation in small amounts and is promptly removed by the liver. In the liver, and to a lesser extent in the kidney, lactic acid is reoxidized to pyruvic acid, which is then metabolized to CO₂ and H₂O. The normal plasma lactate concentration in healthy subjects is approximately 1 mEq/L.^{6,11} The diagnosis of lactic acidosis should be considered in all patients with metabolic acidosis associated with an increased SAG. Lactic acidosis is considered to be present when lactate concentrations exceed 4 to 5 mEq/L in an acidemic patient.

Classically, lactic acidosis has been differentiated into disorders associated with tissue hypoxia (type A lactic acidosis) and disorders associated with deranged oxidative metabolism (type B lactic acidosis), although the distinction between them is blurred (Table 55-6). The etiologies of lactic acidosis can also be categorized on the basis of changes in lactate production and/or utilization.^{4,12} Metabolic disturbances can result in increased tissue pyruvate production or impaired utilization, with proportional increases in lactate concentrations. Increased lactate production is more commonly associated with alterations in tissue redox state, resulting in preferential conversion of pyruvate to lactate. During anaerobic metabolism, reduced nicotinamide adenine dinucleotide accumulates, driving the conversion of pyruvate to lactate and increasing the lactate:pyruvate ratio. States of enhanced metabolic activity (e.g., grand mal seizures, strenuous exercise, or hyperthermia), decreased tissue oxygen deliv-

ery (e.g., severe anemia, hypoxia, circulatory shock, or carbon monoxide poisoning) or impaired oxygen utilization (e.g., cyanide toxicity) all are associated with lactic acidosis. Impaired hepatic clearance of lactate, as seen in hypoperfusion states, liver failure, and alcohol intoxication, can also result in lactic acidosis.

Cardiovascular and septic shock, with resultant tissue hypoperfusion, are the most common causes of lactic acidosis. Poor tissue perfusion and hypoxia influence enzymatic pyruvate and lactate metabolism to stimulate anaerobic glycolysis and to decrease lactate utilization. This leads to hyperlactatemia and lactic acidosis. The mortality rate of this type of lactic acidosis can be as high as 80% and correlates with the degree of hyperlactatemia.

Lactic acidosis associated with liver disease, toxins, and congenital enzyme deficiency can be caused by deranged oxidative metabolism or impaired lactate clearance.^{4,12} The exact role of diabetes mellitus in the induction of lactic acidosis is not clear. It may involve a decrease in pyruvate dehydrogenase activity, the enzyme responsible for pyruvate metabolism. Lactic acidosis in neoplastic disease is uncommon and reported mostly in patients with myeloproliferative disorders. Leukocytes and neoplastic cells in general have high rates of glycolysis. In the case of a large tumor or tightly packed bone marrow, oxygenation can be decreased, favoring the accumulation of lactate. Lactic acidosis has been reported in patients with massive liver tumors, and it has been postulated that the liver uptake of lactate is decreased in these patients. Lactic acidosis associated with seizures is usually transient and occurs because of excessive muscle activity.⁶

A number of medications can cause lactic acidosis.¹³⁻¹⁵ Two of the most common medications associated with the development of lactic acidosis are nucleoside-analog reverse transcriptase inhibitors (NRTIs) (3.9 cases per 1,000 person years) and metformin (0.03 cases per 1,000 person years).^{13,14} The proposed mechanism of NRTI-induced lactic acidosis is the inhibition of the enzyme DNA polymerase gamma that is responsible for mitochondrial DNA synthesis.¹³ Disruption of this enzyme can inhibit the transport of lactate into the mitochondria, leading to an accumulation in the cytoplasm. Stavudine is the NRTI most frequently associated with lactic acidosis, however the combination of stavudine and didanosine confers the highest risk.

The exact mechanism for metformin-induced lactic acidosis is not completely understood and may occur through a number of pathways including a decrease in hepatic intracellular pH, decreasing cardiac output, increasing gut production of lactate, and increased renal loss of bicarbonate.¹⁴ Risk factors for metformin-induced lactic acidosis include the presence of cardiovascular, pulmonary, renal, and hepatic disorders. Metformin should be discontinued during periods of tissue hypoxia (e.g., myocardial infarction, sepsis), for 3 days after contrast media has been administered or 2 days before general anesthesia administration. In the latter two cases, metformin should only be reinstituted when the patient's renal function is stable.

Propylene glycol is commonly used as a solubilizing agent in intravenous drug preparations (e.g., lorazepam) and is predominantly metabolized to lactic acid via the hepatic enzyme alcohol dehydrogenase. The administration of large doses of propylene glycol, particularly to patients with renal or liver insufficiency, can lead to a lactic acidosis with an osmolar gap and thus serial measurement of the osmolar gap can be used to detect propylene glycol accumulation.¹⁵

CLINICAL PRESENTATION

Chronic metabolic acidosis is usually not associated with severe acidemia and is relatively asymptomatic. The major manifestations are in the bones, where chronic acidemia causes bone demineralization with the development of rickets in children and osteomalacia

TABLE 55-6 Causes of Lactic Acidosis

Primary decrease in tissue oxygenation
Shock
Severe anemia
Congestive heart failure
Asphyxia
Carbon monoxide poisoning
Deranged oxidative metabolism
Medications
Catecholamines
Linezolid
Metformin
Nalidixic acid
Nucleoside-analog reverse transcriptase inhibitors (didanosine, stavudine, zidovudine)
Overdose (iron, isoniazid, salicylates, theophylline)
Propofol infusion syndrome
Propylene glycol toxicity (IV lorazepam)
Sodium nitroprusside (secondary to cyanide toxicity)
Streptozocin
Diabetes mellitus
Malignancy
Seizures
Methanol, ethanol, or ethylene glycol
Disorders associated with inborn errors of metabolism

and osteopenia in adults. In infants and children, chronic metabolic acidosis is associated with growth failure and short stature and can be associated with nonspecific symptoms including anorexia, nausea, weight loss, and muscle weakness.

CLINICAL PRESENTATION OF METABOLIC ACIDOSIS

General

- The patient is usually relatively asymptomatic if the acidosis is acute and mild. In those with severe acidemia (pH <7.15 to 7.20) the cardiovascular, respiratory, and central nervous systems can be affected.

Symptoms

- The patient may complain of loss of appetite, nausea, and vomiting.

Signs

- Cardiac: Flushing, a rapid heart rate, wide pulse pressure, and an increase in cardiac output can be seen initially. This can be followed by a reduction in cardiac output, blood pressure, and liver and kidney blood flow.
- Cerebral: Obtundation or coma.
- Metabolic: Insulin resistance; increased protein degradation; increased metabolic demands.
- Gastrointestinal: Nausea, vomiting, loss of appetite.
- Respiratory: Dyspnea, hyperventilation with deep, rapid respirations is seen in those with severe acidosis.
- Chronic acidemia causes bone demineralization with the development of rickets in children and osteomalacia and osteopenia in adults.

Laboratory Tests

- Serum CO₂ is low. Hyperglycemia and hyperkalemia are common. Patients with a pH <7.2 are deemed to have a severe acidosis.

Severe metabolic acidosis is usually associated with acute processes. The manifestations of severe acidemia (pH <7.20) involve the cardiovascular, respiratory, and central nervous systems. Hyperventilation is often the first sign of metabolic acidosis. At a pH of 7.2, pulmonary ventilation increases approximately fourfold, and an eightfold increase has been noted at a pH of 7.16. Respiratory compensation can occur as Kussmaul respirations—the deep, rapid respirations seen commonly in patients with diabetic ketoacidosis. In extremely severe acidosis (pH <6.8), CNS function is disrupted to such a degree that the respiratory center is depressed.

CNS depression correlates more closely with spinal fluid pH than with blood pH. For this reason, neurologic symptoms tend to occur more frequently and to a greater degree in patients with respiratory acidosis because the CO₂ accumulated in the respiratory form readily crosses the blood-brain barrier to cause acidosis in the CNS.¹ Because of the slow penetration of administered bicarbonate into the CNS, the CNS pH fails to normalize as rapidly as blood pH. Therefore patients continue to hyperventilate because of sustained CNS acidity, and severe respiratory alkalosis can occur. Sustained lowering of the PaCO₂ within 12 to 36 hours is to be anticipated during the correction of any metabolic acidosis.¹

Systemic acidosis can cause peripheral arteriolar dilatation, characterized by flushing, a rapid heart rate, and wide pulse pressure. Initially, cardiac output can be increased, but as acidosis becomes more severe, myocardial contractility becomes impaired, and cardiac output decreases. The effects of vagal stimulation are also enhanced at pH levels lower than 7.1, probably as a consequence of

TABLE 55-7 Guidelines for Initial Interpretation of Acid–Base Disorders

Acidosis	
Metabolic	PaCO ₂ (in mm Hg) should decrease by 1.3 times the fall in plasma [HCO ₃ ⁻] (in mEq/L)
Acute respiratory	The plasma [HCO ₃ ⁻] should increase by 0.1 times the increase in PaCO ₂ ± 3
Chronic respiratory	The plasma [HCO ₃ ⁻] should increase by 0.35 times the increase in PaCO ₂ ± 4
Alkalosis	
Metabolic	PaCO ₂ (in mm Hg) should increase by 0.4–0.6 times the rise in plasma [HCO ₃ ⁻] (in mEq/L)
Acute respiratory	The plasma [HCO ₃ ⁻] should decrease by 0.2 times the decrease in PaCO ₂ but usually not to less than 18 mEq/L
Chronic respiratory	The plasma [HCO ₃ ⁻] should fall by 0.35 times the decrease in PaCO ₂ but usually not to less than 14 mEq/L

HCO₃⁻, bicarbonate; PaCO₂, partial pressure of carbon dioxide from arterial blood.

inhibition of acetylcholinesterase. This increases the danger of vagally mediated bradycardia and heart block during acidosis.

Gastrointestinal symptoms of metabolic acidosis include loss of appetite, nausea, and vomiting. Severe acidosis (pH <7.1) interferes with carbohydrate metabolism and insulin utilization, and results in hyperglycemia. Metabolic acidosis alters potassium homeostasis and contributes to the development of hyperkalemia. The magnitude of the effect on serum potassium depends on the type of acidosis: Acidosis caused by mineral acids (e.g., hydrochloric acid) are associated with a greater change in potassium levels than acidosis caused by organic acids (e.g., lactic acidosis), in which the increase in potassium attributable to the acidosis per se is minimal.

COMPENSATION

5 The patient's primary means to compensate for metabolic acidosis is to increase carbon dioxide excretion by increasing respiratory rate. This results in a decrease in PaCO₂. This ventilatory compensation results from stimulation of the respiratory center by changes in cerebral bicarbonate concentration and pH.¹ For every 1-mEq/L (1 mmol/L) decrease in bicarbonate concentration below the average of 24, the PaCO₂ decreases by approximately 1 to 1.5 mm Hg from the normal value of 40 (Table 55–7).

The anticipated PaCO₂ associated with a given bicarbonate concentration for patients with uncomplicated metabolic acidosis can be calculated as¹⁷:

$$\text{PaCO}_2 = (1.5 \times [\text{HCO}_3^-]) + 8 \pm 2$$

For example, 95% of patients with a plasma bicarbonate of 16 mEq/L (16 mmol/L) should have an arterial PCO₂ of 30 to 34 mm Hg. An observed arterial PCO₂ within this range is consistent with physiologic respiratory compensation for a metabolic acidosis and suggests that there is no respiratory disturbance. In contrast, if the PCO₂ is less than 30 mm Hg, a superimposed respiratory alkalosis can be present, whereas if the PCO₂ is greater than 34 mm Hg, a superimposed respiratory acidosis is likely present.

TREATMENT

Metabolic Acidosis

■ CHRONIC METABOLIC ACIDOSIS

6 Asymptomatic patients with mild to moderate degrees of acidemia (plasma bicarbonate of 12 to 20 mEq/L ([12 to 20 mmol/L]; pH

TABLE 55-8 Therapeutic Alternatives for Oral Alkali Replacement

Generic Name	Trade Name(s)	Milliequivalents of Alkali	Dosage Form (s)	Comment
Shohl solution	Bicitra (Willen)	1 mEq Na/mL; equivalent to 1 mEq bicarbonate	Solution (500 mg Na citrate, 334 mg citric acid/5 mL)	Citrate preparations increase absorption of aluminum Bicarbonate preparations can cause bloating because of CO ₂ production
Sodium citrate/citric acid	Various (e.g., Sodamint)	3.9 mEq bicarbonate/tablet (325 mg)	325 mg tablet	
Sodium bicarbonate		7.8 mEq bicarbonate/tablet (650 mg)	650 mg tablet	
	Baking soda (various)	60 mEq bicarbonate/tsp (5 g/tsp)	Powder	
Potassium citrate	Urocit-K (Mission)	5 mEq citrate/tablet	5 mEq tablet	See above
Potassium bicarbonate/potassium citrate	K-Lyte (Bristol)	25 mEq bicarbonate/tablet	25 mEq tablet (effervescent)	
	K-Lyte DS (Bristol)	50 mEq bicarbonate/tablet (double strength)	50 mEq tablet (effervescent)	See above
Potassium citrate/citric acid	Polycitra-K (Willen)	2 mEq K/mL; equivalent to 2 mEq bicarbonate	Solution (1100 mg K citrate, 334 mg citric acid/5 mL)	See above
		30 mEq bicarbonate/unit dose packet	Crystals for reconstitution (3300 mg K citrate, 1002 mg citric acid/unit dose packet)	
Sodium citrate/potassium citrate/citric acid	Polycitra (Willen) Polycitra-LC (Willen)	1 mEq K, 1 mEq Na/mL; equivalent to 2 mEq bicarbonate	Syrup (Polycitra) solution (Polycitra-LC) (Both contain 550 mg K citrate, 500 mg Na citrate, 334 mg citric acid/5 mL)	See above

of 7.2 to 7.4) do not require emergent therapy. They can usually be managed with gradual correction of the acidemia, over a period of days to weeks, using oral sodium bicarbonate or other alkali preparations (Table 55–8). In all forms of chronic metabolic acidosis, primary therapy should be directed at treating the underlying disease state. Gastrointestinal pathology should be treated to reduce ongoing bicarbonate losses, and factors that exacerbate RTA should be treated. If acidemia persists, alkali therapy should be instituted with the goal of normalization of blood pH. The loading dose (LD) of alkali to initially correct the acidemia can be calculated as follows where V_D is the volume of distribution of bicarbonate¹⁸:

$$LD(\text{mEq}) = (V_D \text{HCO}_3^- \times \text{body weight [BW]}) \times (\text{desired } [\text{HCO}_3^-] - \text{current } [\text{HCO}_3^-])$$

For a 60-kg patient with a serum bicarbonate of 15 mEq/L (24 mmol/L to 15 mmol/L), the loading dose is calculated thusly:

$$\begin{aligned} LD(\text{mEq}) &= (0.5 \text{ L/kg} \times 60 \text{ kg}) \times (24 \text{ mEq/L} - 15 \text{ mEq/L}) \\ &= 30 \text{ L} \times 9 \text{ mEq/L} \\ &= 270 \text{ mEq/L} \end{aligned}$$

The calculated loading dose of alkali should be administered over several days to avoid volume overload from the accompanying sodium load. For this scenario, a regimen of 60 to 70 mEq (60 to 70 mmol) three times a day for 3 to 5 days should result in an increase in HCO_3^- levels toward normal. In addition to the calculated loading dose, supplemental alkali must also be provided to replace ongoing losses, which can be approximated to be 2 mEq/kg (2 mmol/kg) per day or 40 mEq (40 mmol) three times a day. In patients with associated volume depletion, bicarbonate replacement can be provided simultaneous with volume resuscitation by substituting bicarbonate for chloride in intravenous crystalloid solutions.

In patients with chronic metabolic acidosis because of gastrointestinal bicarbonate losses, maintenance therapy should provide sufficient alkali to replace ongoing bicarbonate losses. The magnitude of this replacement is variable and can be substantial (>10 mEq/kg [10 mmol/kg] per day). In addition, associated losses of other electrolytes, such as potassium and magnesium, may need to be replaced (see Chap. 54).

Proximal (type II) RTA is a bicarbonate-wasting disorder that requires the administration of large maintenance doses of alkali (10 to 15 mEq/kg [10 to 15 mmol/kg] per day). As alkali replacement raises the serum bicarbonate concentration toward normal, the proximal tubule's capacity to reabsorb bicarbonate is overwhelmed, and renal bicarbonate wasting increases. In children, aggressive therapy of proximal RTA is necessary to avoid growth retardation and osteopenia. Because this is generally a mild, nonprogressive acidosis in adults, the benefit of alkali therapy is frequently outweighed by the risks of increased potassium wasting. In patients with classic distal (type I) RTA, maintenance therapy usually requires only enough alkali to buffer the amount of acid generated from dietary intake and metabolism. This usually approximates 1 to 3 mEq/kg per day (1 to 3 mmol/kg).

7 After initial potassium deficits are replaced, ongoing potassium supplementation may not be required, as renal potassium losses decrease following initiation of appropriate alkali therapy. The use of potassium alkali salts can, however, be desirable in patients with associated nephrolithiasis, because sodium salts can increase urinary calcium excretion.

The metabolic acidosis associated with hyperkalemic distal (type IV) RTA with hyporeninemic-hypoaldosteronemia that is often seen in patients with diabetes mellitus can be corrected by the treatment of hyperkalemia alone (see Chap. 54). The use of supplemental alkali (1 to 2 mEq/kg [1 to 2 mmol/kg] per day) to increase sodium intake and stimulate distal tubular potassium secretion can be beneficial. A minority of patients require the administration of pharmacologic amounts of fludrocortisone.⁴ Type IV RTA resulting from a generalized distal tubular disorder often responds to low doses of alkali (1.5 to 2.0 mEq/kg [1.5 to 2.0 mmol/kg] per day).¹⁹ Corrections of the acidosis along with modest dietary potassium restriction (to 1 mEq/kg per day) will often result in the maintenance of serum potassium levels of 5 mEq/L (5 mmol/L) or less.

ACUTE SEVERE METABOLIC ACIDOSIS

8 The management of patients with life-threatening acute metabolic acidosis (plasma bicarbonate of 8 mEq/L [8 mmol/L] and pH <7.20) is dependent on the underlying cause and the patient's cardiovascular status. In some cases patients will require emergent hemodialysis

therapy (see Chap. 48). Patients with hyperchloremic acidosis (e.g., diarrhea-induced) are unable to regenerate bicarbonate, and the generation of new bicarbonate by the kidneys can require several days before one can observe a meaningful change in their status.¹¹ Thus intravenous alkali therapy is often required for these patients.

CLINICAL CONTROVERSY

The role of alkali therapy in patients with severe lactic acidosis is controversial. Treatment should be directed at the underlying causes as serial bicarbonate administration is often not effective and in some settings can be deleterious.

Although conventional wisdom recommends the use of alkali replacement in patients with severe acidemia caused by the deleterious effects of acidemia on circulatory function,^{6,11,12} studies have not demonstrated improved outcome with alkali replacement.^{20–23}

There are several therapeutic alternatives available for the acute correction of severe metabolic acidosis. Sodium acetate, sodium citrate, and sodium lactate are unreliable sources of alkali because their alkalinizing effect is dependent on their oxidative conversion to bicarbonate. This process is often impaired in critically ill patients, especially those with liver disease or circulatory failure. Although sodium bicarbonate is the most widely used intravenous alkalotic agent,¹¹ several studies suggest that it is frequently ineffective and can actually be deleterious, especially in patients with lactic acidosis.^{20–23} Two of the three remaining alternatives (Carbicarb and dichloroacetate) are investigational and not available in most clinical settings. Tromethamine, or THAM, is a carbon dioxide-consuming, commercially available solution that buffers respiratory as well as metabolic acids.

■ SODIUM BICARBONATE

In theory, sodium bicarbonate administration provides fluid and electrolyte replacement and increases arterial pH, thereby improving cardiac function, perfusion and oxygenation of peripheral tissues, and intracellular pH, and should therefore decrease lactate production and increase clearance. However, sodium bicarbonate administration can actually have paradoxical adverse effects on intracellular pH. When bicarbonate is given by IV infusion, the carbon dioxide generated diffuses more readily than bicarbonate across cell membranes and into cerebrospinal fluid. Therefore the intracellular pH can actually be decreased by administration of bicarbonate.⁴

CLINICAL CONTROVERSY

Although it has been recommended that sodium bicarbonate be administered to raise the arterial pH to approximately 7.20, there are no controlled clinical trials demonstrating that sodium bicarbonate administration is significantly better than general supportive care in reducing morbidity and mortality in these patients.^{4,11,20–23}

Excessive sodium bicarbonate administration can result in (1) a shift of the oxyhemoglobin saturation curve to the left thereby impairing oxygen release from hemoglobin to tissues; (2) sodium and water overload, with subsequent pulmonary congestion and hypernatremia; (3) paradoxical tissue acidosis as a result of the production of CO₂ that freely diffuses into myocardial and cerebral cells;²⁴ and (4) decreased ionized calcium with a resultant decrease in myocardial contractility. If there is an endogenous source of bicarbonate, such as can occur in the case of ketoacidosis or lactic acidosis, a bicarbonate “overshoot” can develop because the ketoac-

ids (acetoacetic acid and β -hydroxybutyric acid) or lactic acid are converted in the liver to bicarbonate once the underlying cause of acidosis is corrected.^{10,11,25} Alkalosis can also result if too much sodium bicarbonate is administered too quickly.

If intravenous sodium bicarbonate is used, one must be mindful that the goals are to increase, not normalize, pH (to approximately 7.20) and plasma bicarbonate (to 8 to 10 mEq/L [8 to 10 mmol/L]). There is no calculative method that will assure attainment of these goals with a given dose of sodium bicarbonate because of the multiplicity of competing processes that can affect acid–base status (e.g., vomiting, potential increases in endogenous acid production, and renal failure) and the marked variability in the volume of distribution of bicarbonate (50% of body weight in patients with mild acidosis to approximately 100% in those with severe acidosis).¹⁸ Adrogue and Madias¹¹ recommended that the dose of sodium bicarbonate be calculated using a distribution volume of 50% of body weight for all patients to avoid overtreatment. The total dose calculated as described previously in the RTA section should be administered as an infusion over one-half to several hours. Followup monitoring of arterial blood gases, beginning no sooner than 30 minutes after the end of the infusion, should be used to guide further therapeutic decisions.

Bicarbonate therapy is generally not necessary in the routine patient with cardiac arrest, even if the initial arrest was unmonitored. The standards and guidelines from the National Conference on Cardiopulmonary and Emergency Cardiac Care state that sodium bicarbonate is most useful in cardiac life support when combined with ventilation in an attempt to maintain near-normal arterial pH during an arrest.²⁶ During a cardiac arrest, sodium bicarbonate (initial dose 1 mEq/kg [1 mmol/kg]) can be administered by rapid, direct intravenous injection. It should be used only after more proven interventions such as defibrillation, cardiac compression, support of ventilation including intubation, and drug therapies such as epinephrine and antiarrhythmic agents have been employed. Subsequent doses of sodium bicarbonate should be based on measurements of arterial blood pH and PaCO₂.

■ TROMETHAMINE

THAM, available as a 0.3 N solution, is a highly alkaline, sodium-free organic amine that acts as a proton acceptor to prevent or correct acidosis.²⁷ THAM combines with hydrogen ions from carbonic acid to form bicarbonate and a cationic buffer. THAM also acts as an osmotic diuretic to increase urine flow, urine pH, and the excretion of fixed acids, CO₂, and electrolytes. At pH 7.4, 30% of THAM is not ionized and therefore can penetrate into cells and neutralize acidic anions of the intracellular fluid. Intracellular pH increases have been noted within 1 hour after the infusion of THAM. There is, however, no clinical or physiologic evidence that this action is beneficial, or that THAM is more efficacious than sodium bicarbonate.^{11,28}

When THAM is used, it must be administered slowly, with careful monitoring to avoid alkalosis. The usual empiric dosage range for tromethamine is 1 to 5 mmol/kg administered intravenously over 1 hour, but doses up to 1.25 mmol/kg can be given over 5 to 15 minutes in acute situations. The dose of THAM can be individualized using the following equation²⁷:

Dose of THAM (in mL) = 1.1 × BW (in kilograms) × base deficit
where base deficit = normal [HCO₃⁻] minus current [HCO₃⁻].

The need for additional THAM is determined by serial measurements of the serum bicarbonate concentration and calculation of the base deficit. Large doses can cause respiratory depression as a result of an increase in blood pH and a decrease in PaCO₂ concentration.²⁸ THAM solution is highly alkaline and can cause severe inflammation, vascular spasm, or tissue damage (necrosis, sloughing, pain, chemical phlebitis, or thrombosis) if infiltration occurs.

Hyperkalemia, hypoglycemia, hypocalcemia, and impaired coagulation have also been reported.^{28,29} This agent should only be used with extreme caution in patients with severe liver or kidney failure.

■ CARBICARB

Carbicarb is an equimolar mixture of sodium carbonate (Na_2CO_3) and sodium bicarbonate (NaHCO_3).^{30,31} It is no longer commercially available in Canada, and its use in the United States remains investigational. Given that the carbonate ion is a stronger base than bicarbonate, Carbicarb preferentially buffers hydrogen ions resulting in the formation of bicarbonate rather than CO_2 . Thus Carbicarb limits, but does not eliminate, the generation of CO_2 . Unlike bicarbonate, which can produce a paradoxical intracellular acidosis and thereby impair cardiac function, Carbicarb appears to correct intracellular acidosis if present.^{32,33} The risk of hypervolemia and hypertonicity after Carbicarb administration is similar to that of bicarbonate. The small number of trials reporting the clinical utility of this agent and its continued investigational status in most of the world limits its use and availability for the foreseeable future.

■ DICHLOROACETATE

Dichloroacetate (DCA), another investigational agent, facilitates aerobic lactate metabolism by stimulating the activity of lactate dehydrogenase, thus reversing hyperlactatemia and elevating blood pH.^{34,35} DCA, when compared to conventional management in controlled studies, however, has not been shown to improve outcome.^{34,36,37} DCA can cause mild drowsiness and peripheral neuropathy, that can be ameliorated or prevented with thiamine supplementation.³⁵ The future role of DCA in the management of metabolic acidosis, particularly lactic acidosis, remains to be clarified.

METABOLIC ALKALOSIS

Pathophysiology

Metabolic alkalosis is a simple acid-base disorder that presents as alkalemia (increased arterial pH) with an increase in plasma bicarbonate. It is an extremely common entity in hospitalized patients with acid-base disturbances. Under normal circumstances, the kidney is readily able to excrete an alkali load. Thus evaluation of patients with metabolic alkalosis must consider two separate issues: (1) the initial process that generates the metabolic alkalosis; and (2) alterations in renal function that maintain the alkalemic state.^{38,39}

Generation ⑨ The generation of metabolic alkalosis can also result from excessive losses of hydrogen ion from the kidneys or stomach or from a gain secondary to the ingestion or administration of bicarbonate-rich fluids. Gastric juice, rich in chloride and hydrogen ion, is secreted at a rate of less than 50 mL/h in the basal state, but can increase up to fivefold with stimulation. In the gastric parietal cells, hydrogen ion and bicarbonate are generated from CO_2 and water.³⁹ The hydrogen ion is secreted into gastric fluid, and the bicarbonate is retained in the ECF. Normally, an amount of bicarbonate equal to the bicarbonate generated in the stomach is eliminated in the alkaline pancreatic and small-bowel secretions, maintaining hydrogen ion balance. With vomiting and nasogastric suctioning, hydrogen ion is lost externally and metabolic alkalosis results. Diarrhea, as seen with secretory villous adenomas and other secretory diarrheas, often results in excessive gastrointestinal losses of chloride-rich, bicarbonate-poor fluid and thus leads to the generation of metabolic alkalosis.

⑩ Diuretic agents acting on the thick ascending limb of the loop of Henle (e.g., furosemide, bumetanide, and torsemide) and distal convoluted tubule (e.g., thiazides), have most commonly been associated with the generation of metabolic alkalosis.⁴⁰ These agents promote the excretion of sodium and potassium almost exclusively

in association with chloride, without a proportionate increase in bicarbonate excretion. Collecting duct hydrogen ion secretion is stimulated directly by the increased luminal flow rate and sodium delivery, and indirectly by intravascular volume contraction, which results in secondary hyperaldosteronism. Renal ammoniogenesis can also be stimulated by concomitant hypokalemia, further augmenting net acid excretion.

Increased renal acid excretion can also be the result of excess mineralocorticoid activity. Elevated mineralocorticoid levels directly stimulate collecting duct hydrogen ion secretion and indirectly increase ammoniogenesis by causing hypokalemia.¹⁶ Increased mineralocorticoid activity can result from Cushing's syndrome, primary hyperaldosteronism, or hyperaldosteronism secondary to increased renin activity (e.g., malignant hypertension). In Bartter's and Gitelman's syndromes, defects in sodium transport in the loop of Henle (Bartter's) or distal convoluted tubule (Gitelman's) lead to hypokalemia, secondary hyperaldosteronism, and metabolic alkalosis.³⁹ In Liddle's syndrome, enhanced sodium reabsorption by the cortical collecting duct epithelial sodium channel results in a syndrome of pseudohyperaldosteronism.³⁸ Administration of high doses of penicillins (e.g., ticarcillin) can produce metabolic alkalosis because they act as nonreabsorbable anions. High concentrations of poorly reabsorbable anions in the distal renal tubule increase luminal flow rate and luminal electronegativity, which enhances the secretion of potassium and hydrogen ion and results in hypokalemia and metabolic alkalosis.

Metabolic alkalosis can also be generated by the gain of exogenous alkali. This can be seen as a result of bicarbonate administration or from the infusion of organic anions that are metabolized to bicarbonate, such as acetate, lactate, and citrate. The milk-alkali syndrome was historically a common cause of metabolic alkalosis in patients with peptic ulcer disease secondary to the ingestion of large quantities of milk products and antacids. With the advent of alternative therapies for dyspeptic syndromes that are far more effective than milk, this syndrome is now rarely seen.

Maintenance Metabolic alkalosis is predominantly maintained because of an abnormality in renal function. Normally, the kidneys are capable of excreting all of the excess bicarbonate presented to them, even during periods of increased bicarbonate loads.⁴ As the serum bicarbonate concentration increases, the filtered bicarbonate load exceeds the maximal rate for bicarbonate reabsorption, and the excess bicarbonate is excreted in the urine. Under normal circumstances, the excess bicarbonate is rapidly excreted, and metabolic alkalosis does not occur or is corrected in a matter of hours.³⁹

⑪ Several mechanisms can impair renal bicarbonate excretion and contribute to the maintenance phase of metabolic alkalosis.³⁸ In general, these mechanisms can be divided into volume-mediated processes (sodium chloride-responsive) and volume-independent processes (sodium chloride-resistant) that are predominantly associated with excess mineralocorticoid activity and hypokalemia (Table 55-9). Intravascular volume depletion maintains metabolic alkalosis through a number of mechanisms. Decreases in the glomerular filtration rate reduce the filtered load of bicarbonate at any given serum concentration, thereby decreasing the kidney's ability to excrete a bicarbonate load. Although this can play a role in patients with chronic kidney disease, it is also an important factor in patients in whom intravascular volume contraction accompanies metabolic alkalosis. Decreased effective arterial blood volume also enhances proximal and distal tubular sodium reabsorption. Sodium reabsorption must be coupled with reabsorption of an anion, such as chloride or bicarbonate, or exchange with a cation, such as potassium or hydrogen, to maintain charge neutrality. In the proximal tubule, increased sodium reabsorption stimulates bicarbonate reabsorption. In the distal nephron, enhanced sodium reabsorption, particularly in the setting of hypokalemia, stimulates hydrogen ion secretion.

TABLE 55-9 Causes of Metabolic Alkalosis Differentiated on the Basis of Their Responsiveness to Sodium Chloride

Sodium chloride–responsive (urinary chloride concentration <10 mEq/L)
Gastrointestinal disorders
Vomiting
Gastric drainage
Villous adenoma of the colon
Chloride diarrhea
Diuretic therapy
Correction of chronic hypercapnia
Cystic fibrosis
Excessive bicarbonate therapy of an organic acidosis
Mild/moderate potassium deficiency
Sodium chloride–resistant (urinary chloride concentration >20 mEq/L)
Excess mineralocorticoid activity
Hyperaldosteronism
Cushing’s syndrome
Bartter’s syndrome
Gitelman’s syndrome
Excessive black licorice intake
Profound potassium depletion
Magnesium deficiency
Liddle’s syndrome
Estrogen therapy
Unclassified
Alkali administration
Milk-alkali syndrome
Massive blood or plasma protein fraction transfusion
Nonparathyroid hypercalcemia
Carbohydrate refeeding after starvation
Large doses of penicillin

Mineralocorticoid excess also plays a significant role in the maintenance of metabolic alkalosis. In patients with volume-responsive metabolic alkalosis, intravascular volume depletion stimulates aldosterone secretion. As discussed earlier, excess mineralocorticoid activity can also underlie the generation of metabolic alkalosis. In either situation, the increased mineralocorticoid effect stimulates collecting duct hydrogen ion secretion. Metabolic alkalosis can also be maintained by persistent hypokalemia, enhancing proximal tubular bicarbonate reabsorption, stimulating ammoniagenesis and increasing distal tubular hydrogen ion secretion.³⁹

Clinical Presentation

There are no unique signs or symptoms associated with mild to moderate metabolic alkalosis, but patients may complain of symptoms related to the underlying cause of the disorder (e.g., muscle weakness with hypokalemia or postural dizziness with volume depletion). They may have a history of vomiting, gastric drainage, or diuretic use, all of which contribute to the development of metabolic alkalosis. Severe alkalemia (blood pH >7.60) has been associated with cardiac arrhythmias, particularly in patients with heart disease, hyperventilation, and hypoxemia.⁴¹ Neuromuscular irritability can be present, with signs of tetany or hyperactive reflexes, possibly caused by the decreased ionized calcium concentration that occurs secondary to the increase in pH. This decrease in ionized calcium may be caused by a conformational change in the albumin molecules to which the calcium is bound, resulting in increased binding, or by decreased competition from hydrogen ions for binding sites on the albumin molecule. Mental confusion, muscle cramping, and paresthesia can also occur. Lastly, patients will be more difficult to liberate from mechanical ventilation.

Compensation

The respiratory response to metabolic alkalosis is hypoventilation, which results in an increased PaCO₂. Respiratory compensation is initiated within hours when the central and peripheral chemoreceptors sense an increase in pH. The PaCO₂ increases 6 to 7 mm Hg for each 10-mEq/L (10 mmol/L) increase in bicarbonate, up to a PaCO₂ of approximately 50 to 60 mm Hg (see Table 55–7) before hypoxia sensors react to prevent further hypoventilation. If the PaCO₂ is normal or less than normal, one should consider the presence of a superimposed respiratory alkalosis, which can be secondary to fever, gram-negative sepsis, or pain.

TREATMENT

Metabolic Alkalosis

Because the body tolerates alkalemia far less well than acidemia, treatment of metabolic alkalosis is nearly always required and should be aimed at correcting the factor(s) responsible for the maintenance of the alkalosis.^{38,39,41} For example, vomiting should be treated with antiemetics, gastric losses of hydrogen ion during nasogastric suction can be modulated by giving histamine blockers such as ranitidine or proton pump inhibitors such as omeprazole, and reducing or discontinuing diuretic therapy.^{42,43} Metabolic alkalosis will persist until the renal mechanism responsible for maintaining the disorder is corrected, despite the fact that the original cause of the elevated plasma bicarbonate may have resolved. For example, hypovolemia should be treated with sodium chloride (i.e., diuretic abuse or nasogastric suction) to allow excretion of bicarbonate by the kidney. However, patients with severely compromised cardiovascular function may not be able to tolerate this therapeutic approach. In situations such as this and/or the presence of life-threatening alkalosis, some have advocated reduction in pH by control of ventilation.⁴ Although controlled hypoventilation, sometimes using inspired CO₂ with supplemental oxygen to prevent hypoxia can be life-saving,⁴ this approach is not universally accepted.^{39,41} Therapy for metabolic alkalosis can be conceptualized on the basis of the sodium chloride responsiveness of the disorders as shown in Fig. 55–4.

SODIUM CHLORIDE–RESPONSIVE DISORDERS

Sodium chloride–responsive disorders usually result from volume depletion and chloride loss, which can accompany severe vomiting, prolonged nasogastric suction, and diuretic therapy. Initially therapy is directed at expanding intravascular volume and replenishing chloride stores. Sodium and potassium chloride–containing solutions should be administered to patients who can tolerate the volume load.^{39,41} Patients with metabolic alkalosis who are volume overloaded or intolerant to volume administration because of congestive heart failure can benefit from the carbonic anhydrase inhibitor acetazolamide. This agent inhibits the action of carbonic anhydrase, thereby inhibiting renal bicarbonate reabsorption. Unfortunately, it also increases the renal losses of potassium and phosphate. Administration of acetazolamide (250 to 375 mg once or twice daily) can promote a sufficient bicarbonate diuresis and return the pH toward normal. However, because the clinical effectiveness of the drug declines as the HCO₃[–] concentration decreases, only rarely will this approach fully correct the alkalosis.³⁸

Acidifying agents including hydrochloric acid, ammonium chloride, and arginine monohydrochloride can be used to treat severe (pH >7.6) symptomatic metabolic alkalosis. In general, this man-

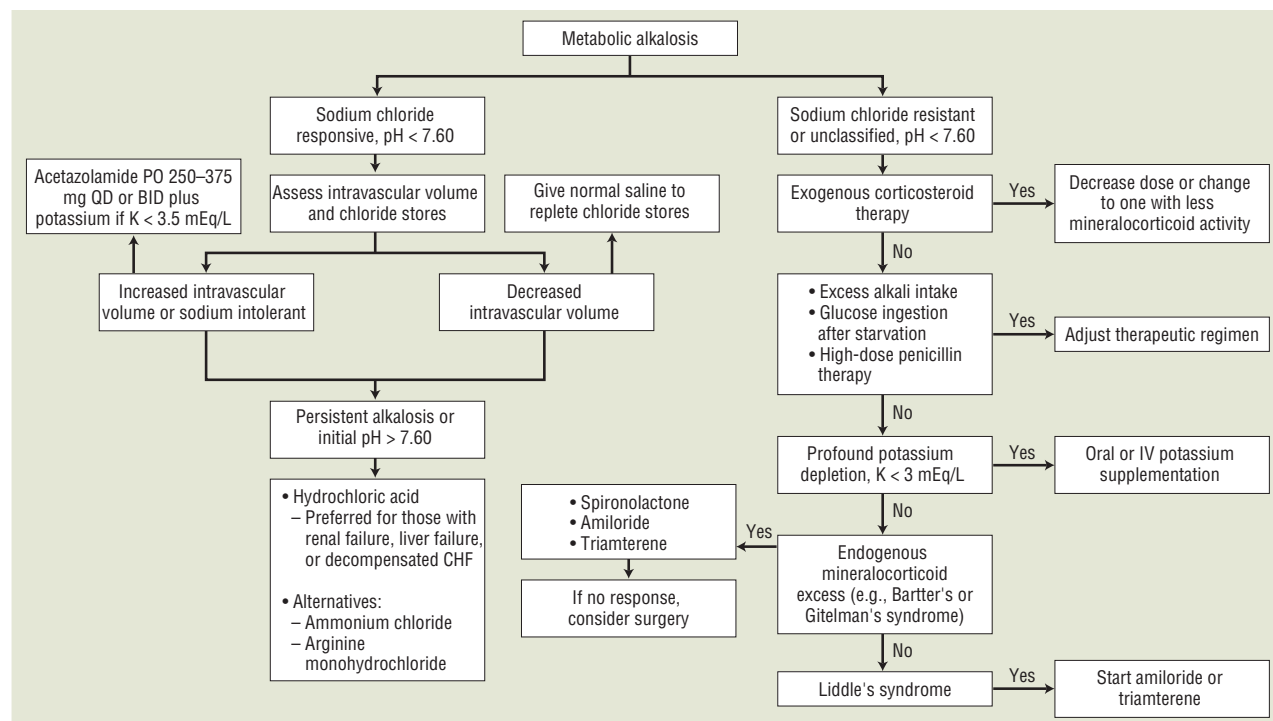

FIGURE 55-4. Treatment algorithm for patients with primary metabolic alkalosis. (BID, twice daily; CHF, chronic heart failure; K, potassium; PO, orally; QD, every day.)

agement is reserved for patients who are unresponsive to conventional fluid and electrolyte management or who are unable to tolerate the requisite volume load because of decompensated congestive heart failure or advanced renal failure.^{38,41} Alternatively, hemodialysis using a low-bicarbonate dialysate can be used for the rapid correction of metabolic alkalosis.

HYDROCHLORIC ACID

Hydrochloric acid is usually infused intravenously via a large central vein as a 0.1 to 0.25 N HCl solution in either 5% dextrose or normal saline, although sterile water has also been used. Extemporaneously prepared solutions can be made by adding 100 to 250 mEq (100 to 250 mEq) of HCl through a 0.22-mm filter into a glass container of saline or dextrose. Hydrochloric acid can also be added to parenteral nutrient solutions and administered via a central line without serious degradation of proteins.⁴⁴ The rate of infusion should be 100 to 125 mL/h (10 to 25 mEq/h [10 to 25 mEq/h]), with frequent monitoring of arterial blood gases. To prevent overcorrection, the infusion should be stopped when the arterial pH decreases to 7.50.³⁹

The dose of hydrochloric acid can be based on an estimate of the total body chloride deficit²⁷:

$$\text{Dose HCl (in mEq)} = [0.2 \text{ L/kg} \times \text{BW (in kilograms)}] \times [103 - \text{observed serum chloride}]$$

where the estimated chloride space is 0.2 times the body weight, and the average serum chloride is 103 mEq/L. Alternatively, the dose can be calculated based on the estimated base deficit⁴¹:

$$\text{Dose HCl (in mEq)} = [0.5 \text{ L/kg} \times \text{BW (in kilograms)}] \times (\text{desired } [\text{HCO}_3^-] - \text{observed } [\text{HCO}_3^-])$$

CLINICAL CONTROVERSY

At present, there are no comparative data that address the relative accuracy of these two formulas for determining the dose of hydrochloric acid.

The dose of hydrochloric acid is usually infused intravenously over 12 to 24 hours.⁴⁵ A severe transient respiratory acidosis can occur if the hydrochloric acid is infused too quickly because of a slower reduction of the elevated bicarbonate concentration in the cerebrospinal fluid than in the extracellular fluid. Improvement is usually seen within 24 hours of initiating therapy. Arterial blood gases and serum electrolytes should be drawn every 4 to 8 hours to evaluate and adjust therapy.

AMMONIUM CHLORIDE

Ammonium chloride has a limited role in the treatment of metabolic alkalosis. The liver converts ammonium chloride (NH_4Cl) to urea and free hydrochloric acid²⁷:

The dose of ammonium chloride can be calculated on the basis of the chloride deficit using the same method as for HCl and assuming that 20 g ammonium chloride will provide 374 mEq (mmol) of H^+ . However, only one-half of the calculated dose of ammonium chloride should be administered so as to avoid ammonia toxicity. Ammonium chloride is available as a 26.75% solution containing 100 mEq of H^+ in 20 mL, which should be further diluted prior to administration. A dilute solution can be prepared by adding 20 mL of ammonium chloride to 500 mL of normal saline and infusing the solution at a rate of no more than 1 mEq/min. Improvement in metabolic status is usually seen within 24 hours. CNS toxicity, marked by confusion, irritability, seizures, and coma, has been associated with more rapid rates of administration. Ammonium chloride must be administered cautiously to patients with renal or hepatic impairment. In patients with hepatic dysfunction, impaired conversion of ammonia to urea can result in increased ammonia levels and worsened encephalopathy. In patients with renal failure, the increased urea synthesis can exacerbate uremic symptoms.²⁷

ARGININE MONOHYDROCHLORIDE

Arginine monohydrochloride at a dose of 10 g/h given intravenously has been used to treat metabolic alkalosis, although it was never FDA

approved for this purpose.²⁷ Like ammonium chloride, arginine must undergo metabolism by the liver to produce hydrogen ions, with a conversion of 100 g to 475 mEq of H⁺. Unlike ammonium chloride, arginine combines with ammonia in the body to synthesize urea; thus it can be used in patients with relative hepatic insufficiency. Patients with renal insufficiency should not receive arginine monohydrochloride because it can significantly elevate blood urea nitrogen (BUN) and is associated with severe hyperkalemia.^{27,29} The increase in potassium is caused by arginine-induced shifts of potassium from the intracellular to the extracellular space.

SODIUM CHLORIDE-RESISTANT DISORDERS

12 Management of these disorders usually consists of treatment of the underlying cause of the mineralocorticoid excess. Patients who are taking corticosteroids can require a dosage reduction or can need to be switched to a corticosteroid with less mineralocorticoid activity (e.g., methylprednisolone). Patients with an endogenous source of excess mineralocorticoid activity can require surgery or the administration of spironolactone, amiloride, or triamterene.^{38,41,46}

Spironolactone is a competitive antagonist of the mineralocorticoid receptor. Amiloride and triamterene are potassium-sparing diuretics that inhibit the epithelial sodium channel in the distal convoluted tubule and collecting duct. All three agents inhibit aldosterone-stimulated sodium reabsorption in the collecting duct. In addition, spironolactone directly inhibits aldosterone-stimulation of the hydrogen ion secretory pump. Thus most patients with mineralocorticoid excess, including Bartter's and Gitelman's syndromes, respond to therapy with these agents.^{38,39,46} Liddle's syndrome, which is a form of pseudohypoaldosteronism caused by overactivity of the epithelial sodium channel, is not responsive to spironolactone but can be treated with either amiloride or triamterene. Although experience is limited, some patients with Bartter's and Gitelman's syndromes may respond to nonsteroidal antiinflammatory agents or angiotensin-converting enzyme inhibitors.^{47,48} Finally, aggressive potassium repletion can correct the alkalosis in those who have not responded to the approaches outlined above.

RESPIRATORY ACID-BASE DISORDERS

As with the metabolic acid-base disturbances, there are two cardinal respiratory acid-base disturbances: respiratory acidosis and respiratory alkalosis. These disorders are generated by a primary alteration in carbon dioxide excretion, which changes the concentration of carbon dioxide, and therefore the carbonic acid concentration in body fluids. A primary reduction in PaCO₂ causes an increase in pH (respiratory alkalosis), and a primary increase in PaCO₂ causes a decrease in pH (respiratory acidosis). Unlike the metabolic disturbances, for which respiratory compensation is rapid, metabolic compensation for the respiratory disturbances is slow. Hence these disturbances can be further divided into acute disorders, with a duration of minutes to hours, and where metabolic compensation has yet to occur, and chronic disorders that have been present long enough for metabolic compensation to be complete.

RESPIRATORY ALKALOSIS

Respiratory alkalosis is characterized by a primary decrease in PaCO₂ that leads to an elevation in pH. The PaCO₂ decreases when the excretion of CO₂ by the lungs exceeds the metabolic production of CO₂. It is the most frequently encountered acid-base disorder, occurring physiologically in normal pregnancy and in persons living at high altitudes.⁴⁵ Respiratory alkalosis also occurs frequently among hospitalized patients (Table 55-10).

TABLE 55-10 Causes of Respiratory Alkalosis

Severe anemia

Peripheral stimulation of respiration

Pulmonary emboli
Asthma

PaCO₂, partial pressure of carbon dioxide from arterial blood.

Pathophysiology

A decrease in PaCO₂ occurs when ventilatory excretion exceeds metabolic production. Because endogenous production of CO₂ is relatively constant, negative CO₂ balance is primarily caused by an increase in ventilatory excretion of CO₂ (hyperventilation). The metabolic production of CO₂, however, can be increased during periods of stress or with excess carbohydrate administration (e.g., parenteral nutrition). Hyperventilation can develop from an increase in neurochemical stimulation via either central or peripheral mechanisms, or be the result of voluntary or mechanical (iatrogenic) hyperventilation.

A decrease in PaCO₂ can occur in patients with cardiogenic, hypovolemic, or septic shock because oxygen delivery to the carotid and aortic chemoreceptors is reduced. This relative deficit in PaO₂ stimulates an increase in ventilation. The hyperventilation in sepsis is also mediated via a central mechanism. Hyperventilation-induced respiratory alkalosis with an elevation in cardiac index and hypotension without peripheral vasoconstriction can therefore be an early sign of sepsis.

Clinical Presentation

Although most patients are asymptomatic, respiratory alkalosis can cause adverse neuromuscular, cardiovascular, and gastrointestinal effects.⁴⁵ During periods of decreased PaCO₂, there is a decrease in cerebral blood flow, which can be responsible for symptoms of light-headedness, confusion, decreased intellectual functioning, syncope, and seizures. Nausea and vomiting can occur, probably as a result of cerebral hypoxia. In severe respiratory alkalosis, cardiac arrhythmias can occur because of sensitization of the myocardium to the arrhythmogenic effects of circulating catecholamines.² Acute respiratory alkalosis has no effect on blood pressure or cardiac output in awake individuals. Anesthetized patients, however, can experience a decrease in both cardiac output and blood pressure, possibly owing to the lack of a tachycardic response.⁴⁹

CLINICAL PRESENTATION OF RESPIRATORY ALKALOSIS

General

- The patient is usually asymptomatic if the condition is chronic and mild.

Symptoms

- The patient may complain of light-headedness, confusion, muscle cramps and tetany, and decreased intellectual functioning.
- Nausea and vomiting can occur, probably as a result of cerebral hypoxia.

Signs

- In severe respiratory alkalosis pH >7.60
- Syncope and seizures
- Cardiac arrhythmias
- Hyperventilation

Laboratory Tests

- Serum chloride concentration is usually slightly increased. Serum ionized calcium, potassium, and phosphorus concentration can be decreased.

The concentration of serum electrolytes can also be altered secondary to the development of respiratory alkalosis. The serum chloride concentration is usually slightly increased, and serum potassium concentration can be slightly decreased. Clinically significant hypokalemia can be a consequence of extreme respiratory alkalosis, although the effect is usually very small or negligible.^{2,49} Serum phosphorus concentration can decrease by as much as 1.5 to 2.0 mg/dL (0.5 to 0.6 mmol/L) because of the shift of inorganic phosphate into cells. Reductions in the blood ionized calcium concentration can be partially responsible for symptoms such as muscle cramps and tetany. Approximately 50% of calcium is bound to albumin, and an increase in pH results in an increase in binding.⁴⁵

Compensation

The initial response of the body to acute respiratory alkalosis is chemical buffering: hydrogen ions are released from the body's buffers—intracellular proteins, phosphates, and hemoglobin—and titrate down the serum bicarbonate concentration. This process occurs within minutes. Acutely, the bicarbonate concentration can be decreased by a maximum of 3 mEq/L (3 mmol/L) for each 10-mm Hg decrease in PaCO_2 ¹⁶ (see Table 55–7). When only physicochemical buffering has occurred, the disturbance is referred to as acute respiratory alkalosis.

Metabolic compensation occurs when respiratory alkalosis persists for more than 6 to 12 hours. In response to the alkalemia, proximal tubular bicarbonate reabsorption is inhibited, and the serum bicarbonate concentration decreases. Renal compensation is usually complete within 1 to 2 days. The renal bicarbonaturia, as well as decreased NH_4^+ and titratable acid excretion, are direct effects of the reduced PaCO_2 and pH on renal reabsorption of chloride and bicarbonate.² The acuity of the respiratory alkalosis can be assessed on the basis of the degree of renal compensation (see Table 55–7). In fully compensated respiratory alkalosis, the bicarbonate concentration decreases by 4 mEq/L (4 mmol/L) below 24 for each 10-mm Hg drop in PaCO_2 . For example, a sustained decrease in PaCO_2 of 20 mm Hg will lower serum bicarbonate from 24 to 14 mEq/L (24 to 14 mmol/L) with a resultant pH of 7.46. Bicarbonate concentrations differing from those anticipated using the preceding guidelines suggest a mixed acid-base disorder.

TREATMENT**Respiratory Alkalosis**

Because most patients with respiratory alkalosis, especially chronic cases, have few or no symptoms and pH alterations are usually mild

(pH not exceeding 7.50), treatment is often not required.⁴¹ The first consideration in the treatment of acute respiratory alkalosis with pH >7.50 is the identification and correction of the underlying cause. Relief of pain, correction of hypovolemia with intravenous fluids, treatment of fever or infection, treatment of salicylate overdose, and other direct measures can prove effective. A rebreathing device, such as a paper bag, can be useful in controlling hyperventilation in patients with the anxiety/hyperventilation syndrome.⁴⁵ Oxygen therapy should be initiated in patients with severe hypoxemia. Patients with life-threatening alkalosis (pH >7.60), particularly if it is a mixed respiratory and metabolic condition and they have complications such as arrhythmia or seizures can require mechanical ventilation with sedation and/or paralysis to control hyperventilation.

Respiratory alkalosis in patients receiving mechanical ventilation is usually iatrogenic. It can often be corrected by decreasing either the set respiratory rate or tidal volume although other measures can also be employed. The use of a capnograph and spirometer in the breathing circuit enables a more precise adjustment of the ventilator settings. Another method of treating respiratory alkalosis is to increase the amount of dead space in the ventilator circuit by placing a known length of tubing between the artificial airway and the “Y” piece of the ventilator. This results in “rebreathing” of expired gas, and therefore an increase in the inspired carbon dioxide concentration, which should increase the carbon dioxide tension of the patient, correcting the respiratory alkalosis. In patients breathing more rapidly than the ventilator settings, sedation with or without paralysis can be employed.

RESPIRATORY ACIDOSIS**Pathophysiology**

Respiratory acidosis occurs when the lungs fail to excrete carbon dioxide resulting in a lower pH. This can be the result of conditions that centrally inhibit the respiratory center, diseases that interfere with pulmonary perfusion or neuromuscular function, and intrinsic airway or parenchymal pulmonary disease (Table 55–11). Acute respiratory acidosis with hypoxemia, hypercarbia, and acidosis is life-threatening. Those disorders that produce an increase in PaCO_2 and hypoxemia to a degree compatible with life (e.g., chronic obstructive pulmonary disease), with or without oxygen therapy, can result in chronic respiratory acidosis (Table 55–12). These patients can function normally without noticeable neurologic defects with PaCO_2 concentrations in the range of 90 to 100 mm Hg (normal, 40 mm Hg), provided adequate oxygenation is maintained.⁴⁹

Clinical Presentation

Respiratory acidosis can produce neurologic symptoms, including altered mental status, abnormal behavior, seizures, stupor, and coma. Hypercapnia can mimic stroke or CNS tumors by producing headache, papilledema, focal paresis, and abnormal reflexes. These CNS symptoms are attributable to the vasodilator effects of CO_2 in the brain that result in an increase in cerebral blood flow.² The CNS response to hypercapnia is extremely variable between patients and is most influenced by the acuity of presentation. Given that chronic hypercapnia blunts the usual respiratory stimulus of an elevated PaCO_2 , hypoxemia rather than hypercapnia provides the primary ventilatory stimulus in patients with severe chronic respiratory acidosis.⁴⁹

The degree to which cardiac contractility and heart rate are altered depends on the severity of the acidosis and the rapidity with which it develops. Modest acute hypercapnia (PaCO_2 of 50 to 55 mm Hg) stimulates a stress-like response, with elevated catecholamines and corticosteroid hormone levels, and can result in increased cardiac output and pulmonary artery pressure.⁵⁰ As the severity

TABLE 55-11 Causes of Acute Respiratory Acidosis

Total parenteral nutrition (increased CO₂ production)

increases, cardiac output declines and vascular resistance decreases leading to refractory hypotension in some patients.²

In respiratory acidosis, the serum potassium concentration increases modestly secondary to cellular shifts. The increases are less than those seen with inorganic metabolic acidosis and are difficult to predict for individual patients (see Chap. 54).

CLINICAL PRESENTATION OF RESPIRATORY ACIDOSIS

General

- The patient is usually symptomatic.

Symptoms

- The patient may complain of confusion or difficulty thinking and headache.

Signs

- In severe respiratory acidosis:
- Cardiac: Increased cardiac output if moderate that decreases if severe. Refractory hypotension can be present in some patients.
- CNS: Abnormal behavior, seizures, stupor, and coma. Papilledema, focal paresis, and abnormal reflexes can also be present.

Laboratory Tests

- Serum potassium concentration can be modestly increased. Hypercapnia can be moderate (PaCO₂ of 50 to 55 mm Hg) to severe (PaCO₂ of >80 mm Hg). Hypoxia (PaO₂ is <70 mm Hg) is often present.

Compensation

The body responds to acute respiratory acidosis with chemical buffering. The increase in PaCO₂ results in increased carbonic acid levels. The carbonic acid dissociates, releasing hydrogen ions, which are buffered by nonbicarbonate buffers (i.e., proteins, phosphate,

TABLE 55-12 Causes of Chronic Respiratory Acidosis

and hemoglobin) and bicarbonate. Thus on the basis of physicochemical factors, increases in PaCO₂ raise the serum bicarbonate concentration. In general, in acute respiratory acidosis, the bicarbonate concentration increases by 1 mEq/L (1 mmol/L) above 24 for each 10-mm Hg increase in PaCO₂ above 40 (see Table 55-7).

Metabolic compensation occurs when respiratory acidosis is prolonged beyond 12 to 24 hours. In response to hypercapnia and acidemia, proximal tubular bicarbonate reabsorption, ammoniogenesis, and distal tubular hydrogen secretion are enhanced, resulting in an increase in the serum bicarbonate concentration that raises the pH toward normal. Renal compensation for chronic hypercapnia generally results in the plasma bicarbonate concentration increasing by 4 mEq/L (4 mmol/L) above 24 for each 10-mm Hg increase in PaCO₂ above 40 (see Table 55-7). The new steady state in acid-base values is generally achieved within 5 days of the onset of hypercapnia in dogs; the time interval necessary for compensation in humans has not been established.

TREATMENT

Respiratory Acidosis

The treatment of respiratory acidosis is dependent on the chronicity of the patient's condition. Respiratory decompensation in patients with chronic elevations in PaCO₂ are frequently seen in those with acute infections and those recently started on narcotic analgesics or oxygen therapy.⁴¹ Aggressive treatment of these conditions can offer considerable benefit and should be initiated. Furthermore, tranquilizers and sedatives should be avoided and supplemental oxygen, if used, should be minimized.

■ ACUTE RESPIRATORY ACIDOSIS

13 When carbon dioxide excretion is severely impaired (PaCO₂ >80 mm Hg) and/or life-threatening, hypoxia is present (PaO₂ <40 mm Hg); the immediate therapeutic goal is to provide adequate oxygenation. Under these circumstances, hypoxia, not acidemia, is the principal threat to life. A patent airway needs to be established, which can necessitate intubation. Excessive secretions must be cleared from the airway and oxygen administered to restore adequate oxygenation. Mechanical ventilation is usually required.

The underlying cause of the acidosis should be treated aggressively (e.g., bronchodilators for treatment of severe bronchospasm; narcotic or benzodiazepine antagonists to reverse the deleterious effects of these agents on the respiratory center). Bicarbonate administration is rarely necessary in the treatment of respiratory acidosis. Furthermore, rapid correction of acidosis with bicarbonate can eliminate the patient's respiratory drive or precipitate metabolic alkalosis. Cautious use of alkali (bicarbonate or THAM) can restore the responsiveness of bronchial muscles to β -adrenergic agonists and thus can be beneficial for those patients with severe broncho-

spasm.⁵⁰ Arterial blood gases should be monitored closely to ensure that the respiratory acidosis is resolving without creating a metabolic alkalosis as the result of compensatory elevation in HCO_3^- and decrease in PaCO_2 . Arterial blood gases should be obtained every 2 to 4 hours during the acute phase and less frequently (every 12 to 24 hours) as the acidosis improves.

■ ACUTE RESPIRATORY ACIDOSIS IN A COMPENSATED CHRONIC RESPIRATORY ACIDOTIC PATIENT

Patients with a history of chronic respiratory acidosis (e.g., those with chronic obstructive pulmonary disease) can experience an acute worsening of their respiratory acidosis. This can result in severe life-threatening hypoxemia. As with acute respiratory acidosis, the goals of therapy are maintenance of a patent airway and adequate oxygenation. Individuals with chronic respiratory acidosis are routinely able to tolerate a low PaO_2 and an elevated PaCO_2 because of compensation (increased number of red blood cells, hemoglobin content, and 2,3-diphosphoglycerate). The drive to breathe in these patients is dependent on hypoxemia rather than hypercarbia. Administration of oxygen to a patient with chronic respiratory acidosis can eliminate this drive to breathe and result in the syndrome of carbon dioxide narcosis. In this case, if the PaO_2 is 50 mm Hg, no oxygen treatment is necessary. If the PaO_2 is <50 mm Hg, oxygen therapy should be initiated carefully using a controlled flow of oxygen.²

Arterial blood gases should be checked periodically to ensure adequate oxygenation. If the PaCO_2 increases during oxygen therapy, it can be a sign of impending carbon dioxide narcosis and oxygen therapy may need to be discontinued. The underlying cause of the acute exacerbation should be aggressively managed. Pulmonary infections should be treated with the appropriate antibiotics and bronchodilators administered as necessary. Excess secretions should be cleared from the airway to allow proper gas exchange. This can involve increasing oral fluid intake to decrease the viscosity of secretions, deep breathing, and postural drainage, suction, or bronchoscopy.

MIXED ACID-BASE DISORDERS

DIAGNOSIS

The diagnosis of a mixed disorder depends on an understanding of the appropriate quantitative response of the compensatory mechanisms for each of the simple acid-base disturbances. To diagnose mixed disorders, one must know how each of the four simple disorders alters pH, PaCO_2 , and $[\text{HCO}_3^-]$ (see Table 55–7). If a given set of blood gases does not decrease within the range of expected responses for a simple acid-base disturbance, a mixed disorder should be suspected. In addition to laboratory information, a thorough history and physical examination of the patient will often lead to the diagnosis, even before the laboratory data are available. Examples of common mixed disturbances follow.

Mixed Respiratory Acidosis and Metabolic Acidosis

In mixed respiratory and metabolic acidosis, there is a failure of compensation. The respiratory disorder prevents the compensatory decrease in PaCO_2 expected in the defense against metabolic acidosis. The metabolic disorder prevents the buffering and renal mechanisms from raising the bicarbonate concentration as expected in the defense against respiratory acidosis. In the absence of these compensatory mechanisms the pH decreases markedly.

Mixed respiratory and metabolic acidosis may develop in patients with cardiorespiratory arrest, in those with chronic lung disease who are in shock, and in metabolic acidosis patients who develop

respiratory failure when treating this mixed disorder, clinicians need to respond to both the respiratory and metabolic acidosis. Improved oxygen delivery must be initiated to improve hypercarbia and hypoxia. Mechanical ventilation may be needed to reduce PaCO_2 . During the initial stage of therapy, appropriate amounts of alkali should be given to reverse the metabolic acidosis (see Treatment, Metabolic Acidosis, above).

Mixed Respiratory Alkalosis and Metabolic Alkalosis

The combination of respiratory and metabolic alkalosis is the most common mixed acid-base disorder. This mixed disorder occurs frequently in critically ill surgical patients with respiratory alkalosis caused by mechanical ventilation, hypoxia, sepsis, hypotension, neurologic damage, pain, or drugs, and with metabolic alkalosis caused by vomiting or nasogastric suctioning and massive blood transfusions. It can also occur in patients with hepatic cirrhosis who hyperventilate, receive diuretics, or vomit, as well as in patients with chronic respiratory acidosis and an elevated plasma bicarbonate concentration who are placed on mechanical ventilation and undergo a rapid decrease in PaCO_2 .

The renal excretion of bicarbonate that usually occurs as compensation for the respiratory alkalosis is prevented by the complicating metabolic alkalosis. Likewise, the retention of PaCO_2 expected to compensate for metabolic alkalosis is prevented by the primary respiratory alkalosis. The failure of compensation that occurs with mixed respiratory and metabolic alkalosis can result in a severe alkalemia.

Administration of sodium chloride and potassium chloride solutions will help correct the metabolic component of this disorder, and adjustment of the ventilator and/or treatment of an underlying disorder that is causing hyperventilation can correct or ameliorate the respiratory component of this mixed disorder.

Mixed Metabolic Acidosis and Respiratory Alkalosis

This mixed disorder is often seen in patients with advanced liver disease, salicylate intoxication, and pulmonary-renal syndromes. The respiratory alkalosis will decrease the PaCO_2 beyond the appropriate range for the respiratory compensation usually seen with metabolic acidosis. The plasma bicarbonate concentration also decreases below the level expected in compensation for a simple respiratory alkalosis. In a sense, the defense of pH for either disorder alone is enhanced; thus the pH can be normal or close to normal, with a low PaCO_2 and a low $[\text{HCO}_3^-]$. Treatment of this disorder should be directed at the underlying cause. Because of the enhanced compensation, the pH is usually closer to normal than in either of the two simple disorders.

Mixed Metabolic Alkalosis and Respiratory Acidosis

This mixed disorder often occurs in patients with chronic obstructive pulmonary disease and chronic respiratory acidosis who are treated with salt restriction, diuretics, and possibly glucocorticoids. When diuretics are initiated, the plasma bicarbonate may increase because of increased renal bicarbonate generation and reabsorption, providing mechanisms for both generating and maintaining metabolic alkalosis. The elevated pH diminishes respiratory drive and may therefore worsen the respiratory acidosis.

Although the pH may not deviate significantly from normal, treatment may need to be initiated to maintain PaO_2 and PaCO_2 at acceptable levels. Because it is often difficult to correctly identify this mixed disorder, it is helpful to observe the patient's response to discontinuation of diuretics and administration of sodium and potassium chloride.² If the patient has a simple metabolic alkalosis, the PaCO_2 will normalize, but it will only minimally affect the PaCO_2 if it is a mixed disorder. Treatment should be aimed at decreasing the

plasma bicarbonate with sodium and potassium chloride therapy, thereby allowing the renal excretion of retained bicarbonate from the diuretic-induced metabolic alkalosis. This therapy should be used cautiously to avoid exacerbating any underlying congestive heart failure.

EVALUATION OF THERAPEUTIC OUTCOMES

Because acid–base disorders are such a common and widespread problem, pharmacists can play a key role in identifying, preventing, and properly treating acid–base abnormalities. Acid–base disorders do not occur only in the intensive care unit setting. Patients in ambulatory and extended care settings have many chronic conditions and drug therapies that commonly affect acid–base balance. Thus pharmacists in all practice settings should use their knowledge to identify patients at high risk for developing drug-related problems which affect acid–base balance and to undertake appropriate prevention and treatment measures to improve the quality of life of the patients they care for.

ABBREVIATIONS

BW: body weight

CNS: central nervous system

DCA: dichloroacetate

ECF: extracellular fluid

H⁺: hydrogen ion

HCO₃⁻: bicarbonate

H₂CO₃: carbonic acid

HIV: human immunodeficiency virus

NH₄⁺: ammonium

PaCO₂: partial pressure of carbon dioxide from arterial blood

PaO₂: partial pressure of oxygen from arterial blood

pH: the negative logarithm (base 10) of the hydrogen ion concentration

pK: the negative logarithm of the dissociation constant

PvCO₂: partial pressure of carbon dioxide from venous blood

PvO₂: partial pressure of oxygen from venous blood

RTA: renal tubular acidosis

SAG: serum anion gap

THAM: tromethamine (Tris[hydroxymethyl]-aminomethane)

UCs: unmeasured cations

UAs: unmeasured anions

SECTION 6 NEUROLOGIC DISORDERS

CHAPTER

56

Evaluation of Neurologic Illness

SUSAN C. FAGAN AND FENWICK T. NICHOLS

KEY CONCEPTS

- 1 The clinical neurologic history and examination are the cornerstones of the neurologic diagnosis and management.
- 2 Through the patient's history one can determine the main symptoms, the mode of onset (gradual or sudden), progression over time (maximal at onset or steadily gaining intensity), and associated illnesses/risk factors.
- 3 The neurologic examination is directed at localization of the disease process so that evaluation and management may be planned appropriately.
- 4 The neurologic examination of a specific patient may be adapted to the patient's specific deficit. For example, a patient with double vision may warrant an extensive cranial nerve examination but a less-extensive assessment of finger strength.

To contribute most effectively to the care of patients with neurologic illness, one must understand the tools used in the diagnosis and management of these patients. In addition, clinicians must be able to gather their own data through a targeted neurologic examination and history taking to ensure optimal pharmacotherapy in neurologic patients. Despite technologic advances that have led to the development of sensitive diagnostic tests in neuroscience, the clinical neurologic history and examination are still the cornerstones of the neurologic diagnosis and management.¹

SIGNS AND SYMPTOMS

- 1 As in all of medicine, obtaining an accurate and complete history is of utmost importance in the evaluation of neurologic diseases. In many instances, the diagnosis can be made on the basis of the history, and the neurologic examination can be tailored to optimally evaluate the

patient and confirm the diagnosis. The clinician depends on the patient or family for the details of the illness. Care must be taken to avoid "leading" the patient. Obtaining an accurate history may be difficult because a number of neurologic diseases may affect patients' speech and memory. 2 Through the patient's history one can determine the main symptoms, the mode of onset (gradual or sudden), progression over time (maximal at onset or steadily gaining intensity), and associated illnesses/risk factors (recent head injury from a motor vehicle accident). The physical examination is important because it can reveal evidence of systemic disease that may have affected the nervous system secondarily (e.g., a seizure in a patient with elevated temperature and stiff neck may suggest meningitis). The neurologic examination is only one component of a complete general physical examination.

THE NEUROLOGIC EXAMINATION

- 3 An assessment of patient effort is necessary to interpret the results of the neurologic examination. It can identify any abnormalities, particularly asymmetry of function, and help to localize the lesion within the nervous system (central versus peripheral and specific location within the central nervous system [CNS] or the peripheral nervous system). The neurologic examination consists of six main components: higher cortical function (mental status), cranial nerves, motor function, reflexes, sensory function, and gait. Table 56-1 describes the common approaches to assessing each of the six domains and includes examples of the diseases in which abnormal findings are common. 4 A targeted neurologic examination can be performed when a specific deficit is suspected. Table 56-2 describes the cranial nerve examination in more detail. The reader is encouraged to consult other references to better understand the intricacies of the neurologic examination. The clinician must synthesize the results of the history and physical examination to arrive at an anatomic localization of the lesion and create a differential diagnosis.

PROCEDURES USED IN THE DIAGNOSIS

In addition to the neurologic examination, certain imaging techniques and procedures may be essential in the diagnosis of neurologic disorders. Lumbar puncture is used to obtain cerebrospinal fluid (CSF). It is used most often as an evaluation of CNS infections such as meningitis and encephalitis, but it is also useful in subarachnoid

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

TABLE 56-1 The Neurologic Examination

Domain	Tests Performed	Diseases
Mental status	While obtaining the history: general mental and emotional status, speech, memory, alertness, abstract reasoning, ability to follow commands (motor integration), ability to communicate	Dementias, stroke, metabolic encephalopathies
Cranial nerves	Visual acuity, visual fields, eye movements, jaw strength, corneal reflex, facial symmetry, auditory acuity, gag reflex, shoulder and neck strength	Myasthenia gravis, Parkinson's disease, stroke, amyotrophic lateral sclerosis (ALS)
Motor function	Motor strength with and without resistance, coordination (rapid alternating movements, finger-to-nose), tremors, atrophy, fasciculations	Stroke, myasthenia gravis, Parkinson's disease, ALS
Reflexes	Biceps, triceps, tendon reflexes, plantar response (Babinski sign is an upgoing toe and is abnormal), superficial cutaneous reflexes (abdominal)	Stroke, spinal cord lesions, endocrine diseases (e.g., diabetes, hypothyroidism), peripheral neuropathy
Sensory function	Asymmetry to pinprick, vibration, temperature	Stroke, peripheral neuropathy, migraine aura, diabetes, spinal cord lesions
Gait	Walking, standing (Romberg test = eyes closed, which will accentuate disequilibrium)	Stroke, Parkinson's disease, spinal cord lesions

hemorrhage, multiple sclerosis, and dementia. Opening pressure, cell count and differential, glucose concentration, total protein concentration, and culture and sensitivity are obtained routinely. A space-occupying lesion in the brain with mass effect is a relative contraindication to lumbar puncture because herniation could result. Prior to performing a lumbar puncture, the patient should be checked for papilledema, which may indicate increased intracranial pressure. The opening CSF pressure usually is less than 180 mm H₂O. Normal CSF is clear and colorless and should not contain any red blood cells or polymorphonuclear cells. The presence of up to five mononuclear cells is considered normal. Total protein in the CSF usually is 45 mg/dL or less. Protein may increase with infection, breakdown of the blood–brain barrier (e.g., tumors, stroke, and trauma), and diabetes.

Electroencephalography (EEG) records the electrical activity of the brain. The record is interpreted by observing the basic rhythms and waveforms, the symmetry of the recording, and abnormal electrical discharges. It also may be used to assess the response to photic stimulation or hyperventilation. It is used primarily in the diagnosis of seizures and may be helpful in the evaluation of patients with altered mental status. EEG also may be used to measure evoked potentials. The evoked potentials are the EEG response to repetitive stimuli (visual, auditory, or tactile) and provide information about the presence of abnormalities and disturbances (but not the cause) in the specific pathways tested.

Electromyography (EMG) and nerve conduction velocities (NCVs) are used to assess the function of the peripheral nerves, neuromuscular junction, and muscles. NCVs are measured by stimulating the nerve and recording the speed of conduction of the impulse. NCVs can be used to detect the presence of localized peripheral nerve injuries (e.g., carpal tunnel) or diffuse symmetric neuropathies (which may be inherited or acquired). EMG assesses muscle dysfunction as a result of primary muscle disease or secondary to nerve injury. This test is used to diagnose peripheral neuropathies (inherited and acquired), Guillain-Barré syndrome, myasthenia gravis, amyotrophic lateral sclerosis, radiculopathies, and muscle diseases.

TABLE 56-2 Cranial Nerve Function and Examples of Testing

- I. Olfactory nerve. Smell: identify odors (coffee, cinnamon, lemon; test each nostril separately).
- II. Optic nerve. Visual acuity: eye chart. Visual fields: peripheral vision and blind spot; funduscopic exam; pupil size and reaction; color vision (rarely done).
- III. Oculomotor (cranial nerves III, IV, and VI have similar functions and are tested as a unit). Eye movements: patient is asked to watch a light as it moved up, down, and on both sides, while eye movements are observed.
- IV. Trochlear. See III.
- V. Trigeminal nerve. Motor: tests power of jaw opening and sideways deviation against the resistance of a hand placed against the jaw. Sensory: test corneal reflex by touching cornea (also nasal mucosa) with a wisp of cotton.
- VI. Abducens. See III.
- VII. Facial nerve. Observe asymmetry of face at rest or on speaking, baring teeth, raising eyebrows, or wrinkling forehead. Reflex eye closure to a threatening movement. Glabellar tap: repetitive tapping over bridge of nose—initial blinking should cease after the first few taps.
- VIII. Auditory nerve. Vestibular division: observe for nystagmus, positional testing. Auditory division: test acuity with light sound; watch, whisper, rubbing of fingers close to ear.
- IX. Glossopharyngeal nerve. Test for gag reflex by touching back of throat with tongue depressor; test swallowing and coughing and note any drooling or pooling of saliva. Test symmetry of palate movement on vocalizing “ah.”
- X. Vagus nerve. Test gag reflex as in IX.
- XI. Spinal accessory nerve. Trapezius and sternomastoid muscles: test power of shrugging shoulders and turning the head to one side against resistance.
- XII. Hypoglossal nerve. Motor function of tongue. Look for wasting and abnormal movements.

The cerebral circulatory system can be imaged or evaluated in a number of different ways depending on the type and location of the abnormality suspected. Imaging techniques can be used to identify local arterial stenosis, aneurysms, or arteriovenous malformations. Atherosclerosis of the extracranial arteries, a frequent cause of stroke, can be evaluated using ultrasound (referred to as *duplex sonography*, *carotid Doppler*, or *color-flow Doppler*), magnetic resonance angiography (MRA), spiral computed tomographic angiography (CTA), or intraarterial angiography. The intracranial arterial circulation can be evaluated using transcranial Doppler, MRA, CTA, or intraarterial angiography. Each technique has its own advantages and disadvantages. Intraarterial angiography provides the best imaging of the smaller arteries of the cerebral circulation but is more invasive than the other measures.

Computed tomography (CT) uses x-rays to produce images of “slices” of the brain that are 1 to 10 mm in thickness. CT revolutionized the practice of neurology by allowing direct imaging of the brain anatomy. CT is currently available in most communities and is used to evaluate patients with intracranial disease. CT scans are used to identify tumors, hemorrhages, infarctions, hydrocephalus, and atrophy. Intravenous contrast agents (a contrast-enhanced scan) can be administered to enhance the image of blood vessels and areas of blood–brain barrier damage that may be caused by abscesses, other inflammatory conditions, tumors, or stroke.

Magnetic resonance imaging (MRI) uses the magnetic properties of the hydrogen atom nucleus and proton to produce computer-processed scans that provide improved anatomic detail when compared with CT scans. MRI offers the advantages of better differentiating between white and gray matter and delineating lesions close to bone (brainstem and cerebellum) and has no radiation risk; however, it is not as readily available as CT and is more expensive. MRI has a proven advantage over CT in evaluating lesions in the posterior fossa and in detecting lesions in the white matter, such as plaques in multiple sclerosis. MRI is also useful in the diagnosis of tumors and very early ischemic stroke (diffusion-weighted imaging). Imaging of the spinal canal and its contents can be accomplished either by MRI myelography or CT myelography.

Other imaging techniques such as positron emission tomography (PET) and single-photon emission computed tomography (SPECT) are considered tests of brain function. These tests are being studied extensively in epilepsy as well as in cerebrovascular disorders, cerebral tumors, movement disorders, and dementia. PET scans use a positron-emitting isotope to display chemical activity and the rates of biologic processes within the brain. This method can assess regional metabolic changes in the brain. The expense, technical complexity (a cyclotron is needed), and limited availability of this technique limit its clinical usefulness.

SPECT scans measure radiotracer uptake by tissues and provide cross-sectional images of the brain. This technique has been used extensively to assess cerebral blood flow. Although the resolution of SPECT is not as good as PET, the availability has led to wide clinical use in disorders such as stroke, dementia, and epilepsy.

CONCLUSION

Assessment of the patient with neurologic disease is challenging. The patient by virtue of the neurologic deficit, may or may not be able to provide reliable information regarding medication history or extent of illness. The clinician must develop alternate strategies to obtain a complete data set and develop a pharmacotherapy plan. Ability to interpret and synthesize the results of the neurologic

examination and other diagnostic tests will help a great deal in this quest.

ABBREVIATIONS

CNS: central nervous system
CSF: cerebrospinal fluid
CT: computed tomography
CTA: computed tomography angiography
EEG: electroencephalogram
EMG: electromyography
MRA: magnetic resonance angiography
MRI: magnetic resonance imaging
NCVs: nerve conduction velocities
PET: positron-emission tomography
SPECT: single-photon-emission computed tomography

JACQUELYN L. BAINBRIDGE AND JOHN R. CORBOY

KEY CONCEPTS

- 1 The etiology of multiple sclerosis (MS) is unknown, and currently there is no cure.
- 2 Multiple sclerosis appears to be an immunologic disorder that is characterized by central nervous system (CNS) demyelination and axonal damage.
- 3 Multiple sclerosis is classified by the nature of progression over time into several categories, which have different clinical presentations and responses to therapy.
- 4 Diagnosis of MS requires dissemination of lesions over time in multiple parts of the CNS, and is made primarily on the basis of clinical symptoms and examination. More recent diagnostic criteria also allow for the use of magnetic resonance imaging (MRI), spinal fluid, and evoked potentials to aid in the diagnosis.
- 5 Acute exacerbations or relapses usually are treated with high-dose glucocorticoids, such as methylprednisolone, and onset of a clinical response to steroid treatment is expected within 3 to 5 days.
- 6 Treatment with interferon β (Avonex, Rebif, or Betaseron), glatiramer acetate (Copaxone), natalizumab (Tysabri), or mitoxantrone (Novantrone) can reduce annual relapse rate, slow progression of disability, slow cognitive decline, and slow changes seen on brain MRIs in relapsing-remitting MS (RRMS).
- 7 The only treatment approved for secondary-progressive MS (SPMS) is mitoxantrone, and, if the patient continues to have superimposed relapses, interferon β_{1b} . There are no proven therapies for primary-progressive MS (PPMS).
- 8 In most cases, treatment with immunomodulating interferon β or glatiramer acetate should begin promptly after the diagnosis of relapsing MS is made and after a single attack if the MRI is suggestive of high risk of further attacks. In RRMS, natalizumab and mitoxantrone should be reserved for those patients who have failed or are intolerant of interferon or glatiramer acetate therapy.
- 9 The definition of treatment inadequacy is unclear. Thus, therapy after interferon β_{1a} (Avonex or Rebif), interferon β_{1b} (Betaseron), or glatiramer acetate (Copaxone) "treatment failure" in RRMS should be individualized. These therapies are collectively referred to as ABC-R therapy. Options include alternating ABC-

R therapy, combining with other agents, using natalizumab or mitoxantrone, or using non-FDA-approved approaches.

- 10 Patients suffering from MS frequently will have symptoms such as spasticity, bladder dysfunction, fatigue, pain, and depression that can require treatment. Patients must be counseled that therapies such as interferon β and glatiramer acetate will not relieve these symptoms. Depression is common in MS and can pose the risk of suicide.

MS is an inflammatory disease of the CNS that affects between 250,000 and 350,000 persons in the United States.¹ The term *multiple sclerosis* refers to two characteristics of the disease: the numerous affected areas of the brain and spinal cord producing multiple neurologic symptoms that accrue over time, and the characteristic plaques or sclerosed areas that are the hallmark of the disease.

1 Although MS was first described almost 140 years ago, the cause remains a mystery, and a cure is still unavailable. Nevertheless, many advances have been made in treating and managing the complications of the disease and improving the quality of life of individuals affected by MS.

EPIDEMIOLOGY

Epidemiologic aspects of MS have been reviewed in a variety of publications.²⁻⁵ MS usually is diagnosed in patients between the ages of 15 and 45 years, and the peak incidence occurs in the fourth decade of life. There are approximately 10,000 new cases diagnosed per year in the United States. Women are afflicted more than men by a ratio of approximately 2:1. Men usually develop the first signs of MS at a later age than women and are also more likely to develop the progressive form of the disease. The most important factors in the determination of risk for developing the disease are geography, age, environmental influences, and genetics. In general, disease prevalence is higher the greater the distance from the equator. Within the United States, the prevalence of MS is higher in states above the 37th parallel. Multiple sclerosis occurs more frequently in whites of Scandinavian ancestry than in other ethnic groups.

ETIOLOGY

It is thought that genetically susceptible individuals between the ages of 10 and 15 years who have lived in a high-risk area for at least 2 years exposed to a crucial environmental agent are at risk for developing MS. Interestingly, an individual who migrates from a low- to a high-risk area prior to the age of 15 years acquires the same chance of developing MS as those who live in a high-risk area all their lives.⁶ If the move is made from a high- to a low-risk area, the individual retains the high risk if the move is made after the age of

Learning objectives, review questions,
and other resources can be found at
www.pharmacotherapyonline.com.

15 years but acquires the lower risk if the move is made prior to this age.⁶ Smoking cigarettes has been associated with both an increased risk of acquiring MS and with more severe progression.⁵

Viral or bacterial infections may be an important environmental cause of MS. Although no clear association has been identified, there are several ways in which a virus or bacteria could play a role in the pathogenesis of MS.⁷ These infections might cause either a direct attack on myelin and the oligodendrocyte, or stimulation of an autoimmune response leading to demyelination. Evidence to support a viral etiology includes increased immunoglobulin G (IgG) synthesis in the CNS, increased antibody titers to certain viruses, and epidemiologic studies that indicate a childhood exposure factor, suggesting that “viral” infections may precipitate exacerbations. Immunoglobulin patterns in the cerebrospinal fluid (CSF) are similar in subacute sclerosing panencephalitis (SSPE) and MS. SSPE is a chronic measles infection of the CNS known to be associated with the production of oligoclonal bands in the CSF.⁸ In addition, viruses have been shown to cause diseases with prolonged incubation periods, myelin destruction, and a relapsing-remitting course in both humans and experimental animal models.⁹

The most compelling evidence against a microbial etiology is the fact that no single infectious agent has been identified as the cause of MS. Many possible agents have been implicated, including mycoplasma, *Chlamydia pneumoniae*, spirochetes, rabies virus, herpes simplex virus, canine distemper virus, coronavirus, human T-cell leukemia virus type I (HTLV-I), MS-associated retrovirus, measles, and most recently, human herpes virus type 6 (HHV-6)^{10,11} and Epstein-Barr virus.^{12,13} However, to date, no causal relationship has been established.⁹

The familial recurrence rate of MS is approximately 5%, with siblings being the most commonly reported relationship.⁴ Concordance data show a higher prevalence of MS between monozygotic than between dizygotic twins, and a recent study has confirmed the overall concordance among monozygotic twins at approximately 25%, with a risk among females of 34% and males just 5%, similar to that seen in dizygotic twins.¹⁴ This is consistent with the idea that an environmental agent is important in the etiology of MS but also suggests a role for one or more genes. Genetic studies have determined an association between MS and the major histocompatibility complex (MHC) and, in particular, with the human leukocyte antigen (HLA) region on the sixth chromosome that is associated with the genetic control of immune mechanisms.^{4,15,16} In African Americans, a locus on chromosome one may be associated with increased susceptibility.¹⁷ In addition, a number of genes have been identified that may alter the speed of progression of the illness, such as apolipoprotein E $\epsilon 4$ homozygosity,¹⁸ although more recent analysis argues against this.¹⁹ Although African Americans are significantly less likely to be diagnosed with MS compared to whites, there is emerging evidence that African Americans are more likely to have a severe disease course²⁰ and respond less well to interferon therapy than whites.²¹

PATHOPHYSIOLOGY

2 The basic physiologic derangement in MS is the stripping of the myelin sheath surrounding CNS axons. This is associated with an inflammatory, perivenular infiltrate consisting of variable numbers and amounts of T and B lymphocytes, macrophages, antibodies, and complement. The lesions are referred to as plaques. Initially, axons, although stripped bare of their myelin sheath, usually are well preserved.²² Recent studies, however, have shown that damage to axons can be significant, even early in the course of the illness.²³ Axonal damage may be seen as a hypointense lesion, or T₁ hole, on MRI, and these correlate with disability.²⁴

It is now well-accepted that MS lesions are heterogeneous, but it remains unclear as to whether this represents differences in the stage

of evolution of the lesions over time, differences in underlying immunopathogenesis, or a combination of the two. As reviewed by Frohman and colleagues,²⁵ acute lesions show demyelination and axonal destruction with lymphocytic hypercellularity, extensive macrophages, loss of oligodendrocytes, but an indistinct margin with little astrocytic proliferation. In contrast, more chronic lesions display less inflammatory lymphocytes but ongoing macrophage deposition with hypertrophic astrocytes and oligodendrocytes with active remyelination.

Acute MS lesions can be divided into four immunopathologic subtypes, with variable degrees of sharpness of borders, loss of specific myelin proteins, and variable numbers of immune cells or immunoglobulins present in the plaques. Types I and II are more consistent with the traditional view of MS as an encephalomyelitis, with type II displaying significant deposition of immunoglobulin and complement. Types III and IV, conversely, appear more consistent with an oligodendrogliaopathy. All type IV patients studied so far have PPMS, but otherwise, there is no obvious association of immunopathology and clinical type.²⁶ These studies have also suggested each patient has only a single pathologic subtype within their nervous system, but multiple pathologies have been seen within a single brain by other investigators.²⁷ Thus, the true extent and nature of MS pathology within and between patients, and over time, remains unclear.

Just as the full dimensions of the neuropathology are uncertain, so is the pathogenesis of the MS plaque. There is substantial evidence, however, to suggest it is an autoimmune process directed against myelin and oligodendrocytes, the cells that make CNS myelin²⁵ (Fig. 57–1). The actual mediator of myelin and axonal destruction has not been established, but may reflect a combination of macrophages, destructive cytokines, and reactive oxygen intermediates. The exact trigger for the activation of the T cells in the periphery remains unclear, but the T cells recognize myelin basic protein (MBP), proteolipid protein, myelin oligodendrocyte glycoprotein, and myelin-associated glycoprotein in the blood of patients with MS. A reduction in T-suppressor cells, or suppressor activity, has been reported during active MS and in patients with progressive disease; however, a relative increase in the T-helper-to-suppressor ratio is not found consistently and does not always correlate with disease activity. In patients with stable or mild disease, increased numbers of cells are found that express messenger RNA (mRNA) for transforming growth factor- β (TGF- β) and interleukin-10 (IL-10) compared with patients with severe disease. The complex interplay of the variable cells and cytokines remains to be elucidated.

CLINICAL PRESENTATION OF MULTIPLE SCLEROSIS

General

- Most patients with multiple sclerosis present with nonspecific complaints. Many have problems with their vision or paresthesias.

Primary Symptoms/Signs

- Visual complaints/optic neuritis
- Gait problems
- Paresthesias
- Pain
- Spasticity
- Weakness
- Ataxia
- Speech difficulty
- Psychological changes
- Cognitive changes
- Fatigue

- Bowel/bladder dysfunction
- Sexual dysfunction
- Tremor

Laboratory Tests

- MS is a diagnosis of exclusion
- Magnetic resonance imaging
- Cerebrospinal fluid studies
- Evoked potentials

Secondary Symptoms

- Recurrent urinary tract infections
- Urinary calculi
- Decubiti
- Muscle contractures
- Respiratory infections
- Poor nutrition
- Depression

Tertiary Symptoms

- Financial problems
- Personal/social problems
- Vocational problems
- Emotional problems

CLINICAL PRESENTATION

3 The clinical presentation of MS is extremely variable among patients and typically varies over time in a given patient. The signs and symptoms of MS can be divided into three categories. Primary symptoms are a direct consequence of conduction disturbances produced by demyelination and axonal damage and reflect the area of the brain or spinal cord that is damaged. Secondary symptoms are complications resulting from primary symptoms. For example, urinary retention, a primary symptom, can lead to frequent urinary tract infections, a secondary symptom. Tertiary symptoms relate to the effect of the disease on the patient's everyday life.²⁸

FIGURE 57-1. Autoimmune theory of the pathogenesis of multiple sclerosis (MS). T-helper cells (CD4+) appear to be key initiators of myelin destruction in MS. These autoreactive CD4+ cells, especially of the T-helper cell type 1 (Th1) subtype, are activated in the periphery, perhaps following a viral infection, and express adhesion molecules on their surfaces that allow them to attach and roll along the endothelial cells that constitute the blood-brain barrier. These activated T cells also produce matrix metalloproteinases that help to create openings in the blood-brain barrier, allowing entry of the activated T cells past the blood-brain barrier and into the CNS. Once inside the CNS, the T cells produce pro-inflammatory cytokines, especially interleukins (ILs) 1, 2, 12, 17, and 23, tumor necrosis factor- α (TNF- α), and interferon γ (INF- γ), which further create openings in the blood-brain barrier, allowing entry of B cells, complement, macrophages, and antibodies. The T cells also interact within the CNS with the resident microglia, astrocytes, and macrophages, further enhancing production of proinflammatory cytokines and other potential mediators of CNS damage, including reactive oxygen intermediates and nitric oxide. The role of modulating, or downregulating, cytokines such as IL-4, IL-5, IL-10, and transforming growth factor- β (TGF- β) also has been described. These cytokines are the products of CD4+, CD8+, CD25+, Th1, and FOX P3 regulatory cells. (Ag, antigens; APC, antigen presenting cell; IgG, immunoglobulin G; Na⁺, sodium ion; MHC, major histocompatibility complex; VLA, very-late antigen; VCAM, vascular cell adhesion molecule.)

The clinical course of MS is classified into four categories.²⁹ At the onset of symptoms, about 85% of patients have attacks—new symptoms lasting at least 24 hours and separated from other new symptoms by at least 30 days—followed by remissions (complete or incomplete). Attacks frequently are referred to as *relapses* or *exacerbations*, and the first attack is called a *clinically isolated syndrome* (CIS). This course is called *relapsing-remitting MS* (RRMS). During the RRMS phase, there is a correlation between new brain MRI lesions and clinical attacks, but typically there are many more new MRI lesions than new clinical symptoms. In RRMS patients, attack frequency tends to decrease over time and becomes independent of the development of progressive disabilities.³⁰ Neurologic recovery following an acute exacerbation is usually quite good early in the disease course, but following repeated relapses, recovery tends to be less complete. Given these features, interpretation and evaluation of potential therapeutic interventions must be done quite cautiously, and control groups are essential in the design of clinical studies.

Up to 10% to 20% of RRMS patients have a benign course, characterized by few relapses, often sensory, with minimal disability accruing over time. Most RRMS patients eventually enter a progressive phase in which attacks and remissions generally are difficult to identify. This is referred to as *secondary-progressive MS* (SPMS). Disability tends to accumulate more significantly during this phase of the illness. New brain MRI lesions, especially those seen only after the injection of contrast material, are less common, and brain atrophy increases.³¹

Approximately 15% of patients never have acute attacks and remissions but have progressive disease from the outset. These patients with *primary progressive MS* (PPMS) have symptoms, especially spastic paraparesis, that may worsen rapidly or relatively slowly over time, and they accrue progressively more disability. In general, PPMS patients tend to have a worse prognosis than those who present initially with RRMS, although more recent data suggest progression may not be as rapid as previously thought.³² Finally, a small percentage of patients may have a mixture of both progression and relapses, referred to as *progressive-relapsing MS* (PRMS).

Progression of the illness throughout the lifetime of the individual can be measured in many ways. The most widely used clinical rating scale in MS is the Expanded Disability Status Scale (EDSS), in which a numerical value ranging from 0 (no disability) to 10 (death from MS) is assigned based on the evaluation of several neurologic functions.³³ The limitations of this scale are the relative insensitivity to clinical changes not involving impairment of gait and ambulation, such as changes in cognition, fatigue, and affect. Other tools, such as the Multiple Sclerosis Functional Composite (MSFC), are being evaluated for possible increased sensitivity and utility in describing changes in MS-related disability over time.³⁴ Increasingly, MRI is being used as an index of both disease activity and progression.³⁵ Specifically, the appearance of new lesions or changes in lesion number, size, and volume (burden of disease) are being used as outcome measures in research studies.

The unpredictable nature of MS makes it impossible to anticipate when an exacerbation will occur. However, certain factors have been reported to aggravate symptoms or even lead to an acute attack (new episode of demyelination), including infections, heat (including fever), sleep deprivation, stress, malnutrition, anemia, concurrent organ dysfunction, exertion, and childbirth.³⁶ Interestingly, many patients experience a significant reduction in acute relapses during the third trimester of pregnancy, followed by a relative increase postpartum.³⁶ There are no significant epidemiologic data that support an association between physical trauma and the development or worsening of MS, but this may reflect inadequacy of the studies published to date.³⁷

Multiple sclerosis usually does not directly diminish life expectancy. The development of secondary complications such as pneumonia or septicemia (secondary to aspiration of mouth contents

TABLE 57-1 Prognostic Indicators in Multiple Sclerosis

Indicator	Favorable Prognosis	Unfavorable Prognosis
Age at onset	<40 years	>40 years
Gender	Female	Male
Initial symptoms	Optic neuritis or sensory symptoms	Motor or cerebellar symptoms
Attack frequency in early disease	Low	High
Course of disease	Relapsing/remitting	Progressive

Data from Kantarci and Wingerchuk,⁵ Swanson,³⁹ McDonald et al.,⁴³ and Polman et al.⁴⁴

with swallowing difficulties, decubitus ulcers, or urinary tract infections) or rapid progression of primary lesions affecting respiratory function can lead to a shorter than expected life span. Most of this decrease in life span is seen in patients with rapidly progressive disease. Suicide rates as high as seven times that expected in the general population have been reported.³⁸ Clinical and demographic factors that have been used to predict prognosis of MS are listed in Table 57-1.^{5,39} Several MRI features also have been shown to correlate with progression of disease (see below).⁴⁰⁻⁴⁴

DIAGNOSIS

4 Multiple sclerosis is a diagnosis of exclusion; symptoms frequently can be attributed to other neurologic diseases, just as many syndromes can mimic MS. Some patients may have typical symptoms consistent with classic CIS, whereas many others may have symptoms that are more vague. In the past, the unpredictable nature of MS and the lack of laboratory tests and imaging techniques specific for the disease led to difficulties in making this diagnosis, especially in the early stages of the disease. The diagnosis remains primarily a clinical one that requires the demonstration of “lesions separated in space and time,” referring to the occurrence of at least two episodes of neurologic disturbance reflecting distinct sites of damage in the CNS that cannot be explained by another mechanism.⁴³ An international panel of MS experts was convened in 2000 to reevaluate current diagnostic criteria and to incorporate MRI knowledge. The result of this panel’s work is the McDonald criteria,⁴³ which allow brain MRI lesions, CSF abnormalities, and visual evoked potential (VEP) studies to substitute for clinical lesions in defining “separated in space and time.” A recent reevaluation of the McDonald criteria has simplified the use of these laboratory studies.⁴⁴ In the new scheme, diagnostic categories are MS, possible MS (for those individuals at high risk of developing MS), and not MS. In comparison with older criteria, the McDonald criteria allow for earlier diagnosis.⁴⁵ A new consensus panel of the American Association of Neurology endorses the utility of MRI for diagnostic purpose,⁴⁶ and the FDA has approved one of the immunotherapies to be used after a single attack of demyelination in the context of an appropriately abnormal brain MRI. Thus the definition of MS itself has been altered by the introduction of MRI technology.

LABORATORY STUDIES

To date, there are no tests specific for MS. Tests that are used frequently include MRI of the brain and spine, CSF evaluation, and evoked potentials. Evidence provided by these studies, used in conjunction with the physical examination and history, aids in establishing the diagnosis of MS.

Imaging Studies

MRI produces images of the brain and spine that reflect damage in the CNS that is characteristic of MS plaques in multiple forms, for

instance in the periventricular white matter areas of the brain, as well as more generalized abnormalities such as brain atrophy. MRI is much more sensitive than computed tomography (CT) scans in the detection of MS lesions⁴⁷ and is considered the preferred imaging technique. It is extremely helpful for diagnosis and useful for prognosis. Patients with a single, typical attack of demyelination (possible MS or CIS, e.g., optic neuritis) and three or more T₂-weighted lesions on the brain MRI have an almost 90% likelihood of developing a second attack (clinically definite MS) over 15 years.⁴¹ Optic neuritis is a common first symptom of MS and is indicative of a lesion or lesions localizing on the optic nerve. In contrast, similar individuals with normal brain MRIs have only a 19% likelihood of developing MS over 15 years.⁴¹ Total volume of T₂-weighted lesions (called T₂ *burden of disease*) at the onset of CIS also appears to correlate with the development of disability.⁴⁷ Lesions that enhance after injection of the contrast material gadolinium indicate new lesions and disruption of the blood-brain barrier and are associated with early conversion to MS in CIS/possible MS patients⁴⁸ but do not correlate well over time with progression of disability. Brain atrophy, even early in the course of the illness, probably correlates better with progression of disability.⁴²

CSF Evaluation

In MS patients, CNS synthesis of IgG is increased, whereas serum IgG levels are normal. Electrophoretic studies of the CSF show that the IgG separates into a small number of discrete bands, which, when similar bands are not seen in the serum samples taken at the same time, are called *oligoclonal bands* (OCBs).⁴⁹ Oligoclonal banding (the presence of two or more oligoclonal bands) of IgG is present in 90% to 95% of patients with clinically definite, established MS but also may be seen in lower percentages of diseases that mimic MS or are quite different clinically.⁴⁹ Increasingly, with advances in MRI, CSF analysis is reserved only for patients with atypical clinical scenarios or individuals with possible MS in whom a CSF positive for OCBs may help to define a more definite diagnosis of MS. Although white blood cell counts are often slightly elevated in the CSF of MS patients, the presence of greater than $50 \times 10^6/\text{mL}$ mononuclear cells in the CSF usually indicates a diagnosis other than MS.⁴⁹

Evoked Potentials

Evoked potentials may be helpful in establishing areas of demyelination that are clinically silent. Slowed conduction of visual, brainstem, and somatosensory potentials can be identified, although the sensitivity and specificity of these tests seem to be somewhat less than that seen with MRI or CSF evaluation. Newer diagnostic criteria allow only for the use of VEPs to aid in formal diagnosis.^{43,44}

Blood Studies

A recent report has suggested that in CIS patients with abnormal brain MRIs and abnormal CSF consistent with MS, presence or absence of antimyelin antibodies in serum may be helpful in defining prognosis for further events consistent with clinically definite MS.⁵⁰ The utility of this test, if any, remains to be defined.

DIFFERENTIAL DIAGNOSIS

A number of disorders can mimic MS. Thus most patients are screened with blood tests for rheumatologic, collagen-vascular, infectious, and sometimes inherited metabolic diseases. MRI may rule out tumors and cervical spondylosis. The use of MRI has led to evaluations for MS in many patients with little or no clinical history consistent with MS; however, almost none of these patients ultimately are diagnosed with MS.⁵¹ There are many causes of nonspecific lesions seen in the subcortical white matter on a brain MRI, and

use of established criteria for distinguishing MS lesions from other etiologies (e.g., migraine, hypertension, age older than 50 years, and others) enhances diagnostic accuracy. Electromyography may help in diagnosing amyotrophic lateral sclerosis and neuropathies.

TREATMENT

Multiple Sclerosis

Treatment of MS falls into three broad categories: symptomatic therapy, treatment of acute attacks, and disease-modifying therapies to alter the natural course of the disease. Symptomatic management of the disease is of utmost importance to maintain the patient's quality of life. Treatment of acute attacks will shorten the duration and possibly decrease the severity of the attack. Disease-modifying therapies that alter the course of the illness are most important to diminish progressive disability over time.

A number of different treatment modalities have been studied in the last 30 years, but many older trials had flawed designs. There are no universally accepted treatment algorithms, and treatments vary among clinicians and centers. Perhaps more important, treatment decisions frequently are based on the wishes and goals of individual patients. One potential algorithm for the immunotherapy of RRMS is shown in Fig. 57–2.

CLINICAL CONTROVERSY

When patients initially show signs of RRMS, many practitioners begin treatment with interferon β or glatiramer acetate (ABC-R medications). However, it is controversial which medication to use, and when to start. The role of natalizumab remains unclear. Most practitioners assist patients in making the decision of which medication best fits their lifestyle and offers the maximum efficacy. In patients with severe depression, interferon therapy is contraindicated, and patients are encouraged to use glatiramer acetate. None of the therapies should be used during pregnancy, while attempting to get pregnant, or while breastfeeding.

TREATMENT OF ACUTE EXACERBATIONS

5 Mild acute exacerbations that do not produce functional decline may not require treatment. When functional ability is affected, although treatment suggestions may vary among clinicians, the standard intervention is intravenous injection of high-dose corticosteroids. Results from a large trial of optic neuritis suggest,^{52,53} and the American Academy of Neurology recommends,⁵⁴ that if treatment with steroids is warranted, it is best to use intravenous methylprednisolone. The mechanism of action for corticosteroids in MS is unknown, but it is speculated that steroids improve recovery by decreasing edema in the area of demyelination. Intravenous methylprednisolone has been shown to shorten the duration of acute exacerbations,⁵³ and it may delay repeat attacks for up to 2 years after optic neuritis,⁵⁴ although it has not been shown definitively to affect the progression of disease.⁵⁵ More recently, many practitioners are using high doses of oral methylprednisolone, especially mixing the lyophilized powder in flavored drinks such as smoothies, but there are no comparative data to define this as an equivalent way to deliver the medication.

Methylprednisolone doses can range from 500 to 1,000 mg/day, given intravenously. The duration of therapy is variable and can range from 3 to (rarely) 10 days depending on clinical response. If improvement occurs, it usually begins to be seen after 3 to 5 days. Short-term use of this nature is often accompanied by sleep disturbance, a metallic taste, and rarely gastrointestinal upset. Patients with diabetes mellitus or a predilection to diabetes mellitus may have significant

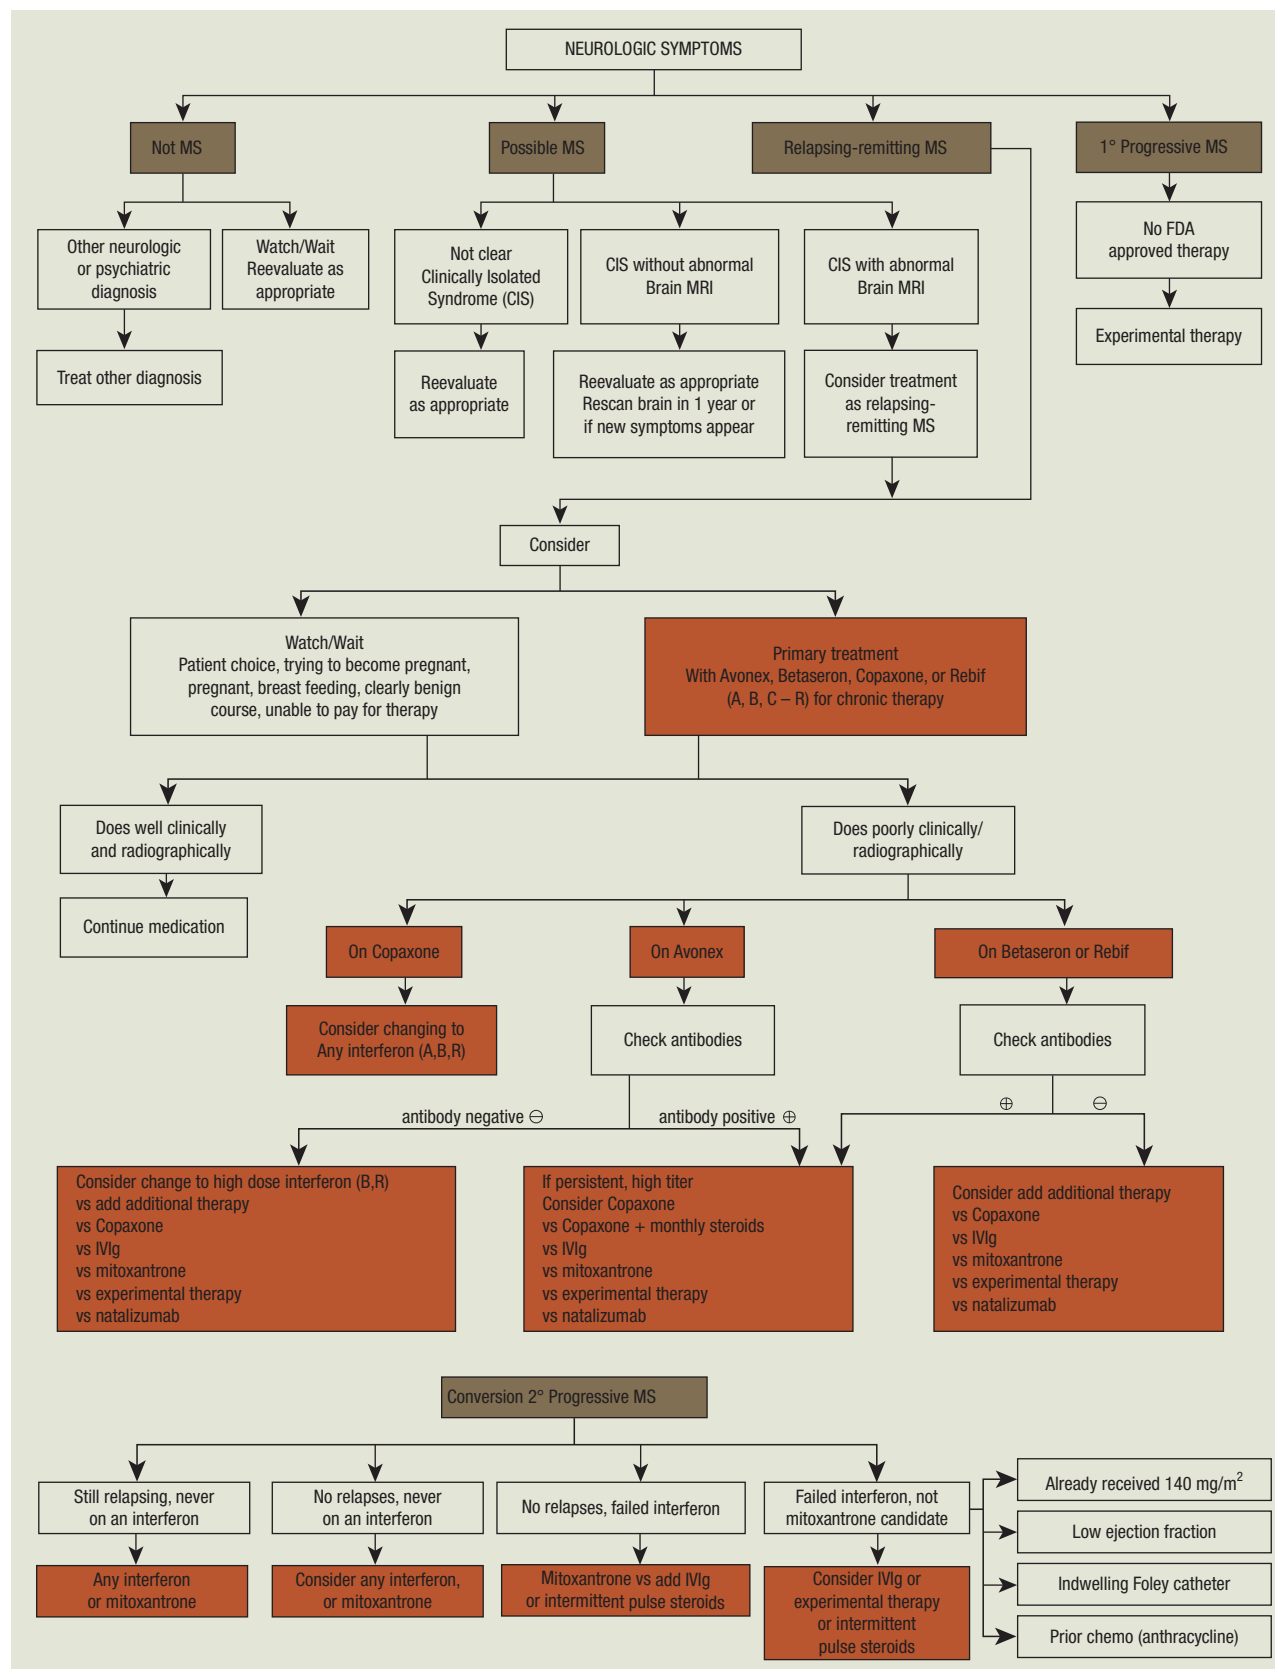

FIGURE 57-2. An algorithm for management of relapsing-remitting multiple sclerosis. (ABC-R, interferon β_{1a} [Avonex], interferon β_{1b} [Betaseron], glatiramer acetate [Copaxone], and interferon β_{1a} [Rebif]; IVIg, intravenous immunoglobulin.)

elevations of blood sugars requiring the use of insulin. Longer durations of intravenous methylprednisolone therapy are associated with acne and fungal infections, mood alteration and rarely, gastrointestinal hemorrhage (especially if used in hospitalized patients or those taking aspirin concurrently).

A very small number of patients have very severe attacks, manifested by hemiplegia, paraplegia, or quadriplegia. If these patients fail to improve with aggressive steroid therapy, plasma exchange every other day for seven treatments can be beneficial for approximately 40% of patients.⁵⁶

CLINICAL CONTROVERSY

If a patient taking interferon decompensates and has high levels of neutralizing antibodies in the blood, most practitioners will stop the medication. In this situation it is controversial whether to rechallenge the patient at a later date with interferon therapy. Many clinicians will only rechallenge with interferon therapy if the patient does not do well on other therapies.

DISEASE-MODIFYING THERAPY

Interferon β_{1b} and Interferon β_{1a}

6 Interferon β_{1b} (Betaseron) was the first agent proven to favorably alter the natural history of the illness.⁵⁷ In Table 57–2 this agent as well as other disease modifying therapies (DMTs) are listed with evidence-based recommendations from the American Academy of Neurology.⁵⁷ Interferon β_{1b} is a nonglycosylated synthetic analog of recombinant interferon β and is produced in *Escherichia coli*. Although the exact mechanism of action is unknown, its effect in MS may be caused by its immunomodulating properties, including the ability to augment suppressor cell function and reduce interferon- γ secretion by activated lymphocytes, its macrophage-activating effect, and its ability to downregulate the expression of interferon- γ -induced class II MHC gene products on antigen-presenting glial cells.⁵⁷ Interferon β_{1b} also suppresses T-cell proliferation and may decrease blood-brain barrier permeability.⁵⁷ In general, all interferons exert these actions in the periphery and at the blood-brain barrier level. Interferons work at the blood-brain barrier level by decreasing matrix metalloproteinases.

TABLE 57-2 Evidenced-Based Recommendations for Disease Modifying Treatment of Multiple Sclerosis

Recommendations	Recommendation Grades ^a
Interferon β	
• Interferon β has been shown to reduce attack rates in patients with MS or those with CIS who are at high risk of developing MS	A-I
• It is appropriate to consider interferon β for any patient with clinically definite MS or who already has RRMS or SPMS and is still experiencing relapses	A-I
• The effectiveness of interferon β in patients with SPMS but without relapses is uncertain	U-I
• Route of administration of interferon β products is probably not clinically important with regards to efficacy; however, the side effect profile does differ	B-II
• Rate of production of neutralizing antibodies is probably less with interferon β_{1a} than with interferon β_{1b}	B-I
• Presence of neutralizing antibodies may be associated with a reduction in the clinical effectiveness of interferon β treatment	C-I
Glatiramer acetate	
• Glatiramer acetate has been shown to reduce the attack rate in patients with RRMS	A-I
• Treatment with glatiramer acetate may slow sustained disability progression in RRMS	C-I
Mitoxantrone	
• Mitoxantrone probably reduces the attack rate in patients with relapsing forms of MS	B-II, III
• Mitoxantrone may have a beneficial effect on disease progression in MS	C-II, III

CIS, Clinically isolated syndrome; RCT, randomized controlled trial; RRMS, relapsing-remitting MS; SPMS, secondary-progressive MS.

^aStrength of recommendations: A: established. B: probable. C: possible. U: inadequate data to support recommendation.

Quality of evidence: Class I, evidence from one or more prospective, randomized, controlled clinical trial; Class II, evidence from cohort or RCT not meeting criteria for class I; Class III, evidence from other controlled trials; Class IV, Evidence from uncontrolled studies, case reports, case series or expert opinion.

Reprinted with permission from Goodin et al.⁵⁷

Interferon β_{1b} is administered subcutaneously every other day at a dose of 8 million international units. Clinical trials have demonstrated that at these doses, interferon β_{1b} significantly reduces annual relapse rate and MRI burden of disease compared with placebo. With respect to clinical disability, however, no significant differences were noted between the interferon- and placebo-treated groups.⁵⁷ Betaseron is packaged in partially premixed syringes (0.3 mg in 15 prefilled blister units) with a new formulation that does not require refrigeration, and can be used with an autoinjector. Betaseron costs approximately \$19,632 per year.

Interferon β_{1a} (Avonex and Rebif) is a natural-sequence glycosylated interferon produced in Chinese hamster ovary cells. Avonex is given as 30 mcg (6 million international units) intramuscularly (IM) once weekly. The prefilled syringes (33 mcg/0.5 mL, 4 per package) should be refrigerated but can be kept at room temperature for 30 days. Avonex costs approximately \$18,360 per year. Rebif is made in a very similar fashion as Avonex but given as either 22 or 44 mcg (0.5 mL) subcutaneously three times weekly. It is supplied in a 0.5-mL prefilled syringe with an autoinjector and costs approximately \$21,163 per year. Rebif also should be kept refrigerated, but it is stable at room temperature for 30 days.

When given 30 mcg intramuscularly once weekly for two years,⁵⁷ patients receiving interferon β_{1a} (Avonex) demonstrated, compared with patients receiving placebo, statistically significant reductions in annual relapse rate (by approximately one-third) as well as disease progression, which was defined as a confirmed decrease of one point on the EDSS. Disease progression also was assessed by MRI studies, and patients receiving active drug had significantly fewer new enhancing lesions compared with placebo-treated patients. Similar results were seen with higher dose (44 mcg), more frequent administration (three times weekly), and subcutaneous injection of interferon β_{1a} (Rebif).⁵⁸ Other studies reveal significant effects on slowing brain atrophy⁵⁹ and the progression of cognitive decline⁶⁰ in patients treated with Avonex. Taken together, these observations show that interferon β possesses significant disease-modifying activity.

Side effects are similar with all the interferons. Baseline complete blood counts, platelet determinations, and liver function tests should be documented before starting therapy, at 1 month, then every 3 months for one year, and every 6 months thereafter. Small percentages of patients develop depressed cell counts and liver enzyme elevations that are usually transient and respond to discontinuation of therapy. Rare patients have developed true liver failure requiring liver transplant, and the package inserts for interferon- β products have been altered, reflecting this risk. The most common adverse effects include injection-site redness, swelling, and rarely necrosis, as well as flu-like symptoms (e.g., fever, chills, myalgias). These symptoms can be mild or severe and are seen in most patients. The flu-like side effects typically occur for up to 24 hours after injection and abate within 1 to 3 months after starting the injections, but they persist in some patients. Injection-site reactions probably are worse with interferon β_{1b} , can occur at any time, and can be lessened by using appropriate injection technique, including site rotation (thighs and buttocks), hydrocortisone cream, applying ice before and after the injection, or use of an autoinjector. Injecting the medications at body temperature (place under armpits) will decrease injection-site pain. Nonsteroidal antiinflammatory agents or acetaminophen taken before and at regular intervals for 24 hours after administration may alleviate the flu-like symptoms. Initiation of one-quarter or one-half the standard dose, and then increasing to full dosage over 1 to 2 months, also may be beneficial in reducing flu-like side effects.⁶¹ Some authors suggest that because of the transient immune activation that can occur following the introduction of interferon β , a short burst of oral prednisone can alleviate some adverse effects.⁶¹

Less commonly reported side effects include shortness of breath, tachycardia, thyroid dysfunction, and depression. Clinicians must monitor patients carefully for signs of depression and treat accord-

ingly. Although depression is a common finding in MS patients, all the interferons, especially interferon β_{1b} , can produce depressive symptoms. Patients who develop depression should be monitored closely because there can be a risk for suicide. The other side effects usually are transient. Most patients will not feel better or have improvement in symptoms when taking interferons, and many will experience side effects; thus compliance can become a major issue. Finally, safety data on interferon β in pregnancy and lactation are lacking. Abortifacient activity in primates has been noted, however. Until adequate safety data are available, women should be counseled as to appropriate contraception while using these products.

Although the adverse-effect profile of interferon β_{1a} resembles that of interferon β_{1b} , intramuscular interferon β_{1a} (Avonex) may hold several advantages, including markedly fewer local injection-site reactions and once-weekly administration versus subcutaneous injection every other day (or 3 days per week with Rebif).

Glatiramer Acetate (Copaxone)

Glatiramer acetate (Copaxone, formerly known as copolymer-1) is a synthetic polypeptide consisting of L-alanine, L-glutamic acid, L-lysine, and L-tyrosine. Although the precise mechanism of action of this compound is unknown, glatiramer acetate appears to mimic the antigenic properties of MBP.⁶² This agent also may act by directly binding to MHC class II receptors and inhibiting binding of MBP peptides to T-cell receptor complexes.⁶² Recently, glatiramer acetate has demonstrated that it induces Th2 (anti-inflammatory) lymphocytes in experimental allergic encephalomyelitis (EAE).⁶² This is thought to contribute to “bystander” suppression at the site of the MS lesion and thereby reduce inflammation, demyelination, and axonal damage.⁶³ Glatiramer acetate also may suppress T-cell activation, and recent studies suggest it may be associated with a neuroprotective effect by inducing brain-derived neurotrophic factor.⁶⁴

Given as a daily 20-mg subcutaneous dose, glatiramer acetate appears to have a relatively mild adverse effect profile. Mild pain and pruritus at the injection site are the most frequent patient complaints. Approximately 10% of patients will experience a one-time transient reaction consisting of chest tightness, flushing, and dyspnea beginning several minutes after injection and lasting usually no longer than 20 minutes. If patients have no history or evidence of coronary artery disease, they may be assured these reactions are almost always self-limited and benign. Several adverse effects that have been associated with the interferons, including flu-like symptoms and depression, do not appear to be provoked by glatiramer acetate. Multicenter trials with glatiramer acetate have demonstrated significant reductions in mean annual relapse rate (approximately 29%) that are comparable with the interferons.⁵⁷ An extension trial, completed after the original, pivotal 2-year study, suggests that glatiramer acetate may slow the progression of disability in patients with RRMS.⁶³ Glatiramer acetate also slows development of T₁ holes on brain MRIs,⁶⁵ and long-term uncontrolled data show that it remains safe and effective for individuals who continue to take it over 10 years.⁶⁶ The annual cost of glatiramer acetate is approximately \$19,749 (20 mg/mL in 30 prefilled syringes). The product is stored in the refrigerator but can be kept at room temperature for up to 1 week.

CLINICAL CONTROVERSY

Because of the potential for progressive multifocal leukoencephalopathy (PML), controversy surrounds the proper selection of patients for natalizumab therapy. With the enhanced efficacy of natalizumab over other disease modifying therapies, some clinicians might be tempted to use this drug in patients with early disease and frequent relapses or progressive MS. The limitations imposed by the Tysabri Outreach: Unified Commitment to Health (TOUCH) program make the medication unavailable for these patients.

Natalizumab (Tysabri)

Natalizumab is a partially humanized monoclonal antibody directed at the cell surface adhesion molecule $\alpha_4\beta$ -integrin (also known as very-late antigen 1, VLA-1). Natalizumab works by attaching to VLA-1 and blocking its interaction with its ligand on CNS endothelium vascular cell adhesion molecule (VCAM)-1. Thus, activated lymphocytes are denied entry past the blood-brain barrier. In a phase II study, compared to placebo, natalizumab significantly reduced the number of new gadolinium-enhancing lesions by more than 90%, and diminished relapses as well.⁶⁷ In a 2-year phase III trial (Atrial Fibrillation Follow-Up Investigation of Rhythm Management [AFFIRM]), compared to placebo, annual relapse rate was reduced by more than 60%, gadolinium-enhancing lesions were lessened by more than 90%, and progression of disability was significantly delayed.⁶⁸ In a separate, 2-year, phase III trial (The Safety and Efficacy of Natalizumab in Combination with Interferon Beta-1a in Patients with Relapsing Remitting Multiple Sclerosis [SENTINEL]) in patients already taking interferon β_{1a} (Avonex), those who had natalizumab added to interferon β_{1a} had a relapse rate reduction of more than 50% and gadolinium-enhancing lesion reduction of 84% compared to patients who continued with interferon β_{1a} alone.⁶⁹ In these trials natalizumab was injected intravenously every 4 weeks and was relatively well tolerated, although approximately 1% of patients developed infusion reactions, and 6% developed neutralizing antibodies that diminished the efficacy of the drug.

On November 23, 2004, the FDA approved natalizumab, with the stipulation that the studies would continue, for use in relapsing MS in patients with inadequate response or intolerance to other MS therapies. In February 2005, Biogen and Elan voluntarily removed natalizumab from the market after receiving reports of two patients (one patient from the SENTINEL trial, and one patient in a Crohn disease study), who both died after developing PML, a rare brain infection most commonly seen in patients infected with human immunodeficiency virus (HIV).^{70–72} One other patient who developed PML in the SENTINEL trial survived.^{70–72} Further safety analysis did not identify other cases, and on March 9, 2006, an FDA panel reviewing the data suggested reapproval of natalizumab for use in relapsing patients, who would be required to be placed in an ongoing safety registry (TOUCH). On June 5, 2006, the FDA reapproved use of natalizumab in the United States, and infusions began shortly thereafter.

Natalizumab is indicated as monotherapy, 300 mg every 4 weeks as an infusion. It is indicated for the relapsing forms of MS to delay the accumulation of physical disability and decrease the number of relapses in patients who have a documented inadequate response or intolerance to traditional MS therapies. The wholesale cost of natalizumab is approximately \$2,600 per infusion or \$31,200 annually (300 mg per 15 mL), which does not include nursing and other fees.⁷³

CLINICAL CONTROVERSY

Lifetime exposure to mitoxantrone cannot exceed 140 mg/m². This poses a problem when deciding which patients should receive the therapy, as well as when in the disease course they should receive it. Many clinicians feel that treatment should be initiated as soon as the patient meets criteria, whereas others believe therapy should be delayed to not exceed to maximum lifetime dose.

Mitoxantrone

7 Mitoxantrone (Novantrone), a member of the anthracenedione family, is approved by the FDA for reducing neurologic disability and the frequency of clinical relapses in patients with SPMS (chronic), PRMS, or worsening RRMS.⁷⁴ The MRI outcomes, however, were not as robust as those typically seen in the trials of relapsing patients alone.⁷⁵ Mitoxantrone is administered as a brief (5- to 15-minute) intravenous infusion dosed at 12 mg/m² every 3 months. An evaluation

of left ventricular ejection fraction is required prior to administration of each dose and if signs or symptoms of congestive heart failure develop. The maximum allowable lifetime cumulative dose of mitoxantrone is 140 mg/m². Other potential side effects noted with this agent are nausea, alopecia, menstrual disorder, amenorrhea, upper respiratory tract infection, urinary tract infection, and leukopenia. The role mitoxantrone will play in the treatment of MS remains unclear because potential cardiac toxicity appears to limit its long-term use. In addition, although patients with SPMS were included in the mitoxantrone in MS (MIMS—Effect of Mitoxantrone on MRI in Progressive MS) trial, resulting in FDA approval for use in SPMS, there was no substudy documenting slowing of progression specifically in this subgroup of patients.^{74,75} Thus, support for use of mitoxantrone in this context is less strong.⁵⁷ The average wholesale cost of mitoxantrone is approximately \$1,982 (average male) or \$1,586 (average female) per infusion and will vary based on the patient's body surface area. Nursing, pharmacy, and technical fees must also be added to this estimate.

■ REMAINING QUESTIONS FOR DMT

8 Despite encouraging results from well-conducted clinical trials, several relevant issues remain. The most important question in the use of the DMTs is when to begin therapy. The Medical Advisory Board of the National Multiple Sclerosis Society has adopted recommendations regarding the use of the current MS DMTs, these are summarized in Table 57-3.⁷⁶

Decisions about the use of any medication rest on determination of the severity of the illness, the efficacy of the medication, and the side effects and costs related to the therapy. Clearly, these drugs slow the course of the illness but do not suppress it completely, and in some individuals, there is no apparent benefit. There is now, however, overwhelming evidence that the vast majority of untreated patients will have progressive disease over time. Pathologic data clearly show that even in acute lesions there is significant axonal damage that is essentially irreversible. MRI data show that 80% to 90% of all new enhancing lesions are asymptomatic, suggesting that a “quiet” clinical course does not necessarily mean there is not ongoing disease activity that ultimately will be reflected in cognitive problems and progressive spastic paraparesis.

TABLE 57-3 Disease Management Consensus Statement

- Initiation of therapy with an interferon β medication (Avonex, Betaseron, Rebif) or glatiramer acetate is advised as soon as possible following a definite diagnosis of MS with active, relapsing disease, and can also be considered for selected patients with a first attack who are at high risk of MS.
- Natalizumab is FDA approved for patients who have had an inadequate response to, or are not able to tolerate other MS therapies.
- Mitoxantrone can be considered for patients with relapsing worsening disease or patients with secondary-progressive MS who are worsening, whether or not relapses are occurring.
- Patients' access to medication should not be limited by the frequency of relapses, age, or level of disability.
- Treatment is not to be stopped during evaluation for continuing treatment.
- Therapy is to be continued indefinitely, unless there is clear lack of benefit, intolerable side effects, new data that reveal other reasons for cessation, or better therapy becomes available.
- Interferon β s (Avonex, Betaseron, Rebif), glatiramer acetate (Copaxone), mitoxantrone (Novantrone), and natalizumab (Tysabri), are all FDA approved for patients with MS and should be included in formularies and covered by third-party payers so that physicians and patients can determine the most appropriate agent on an individual basis.
- Movement from one immunomodulating drug to another should be permitted for medical reasons.
- None of these agents are approved for use in women trying to become pregnant, who are pregnant, or nursing mothers.

Data from Miller et al.⁷⁶

Furthermore, it is now known that very early therapy is effective. In patients with CIS and two or more T₂ lesions on brain MRI (i.e., at high risk for developing clinically definite MS), placebo-controlled studies with all three of the interferon agents have shown significant delay in a second attack and positive outcomes on a variety of MRI measures (BENEFIT = Betaferon in Newly Emerging Multiple Sclerosis for Initial Treatment; CHAMPS = Controlled High Risk Subjects Avonex Multiple Sclerosis Prevention Study; and ETOMS = Early Treatment of Multiple Sclerosis).⁷⁷⁻⁷⁹ Thus very early therapy is potentially warranted, and interferon β_{1b} and interferon β_{1a} (Avonex) are approved by the FDA after CIS in those with abnormal MRIs consistent with demyelination. The National MS Society recommends that patients with relapsing disease should be placed on Avonex, Betaseron, Copaxone, or Rebif (ABC-R) therapy immediately after the diagnosis.⁷⁶

A second major issue is which drug to use in which patient. There has not been a single, randomized study comparing all four ABC-R drugs with one another in a similar patient population at the same time.⁸⁰ The pivotal placebo-controlled trials produced results that were more similar than different when comparing across trials, including a nearly identical one-third reduction in relapse rate for all four drugs over 2 years. There has been speculation for some time, however, that higher dose or more frequent administration of interferon (Rebif or Betaseron) may be more beneficial than the lower dose once-weekly use of interferon (Avonex). To address this issue, two comparative trials of Avonex versus Betaseron (INCOMIN = Independent Comparison of Interferon)⁸¹ and Avonex versus Rebif (EVIDENCE = Evidence of Interferon Dose-Response: European North American Comparative Efficacy)⁸² have now been completed. In both cases, Avonex was used in the standard 30 mcg per week intramuscular injection, and the other interferons were used at the usual higher dose, more frequent subcutaneous administration, as in a typical clinical practice. In both studies, there were small but statistically significant differences favoring Betaseron or Rebif in a variety of clinical and MRI measures of efficacy, and it was this short-term (6-month) comparative trial⁸² that resulted in FDA approval of Rebif in the United States in 2002. More recently, a randomized, controlled, open-label comparison of interferon β_{1a} at 22 mcg per week versus interferon β_{1b} 250 mcg every other day reported no difference in relapse rate, time to first relapse, or time to sustained progression over a 24 month study.⁸³ There also have been a variety of other open label comparison trials that were uncontrolled and nonrandomized, and these typically have not shown significant differences in efficacy between the various interferon β products used in the usual manner.

There were many scientific objections to these trials, most important of which was lack of control of dosing versus frequency of administration, absence of blinding of clinical outcomes, and the use of novel primary outcome measures with unclear biologic or clinical significance. In addition, published around the same time was a trial comparing 60 mcg with the standard 30 mcg Avonex in a weekly injection that showed no difference over a 2-year study.⁸⁴ Thus, many would conclude there are relatively modest differences between the various interferon preparations, all of which have significant limitations in efficacy, as does glatiramer acetate.

A concern with all three interferon products that further muddies our understanding of the clinical differences between the interferon products is the development of neutralizing antibodies. In clinical trials, 30% to 40% of patients receiving interferon β_{1b} developed antibodies directed against the drug.⁸⁵ In these patients, the exacerbation rate was similar to that in placebo-treated patients. In patients on interferon β_{1b} neutralizing antibodies can occur first at 3 to 6 months and up to 18 months. This product tends to be the most antigenic.⁸⁵ With interferon β_{1a} , neutralizing antibodies were found in 22% of early trials of Avonex, but later studies reported that only 2% to 5% of treated patients developed antibodies; this decrease was caused by a

formulation change of the drug making it the least antigenic.^{84,85} Percentages for Rebif are intermediate, therefore moderately antigenic, at approximately 12% and can occur in the first 9 to 15 months of treatment, which is the same time frame for antibody production with Avonex.^{58,85,86} The long-term clinical significance of these findings, however, are still not completely clear. Three recent studies, however, have further confirmed the effect of neutralizing antibodies on relapses, MRI lesions, and progression of disability.^{86–89} Whether these antibodies are truly cross-reactive between products is unknown, as is the duration during which antibodies can be detected. There are no general consensus guidelines regarding when to test for neutralizing antibodies, which assay to use, or what titer cutoff to apply to patients in clinical settings.⁹⁰ An important question is whether production of antibodies might be diminished with treatments such as corticosteroids. Another concern of practitioners is the relationship between active ingredients and varying excipients of interferon therapies and the production of neutralizing antibodies. Significant neutralizing antibodies have not been seen with glatiramer acetate, but neutralizing antibodies are seen in approximately 6% of patients treated with natalizumab, and the antibodies seem to diminish efficacy.⁶⁹

9 We now have experience for more than a decade with MS patients taking DMTs, yet continuing to have more relapses, more lesions on MRI, more disability, and ongoing slippage into SPMS.⁹¹ There is no accepted definition of treatment inadequacy, although the Canadian MS Research Council⁹² has suggested a relatively simple approach that incorporates the elements of relapse rate, new MRI lesions, and change on the EDSS. If a patient develops significant and persistent interferon antibodies, movement to a noninterferon (glatiramer acetate, natalizumab, mitoxantrone, or possibly intravenous immunoglobulin) is reasonable. When failing low-dose interferon, options include changing to a higher dose, more frequent administration of interferon, or changing to a noninterferon. A second option is addition of an immunosuppressant agent, such as monthly intravenous methylprednisolone, azathioprine, methotrexate, or mycophenolate. As noted above, the addition of natalizumab to interferon β_{1a} was effective but produced rare cases of PML, and thus this combination will not be used in the future. Small, uncontrolled trials adding mitoxantrone to ABC-R DMT suggest this might be a promising approach for those with ongoing disease activity in spite of DMT. Mitoxantrone or natalizumab will be options for those with relatively severe RRMS, or those who have failed or were intolerant of one or more ABC-R medications.

■ SYMPTOMATIC MANAGEMENT

10 Many of the symptoms of MS do not require pharmacologic management or do not respond to it. This section covers the primary symptoms in which pharmacologic management may be of benefit (Table 57–4).^{28,92–95} See the preceding section (Imaging Studies) on the treatment of acute exacerbations for a discussion on optic neuritis.

Gait Difficulties and Spasticity

Problems with gait can be caused by spasticity, weakness, ataxia, defective proprioception, or a combination of these factors. Spasticity is amenable to pharmacologic intervention, whereas physical therapy may be required in treating gait disturbances owing to any of the other factors. Spasticity is encountered commonly and tends to affect the legs more markedly than the arms. Spasticity can result in falls; however, in the later stages of the disease, the increased muscle tone of a spastic limb often lends strength to patients with underlying weakness. Therefore, when using muscle relaxants, one must be careful not to decrease the tone to an extent that ambulation is actually hindered.^{28,93} Baclofen (Lioresal), a γ -aminobutyric acid (GABA) analog, is the preferred agent and usually is started in dosages of 10 mg three times daily and titrated upward to achieve the desired

TABLE 57-4 Treatment of Selected Primary MS Symptoms

Spasticity	Bladder Symptoms	Sensory Symptoms	Fatigue
Baclofen	Propantheline	Carbamazepine	Amantadine
Dantrolene	Oxybutynin	Phenytoin	Antidepressants
Diazepam	Dicyclomine	Amitriptyline or other TCAs	Modafinil
Tizanidine	DDAVP	Gabapentin	Methylphenidate
Tiagabine	Self-catheterization	Lamotrigine	Dextroamphetamine
Gabapentin	Imipramine or amitriptyline	Pregabalin	
Pregabalin	Prazosin		
Botulinum toxin type A	Botulinum toxin type A		
	Solifenacin

	Trospium		
	Hyoscyamine		

DDAVP, desmopressin acetate; TCA, tricyclic antidepressant.

Data from Schapiro,²⁸ Freedman et al.,⁹² Mitchell,⁹³ Kinn and Larson,⁹⁴ and Stenager et al.⁹⁵

response. Most patients achieve a satisfactory response with dosages between 40 and 80 mg/day; however, dosages higher than the recommended daily maximum of 80 mg are required by some patients.^{28,93} Continuous intrathecal administration of baclofen may be an option for patients unable to tolerate or unresponsive to oral therapy. Baclofen should not be discontinued abruptly to avoid the possibility of seizures.⁹³ Small doses of diazepam (Valium) (e.g., 0.5–1 mg) often are added to baclofen in patients in whom optimal response has not been achieved. Tizanidine (Zanaflex) can be added in small dosages to baclofen with sometimes great results and smaller doses of each drug.

Another effective agent, with a different mechanism of action is tizanidine. This short-acting, α -adrenergic agonist acts in the CNS to reduce spasticity by increasing presynaptic inhibition of motor neurons. It appears to have efficacy comparable with that of baclofen.⁹³ Dosage must be titrated slowly over 2 to 4 weeks, starting with 4 mg at bedtime with adjustments based on clinical response. Effective tolerated dosages have ranged from 2 to 36 mg/day. Sedation, dizziness, and dry mouth are the most commonly reported adverse effects, but hypotension also can occur, as well as a rare but severe hepatotoxicity. In patients who are unable to tolerate baclofen or tizanidine, diazepam (Valium; 2–10 mg/day, clonazepam [Klonopin; 1–3 mg/day]), or dantrolene sodium (Dantrium; 100–400 mg/day), may be considered as alternatives, but they generally are less effective than either baclofen or tizanidine. Mild spasticity also may respond to moderately high doses of gabapentin (Neurontin; 1,800–3,600 mg/day); Tiagabine (Gabitril 8–56 mg/day) may be useful in some patients with spasticity, but side effects can prohibit its use. Pregabalin (Lyrica; 75–300 mg/day) has similar features and mechanism of actions as gabapentin. Although it is approximately three times more potent and does not saturate the L-system transporter system in the gastrointestinal system, it may prove useful in the treatment of spasticity in MS patients.

Botulinum toxin type A (Botox; dose depending on the muscles injected) has been shown to be effective in improving spasticity.²⁸ The amount of toxin required to exert an effect on spasticity is often too excessive to use safely in the larger muscles; therefore, its use is best limited to smaller areas of focal muscle spasm.

Tremor

Cerebellar symptoms such as tremor can be troubling and difficult to control. Medications that can be helpful include propranolol, primidone, and isoniazid.

Bowel and Bladder Symptoms

Patients commonly complain of incontinence, urgency, frequency, and nocturia, which are indications of a hyperreflexic bladder (i.e.,

inability to store urine). A number of anticholinergic agents, including oxybutynin chloride (Ditropan; 10–20 mg/day), tolterodine (Detrol; 2–4 mg/day), propantheline bromide (Pro-Banthine; 45–90 mg/day), hyoscyamine (Levsin; 0.75–1.5 mg/day), and dicyclomine hydrochloride (Bentyl; 30–80 mg/day) are used to treat this problem if symptoms are mild. Ditropan is now also available in an extended-release formulation (5 and 10 mg). In addition, tricyclic antidepressants, such as imipramine (Tofranil) and amitriptyline (Elavil), have been used for their anticholinergic properties. With all anticholinergic agents, great care must be used to avoid the problem of constipation, which is worsened by the patient's natural instinct to limit fluid intake (owing to the increasing urge to urinate). Newer medications include antimuscarinic agents such as trospium chloride (Sanctura; 40 mg/day), solifenacin succinate (Vesicare; 5–10 mg/day), and darifenacin hydrobromide (Exelbyx; 7.5–15 mg/day). As an alternative, the synthetic antidiuretic hormone preparation desmopressin acetate (DDAVP; 0.2–0.6 mg/day) has been reported to be effective in the treatment of urgency and incontinence.⁹⁴ Use of DDAVP probably is best limited to bedtime so as to improve sleep and because there can be significant problems with hyponatremia and possible seizures if overused. Patients with significant sphincter dyssynergia may benefit from the oral use of α -adrenergic blockers such as prazosin (Minipress; 10–40 mg/day) or intramuscular use of botulinum toxin type A (Botox; dose depends on the muscles injected).

Intermittent self-catheterization with or without a concomitant anticholinergic agent is recommended in patients with large postvoid urine residual volumes (greater than 100 mL) or when the urinary problem is hyporeflexic in nature (failure to empty). Patients with large postvoid residual volumes are at risk for developing urinary tract infections (UTIs) and often are prescribed urinary acidifiers such as vitamin C or antiseptics such as methenamine mandelate to prevent infections. Antibiotics used for UTI prophylaxis include sulfamethoxazole/trimethoprim, cephalexin, cinoxacin, and nitrofurantoin.

Constipation is the most common bowel complaint. Increases in dietary fiber and hydration may alleviate this problem, but in some instances laxatives or enemas may be necessary.²⁸

CLINICAL CONTROVERSY

In a depressed patient with a new diagnosis of MS, it is controversial whether to start interferon therapy because depression is a side effect of the interferon therapies, and the incidence of suicide is higher in this population. Practitioners generally start depressed MS patients on an antidepressant along with the interferon and monitor them closely. Interferon should never be started in a severely depressed patient.

Major Depression

Major depression is common in patients with MS, and the risk of suicide may be increased markedly compared with healthy subjects.⁹⁵ Patients should be monitored closely for the development of major depressive symptomatology and treated accordingly (see Chap. 71). Interferon products should be used cautiously in patients with significant depression.

Sensory Symptoms

Numbness and paresthesia are frequent sensory complaints but usually do not require treatment. Some MS patients may develop acute or chronic pain syndromes,⁹³ such as trigeminal neuralgia and painful dysesthesias, for which treatment is necessary. Carbamazepine (Tegretol; 400–1,200 mg/day) is the preferred agent for the treatment of trigeminal neuralgia, and it is used in the same doses that are used for the treatment of seizure disorders.

Sexual Dysfunction

Sexual dysfunction in both men and women are common in MS, and counseling should be offered to both partners. Sildenafil citrate (Viagra), tadalafil (Cialis), and vardenafil (Levitra) are very effective for men with MS who have erectile dysfunction. Other options for men include alprostadil injection (Caverject) or intraurethral suppositories (MUSE). Viagra is currently being studied in the female population with MS and sexual dysfunction.

Fatigue

Fatigue, one of the most common complaints in MS patients, can be severely disabling, but treatment is often overlooked. Typically present in the late to middle afternoon, it can increase with heat exposure, exertion, intercurrent infection, spasticity, weakness, and depression. Amantadine hydrochloride (100 mg twice daily) is used often and may offer significant relief.^{28,92} Pemoline (Cylert), a commonly used therapy, was voluntarily withdrawn from the U.S. market by all manufacturers in late 2005 because of increased risk of liver toxicity. Methylphenidate (Ritalin) and dextroamphetamine (Dexedrine) are used commonly for fatigue in MS. Modafinil (Provigil), at 100 mg twice daily, is helpful for MS-related fatigue.

The aminopyridines, 4-aminopyridine and 3,4-diaminopyridine,⁹⁶ are potassium channel blockers that are currently under investigation in the symptomatic treatment of MS. These agents may improve conduction in demyelinated axons and may improve strength and decrease heat sensitivity.

COMPLEMENTARY AND ALTERNATIVE THERAPIES FOR MS

A large percentage of patients with MS use complementary and alternative medicine (CAM) instead of, or in addition to, disease-modifying and symptomatic therapies. Common CAM therapies include diet and dietary supplements, such as vitamins, minerals, and herbs. Antioxidant supplements vitamin A, C, E, α -lipoic acid (ALA), coenzyme Q10 (CoQ₁₀), grape seed, and pine bark extracts have suggestive evidence of benefiting MS patients by making them “feel better overall.” However, for patients with MS, there is a theoretical risk involved with taking antioxidant supplements owing to their ability to stimulate the immune system (T cells and macrophages). Stimulating the immune system in patients with MS could be counterproductive, possibly worsening or exacerbating their disease, and may counteract the effects of immunomodulators. Other immune-stimulating supplements that should be used with caution are garlic, ginseng (Asian and Siberian), echinacea, cat's claw, astragalus, alfalfa, and stinging nettle. A few agents that may pose a problem in MS but may have benefit are zinc, melatonin (for insomnia), and dehydroepiandrosterone (DHEA).⁹⁷

In general, there is insufficient data supporting the effectiveness and safety of CAM therapies for MS. However, for patients with MS who are willing to try new approaches with limited evidence, CAM may be a consideration in some cases. Healthcare providers can be a source of objective information regarding the use of CAM for MS and can assist their patients in making the best decision.⁹⁷

PHARMACOECONOMIC CONSIDERATIONS

As with many therapeutic decisions, economic cost, both to the individual and to society, must be considered. Currently, the annual cost of the new potentially disease-modifying therapies is considerable. The Red Book average wholesale price (used for all products in this chapter) of Avonex and each of the currently available interferons is between \$18,000 and \$21,100 per patient per year. Given this expense, it must be remembered that these therapies are not

curative and that individual patients may experience variable results. Future investigations evaluating these therapeutic modalities clearly will need to address not only clinical but also economic and humanistic outcomes.

EVALUATION OF THERAPEUTIC OUTCOMES

Response to treatment of acute exacerbations of MS is seen commonly within days. With respect to DMTs, it is important for the clinician to recognize that over the short term (days to weeks), little or no apparent benefit may be noted by either patient or clinician. Evaluation of therapeutic outcomes, such as decreased MS exacerbations and hospitalizations or perhaps slowed disease progression and disability (as measured using scales such as EDSS), must be conducted over a period of months to years. Patients should be provided with realistic goals and expectations of these treatment options and encouraged to participate in the evaluation of therapeutic response. Initially, it may be important to reevaluate patients at relatively short time intervals to monitor for adverse effects.

Safety monitoring of patients on interferon includes regular laboratory monitoring, patient observation, and questioning for adverse effects or changing disability, and regular neurologic examinations. Specific laboratory monitoring for individuals on interferon therapy should include a complete blood count, platelet count, and liver function tests. These should be completed at baseline, every 3 months for 1 year, and every 6 months yearly thereafter. Glatiramer acetate requires no laboratory monitoring. In addition to counseling patients regarding the adverse effects associated with these drugs, pharmacists should actively encourage patients to comply with their prescribed regimens.

CONCLUSIONS

Multiple sclerosis is an inflammatory disease of the CNS that strikes young, genetically susceptible individuals living in high-risk geographic areas. Although the exact etiology of MS is unknown, it is likely that MS is an autoimmune disease triggered by an as yet undetermined environmental agent or agents. There is no cure, but quality of life can be improved through symptomatic management, and the disease course is partially suppressed by presently available DMTs.

ACKNOWLEDGMENT

The authors acknowledge the contributions of Sarah Johnson, PharmD, Leann Nguyen, PharmD, Katherine Hays, PharmD, Christien Paynter, PharmD, Kai Davids, PharmD, Kevin Fanciulli, and Eugene Medley, MS, Khaloud Alsilmi, BS Pharm, and Joan Kaufman, illustrator, for their contributions to this chapter.

ABBREVIATIONS

ABC-R: Avonex, Betaseron, Copaxone, and Rebif
 CAM: complementary or alternative medicine
 CIS: clinically isolated syndrome
 CNS: central nervous system
 CSF: cerebrospinal fluid
 CT scan: computed tomographic scan
 DDAVP: desmopressin
 DHEA: dehydroepiandrosterone
 DMT: disease modifying therapy

EAE: experimental allergic encephalomyelitis

EDSS: expanded disability status scale

FDA: food and drug administration

GABA: γ -aminobutyric acid

HHV-6: human herpes virus type 6

HIV: human immunodeficiency virus

HLA: human leukocyte antigen

HTLV: human T-cell leukemia virus

IgG: immunoglobulin G

IL-2: interleukin-2

IL-10: interleukin-10

MHC: major histocompatibility complex

MIMS: Effect of Mitoxantrone on MRI in Progressive MS (trial)

MRI: magnetic resonance imaging

MS: multiple sclerosis

MSFC: Multiple Sclerosis Functional Composite

OCBs: oligoclonal bands

PML: progressive multifocal leukoencephalopathy

PPMS: primary-progressive multiple sclerosis

PRMS: primary-relapsing multiple sclerosis

RRMS: relapsing-remitting multiple sclerosis

SPMS: secondary-progressive multiple sclerosis

SSPE: subacute sclerosing panencephalitis

TGF- β : transforming growth factor- β

UTI: urinary tract infection

VEP: visual evoked potential

VLA-1: very late antigen 1

SUSAN J. ROGERS AND JOSE E. CAVAZOS

KEY CONCEPTS

- 1 Patient-specific treatment goals should be identified. Treatment goals can change over time. In general, the goal of treatment should be that the patient be free of seizures and have no adverse effects.
- 2 Accurate diagnosis and classification of seizure/syndrome type is critical to selection of appropriate pharmacotherapy.
- 3 Patient characteristics such as age, comorbid conditions, ability to comply with the prescribed regimen, and presence or absence of insurance coverage also can influence the choice of antiepileptic drugs.
- 4 Pharmacotherapy of epilepsy is highly individualized and requires titration of dose to optimize antiepileptic drug therapy (maximal seizure control with minimal or no side effects). Approximately 50% to 70% of patients can be maintained on one antiepileptic drug.
- 5 If the therapeutic goal (freedom from seizures and minimal to no adverse effects) is not achieved with monotherapy, a second drug can be added or a switch to an alternative single antiepileptic drug can be made. It is suggested that the second antiepileptic drug should have a different mechanism of action from the first, although there is no evidence in humans to support this.
- 6 Some patients eventually can discontinue antiepileptic drug therapy. Several factors predict successful withdrawal of antiepileptic drugs.
- 7 The appropriate use of antiepileptic drugs requires a thorough understanding of their clinical pharmacology, for example, mechanism of action, pharmacokinetics, adverse reaction, dosage forms, and drug interactions.

Epilepsy is a disorder that is best viewed as a symptom of disturbed electrical activity in the brain, which may be caused by a wide variety of etiologies. It is a collection of many different types of seizures that vary widely in severity, appearance, cause, consequence, and management. Seizures that are prolonged or repetitive can be life-threatening. The effect epilepsy has on patients' lives can be significant and extremely frustrating. Indeed, studies have shown that patients with epilepsy who do not experience complete seizure control have lower

self-reported quality-of-life scores than patients who are seizure-free. It is also important to recognize that seizures can be just one (albeit the most obvious) symptom of an epileptic disorder. Not uncommonly, patients have other comorbid disorders, including depression, anxiety, and potentially neuroendocrine disturbances. Patients with epilepsy also may display neurodevelopmental delay, memory problems, and/or cognitive impairment. Although, by convention, the focus of drug treatment is on the abolition of seizures, clinicians also need be attentive to addressing these common comorbidities.

EPIDEMIOLOGY

Each year, 120 per 100,000 people in the United States come to medical attention because of a newly recognized seizure.¹ At least 8% of the general population will have at least one seizure in a lifetime. However, it is common to have a seizure and not have epilepsy. The rate of recurrence of a first unprovoked seizure within 5 years ranges between 23% and 80%. Children with an idiopathic first seizure and a normal electroencephalogram (EEG) have a particularly favorable prognosis. Some seizures occur as single events resulting from withdrawal of central nervous system (CNS) depressants (e.g., alcohol, barbiturates, and other drugs) or during acute neurologic illnesses or systemic toxic conditions (e.g., uremia or eclampsia). Some patients will have seizures only associated with fever. These febrile seizures do not constitute epilepsy.¹

Epilepsy is a chronic disorder characterized by recurrent unprovoked seizures.¹ The age-adjusted incidence of epilepsy is 44 per 100,000 person-years. Each year, approximately 125,000 new epilepsy cases occur in the United States; only 30% are in people younger than 18 years of age at the time of diagnosis. There is a bimodal distribution in the occurrence of the first seizure, with one peak occurring in newborn and young children and the second peak occurring in patients older than 65 years of age. The relatively high frequency of epilepsy in the elderly is now being recognized.

ETIOLOGY

Seizures occur because a group of cortical neurons discharge abnormally in synchrony. Anything that disrupts the normal homeostasis of neurons and their stability can trigger hyperexcitability and seizures. There are thousands of medical conditions that can cause epilepsy, from genetic mutations to traumatic brain injury. A genetic predisposition to seizures has been observed in many forms of primary generalized epilepsy. Patients with mental retardation, cerebral palsy, head injury, or strokes are at an increased risk for seizures and epilepsy. The more profound the degree of mental retardation as measured by the intelligence quotient (IQ), the greater is the incidence of epilepsy. In the elderly, seizures are primarily of partial onset associated with the focal neuronal injury induced by strokes, neuro-

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

degenerative disorders (e.g., Alzheimer disease), and other conditions. In some cases, if an etiology of seizures can be found and corrected, the patient may not require chronic antiepileptic drug (AED) treatment. Patients can also present with unprovoked seizures that do not have an identifiable cause, and thus by definition have idiopathic or cryptogenic epilepsy. *Idiopathic etiology* is the term used for suspected primary generalized seizures, whereas *cryptogenic etiology* is used if no obvious cause is found for partial-onset seizures. The incidence of idiopathic epilepsy is higher in children.²

Many factors have been shown to precipitate seizures in susceptible individuals. Hyperventilation can precipitate absence seizures. Sleep, sleep deprivation, sensory stimuli, and emotional stress increase the frequency of seizures. Hormonal changes occurring around the time of menses, puberty, or pregnancy have also been associated with the onset of or an increased frequency of seizures. A careful history should be obtained from patients presenting with seizures because theophylline, alcohol, high-dose phenothiazines, antidepressants (especially maprotiline or bupropion), and street drug use have been associated with provoking seizures. Perinatal injuries and small gestational weight at birth are also risk factors for the development of partial-onset seizures. Immunizations have not been associated with an increased risk of epilepsy.

PATHOPHYSIOLOGY

Seizures result from excessive excitation or in the case of absence seizures from disordered inhibition of a large population of cortical neurons.³ This is reflected on EEG as a sharp wave or *spike*. Initially, a small number of neurons fire abnormally. Normal membrane conductances and inhibitory synaptic currents break down, and excess excitability spreads, either locally to produce a focal seizure or more widely to produce a generalized seizure. This onset propagates by physiologic pathways to involve adjacent or remote areas. The clinical manifestations depend on the site of the focus, the degree of irritability of the surrounding area of the brain, and the intensity of the impulse.³

There are multiple mechanisms that might contribute to synchronous hyperexcitability including: (1) alterations in the distribution, number, type and biophysical properties of ion channels in the neuronal membranes; (2) biochemical modifications of receptors; (3) modulation of second messaging systems and gene expression; (4) changes in extracellular ion concentrations; (5) alterations in neurotransmitter uptake and metabolism in glial cells; and (6) modifications in the ratio and function of inhibitory circuits. In addition local neurotransmitter imbalances could be a potential mechanism for focal epileptogenesis, but human studies on presurgical patients have not shown consistent differences. However, transitory imbalances between the main neurotransmitters, glutamate (excitatory) and γ -aminobutyric-acid (GABA) (inhibitory), and neuromodulators (e.g., acetylcholine, norepinephrine, and serotonin) might play a role in precipitating seizures in susceptible patients.³

Control of abnormal neuronal activity with AEDs is accomplished by elevating the threshold of neurons to electrical or chemical stimuli or by limiting the propagation of the seizure discharge from its origin. Raising the threshold most likely involves stabilization of neuronal membranes, whereas limiting the propagation involves depression of synaptic transmission and reduction of nerve conduction.³

Prolonged seizures can result in neuronal injury in vulnerable neuronal populations resulting in functional deficits, primarily in memory, and in permanent changes of wiring of the neuronal circuitry. Sprouting and reorganization of neuronal projections might lead to a chronic susceptibility to seizures, neuronal destruction, and brain damage. Also, the continued exposure to glutamate may contribute to neuronal damage. Although individual seizures as such do not cause a significant decrease in intelligence, it has been

suggested that patients suffering a large number (greater than 100) of generalized tonic-clonic (GTC) seizures who have multiple episodes of status epilepticus can be at risk for eventual cognitive declines.

CLINICAL PRESENTATION

The International League Against Epilepsy (ILAE) has proposed two major schemes for the classification of seizures and epilepsies: the International Classification of Epileptic Seizures and the International Classification of the Epilepsies and Epilepsy Syndromes.^{4,5}

The International Classification of Epileptic Seizures (Table 58–1) combines the clinical description with certain electrophysiologic findings to classify epileptic seizures. Seizures are divided into two main pathophysiologic groups—partial seizures and generalized seizures—by EEG recordings and clinical symptomatology.

Partial (focal) seizures begin in one hemisphere of the brain and—unless they become secondarily generalized—result in an asymmetric motor manifestation. Partial seizures manifest as alterations in motor functions, sensory or somatosensory symptoms, or automatisms. Partial seizures with no loss of consciousness are classified as *simple partial* (SP). In some cases, patients will describe somatosensory symptoms as a “warning” prior to the development of a GTC seizure. These warnings are in fact simple partial seizures and frequently are termed *auras*.

Partial seizures with an alteration of consciousness are described as *complex partial* (CP). With CP seizures, the patient can have automatisms, periods of memory loss, or aberrations of behavior. Some patients with CP epilepsy have been mistakenly diagnosed as having psychotic episodes. CP seizures also can progress to GTC seizures. Patients with CP seizures typically are amnesic to these events.

Generalized seizures have clinical manifestations that indicate involvement of both hemispheres. Motor manifestations are bilateral, and there is a loss of consciousness. Generalized seizures can be further subdivided by EEG and clinical manifestations. A partial seizure that becomes generalized is referred to as a *secondarily generalized seizure*.

Generalized absence seizures are manifested by a sudden onset, interruption of ongoing activities, a blank stare, and possibly a brief upward rotation of the eyes. They generally occur in young children through adolescence. It is important to differentiate absence seizures from complex partial seizures.

TABLE 58-1 International Classification of Epileptic Seizures

I. Partial seizures (seizures begin locally)
A. Simple (without impairment of consciousness)
1. With motor symptoms
2. With special sensory or somatosensory symptoms
3. With psychic symptoms
B. Complex (with impairment of consciousness)
1. Simple partial onset followed by impairment of consciousness—with or without automatisms
2. Impaired consciousness at onset—with or without automatisms
C. Secondarily generalized (partial onset evolving to generalized tonic-clonic seizures)
II. Generalized seizures (bilaterally symmetrical and without local onset)
A. Absence
B. Myoclonic
C. Clonic
D. Tonic
E. Tonic-clonic
F. Atonic
G. Infantile spasms
III. Unclassified seizures
IV. Status epilepticus

Data from Commission on the Classification and Terminology of the International League Against Epilepsy.^{4,5}

GTC seizures are what many people think of as epilepsy. The seizure results in a sudden sharp tonic contraction of muscles followed by a period of rigidity and clonic movements. During the seizure, the patient may cry or moan, lose sphincter control, bite the tongue, or develop cyanosis. After the seizure, the patient may have altered consciousness, drowsiness, or confusion for a variable period of time (postictal period) and frequently goes into a deep sleep. Tonic and clonic seizures can occur separately.

Brief shock-like muscular contractions of the face, trunk, and extremities are known as *myoclonic jerks*. They can be isolated events or rapidly repetitive. A sudden loss of muscle tone is known as an *atonic seizure*. This can be described as a head drop, the dropping of a limb, or a slumping to the ground. These patients often wear protective head ware to prevent trauma.

The International Classification of Epilepsies and Epilepsy Syndromes adds components such as age of onset, intellectual development, findings on neurologic examination, and results of neuroimaging studies to define epilepsy syndromes more fully. Syndromes can include one or many different seizure types (e.g., Lennox-Gastaut syndrome). The syndromic approach includes seizure type(s) and possible etiologic classifications (e.g., idiopathic, symptomatic, or unknown). *Idiopathic* describes syndromes that are presumably genetic but also those in which no underlying etiology is documented or suspected. A family history of seizures is commonly present, and neurologic function is essentially normal except for the occurrence of seizures. *Symptomatic* cases involve evidence of brain damage or a known underlying cause. A *cryptogenic* syndrome is assumed to be symptomatic of an underlying condition that cannot be documented. *Unknown* or *undetermined* is used when no cause can be identified. This syndromic classification is more important for prognostic determinations than for a classification based simply on seizure type. The syndrome classification scheme requires more information and, in return, provides a more powerful tool for comprehensive clinical management. A patient's epilepsy is classified based on seizure type (i.e., generalized versus partial) and syndromic type (i.e., idiopathic, symptomatic, or cryptogenic).

CLINICAL PRESENTATION OF EPILEPSY

General

In most cases, the healthcare provider will not be in a position to witness a seizure. Many patients (particularly those with CP or GTC seizures) are amnesic to the actual seizure event. Obtaining an adequate history and description of the ictal event (including time course) from a third party (e.g., significant other, family member, or witness) is critically important. With treatment the typical clinical presentation of the seizure may change.

Symptoms

Symptoms of a specific seizure will depend on seizure type. Although seizures can vary between patients, they tend to be stereotyped within an individual.

- CP seizures can include somatosensory or focal motor features.
- CP seizures are associated with altered consciousness.
- Absence seizures can be almost nondetectable with only very brief (seconds) periods of altered consciousness.
- GTC seizures are major convulsive episodes and are always associated with a loss of consciousness.

Signs

Interictally (between seizure episodes), there are typically no objective or pathognomonic signs.

Laboratory Tests

There are currently no diagnostic laboratory tests for epilepsy. In some cases, particularly following GTC (or perhaps CP) seizures, serum prolactin levels can be transiently elevated. Laboratory tests can be done to rule out treatable causes of seizures (e.g., hypoglycemia, altered electrolyte concentrations, infections, etc.) that do not represent epilepsy.

Other Diagnostic Tests

- EEG is very useful in the diagnosis of various seizure disorders.
- An epileptiform EEG is found in only approximately 50% of the patients who have epilepsy.
- A prolactin serum level obtained within 10 to 20 minutes of a tonic-clonic seizure can be useful in differentiating seizure activity from pseudoseizure activity but not from syncope.⁶
- Although magnetic resonance imaging (MRI) is very useful (especially imaging of the temporal lobes), a computed tomography (CT) scan typically is not helpful except in the initial evaluation for a brain tumor or cerebral bleeding.

TREATMENT

Epilepsy

■ DESIRED OUTCOME

- 1 The ultimate goal of treatment for epilepsy is complete elimination of seizures and no side effects with an optimal quality of life. The best quality of life is associated with a seizure-free state.⁷ Often, however, a balance between efficacy and side effects must be reached because with the older AEDs used as monotherapy, fewer than 50% of patients become seizure-free.

Because therapy is continued for many years (often a lifetime), chronic side effects must be considered. If the patient is overly sedated or develops other significant side effects, some seizure control may have to be sacrificed to improve functioning. The patient should be involved in deciding what balance between frequency of seizures and the occurrence of side effects is most appropriate. The newer AEDs offer alternatives for balancing seizure frequency and drug side effects.

Providing optimal quality of life goes beyond balancing seizures and side effects. It involves assessing all the concerns of a patient with epilepsy, such as, issues about driving, their future, forming relationships, safety, social isolation, social stigma, and so on. It is also important to recognize that patients with epilepsy can have other neuropsychiatric comorbidities such as depression, anxiety, and sleep disturbances that need treatment.^{8,9} Depression is especially important because it has been shown to have a significant impact on quality of life in the patient with treatment-resistant epilepsy.¹⁰

■ GENERAL APPROACH TO TREATMENT

- 2 The general approach to treatment involves identification of goals, assessment of seizure type and frequency, development of a care plan, and a plan for followup evaluation. During the assessment phase, it is critical to establish an accurate diagnosis of the seizure type and classification to help determine the appropriate initial AEDs. Patient-specific treatment goals must be identified, and these can change over time. Despite appropriate AED treatment, approximately 30% to 35% of patients will be refractory to treatment. In this setting, seizure freedom may not be obtained, and more obtainable outcomes should be established (e.g., decrease in the number of seizures and minimized drug adverse effects).

3 Patient characteristics such as age, medical condition, ability to comply with a prescribed regimen, and insurance coverage also should be explored because these can influence AED choices or help to explain nonadherence to the regimen, a lack of response, or unexpected adverse effects.

Once the assessment is complete, for patients with new-onset seizures, the choice is whether to use drug therapy and, if so, which one. For a patient with long-standing epilepsy, adequacy of the current medication regimen must be evaluated. An AED should not be considered ineffective unless the patient has experienced unacceptable adverse effects with continued seizures.

4 If a decision is made to start AED therapy, monotherapy is preferred, and approximately 50% to 70% of all patients with epilepsy can be maintained on one drug.^{11,12} However, many of these patients are not seizure free. The percentage of patients who are seizure free on one drug varies by seizure type. The prognosis for 12-month seizure freedom is best for those who have only GTC seizures (48% to 55%), worst for those who have only CP seizures (23% to 26%), and intermediate for those with mixed seizure types (25% to 32%).¹² Drugs can be combined in an attempt to help the patient become seizure-free. Combining AEDs with different mechanisms of action can be advantageous, although this approach is as yet unproven. Approximately 65% of patients can be expected to be maintained on one AED and be considered well controlled, although not necessarily seizure-free.

CLINICAL CONTROVERSY

It is believed by some that the upregulation of certain brain efflux transporters such as P-glycoprotein and multidrug-resistant-protein may play a role in drug-resistant epilepsy. The efflux transporters are believed to transport antiepileptic drugs away from the epileptic focus, thus preventing therapeutic concentrations from reaching the site. It is not known if the upregulation is due to genetic or acquired/induced mechanisms or possibly both. P-glycoprotein is encoded in humans by a gene family comprising two genes: MDR1 (ABCB1) and MDR2 (ABCB4). MDR1 appears to be important for the expression of the transporter at the blood–brain barrier. The gene is highly polymorphic with a common polymorphism occurring as C3435T. In one study, C3435T was found to be more prevalent in patients with drug-resistant epilepsy; however, a larger study conducted later was unable to validate these results. A smaller study did partially validate the results.¹³

5 Of the 35% of patients with unsatisfactory control, 10% will be well controlled with a two-drug treatment. Of the remaining 25%, 20% will continue to have unsatisfactory control despite multiple drug treatment. It has been suggested that there may be a genetic predisposition to epilepsy that is refractory to drug therapy. Some of these patients will become surgical candidates. For some patients, an implantable device such as the vagal nerve stimulator can be an additional nonpharmacologic option.

Once the care plan is established, a prescription is generated for a specific AED. Patient education and assurance of patient understanding of the plan are essential. Detailed directions regarding titration, what to do in the event of a treatment-emergent side effect, and what to do if a seizure occurs must be provided to patients. Documentation of the assessment, care plan, and educational process is essential. Providing the patient with a seizure and side-effect diary will assist in the followup and evaluation phase. At the followup stage of treatment (which can be done in the hospital, clinic, pharmacy, or by phone), the treatment goals must be reviewed. If the goal has been achieved, new goals should be identified. For example, if the GTC seizures are now controlled, the goal may be to control partial seizures. If a patient

fails to respond to the first AEDs, trials with other AEDs should be attempted as appropriate. Completion of the evaluation often requires a reassessment of the patient and development of a new care plan taking into account patient compliance, efficacy, and safety of the initial treatment.

Medication noncompliance can be the single most common reason for treatment failure. It is estimated that up to 60% of patients with epilepsy are noncompliant.¹⁴ The rate of noncompliance is increased by the complexity of the drug regimen and by doses taken three and four times a day. Frequent uncontrolled seizures can also predispose a patient to noncompliance secondary to confusion over whether the drug was taken. Noncompliance is not influenced by age, sex, psychomotor development, or seizure type.¹⁴

Epilepsy is a clinical diagnosis defined by recurrent seizures. Difference of opinion exists as to when the most appropriate time is to initiate AED therapy. Some clinicians start AED treatment after the first seizure, whereas others do not initiate treatment until a second, unprovoked seizure has occurred. Still others initiate prophylactic treatment following a CNS insult thought likely to cause epilepsy eventually (e.g., stroke or head trauma). Appropriate treatment decisions vary depending on individual patient clinical characteristics and circumstances.

Drug treatment may not be indicated in patients whose seizures have minimal impact on their lives or those who have had only a single seizure. If a patient presents after a single isolated seizure, one of three treatment decisions can be made: treat, possibly treat, or do not treat. These decisions are based on the probability of the patient having a second seizure (Table 58–2). For patients with no risk factors, the probability of a second seizure is less than 10% in the first year and approximately 24% by the end of 2 years. If risk factors are present, the recurrence rate can be as high as 80% after 5 years.¹⁵ The decision on whether to start AED therapy often depends on patient-specific factors such as epilepsy syndrome, seizure etiology, presence of a neuroanatomic defect, and the EEG, as well as, the patient's lifestyle and preferences. Patients who have had two or more seizures generally should be started on AEDs.

WHEN TO STOP ANTIEPILEPTIC DRUGS

6 The AEDs used to control seizures may not need to be given for a lifetime. Polypharmacy can be reduced, and some patients can discontinue AEDs altogether. In reducing polypharmacy, the drug considered less appropriate for the seizure type (or the agent deemed most responsible for adverse effects) should be discontin-

TABLE 58-2 Recurrence Risk for Patients Experiencing One Unprovoked Seizure		
Type of Patient	First-Year Risk (%)	Fifth-Year Risk (%)
Adults with single unprovoked seizure		34
No CNS insult	10	29
Influence of family history		
Sibling with seizure	29	46
No sibling with seizures	7	27
EEG patterns		
GSW on EEG	15	58
Normal EEG	9	26
Occurrence of previous seizure	10	39
Caused by an illness or childhood febrile seizure		
Remote symptomatic with Todd paresis	26	48
	41	75
Status epilepticus at onset	37	56
Prior acute seizure	60	80
Idiopathic	10	29

CNS, central nervous system; EEG, electroencephalogram; GSW, generalized spikes and waves. Data from Leppik¹⁵ and Gross-Tsur et al.¹⁷

ued first. In some cases, decreasing the number of AEDs a patient is receiving can decrease side effects and increase cognitive abilities. This improvement in cognition may be small, especially if the patient is on a drug that primarily affects psychomotor speed with less effect on higher-order cognitive functioning.

7 Factors favoring successful withdrawal of AEDs include a seizure-free period of 2 to 4 years, complete seizure control within 1 year of onset, an onset of seizures after age 2 but before age 35, and a normal neurologic examination and EEG. Factors associated with a poor prognosis in discontinuing AEDs, despite a seizure-free interval, include a history of a high frequency of seizures, repeated episodes of status epilepticus, a combination of seizure types, and development of abnormal mental functioning. Children who have irregular generalized spike and wave activity in EEG recordings prior to discontinuation of treatment may have a higher relapse rate (67%) compared with children without epileptiform activity (33%) or children with other types of epileptiform activity (33%) in their last EEG recordings before discontinuation. A 2-year seizure-free period is suggested for absence and rolandic epilepsy, whereas a 4-year seizure-free period is suggested for SP, CP, and absence seizures associated with tonic-clonic convulsions. AED withdrawal generally is not suggested for patients with juvenile myoclonic epilepsy, absence with clonic-tonic-clonic seizures, or clonic-tonic-clonic seizures. The American Academy of Neurology (AAN) has issued guidelines for discontinuing AEDs in seizure-free patients.¹⁶ After assessing the risks and benefits to both the patient and society, AED withdrawal can be considered in a patient meeting the following profile: seizure free for 2 to 5 years, a history of a single type of partial seizure or primary GTC seizures, a normal neurologic exam and normal IQ, and an EEG that has been normalized with treatment. When these factors are present, the relapse rate is expected to be less than 32% for children and 39% for adults.

AED withdrawal should be done gradually, especially in patients with profound developmental disabilities. Some patients will have a recurrence of seizures as the AEDs are withdrawn. Sudden withdrawal is associated with the precipitation of status epilepticus. Withdrawal seizures are of particular concern for agents such as benzodiazepines and barbiturates. Seizure relapse has been reported to be more common if these AEDs are withdrawn over 1 to 3 months than over 6 months.

The risk of seizure relapse has been estimated at 10% to 70%. A meta-analysis determined that the relapse rate was 25% after 1 year and 29% after 2 years. Recurrence of seizures tends to occur early with at least one-half of the recurrences within 6 months of AED withdrawal and 60% to 90% within 1 year. Late reoccurrences are uncommon. Patients who relapse will generally become seizure free and in remission after AEDs are restarted although not necessarily immediately. The underlying epilepsy syndrome appears to determine prognosis for long-term remission.¹⁷

CLINICAL CONTROVERSY

It is not entirely clear which patients with epilepsy will require lifelong treatment. Although many clinicians feel that AED therapy is lifelong, others would argue that certain patients with idiopathic epilepsy and a normal neurologic examination and EEG are candidates for AED withdrawal following a prolonged period of seizure freedom (e.g., greater than 2 to 3 years). A large amount of the data supporting discontinuing AEDs have been obtained from children. Some adults will be reticent to discontinue AED therapy even if the clinician is in favor of it because of the fear of having a seizure and the consequences (e.g., loss of driver's license) that it would entail. The patient should agree and must be a willing participant in the plan to reduce or withdraw AED therapy.

■ NONPHARMACOLOGIC THERAPY

Nonpharmacologic therapy for epilepsy includes diet, surgery, and vagus nerve stimulation (VNS). A vagal nerve stimulator is an implanted medical device that is FDA approved for use as an adjunctive therapy in reducing the frequency of seizures in adults and adolescents older than 12 years of age with partial-onset seizures that are refractory to AEDs. It is also used off-label in the treatment of generalized epilepsy.
