6 Rectal cancer involves those tumors found below the peritoneal reflection in the most distal 15 cm of the large bowel, and as such is distinct from colon cancer in that it has a propensity for both local and distant recurrence. The higher incidence of local failure and overall poorer prognosis associated with rectal cancer is a result of anatomic limitations in excising adequate radial margins around the rectal tumor. Although an abdominoperineal resection of the tumor and adjacent tissues results in a high probability of local control and long-term survival, the sequelae, including need for a permanent colostomy and high incidence of sexual and genitourinary dysfunction, has led to investigation of approaches that use multimodal therapies that preserve the integrity of the anal sphincter.⁸² In addition, adjuvant therapy after surgical resection is an important aspect of treatment of the primary tumor. The effectiveness of postoperative XRT and fluorouracil-based chemotherapy for stage II or III rectal cancer is well established. Although T₁ tumors with a favorable histology may be treated successfully with local excision alone, adjuvant XRT plus chemotherapy should be offered for larger lesions. Similar to adjuvant therapy for colon cancer, fluorouracil provides the basis for chemotherapy regimens for rectal cancer. The XRT decreases the rate of local pelvic recurrences, whereas the fluorouracil decreases the risk of distant tumor recurrence and enhances the effectiveness of the XRT. The optimal delivery schedule for these two therapies is the subject of ongoing investigation, but many trials have demonstrated improved local control and survival for patients who receive a combination of postoperative XRT and chemotherapy as compared to surgery alone. In 1990, based on results from the Gastrointestinal Tumor Study Group and the Mayo Clinic–North Central Cancer Treatment Group studies, the National Cancer Institute Consensus Conference recommended that standard postoperative adjuvant treatment for patients with stage II or III rectal tumors should consist of six cycles of fluorouracil-based chemotherapy with concurrent pelvic XRT.⁸³ The Gastrointestinal Tumor Study Group trial was designed to evaluate adjuvant postoperative treatment for patients with stage II or III rectal cancer and demonstrated that combined chemotherapy and radiation therapy improved recurrence rate and survival compared

to chemotherapy or radiotherapy alone.⁸⁴ The Mayo Clinic–North Central Cancer Treatment Group trial compared postoperative XRT alone, postoperative XRT with concurrent fluorouracil plus semustine chemotherapy, and pre- and postirradiation chemotherapy in a similar population of 204 patients with rectal cancer.⁸⁵ This was the first randomized trial in which one cycle of combination chemotherapy was given before and after XRT in addition to the administration of fluorouracil during XRT. The use of combined chemotherapy and XRT significantly affected local recurrence, relapse-free survival, and OS as compared to XRT alone. These studies established fluorouracil plus XRT as the foundation for adjuvant therapy in stages II and III rectal cancer.

Additional trials have sought to determine optimal combinations of concurrent radiation and fluorouracil. Many treatment centers now administer continuous-infusion fluorouracil throughout the 5- or 6-week schedule of postoperative XRT for rectal cancer. Several schedules for combining fluorouracil with postoperative XRT provide similar relapse-free survival and OS but differ with regard to toxicity profile and catheter requirements for drug administration.⁸⁶ The integration of capecitabine as an alternative to fluorouracil and the incorporation of other agents available in the treatment of colorectal cancer into adjuvant therapy for rectal cancer is under investigation.

Preoperative (Neoadjuvant) Therapy **6** Interest in preoperative or neoadjuvant therapy has increased based on advances in imaging techniques to more accurately stage rectal tumors preoperatively and the success of combined XRT plus fluoropyrimidine-based chemotherapy administered in the postoperative setting. Preoperative XRT, by shrinking and thereby downstaging the tumor prior to surgical resection, improves sphincter preservation, but the primary concern with this approach is potential overtreatment with XRT in some patients.

Neoadjuvant chemoradiotherapy may further enhance tumor shrinkage and improve the rate of tumor resectability with rectal sphincter preservation. The European Organization for Research and Treatment of Cancer 22921 trial evaluated the addition of fluorouracil plus leucovorin to preoperative XRT and showed an improvement in tumor shrinkage with lower lymph node involvement. However, long-term local control and survival outcomes need to be assessed.⁸⁷ The 2007 NCCN guidelines for rectal cancer indicate that postoperative infusional fluorouracil-based chemotherapy plus XRT is the preferred treatment for resectable T₃N₀ or any T₂N₁₋₂ lesions (category 1 recommendation).⁸⁸ Neoadjuvant fluorouracil or capecitabine chemoradiation followed by abdominoperineal resection or low anterior resection should be considered for locally unresectable tumors. Postoperative therapy, either as chemotherapy alone or combined chemoradiotherapy should be administered to all patients who received preoperative chemotherapy for rectal cancer.⁸⁸

■ METASTATIC DISEASE

Initial Therapy

7 Several advances have been made in developing efficacious treatment options for metastatic colorectal cancer. Whereas surgery and XRT are usually used to manage isolated sites of tumor, chemotherapy is most useful for patients with disseminated disease and is the primary treatment modality for unresectable metastatic colorectal cancer.

Surgery Complete surgical resection of discrete hepatic, pulmonary, abdominal, or brain metastases in patients with colorectal cancer, if possible, may offer selected patients an opportunity to experience extended DFS. Patients who have from one to three small nodules isolated to the liver, lungs, or abdomen have the most favorable outcomes. Up to 25% of patients will present with hepatic metastases at time of diagnosis, and 60% of patients with colorectal cancer will

develop hepatic metastases sometime during the course of their disease. Approximately 35% of patients who undergo resection of hepatic-limited metastases can be cured.⁸⁹ These results are drastically better than those in patients with unresectable metastatic colorectal cancer, in whom 5-year survival is uncommon. Patients with no significant general medical risk factors, fewer than four hepatic lesions, CEA levels less than 200 ng/mL, small tumor size, lack of extrahepatic tumor, and adequate surgical margins have the best opportunity for an improved long-term outcome. The primary site of tumor should also be completely resected. Ablative therapies that involve destroying the tumor through freezing and thawing (cryoablation), heat (radiofrequency), or alcohol injection may be useful for patients who have very small hepatic lesions and are unable to undergo liver resection surgery, but are less successful than surgical interventions. Outcomes associated with resection of isolated pulmonary, abdominal, and brain metastases have been less studied, but this approach is potentially curative and should be considered for patients with resectable disease who are appropriate surgical candidates.

Because about two-thirds of patients who undergo resection of hepatic metastases will have disease recurrence, postsurgery therapies (e.g., adjuvant systemic and hepatic arterial infusion chemotherapy) have been studied in an attempt to improve long-term outcomes. A randomized trial that compared 6 months of hepatic floxuridine and dexamethasone plus IV fluorouracil with leucovorin to IV fluorouracil with leucovorin alone following resection of hepatic metastases in 156 patients showed improved 2-year DFS (86% vs. 72%) and hepatic recurrence-free survival at 2 years (90% vs. 60%) with the combined therapy.⁹⁰ Many practitioners offer adjuvant chemotherapy to selected patients following potentially curative hepatic resection, but further studies, especially those involving more active agents, are needed to determine an optimal treatment regimen.⁹¹

Radiation Symptom control is the primary goal of XRT for patients with advanced or metastatic colorectal cancer.

Chemotherapy **7** Accepted initial chemotherapy regimens for metastatic colorectal cancer consist of oxaliplatin plus fluorouracil and leucovorin, irinotecan plus fluorouracil and leucovorin, bevacizumab plus a fluorouracil-based regimen, capecitabine alone, or fluorouracil plus leucovorin alone (Table 133–11). The site(s) of tumor involvement and history of prior chemotherapy help to define an appropriate management strategy. In general, treatment options are similar for metastatic cancer of the colon and rectum.

Currently, most metastatic colorectal cancers are incurable and treatment goals are to reduce patient symptoms, improve quality-of-life, and extend survival. Two recent meta-analyses have estimated the magnitude of benefit and harm associated with palliative chemotherapy for metastatic colorectal cancer. In a pooled analysis of randomized trials comparing chemotherapy to observation or supportive care alone, a total of nine trials that included 614 patients were evaluated.⁹² All trials used fluorouracil-based chemotherapy, but three trials in which hepatic arterial or portal vein administration was used were also included. Several trials allowed delayed or discretionary use of chemotherapy in patients assigned to observation or supportive care alone; 12% to 57% of control patients received at least one course of chemotherapy. Despite these discrepancies, chemotherapy was associated with a significant reduction in mortality at 1 (RR 0.69) but not 2 years (RR 0.93). The second meta-analysis analyzed individual patient data and summary statistics from 13 randomized trials that included 1,365 patients.⁹³ Eligible trials compared palliative chemotherapy given via any route of administration to supportive care alone or treatments not involving chemotherapy. Trials that allowed chemotherapy use in control patients were not excluded. In the analysis of seven trials in which individual patient data were available, palliative chemotherapy was

TABLE 133-11 Chemotherapeutic Regimens for Metastatic Colorectal Cancer

	Regimen	Major Dose-Limiting Toxicities/Comments
Initial therapy		
<i>Oxaliplatin plus fluorouracil plus leucovorin</i>		
Oxaliplatin plus bimonthly infusional fluorouracil; FOLFOX ⁹⁷	Oxaliplatin 85 mg/m ² IV day 1 plus bolus fluorouracil 400 mg/m ² IV plus leucovorin 200 mg/m ² IV followed by fluorouracil 600 mg/m ² IV in 22-hour infusion on days 1 and 2, every 2 weeks	Sensory neuropathy, neutropenia
mFOLFOX6	Oxaliplatin 85 mg/m ² IV day 1 plus leucovorin 400 mg/m ² IV on day 1 followed by fluorouracil 400 mg/m ² IV bolus on day 1, then 1200 mg/m ² /day × 2 days (total 2,400 mg/m ² over 46–48 hours) continuous infusion, repeat every 2 weeks	Sensory neuropathy, neutropenia; easier administration as compared to FOLFOX4
<i>Irinotecan plus fluorouracil plus leucovorin</i>		
Irinotecan plus infusional fluorouracil; FOLFIRI ¹⁰⁴	Irinotecan 180 mg/m ² IV plus leucovorin 400 mg/m ² IV plus bolus fluorouracil 400 mg/m ² IV, followed by fluorouracil 2,400 mg/m ² continuous IV infusion over 46 hours on day 1, repeated every 2 weeks	Nausea, diarrhea, mucositis, neutropenia
Biweekly irinotecan plus infusional fluorouracil ⁹⁹	Irinotecan 180 mg/m ² IV day 1 plus leucovorin 400 mg/m ² then fluorouracil 400 mg/m ² IV, followed by fluorouracil 600 mg/m ² continuous IV infusion over 22 hours, days 1 and 2, repeated every 2 weeks	Neutropenia, diarrhea
Irinotecan plus bolus fluorouracil; IFL; Saltz regimen ¹⁰⁰	Irinotecan 125 mg/m ² IV plus fluorouracil 500 mg/m ² IV plus leucovorin 20 mg/m ² IV weekly for 4 of 6 weeks	Diarrhea (increased as compared to FOLFIRI), neutropenia
<i>Bevacizumab</i>		
Bevacizumab plus fluorouracil-based regimens	Bevacizumab 5 mg/kg IV every 2 weeks plus fluorouracil and leucovorin (given in any schedule below) or IFL or FOLFOX or FOLFIRI	Hypertension, thrombosis, proteinuria from bevacizumab added to toxicities of regimen chosen
<i>Capecitabine</i>		
Capecitabine monotherapy ¹⁰⁶	See Table 133–10 ^a	Diarrhea, hand–foot syndrome
CapOx	Oxaliplatin 130 mg/m ² day 1 plus capecitabine 850 mg/m ² twice a day for 14 days, repeat every 3 weeks	Diarrhea, hand–foot syndrome, neuropathies
<i>Fluorouracil plus leucovorin only</i>		
Weekly, high-dose leucovorin; Roswell Park regimen ¹⁴⁶	See Table 133–10 ^a	Diarrhea, mucositis
Consecutive day, low-dose leucovorin; Mayo Clinic regimen ¹⁴⁶	See Table 133–10 ^a	Mucositis, neutropenia
Bolus plus infusional fluorouracil; (LV5FU2) ⁹⁷ ; de Gramont regimen	See Table 133–10 ^a	Neutropenia, mucositis
Salvage therapy^b		
<i>Irinotecan</i>		
Weekly irinotecan ¹⁰⁰	Irinotecan 125 mg/m ² IV every week for 4 of 6 weeks	Neutropenia, diarrhea
Every 3-weeks irinotecan ¹¹⁶	Irinotecan 350 mg/m ² IV every 3 weeks	Neutropenia, diarrhea (less-than-weekly irinotecan)
<i>Oxaliplatin plus fluorouracil plus leucovorin</i>		
Oxaliplatin plus bimonthly infusional fluorouracil; FOLFOX ¹⁴⁷	Same as FOLFOX4 above	Sensory neuropathy, neutropenia
<i>Cetuximab</i>		
Cetuximab plus irinotecan ^{c,122}	Continue irinotecan as previously dosed, plus cetuximab 400 mg/m ² IV loading dose, then cetuximab 250 mg/m ² IV weekly thereafter	Asthenia, diarrhea, nausea, acneiform rash, vomiting
Cetuximab ^{d,122}	Cetuximab 400 mg/m ² IV loading dose, then cetuximab 250 mg/m ² IV weekly thereafter	Papulopustular, follicular rash, asthenia, constipation, diarrhea
<i>Fluorouracil</i>		
Protracted continuous infusion ¹¹⁷	Fluorouracil 250–300 mg/m ² per day continuous IV infusion until disease progression	Mucositis, hand–foot syndrome
Investigational		
CapOx ¹⁴⁸	Same as CapOx above.	Diarrhea, sensory neuropathy
CapIri ¹⁴⁸	Capecitabine 1,000 mg/m ² orally twice daily days 1–14 plus irinotecan 100 mg/m ² IV days 1 and 8; repeat every 3 weeks	Diarrhea, neutropenia

^aDoses and schedules the same as those in the adjuvant setting.^bSee Fig. 133–6 for comments on salvage regimens.^cIf irinotecan-refractory disease.^dIf patient cannot tolerate irinotecan.

shown to reduce the risk of death by 35%, which translates to a prolongation of median survival by 3.7 months. The investigators were unable to determine the effect of treatment on toxicities or quality-of-life because of inadequate data. However, the results of both analyses suggest that palliative chemotherapy is beneficial and improves survival in metastatic colorectal cancer. Because many patients assigned to control arms eventually received chemotherapy,

the magnitude of survival benefit associated with chemotherapy could be underestimated.

Fluorouracil continues to be incorporated into current first-line chemotherapy regimens used for metastatic colorectal cancer. When administered in bolus injection treatment schedules, fluorouracil is given most frequently with leucovorin. The addition of irinotecan to fluorouracil plus leucovorin significantly improves

response rates, progression-free survival (PFS), and median survival. Oxaliplatin in combination with fluorouracil and leucovorin has shown improvements in median survival when compared to the combination of irinotecan plus fluorouracil and leucovorin in the initial treatment of metastatic colon cancer. The addition of bevacizumab to fluorouracil-based regimens improves efficacy compared to chemotherapy alone. Either of these three- or four-drug combinations may be considered as first-line therapy for metastatic colorectal cancer. Ongoing trials are evaluating the sequencing of these regimens and comparing the efficacy of combinations of fluorouracil plus leucovorin, to investigational treatments with capecitabine, oral fluoropyrimidines and newer agents, such as cetuximab. Table 133-12 summarizes comparative outcome data from potentially useful chemotherapeutic treatments for metastatic colorectal cancer.

7 Fluorouracil-Based Regimens. Fluorouracil has been administered as a single agent by IV bolus injection but response rates are only 10% to 20%.⁹⁴ As such, IV bolus fluorouracil as a single agent is considered ineffective for metastatic colorectal cancer. A variety of continuous IV infusion fluorouracil regimens have been developed to increase the duration of drug exposure during the S-phase of the cell cycle and increase cytotoxicity. Despite differences in dose intensity among the different regimens, no clear survival advantages or trends are observed for any particular regimen. However, in comparison to IV bolus fluorouracil, response rates with continuous infusion fluorouracil are about doubled. In a meta-analysis of six randomized trials evaluating 1,219 patients with advanced colorectal cancer that compared continuous infusion and bolus IV fluorouracil, a significantly higher tumor response rate (22% vs. 14%) and OS benefit (overall HR 0.88) were observed in patients

TABLE 133-12 Comparative Outcomes from Selected Trials in Metastatic Colorectal Cancer

Trial	Number	Outcome Measures	Results
First-line			
Goldberg et al. ¹⁰³	795	Primary: TTP; secondary: OS, RR, time to treatment discontinuation	Median TTP: IFL vs. FOLFOX 6.9 vs. 8.7 months ($P = 0.0014$). Median survival 15.0 months with IFL vs. 19.5 months with FOLFOX ($P = 0.001$). Response rate with FOLFOX (45%) higher compared to IFL (31%; $P = 0.002$) and IROX (35%, $P = 0.03$). TTP and OS with IROX (6.5 and 17.4 months) no different from FOLFOX.
de Gramont et al. ¹⁴⁷	420	Primary: PFS; secondary: RR, OS, tolerability, QOL	Median PFS: 9.0 vs. 6.2 months ($P = 0.0003$); RR: 50.7 vs. 22.3% ($P = 0.0001$), oxaliplatin plus LV5FU2 vs. LF5FU2 alone; no difference in OS (16.2 vs. 14.7 months) or QOL between oxaliplatin plus LV5FU2 vs. LV5FU2 alone
Saltz et al. ¹⁰⁰	683	Primary: PFS; secondary: RR, OS	Median PFS longer with IFL (7.0 months) vs. FU/LV (4.3 months; $P = 0.004$); PFS similar with irinotecan alone (4.2 months) compared to FU/LV; RR higher with IFL vs. FU/LV (50 vs. 28%; $P < 0.001$); median survival longer with IFL (14.8 months) vs. 12.6 months with FU/LV ($P = 0.04$), which was similar to irinotecan (12.0 months)
Douillard et al. ⁹⁹	387	Primary: RR; secondary: TTP, response duration, TTF, OS, QOL	Significantly higher RR with infusional IFL vs. infusional FU/LV alone (35 vs 22%; $P < 0.005$) by ITT; TTP longer with IFL (6.7 vs. 4.4 months; $P < 0.001$) and OS longer with IFL vs. infusional FU/LV alone (17.4 vs. 14.1 months; $P = 0.031$)
Tournigand et al. ¹⁰⁴	226	Test the best sequence of FOLFIRI vs. FOLFOX6; primary: second PFS; secondary: PFS, OS, RR, safety	Median survival 21.5 months with FOLFIRI then FOLFOX6 vs. 20.6 months with FOLFOX6 then FOLFIRI; median PFS also no different (14.2 vs. 10.9 months), or RR or median PFS with first treatment: FOLFOX6 54% and 8.0 months, vs. 56% and 8.5 months with FOLFIRI
Hurwitz et al. ¹⁰⁷	925	Primary: OS; secondary: PFS, RR, response duration, QOL	Bevacizumab plus IFL increased median survival (20.3 months) vs. IFL alone (15.6 months; $P = 0.00003$), PFS (10.6 vs. 6.24 months; $P < 0.00001$), RR (45% vs. 35%; $P = 0.0029$), and duration of response (10.4 vs. 7.1 months; $P = 0.0014$)
Twelves ¹⁰⁶	1,207	Primary: RR; secondary: TTP, OS, response duration	Tumor response to capecitabine greater than with FU/LV (25.7 vs. 16.7%; $P < 0.0002$), but no difference in median TTP (4.6 vs. 4.7 months) or median survival (392 vs. 391 days)
Hochster ¹⁰⁸	360	Primary: toxicity; secondary RR, TTP, OS	Grade 3/4 toxicity not increased with bevacizumab. TTP, RR, and OS all greater when bevacizumab added to CAPOX, FOLFOX or bolus fluorouracil/leucovorin. Median survival with bevacizumab containing regimens was 24.4 months vs. 18.4 months without bevacizumab (not a randomized trial)
Second-line			
Rougier et al. ¹¹⁷	267	Primary: OS; secondary: PFS, RR, symptom-free survival, adverse effects, QOL	Irinotecan improved median PFS (4.2 vs. 2.9 months; $P = 0.030$) compared to infusion fluorouracil and 1-year survival (45% vs. 35%; $P = 0.035$) but not median OS (10.8 vs. 8.5 months). Median pain-free survival was similar ($P = 0.06$; 10.3 vs. 8.5 months) between irinotecan and fluorouracil, as was QOL
Cunningham et al. ¹¹⁶	279	Primary: OS; secondary: performance status, body weight, tumor-related symptoms, QOL	Compared to best supportive care, OS was improved with irinotecan (13.8% 1-year survival vs. 36.2%; $P = 0.0001$); survival without deterioration in performance status, weight loss greater than 5%, and pain-free survival were also improved with irinotecan
Cunningham et al. ¹²²	329	Primary: RR; secondary: TTP, OS	Addition of cetuximab to continuing irinotecan associated with 22.9% response rate compared to 10.9% with cetuximab alone ($P = 0.0074$); median survival with cetuximab plus irinotecan similar to cetuximab alone (8.6 vs. 6.9 months; $P = 0.48$), but TTP was longer with cetuximab plus irinotecan (4.1 vs. 1.5 months; hazard ratio 0.54; 95% CI, 0.42–0.71)
Giantonio et al. ¹²⁰	829	Primary: OS; secondary: PFS, RR, toxicity	Addition of bevacizumab to FOLFOX4 in patients previously treated with irinotecan and a fluoropyrimidine improved median OS (12.2 vs. 10.8 months; $P = 0.001$), PFS (7.3 vs. 4.7 months; $P < 0.0001$), and overall RR (22.7% vs. 8.6%, $P < 0.0001$) compared to FOLFOX4 alone
Van Cutsem et al. ¹⁴⁹	463	Primary: PFS; secondary: objective RR, OS, safety	Panitumumab plus BSC prolonged PFS compared to BSC alone, with a median PFS of 8 weeks with panitumumab (hazard ratio 0.54; 95% CI, 0.44–0.66)

BSC, best supportive care; FU5LV2, bolus plus infusional fluorouracil and leucovorin; FU/LV, fluorouracil plus leucovorin; IFL, irinotecan plus fluorouracil plus leucovorin; IROX, irinotecan plus oxaliplatin; ITT, intention to treat; OS, overall survival; PFS, progression-free survival; QOL, quality-of-life; RR, response rate; TTF, time-to-treatment failure; TTP, time-to-tumor progression.

receiving fluorouracil by continuous IV infusion.⁹⁵ However, these effects are generally considered as marginal. Increased acceptance and added clinical benefit with continuous infusion fluorouracil has been demonstrated when fluorouracil is administered with other agents and is becoming more commonplace in clinical practice.

Numerous studies have evaluated various doses and administration schedules of fluorouracil plus leucovorin in an attempt to improve treatment response rates and survival in metastatic colorectal cancer. Response rates of 14% to 58% have been observed with a variety of doses of fluorouracil in combination with leucovorin at doses ranging from 20 to 500 mg/m².⁴⁵ The administration sequence and timing of leucovorin may be important factors in the efficacy of biochemical modulation with leucovorin. Leucovorin administration prior to fluorouracil is the most effective approach to enable intracellular-reduced folates to accumulate prior to fluorouracil administration. Despite significantly higher response rates and improved PFS achieved with leucovorin-modulated fluorouracil regimens, their effect on OS is modest.

The Mayo Clinic regimen was the reference regimen in metastatic colon cancer for many years, but the limitations of this regimen are becoming more apparent. A collaborative trial compared the Mayo Clinic regimen to the Roswell Park regimen in 372 patients with metastatic disease.⁹⁶ No differences in tumor response (35% vs. 31%), median survival (9.3 months vs. 10.7 months), or palliative responses were observed. The Mayo Clinic regimen was associated with significantly more leukopenia and stomatitis, whereas the Roswell Park regimen caused more diarrhea and required more hospitalizations to manage toxicity.

The Mayo Clinic regimen has also been compared to bimonthly and weekly regimens of infusional fluorouracil. Higher response rates of 24% to 54% have been noted in bimonthly regimens of fluorouracil administered first as an IV bolus infusion followed by a 22-hour continuous infusion in combination with high-dose leucovorin administered over 2 hours.¹¹⁰ Although the bimonthly combined IV bolus and continuous infusion fluorouracil schedule (de Gramont regimen) did not improve median survival as compared to the Mayo Clinic schedule, it was associated with a lower incidence of severe granulocytopenia, diarrhea, and mucositis.⁹⁷ High response rates (39% to 58%) have also been observed in previously untreated and treated patients receiving weekly fluorouracil as a continuous 24-hour infusion in combination with high-dose leucovorin given over 2 to 24 hours. In a recent trial of untreated metastatic colorectal cancer, 497 patients were randomly assigned to receive the Mayo Clinic regimen of fluorouracil/leucovorin or fluorouracil 2,600 mg/m² as a 24-hour continuous infusion alone or in combination with high-dose leucovorin weekly.⁹⁸ Although median survival rates were not different between groups, PFS was prolonged when weekly fluorouracil was administered with high-dose leucovorin. Similar to other toxicity results, leukopenia and mucositis were more frequent in patients receiving bolus fluorouracil plus leucovorin (Mayo Clinic regimen), whereas patients receiving continuous infusion fluorouracil plus leucovorin experienced more diarrhea and hand-foot syndrome.

In summary, the Mayo Clinic regimen of fluorouracil plus low-dose leucovorin remains an acceptable regimen, but a weekly schedule of leucovorin plus fluorouracil (either bolus or continuous infusion) may be more convenient for the patient in terms of fewer scheduled clinic appointments, less interference with work schedules, and ease of dose adjustments based on toxicity. Bimonthly infusions of fluorouracil given over 2 days produce higher response rates when compared to daily regimens and are gaining in acceptability. However, the incorporation of newer agents into treatment regimens rather than continual adjustments of fluorouracil and leucovorin doses and administration schedules have led to the greatest advances in drug therapy for metastatic colorectal cancer.

7 Fluorouracil and Leucovorin Plus Irinotecan. Based on irinotecan's activity against untreated and fluorouracil-resistant colorectal cancer, several investigations have been completed to determine whether the addition of irinotecan to fluorouracil plus leucovorin as initial therapy for metastatic disease could further improve survival. In a randomized trial of 387 previously untreated patients with advanced colorectal cancer, irinotecan plus fluorouracil and leucovorin was compared to fluorouracil plus leucovorin with regard to tumor response, survival, and quality-of-life (see Table 133-12).⁹⁹ Patients randomized to fluorouracil plus leucovorin could receive weekly fluorouracil (2,600 mg/m²) as a 24-hour IV infusion plus leucovorin (500 mg/m²), or the de Gramont regimen of IV bolus and infusional fluorouracil. For the three-drug treatment, a weekly regimen of irinotecan (80 mg/m²) with a 24-hour infusion of fluorouracil (2,300 mg/m²) plus leucovorin 500 mg/m², or an every 2-week regimen consisting of irinotecan (180 mg/m²) on day 1 with IV bolus fluorouracil (400 mg/m²) followed by a 22-hour IV infusion (600 mg/m²) plus leucovorin (200 mg/m²) given on days 1 and 2) can be used. Tumor response, median time-to-disease progression, and OS were all greater in the irinotecan group. Diarrhea and neutropenia were the most common toxicities and were worse in the irinotecan-containing groups. Diarrhea was the most common reason for dose reduction or treatment discontinuation with the weekly regimens, and led to hospital admission for 32% of patients receiving irinotecan as compared to 12% of patients who received only fluorouracil plus leucovorin. Neutropenia was the most common cause of dose reductions with the every-2-week regimens. Results from questionnaires indicated that quality-of-life consistently declined later in the irinotecan group.

A second randomized trial compared the addition of irinotecan (125 mg/m²) to weekly fluorouracil plus leucovorin (fluorouracil 500 mg/m² IV bolus plus leucovorin 20 mg/m² IV bolus, each given weekly for 4 weeks, repeated every 6 weeks) to the Mayo Clinic regimen and to irinotecan alone (125 mg/m² IV weekly for 4 weeks, repeated every 6 weeks) as first-line therapy in 683 patients with metastatic colorectal cancer.¹⁰⁰ The combination of irinotecan, fluorouracil, and leucovorin resulted in significantly increased tumor response rates and improved PFS and OS as compared to fluorouracil plus leucovorin and irinotecan alone, respectively. The combined incidence of grade 3 or 4 diarrhea was 22.7% with the three-drug combination, as compared to 13.2% with fluorouracil plus leucovorin and 31% with irinotecan alone. However, the incidence of grade 3 diarrhea was almost threefold greater with triple-drug therapy as compared to the two-drug regimen. Midcycle dose reductions caused by neutropenia, which were more common with the three-drug treatment, could potentially have lowered subsequent risk of grade 4 diarrhea. Mucositis was more frequent in the fluorouracil plus leucovorin group. Quality-of-life analyses did not indicate that the addition of irinotecan to fluorouracil plus leucovorin compromised quality-of-life.

The most common adverse effects of irinotecan in these regimens are diarrhea, neutropenia, nausea and vomiting, asthenia, abdominal pain, and alopecia; diarrhea and neutropenia are dose limiting.^{99,100} Two distinct patterns of diarrhea have been described. Early-onset diarrhea occurs during or within 2 to 6 hours after irinotecan administration and is characterized by lacrimation, diaphoresis, abdominal cramping, flushing, and/or diarrhea. These cholinergic symptoms, thought to be caused by inhibition of acetylcholinesterase, respond to atropine 0.25 to 1 mg given intravenously or subcutaneously. Approximately 10% of patients experience the acute symptoms during or shortly following the irinotecan. More commonly, late-onset diarrhea occurs 1 to 12 days after irinotecan administration, and may last for 3 to 5 days. Late-onset diarrhea may require hospitalization or discontinuation of therapy, and fatalities have been reported. The incidence of late-onset diarrhea was as high

as 39% in some studies, but is now much lower with aggressive antidiarrheal intervention.⁴⁵ Aggressive intervention with high-dose loperamide therapy should consist of 4 mg taken at the first sign of soft or watery stools, followed by 2 mg orally every 2 hours until symptom-free for 12 hours; this regimen can be modified to 4 mg every 4 hours taken during the night.

The severity of delayed diarrhea has been correlated with the systemic exposure (i.e., area under the concentration-versus-time curve) of irinotecan and SN-38 (irinotecan's active metabolite) and with genetic polymorphisms in the enzyme uridine diphosphate-glucuronosyltransferase (UGT1A1), which is responsible for the glucuronidation of SN-38 to inactive metabolites. Reduced or deficient levels of the UGT1A1 enzyme are observed in Gilbert syndrome, a familial hyperbilirubinemia disorder, and correlate with irinotecan-induced diarrhea and neutropenia.¹⁰¹ A test for deficiency in this enzyme was recently approved and clinicians can consider obtaining these results for individual patients prior to initiating irinotecan-based therapy to see if a dose-reduction is warranted.

Based on these studies, the addition of irinotecan to fluorouracil plus leucovorin (FOLFIRI or IFL) increases survival when compared to fluorouracil plus leucovorin in the first-line treatment of metastatic colorectal cancer. These data support the current consensus that the three-drug treatment regimen be considered a first-line option for metastatic colorectal cancer. Accordingly, irinotecan received FDA approval in 2000 as first-line therapy for metastatic colorectal cancer in combination with fluorouracil and leucovorin. FOLFIRI is preferred for most patients because it has fewer toxicities than IFL.

8 Fluorouracil and Leucovorin Plus Oxaliplatin. Oxaliplatin, a 1,2-diaminocyclohexane platinum carrier ligand with a mechanism of action similar to cisplatin, in combination with infusional fluorouracil plus leucovorin, is FDA-approved for use in first-line and salvage regimens for metastatic colorectal cancer (see Table 133–11). Oxaliplatin differs from cisplatin in that the DNA damage induced by oxaliplatin may not be as easily recognized by the DNA MMR complex.¹⁰² Thus oxaliplatin-induced DNA damage may play a particularly important role in colorectal cancers that are associated with defects in MMR genes, which are common in HNPCC. Oxaliplatin's incorporation into fluorouracil-based regimens as first-line therapy for metastatic colorectal cancer is associated with higher response rates, improved PFS, and variable effects on OS. A comparison of the de Gramont regimen, with or without oxaliplatin 85 mg/m² as a 2-hour infusion on day 1 (FOLFOX4 regimen), was designed to evaluate PFS as a primary end point in 420 previously untreated patients with metastatic disease.⁹³ Tumor response (50.7% vs. 22.3%) and PFS (median: 9 months vs. 6.2 months) were improved with oxaliplatin compared to fluorouracil plus leucovorin alone; the difference in OS did not reach statistical significance (median: 16.2 months vs. 14.7 months). Although the three-drug regimen was associated with higher frequencies of grade 3 and 4 toxicities, primarily neutropenia, diarrhea, and neurosensory toxicity, they did not significantly impair quality-of-life.

Intergroup Trial N9741, a comparison of oxaliplatin plus fluorouracil and leucovorin (FOLFOX4) to weekly irinotecan plus IV bolus fluorouracil and leucovorin (IFL), and a combination of irinotecan plus oxaliplatin (IROX) in 795 patients with previously untreated metastatic colorectal cancer showed superior efficacy with FOLFOX4.¹⁰³ The IROX arm showed no advantage over either of the other two arms. Significant improvements in response rates, PFS, and median survival were seen with FOLFOX4 as compared to IFL (see Table 133–12).¹⁰³ The study design allowed patients who failed either regimen to crossover to irinotecan or oxaliplatin, depending on their initial treatment assignment. Sixty percent of patients who failed FOLFOX4 received salvage irinotecan, whereas 24% of IFL failures received salvage oxaliplatin. The impact that this

crossover had on survival is unknown, but may have resulted in improved survival for the FOLFOX4 arm. In addition, the method of fluorouracil administration, and its impact on study results, has been called into question. Patients on the IFL arm received weekly IV bolus fluorouracil, while patients on the FOLFOX4 arm were administered fluorouracil as IV bolus followed by continuous infusion IV, which is known to increase response rates. Consequently, it is not possible to evaluate the true contributions of oxaliplatin and irinotecan combined with fluorouracil plus leucovorin in this study. The deletion of fluorouracil (or any fluorinated pyrimidine) from a first-line regimen may be undesirable.

In a phase III cooperative group study, a simplified combined bolus and infusional fluorouracil regimen with irinotecan (FOLFIRI) was compared to oxaliplatin combined with the same fluorouracil plus leucovorin schedule (FOLFOX6) in previously untreated patients with advanced colorectal cancer to determine whether the sequence of administration of both regimens differed with regard to efficacy and toxicities.¹⁰⁴ Patients were randomized to receive initial treatment with FOLFIRI or FOLFOX6, and at disease progression the patients then received the alternate regimen. Both sequences resulted in similar response rates, PFS, and median survival, but the grade 3 or 4 toxicity profiles were different. Neurotoxicity, neutropenia, and thrombocytopenia were more common with FOLFOX6, while febrile neutropenia, nausea/vomiting, mucositis, and fatigue were significantly more frequent with FOLFIRI.

Oxaliplatin has minimal renal toxicity, myelosuppression, and nausea and vomiting when compared to other platinum-based drugs. Oxaliplatin is associated with both acute and persistent neuropathies.¹⁰⁵ The acute neuropathies occur with 1 to 2 days of dosing and resolve within 2 weeks. The neuropathies usually occur peripherally, but may also occur in the jaw and tongue. A rare acute syndrome of pharyngolaryngeal dysesthesia (1% to 2% of patients) is characterized by subjective sensations of difficulty in swallowing and shortness of breath. Overall, acute neuropathies occur in approximately 90% of patients, and are precipitated or exacerbated by exposure to cold temperatures or cold objects. Thus patients should be instructed to avoid cold drinks and use of ice, and to cover skin before exposure to cold or cold objects. Several prophylactic and treatment strategies have been studied with varying degrees of success. Carbamazepine, gabapentin, amifostine, and calcium and magnesium infusions have been used to both prevent and treat oxaliplatin-induced neuropathies. Persistent neuropathy is typically a cumulative adverse effect, occurring after 8 to 10 cycles, and is seen mostly in patients who are responding to therapy.¹⁰³ The neuropathy is characterized by paresthesia, dysesthesia, and hypoesthesia, but may also include deficits in proprioception that can interfere with daily activities (e.g., writing, buttoning, swallowing, and difficulty walking as a result of impaired proprioception), and occur in half of patients receiving oxaliplatin with infusional fluorouracil plus leucovorin, but usually resolve with dosage reductions or cessation of oxaliplatin therapy.¹⁰⁵

CLINICAL CONTROVERSY

The results of N9741 have been debated between clinicians since their presentation. Whether an irinotecan-containing regimen (IFL or FOLFIRI) or FOLFOX4 should be the first regimen used in metastatic colon cancer is an unanswered question. Sequencing trials suggest that it does not matter and most patients should receive both irinotecan- and oxaliplatin-containing regimens at some point during treatment for their disease.

9 Capecitabine. Capecitabine (Xeloda) is an oral, tumor-activated and tumor-selective fluoropyrimidine carbamate. Capecitabine is converted to fluorouracil through a three-step activation

process, the final step being activation by thymidine phosphorylase, which is present in greatest concentrations at the tumor site. These activation steps lead to about a 3-fold increase in tumor and 1.4-fold increase in hepatic fluorouracil levels. Capecitabine was compared to fluorouracil plus leucovorin as first-line therapy for metastatic colorectal cancer in two randomized phase III trials. In a pooled analysis of 1,207 patients randomized to capecitabine (1,250 mg/m² orally twice daily for 14 days, repeated every 3 weeks) or the Mayo Clinic regimen, tumor response to capecitabine was superior to that of fluorouracil plus leucovorin (25.7% vs. 16.7%).¹⁰⁶ Time-to-tumor-progression and median survival, however, were no different. Hand-foot syndrome was more common with capecitabine, whereas grade 3 or 4 neutropenia and stomatitis were more common with fluorouracil plus leucovorin. The convenience of oral administration and different toxicity profile make capecitabine a useful alternative to IV fluorouracil regimens in the setting of metastatic disease. However, because the IV treatment arm in these comparative studies could be considered more toxic than the weekly IV fluorouracil plus leucovorin treatment schedule, it is premature to conclude that capecitabine is as efficacious as and less toxic than all parenteral fluorouracil-based regimens. Infusional fluorouracil is generally considered to be superior to bolus administration, and oral capecitabine may mimic this method of fluorouracil administration. These data, along with capecitabine's ease of administration, and data that irinotecan and oxaliplatin appear to have a greater effect when combined with infusional fluorouracil has led to capecitabine being evaluated as a replacement for infusional fluorouracil.

Both irinotecan and oxaliplatin have been combined with capecitabine and preliminary data suggest these combinations will be safe and effective in the initial treatment of metastatic colorectal cancer. The current FDA-approved indication for capecitabine in metastatic colon cancer is when therapy with a fluoropyrimidine alone is desired. Replacement of fluorouracil-leucovorin with capecitabine in other regimens is not currently approved, although longer follow-up of completed trials may show that capecitabine is a suitable replacement for infusional fluorouracil in combination with either irinotecan or oxaliplatin.

8 Biologic Therapy. Bevacizumab (Avastin) is a recombinant, humanized monoclonal antibody that inhibits vascular endothelial growth factor. Bevacizumab, in combination with intravenous fluorouracil-based chemotherapy, was FDA approved in 2004 for initial treatment of patients with metastatic colorectal cancer. This represents the third available combination regimen for first-line treatment. Results from two randomized trials show increased benefit as compared to chemotherapy alone.

A phase III trial of bevacizumab in combination with IFL as first-line therapy in patients with metastatic colorectal cancer has also been completed. Patients were randomized to receive IFL plus placebo or IFL plus bevacizumab 5 mg/kg every 2 weeks.¹⁰⁷ The addition of bevacizumab to IFL therapy resulted in an increase in response rate (34.7% vs. 44.9%) and median (15.6 vs. 20.3 months) and PFS (6.24 vs. 10.6 months) as compared to IFL alone. The frequency of typical adverse effects associated with IFL chemotherapy was not increased with the addition of bevacizumab. Grade 3 hypertension was significantly increased in the bevacizumab group. The incidence of other safety concerns with bevacizumab, such as bleeding, thromboembolism, and proteinuria, were not increased in the bevacizumab group as compared to placebo. The hypertension is easily managed with oral antihypertensive agents. The risk of gastrointestinal perforation was increased by the addition of bevacizumab to IFL, and patients complaining of abdominal pain associated with vomiting or constipation should be considered for this rare, but potentially fatal complication. Bevacizumab is also associated with a twofold increased risk of arterial thrombotic events, with patients who are older than age 65 years or who have a

prior history of arterial thrombotic events at greatest risk. Nevertheless, because these individuals derive the same survival benefits with bevacizumab as other patients, they may be appropriate candidates to receive bevacizumab.

The use of bevacizumab with FOLFOX4 in the initial treatment of metastatic colon cancer was recently reported. In this trial, the first cohort of patients were randomized to three oxaliplatin-based regimens (TREE-1 [arm 1: oxaliplatin plus infusional 5-FU; arm 2: oxaliplatin plus bolus 5-FU; arm 3: oxaliplatin plus oral capecitabine]) while the second cohort of patients (TREE-2) received the same regimens plus bevacizumab as their first-line treatment for metastatic colon cancer. The addition of bevacizumab was associated with increased overall response rate and longer time to progression and median survival, although these differences were not significant as a consequence of the small sample size. Overall median survival with the addition of bevacizumab was 18.4 months in the TREE-1 cohort and 24.4 months in the TREE-2 cohort.¹⁰⁸ In a separate phase III trial, the addition of bevacizumab to oxaliplatin-based chemotherapy (XELOX or FOLFOX) significantly improved PFS.¹⁰⁹ Studies to compare the addition of bevacizumab to FOLFOX4 versus irinotecan-based combinations of bevacizumab are ongoing.

Investigational Approaches

Targeted Agents. Preliminary results with cetuximab in the first-line metastatic setting combined with either FOLFOX or FOLFIRI suggest that the combination improves response rates to either chemotherapy regimen without adding substantial toxicity.¹¹⁰ Similar results have been reported with panitumumab,¹¹¹ but for reasons that are not well-understood, the addition of panitumumab to bevacizumab plus irinotecan- or oxaliplatin-containing chemotherapy *reduced* PFS in the Panitumumab Advanced Colorectal Cancer Evaluation Study (PACCE) trial. Whether two monoclonal antibodies can be safely and effectively combined with standard chemotherapy in the first-line treatment of metastatic colorectal cancer remains to be determined.

Hepatic Artery Infusion. Although hepatic chemotherapy infusion for metastatic colorectal cancer remains an area of investigation, it has not been shown to be superior to systemic chemotherapy. The rationale for hepatic artery infusion (HAI) is based on the principle that normal liver hepatocytes and early micrometastases obtain their primary blood supply from the portal vein. In contrast, tumors in the liver are thought to receive most of their blood supply via the hepatic artery.⁹¹ Consequently, drug administration via the hepatic artery should result in delivery of high drug concentrations to the tumor cells with a much lower exposure to normal liver tissue.

Because the liver is a common site of colorectal cancer metastasis, and the only site of metastatic involvement in up to one-third of patients, hepatic-directed therapies continue to be explored. Historically, floxuridine and fluorouracil have undergone the most study for hepatic artery infusion, but other active agents such as irinotecan and oxaliplatin have also been studied. Trials involving HAI have been conducted in patients with unresectable liver metastases and as adjuvant therapy following curative resection of isolated metastases.

Regional HAI can be accomplished using a hepatic arterial port, a totally implantable pump, or a percutaneously placed catheter into the hepatic artery that is connected to an external pump. Early trials of HAI revealed objective response rates ranging from 30% to 88%, many of which were observed in previously treated patients, and increased survival rates as compared to historic controls. Because supportive care alone is no longer considered standard of care for metastatic disease, when HAI was compared to systemic chemotherapy, most comparisons did not yield a survival benefit.⁹¹ Furthermore, most studies allowed patients in the systemic therapy treatment groups to crossover to HAI upon tumor progression; therefore the impact of these treatments on survival is difficult to

interpret. Most recently, HAI was compared to systemic fluorouracil plus leucovorin in patients with hepatic-only metastasis.¹¹² HAI was associated with significantly longer OS (median: 24.4 vs. 20 months, $P = 0.0034$) and time-to-hepatic-progression (median: 9.8 vs. 7.3 months, $P = 0.034$) as compared to systemic chemotherapy. As expected, time-to-extrahepatic-progression was longer (14.8 vs. 7.7 months, $P = 0.029$) with systemic chemotherapy. This study has been criticized for the systemic chemotherapy treatment arm, which is considered less-than-optimal therapy by current standards.

Given the significant improvements with systemic chemotherapy for metastatic disease achieved with systemic chemotherapy over the past several years, attention has been directed to HAI with nonfluoropyrimidines, including irinotecan, oxaliplatin, and biologic agents. Early studies show promising results, but it is not clear whether this approach offers any advantage compared to systemic therapy.

Because of toxicities associated with HAI, most patients require some transient interruption of therapy, a decrease in dosage, or discontinuation of therapy. Furthermore, extrahepatic disease progression with HAI therapy alone remains a clinical problem. Although increased response rates and a trend toward improved survival have been reported, the costs and toxicities with this approach are significant. Therefore, for the minority of patients who present with unresectable disease to the liver only, HAI may represent a reasonable therapeutic option, but it is not considered standard therapy at this time.

Approach to Selecting an Initial Metastatic Regimen Practitioners can select first-line treatment for metastatic colorectal cancer from among four treatments: oxaliplatin plus fluorouracil plus leucovorin (FOLFOX); irinotecan plus fluorouracil plus leucovorin (FOLFIRI or IFL); bevacizumab plus fluorouracil-based chemotherapy; and capecitabine-based therapy. The most important factor in patient survival is not the initial regimen but whether or not patients receive all three active chemotherapy drugs (fluorouracil, irinotecan, and oxaliplatin) at some point in their treatment course.¹¹³ Based on the comparable results of FOLFIRI versus FOLFOX6, combined with the inferiority of IFL to FOLFOX4, either of these regimens is considered the reference standard in metastatic colorectal cancer. The IFL regimen is rarely used in clinical practice. Similar to the adjuvant setting, patient-specific factors may lead practitioners to choose between FOLFOX and FOLFIRI. Preexisting neuropathies may lead to FOLFIRI being chosen initially, whereas increased bilirubin or known UGT1A1 deficiency (known risk factors for delayed diarrhea) may lead to FOLFOX as the initial choice. The 2007 NCCN guidelines recommend the addition of bevacizumab to any initial fluorouracil-based regimen unless contraindicated.¹¹⁴

Capecitabine may be an appropriate substitute for intravenous fluorouracil in these combination regimens; the 2007 NCCN guidelines list CapOx plus bevacizumab as an acceptable initial regimen based on preliminary data demonstrating equivalence to oxaliplatin plus continuous infusion 5-FU.¹¹⁵ Fluorouracil plus leucovorin alone or capecitabine monotherapy is also appropriate first-line treatment for those individuals who cannot tolerate three-drug combination regimens.

Second-Line Therapy

Systemic chemotherapy represents the mainstay of therapy for patients whose disease progresses following initial treatment for metastatic disease. Figure 133–6 depicts an algorithm for treatment of refractory metastatic disease. Treatment options are based on the type of and response to prior treatments, the site and extent of disease, and patient factors and treatment preferences.

Systemic Chemotherapy On disease progression following standard initial therapy, appropriate treatment options may include oxaliplatin plus fluorouracil and leucovorin with or without bevaciz-

umab, irinotecan plus cetuximab, cetuximab, irinotecan, continuous-infusion fluorouracil, capecitabine plus oxaliplatin, capecitabine, intrahepatic therapy for selected patients, supportive care, or participation in a clinical trial. The choice of specific agents depends primarily on the type of prior therapy received. Because most patients will have received a combination of a pyrimidine with either irinotecan or oxaliplatin, second-line therapy with the alternate regimen should be considered. Patient survival can exceed 2 years.

Irinotecan. Two important trials have delineated an appropriate standard of care for patients who experience disease progression with fluorouracil therapy for metastatic colorectal cancer.^{116,117} The results of these trials demonstrate a survival benefit associated with irinotecan, which was FDA approved in 1996 as second-line therapy for recurrent or progressive disease following fluorouracil. In phase II studies of previously treated patients with metastatic colorectal cancer, objective response rates of 13% to 27% have been observed.^{116,117}

In a phase III trial of 189 patients with metastatic colorectal cancer that had progressed within 6 months of treatment with fluorouracil, irinotecan was compared to supportive care alone with regard to survival, quality-of-life, and other clinical variables.¹¹⁶ Irinotecan was administered as 350 mg/m² IV every 3 weeks; the dose was reduced to 300 mg/m² for individuals who were 70 years of age or older, had a World Health Organization performance status of 2, or who had clinical risk factors for developing excessive treatment-related toxicity. Supportive care could include any symptomatic therapy with the exception of irinotecan or any other topoisomerase I inhibitor. With the exception of more patients with poor performance status in the supportive care group, baseline patient characteristics were similar between groups. Median survival was 9.2 months with irinotecan, as compared to 6.5 months with supportive care alone. One-year survival was significantly greater with irinotecan (36.2% vs. 13.8%) and was not associated with significantly worse quality-of-life scores except for diarrhea. Clinical variables such as cognitive functioning, pain, dyspnea, and appetite loss were in favor of irinotecan therapy. The most common grade 3 or 4 side effects with irinotecan included leukopenia and neutropenia (22%), diarrhea (22%), nausea (14%), and vomiting (14%). Seventy-two percent of patients receiving irinotecan required hospital admission for adverse events, as compared to 63% of supportive care patients. Thus irinotecan was associated with an improved survival and quality-of-life as compared to supportive care alone that appeared to balance treatment-related toxicities.

A comparison of irinotecan to continuous-infusion fluorouracil in a similar population of 267 patients allocated patients to irinotecan, 300 to 350 mg/m² IV every 3 weeks, or one of three continuous-infusion fluorouracil regimens: leucovorin 200 mg/m² IV over 2 hours followed by IV bolus fluorouracil (400 mg/m²) and 22-hour continuous-infusion fluorouracil (600 mg/m²), given the first 2 days of every 2-week period; fluorouracil 250 to 300 mg/m² as prolonged continuous IV infusion until disease progression; or fluorouracil 2,600 to 3,000 mg/m² per day IV over 24 hours, with or without leucovorin (20 to 500 mg/m² IV), given weekly for 6 weeks, with a 2-week rest period between cycles.¹¹⁷ Median followup after 15 months revealed a longer 1-year survival (45% vs. 32%) and median survival (10.8 months vs. 8.5 months) with irinotecan, as compared to fluorouracil. Sixty-nine percent of patients receiving irinotecan experienced at least one grade 3 or 4 toxicity, as compared to 54% of patients receiving fluorouracil. The most common toxicities with irinotecan were diarrhea, neutropenia, pain, vomiting, and asthenia, while pain, asthenia, diarrhea, and dermatologic toxicities were most common with fluorouracil. There was no difference in hospitalization requirement for adverse effects between treatments.

Based on these results, irinotecan should be considered standard second-line therapy for patients who have failed prior treatment with fluorouracil-based regimens. Initial administration of irinote-

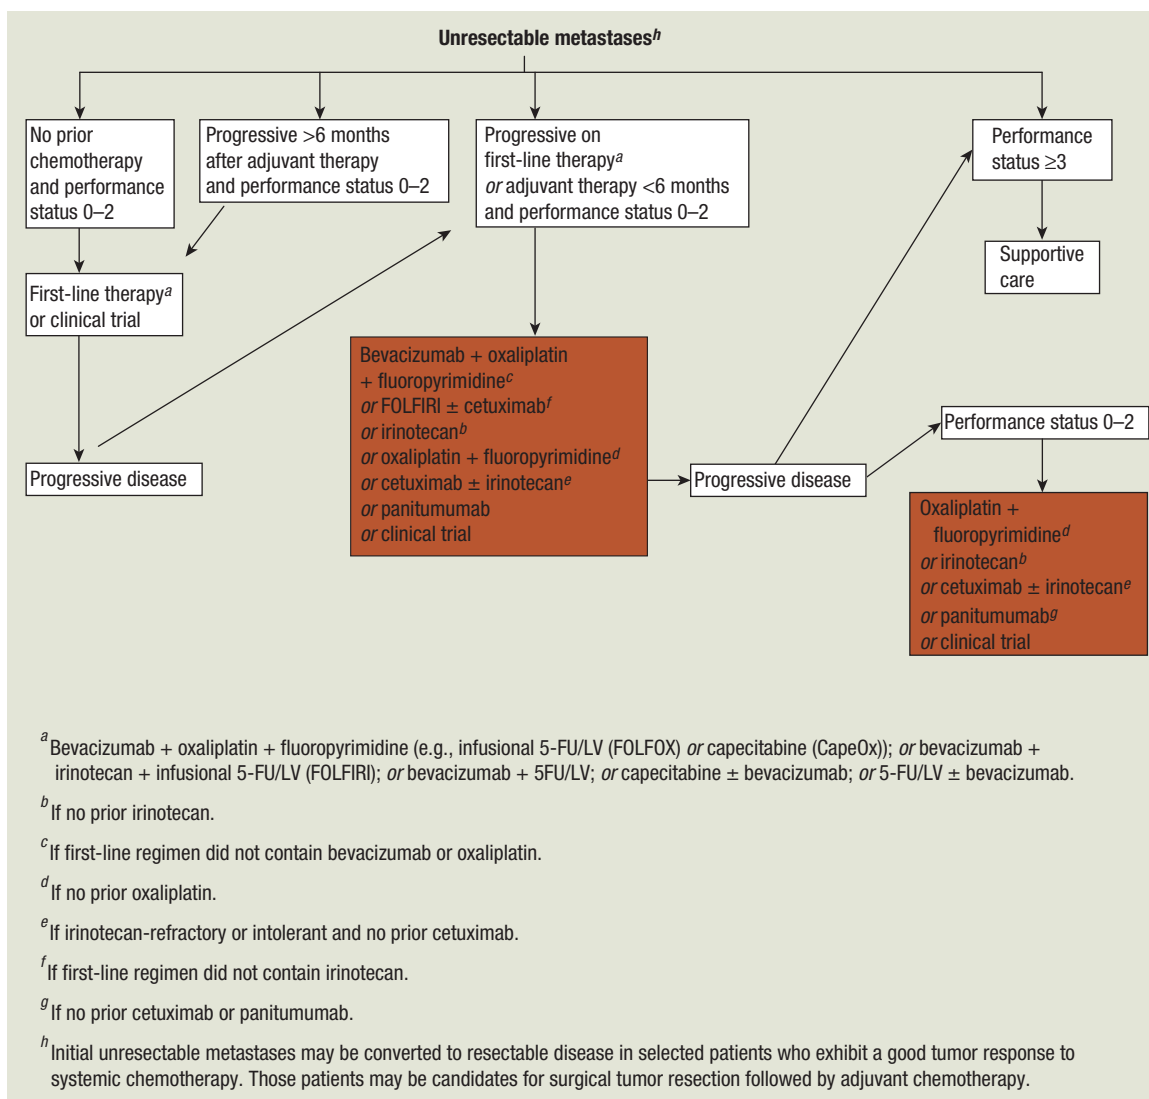

FIGURE 133-6. Algorithm for treatment of unresectable or refractory metastatic colorectal cancer.

can at the lower dose should be considered for patients who have received significant prior pelvic or abdominal irradiation. Protracted continuous-infusion fluorouracil could be considered for those individuals with disease that no longer responds to bolus IV fluorouracil plus leucovorin or irinotecan.

Oxaliplatin. For patients who received primary treatment with irinotecan and fluorouracil, oxaliplatin plus fluorouracil and leucovorin should be considered. Despite the low activity of single-agent oxaliplatin against fluorouracil-refractory disease, when oxaliplatin has been administered in a bimonthly regimen with high-dose leucovorin and continuous fluorouracil infusion, a 20.6% response rate with a median survival in excess of 10 months has been reported.¹¹⁸ The combination of oxaliplatin plus fluorouracil and leucovorin is also effective as salvage therapy after initial treatment with irinotecan plus fluorouracil and leucovorin, with a response rate of approximately 20%.¹¹⁹ Although irinotecan can be used effectively as a single agent in colorectal cancer, it should be noted that oxaliplatin does not have substantial activity alone, and should only be given in combination with a fluoropyrimidine.

In patients who did not receive bevacizumab in their initial treatment, FOLFOX plus bevacizumab is recommended based on phase III data. Results from Eastern Cooperative Group 3200 demonstrated that bevacizumab, in combination with FOLFOX4, improved survival in patients with previously treated advanced colorectal cancer.¹²⁰ It should be noted that patients were excluded

if they received prior oxaliplatin or bevacizumab and the dose of bevacizumab was 10 mg/kg instead of 5 mg/kg. Median survival was improved from 10.7 to 12.5 months ($P = 0.0018$). There are no substantial data to support the use of bevacizumab after progression on first-line bevacizumab.

10 Biologic Therapy. Cetuximab (IMC-C225, Erbitux) is a chimeric monoclonal antibody directed against an EGFR that received FDA approval in 2004. Cetuximab may be administered in combination with irinotecan, but can be used as a single agent in patients who cannot tolerate irinotecan-based chemotherapy.

In a phase II study, patients with EGFR-expressing metastatic colorectal cancer who had failed an irinotecan-based regimen received open-label cetuximab, 400 mg/m² IV as a loading dose, followed by weekly infusions of 250 mg/m² IV until disease progression.¹²¹ Of 57 patients treated, 5 achieved a partial response, with a minor response or stable disease developing in 21 additional patients. The median survival was 6.4 months. The most common grade 3 or 4 adverse events were papulopustular, follicular skin rash (18% grade 3) and adverse effects characterized as asthenia, lethargy, malaise, or fatigue (9% grade 3).

The combination of cetuximab plus irinotecan was also compared to cetuximab as a single agent in patients with EGFR-positive colorectal cancer that had progressed on irinotecan. Three hundred and twenty-nine patients were randomized in a 2:1 ratio to receive cetuximab plus continuation of the irinotecan or cetuximab alone.¹²² The objective

tumor response rates, 22.9% and 10.8% with cetuximab plus irinotecan and cetuximab alone, respectively, were very encouraging, and resulted in the endorsement of cetuximab by the FDA via accelerated approval. Median survival was 8.6 months for the combination and 6.9 months with monotherapy ($P = 0.48$). Time-to-disease-progression was significantly longer with cetuximab plus irinotecan than with cetuximab alone (4.1 vs. 1.5 months; HR 0.54), even among patients who also had oxaliplatin-refractory disease. The incidence of grade 3 or 4 adverse effects was as anticipated based on previous trials; asthenia and acne-like rash occurred most commonly with cetuximab alone, and in addition to typical irinotecan-related side effects (e.g., nausea, vomiting, and diarrhea) with combination treatment. Interestingly, tumor response was not associated with the intensity of EGFR-positive staining. Because patients who experienced disease progression on monotherapy were allowed to crossover to combination treatment, any difference in OS between the two groups is difficult to ascertain.

Preliminary data also suggest that cetuximab adds benefit to oxaliplatin-based regimens and in the first-line setting. A 2006 abstract demonstrated similar efficacy when cetuximab was added to either FOLFOX or FOLFIRI in the initial treatment of metastatic colon cancer.¹¹⁰ The use of cetuximab with FOLFOX in the salvage setting is currently unknown.

Cetuximab should be considered in patients with irinotecan- and oxaliplatin-refractory colorectal cancer. As a single agent, cetuximab is associated with a 23% improvement in OS compared to best supportive care.¹⁵⁰ Current evidence does not support restricting the use of cetuximab to patients with immunohistochemical evidence of EGFR-positive staining.¹¹⁴

Panitumumab (ABX-EGF, Vectibix) is a fully human monoclonal antibody targeted to the EGFR that was FDA approved for use in patients with metastatic colorectal cancer that no longer responds to previous therapy.¹²³ The approval was based on a comparison of panitumumab to best supportive care in patients who had experienced disease progression after standard chemotherapy, including a fluoropyrimidine, irinotecan, and oxaliplatin. Patients received best supportive care or panitumumab (6 mg/kg IV every 2 weeks) until tumor progression. Those patients who received panitumumab showed a 46% decrease in the rate of tumor progression compared to those who only received best supportive care (HR 0.54, 95% CI 0.44 to 0.66). As expected, dermatologic toxicities were observed in patients receiving panitumumab, as well as fatigue, abdominal pain, nausea, and diarrhea. Only one hypersensitivity reaction was reported. As with cetuximab, EGFR-positivity with immunohistochemistry should not be used to determine appropriate candidates for panitumumab. Additional studies with investigational monoclonal antibodies are ongoing.

CLINICAL CONTROVERSY

Currently, cetuximab and panitumumab are only approved by the FDA for patients with documented EGFR-positive tumors. Mounting clinical evidence suggests that patients with EGFR-negative tumors may derive the same benefit,¹²⁴ but insurance coverage for patients with EGFR-negative tumors may be difficult to obtain.

Miscellaneous Salvage Chemotherapy. Similar to initial treatment of metastatic colon cancer, capecitabine is being investigated as a replacement for infusional fluorouracil in salvage regimens in combination with irinotecan or oxaliplatin.

One interesting subject of debate is whether treatment could be suspended once disease stabilization occurs and restarted upon disease progression. In the OPTIMOX study, patients were randomized to receive continuous FOLFOX4 until disease progression, or a simplified regimen, FOLFOX7, with intermittent oxaliplatin.¹²⁵

The results of this study demonstrated that oxaliplatin could be stopped after six cycles of chemotherapy, but that an appropriate strategy to reintroduce chemotherapy needed to be developed. Ongoing studies are evaluating various agents as maintenance treatments in conjunction with a similar intermittent treatment regimen. Patients who fail standard treatment for metastatic colorectal cancer should be encouraged to participate in a clinical trial evaluating new treatment approaches for this incurable disease.

Hepatic-Directed Therapies. Patients with hepatic-predominant disease whose disease progresses with systemic therapy may be candidates for chemoembolization, cryotherapy, or radiofrequency ablation. Percutaneous ethanol injection can be performed but is considered relatively ineffective against colorectal hepatic metastases.¹²⁶ Response rates to HAI therapy in patients who are refractory to fluorouracil-based therapy may be as high as 33%.

The largest experience with hepatic arterial chemoembolization has been seen in patients with metastatic carcinoid tumors or primary hepatocellular carcinomas. Most recently, small trials have been expanded to include hepatic metastases caused by colorectal cancer. Hepatic arterial chemoembolization delivers high concentrations of cytotoxic agents directly to the tumor and results in the embolization or devascularization of the liver, which blocks perfusion of the tumor and eliminates its blood supply. This procedure involves the instillation of a mixture that incorporates chemotherapeutic agents, radioactive contrast dye, and/or an embolic agent directly into the hepatic artery. Agents and doses most commonly studied include doxorubicin (40 to 60 mg), mitomycin (10 to 20 mg), and cisplatin (100 to 150 mg), which are usually dissolved in about 10 to 15 mL of a radiographic contrast dye.¹²⁷ Addition of an embolic agent to the mixture, such as a gelatin sponge (Gelfoam), polyvinyl alcohol particles, bovine collagen, or iodized poppy seed oil (Lipiodol and Ethiodol), results in either a temporary or permanent occlusion of the hepatic artery. Although approximately 80% of patients in one trial experienced a response, the number of patients with colorectal cancer who have undergone this procedure thus far is relatively low and patients still experience eventual disease progression. However, preliminary results from small series suggest that the high tumor responses might be associated with a survival benefit, and randomized trials comparing systemic therapy to hepatic chemoembolization for unresectable disease are ongoing.

Cryosurgery involves placement of a cryoprobe into the tumor, either percutaneously or intraoperatively, and then lowering the probe temperature to 100°C (148°F).¹²⁶ This is repeated in cycles, resulting in formation of an ice ball that causes tumor destruction. Cryosurgery may be used alone or in conjunction with other localized procedures, such as radiofrequency ablation, which is becoming increasingly used for colorectal liver metastases. The technique involves placement of a chilled perfusion electrode needle into the tumor with subsequent application of alternating electrical current through the electrode, resulting in thermal coagulative necrosis of the tumor.¹²⁶ Laser interstitial thermal therapy represents an alternate method for causing tumor coagulative necrosis using a laser. Radiofrequency ablation is also being evaluated in conjunction with HAI, in an effort to reduce local recurrence of metastatic tumors. Procedure-related complications can include bleeding, coagulopathy, liver abscess, biliary stricture, and pleural effusion.¹²⁶ Although these approaches represent potential treatment strategies for patients with unresectable, yet limited hepatic metastases, additional experience is needed to determine long-term outcomes. Furthermore, extrahepatic sites of disease continue to be a problem even for those individuals in whom the liver tumors can be eradicated.

New Strategies and Agents in Development

At present, fluorouracil plus leucovorin, bevacizumab, capecitabine, irinotecan, oxaliplatin, and cetuximab are the most frequently used

chemotherapeutic agents for cancer of the colon and rectum. New chemotherapy agents have been studied in an attempt to further improve antitumor efficacy and reduce treatment toxicities. Oral fluorinated pyrimidines and TS inhibitors, such as fluorouracil prodrugs and inhibitors of fluorouracil catabolism, can prolong in vivo fluorouracil exposure and enhance antitumor effects without the use of continuous IV infusions. But traditional chemotherapy agents, which target rapidly dividing cells, kill both malignant and nonmalignant cells, and new cancer therapies are needed to improve therapeutic outcomes. In particular, targeted therapies aimed at the underlying cancer pathology are increasingly being developed and used in colorectal cancer treatment. A variety of agents targeted toward augmenting the host immune system response have undergone, or are currently undergoing, study for colorectal cancer, including monoclonal antibodies and tumor vaccines. Another potential strategy is regulating tumor growth through the inhibition of various cell signal-transduction pathways. Agents that can alter microenvironmental factors that support angiogenesis and tumor metastases may also be of benefit.

In addition, observations that various tumor characteristics (e.g., TS expression), patient drug-metabolizing enzymes (e.g., DPD and plasma uracil-to-dihydrouracil ratio), and molecular markers (e.g., chromosome 18q allelic loss, microsatellite instability, and *p53* mutation or loss) may predict prognosis and response to certain therapies and provide the rationale for pharmacogenomic strategies to select first-line therapies for individual patients.^{128–130} Although patients who are deficient in DPD experience severe and potentially life-threatening toxicities with conventional doses of fluorouracil, determination of DPD activity is relatively time-consuming and the techniques are not amenable to routine clinical practice. As an alternative, plasma ratio determinations of uracil and dihydrouracil, which are more easily obtainable, can identify individuals with DPD deficiency and who are at risk of developing significant toxicities. Of factors predictive for tumor sensitivity to fluorouracil, TS expression has been most studied. Results from in vitro studies demonstrate that pretreatment intratumoral TS levels are inversely correlated to tumor response to fluorouracil. Whether increased tumor TS expression reflects a biologically more aggressive tumor or is directly related to fluorouracil resistance is unknown. Studies are underway to use this and other information to identify rational therapeutic approaches for select patients.

PHARMACOECONOMIC CONSIDERATIONS

The estimated expenditures for colorectal cancer in the United States alone are between \$5.3 and \$6.5 billion per year.¹³¹ The total lifetime cost for managing a patient with cancer of the colon based on North American data is close to \$100,000.¹³¹ Costs for patients with rectal cancer are approximately 15% higher because of the added expense of XRT. The highest of costs of treatment are incurred during the initial and terminal phases of care. Thus, a long-term approach is needed to accurately estimate the cost of treating patients diagnosed with colorectal cancer. In addition, long-term cancer-related excess costs were calculated with the Surveillance, Epidemiology, and End Results (SEER)-Medicare-linked database as \$33,700 and \$36,500 for colon and rectal cancer, respectively.¹³¹ The impact of changes in clinical practice on treatment costs, such as increased use of adjuvant therapy, changes in duration of hospital stay and outpatient delivery of health services, and incorporation of costly agents into standard treatment regimens, must also be continually considered.

The cost of the drugs alone (based on 95% of Average Wholesale Price (AWP) in 2004) were estimated for a 70-kg, 170-cm tall patient with colorectal cancer for a typical treatment period of 8 weeks.¹³¹ The cost of biweekly infusional fluorouracil plus leucovorin (LV5FU2) is only about \$263, but the incorporation of irinote-

can (FOLFIRI) or oxaliplatin (FOLFOX) increases drug costs to \$9,381 and \$11,889, respectively. Total drug costs are about \$21,000 with the addition of bevacizumab; an 8-week treatment course of standard cetuximab-containing regimens costs about \$31,000. Thus, while the availability of these newer cytotoxic and biologic agents has extended median survival of patients with metastatic colorectal cancer, the economic impact of drug therapy alone on the healthcare system is of increasing importance.

The cost-effectiveness of therapeutic regimens in various treatment settings has also been evaluated. The addition of irinotecan to fluorouracil and leucovorin as first-line therapy for metastatic disease was supported in the United Kingdom based on an incremental cost-effectiveness ratio of £14,794 per life-year gained.¹³² A comparison of the costs and effects of FOLFOX compared to IFL, based on the perspective of a United States payer, showed total costs of \$94,693 for FOLFOX and \$66,231 for IFL, with a gain in survival of 4.4 months with FOLFOX at an incremental cost-effectiveness ratio of \$80,410 per life-year gained.¹³² The associated \$11,890 per quality-adjusted life-year gained is considered an acceptable oncology intervention within the United States healthcare system.

In adjuvant treatment, a cost-effectiveness analysis of FOLFOX4 compared to LV5FU2 from a Medicare perspective showed an incremental cost-effectiveness ratio with FOLFOX4 of \$20,603 per life-year gained and \$22,804 per quality-adjusted life-year gained.¹³³ At a threshold of \$50,000 per quality-adjusted life-year, FOLFOX4 would be viewed as cost-effective adjuvant therapy for stage III colon cancer. Substitution of intravenous fluorouracil with oral capecitabine may have positive economic effects, but data are limited.¹³² Reduced costs for capecitabine with regard to drug administration and drug-related adverse effects offset its higher acquisition cost as compared to fluorouracil plus leucovorin in adjuvant therapy for stage III colon cancer, but a cost-effectiveness analysis was not reported.¹³⁴

The cost-effectiveness of combination chemotherapy with cetuximab, bevacizumab, or panitumumab in the United States has not been established. A report by the National Institute for Health and Clinical Excellence (NICE) suggests that neither first-line bevacizumab nor second-line or subsequent treatment cetuximab would be considered cost-effective.¹³²

Colorectal cancer screening is regarded as cost-effective, but only approximately 35% of the population age 50 years and older undergoes regular screening.¹³⁵ The cost-effectiveness of standard methods varies. Base-case estimates, adjusted to year 2000 dollars, were \$6,300 to \$19,700 per life-year saved, \$13,600 to \$36,300 per life-year saved, and \$7,300 to \$22,000 per life-year saved for FOBT, sigmoidoscopy, and colonoscopy, respectively.¹³⁵ When adjusted average cost-effectiveness ratios were calculated and compared among FOBT, colonoscopy, and sigmoidoscopy, colonoscopy was the most cost-effective screening strategy when performed every 10 years. Based on an average estimated adherence rate with FOBT or sigmoidoscopy of approximately 50%, the ability to offer patients a choice of screening alternatives has been proposed in an attempt to increase acceptance of screening.¹³⁵ A base-rate estimate of the cost-effectiveness of offering a choice of cancer screening options to individuals age 50 years and older is \$11,900 per life-year gained.¹³⁵ Because most accepted screening strategies have cost-effectiveness ratios that are well below the accepted benchmark of \$50,000 per life-year saved, this strategy is considered cost-effective. As many as 12,000 deaths each year might be prevented if all individuals who were candidates for colorectal screening participated in a regular program.¹³⁵

EVALUATION OF THERAPEUTIC OUTCOMES

The goal of monitoring is to evaluate whether the patient is receiving any benefit from the management of the disease or to detect recurrence. Similarly, followup examinations help to determine

whether preventive interventions or screening studies effectively reduce an individual’s risk for developing colorectal cancer or presenting with an advanced stage of disease. During treatment for active disease, patients should undergo monitoring for measurable tumor response, progression, or new metastases; these tests may include chest CT scans or radiographs, abdominal or pelvic CT scans or radiographs, depending on the site of disease being evaluated for response, and CEA measurements every 3 months if the CEA is or was previously elevated. In addition, a complete blood cell count should be obtained prior to each course of chemotherapy administration to ensure that hematologic indices are adequate. Baseline liver function tests and an assessment of renal function should be evaluated prior to and periodically during therapy. These tests and other selected serum chemistries should also be evaluated with the development of any new symptoms or significant change in disease status. Patients should be evaluated during every treatment visit for the presence of anticipated side effects, which generally include loose stools or diarrhea, nausea or vomiting, mouth sores, fatigue, and fever, as well as other side effects such as neuropathy and skin rash that are typically associated with oxaliplatin and cetuximab, respectively. Patients receiving bevacizumab should be evaluated for hypertension and proteinuria.

Symptoms of recurrence such as pain syndromes, changes in bowel habits, rectal or vaginal bleeding, pelvic masses, anorexia, and weight loss develop in less than 50% of patients. A greater percentage of recurrences are detected in asymptomatic patients because of increased serum CEA levels that lead to further examination. Although the value of CEA monitoring for asymptomatic disease recurrence is questioned by some because of the related expense and emotional stress associated with false-positive elevations, CEA monitoring plays an important role in postoperative followup studies for most individuals. A PET scan can be considered to identify localized sites of metastatic disease when a rising CEA level suggests metastatic disease but CT scans and other imaging studies are negative.

Patients who undergo curative surgical resection, with or without adjuvant therapy, require close followup based on the premise that early detection and treatment of recurrence could still render them cured. In addition, early treatment for asymptomatic metastatic colorectal cancer appears superior to delayed therapy. Specific practice guidelines for postoperative surveillance examinations were developed by ASCO (Table 133–13). These guidelines also recommend against routinely monitoring liver function tests, complete blood cell count, FOBT, annual chest radiographs in asymptomatic patients.¹³⁶

Recent advances in the treatment for cancer of the colon and rectum now offer the potential to improve patient survival but for many patients, improved DFS and PFS represent equally important therapeutic outcomes. Although treatment approaches for metastatic colorectal cancer have been historically assessed by their ability to produce a measurable objective tumor response, which is generally believed necessary for any treatment to improve survival, the effects of therapies on survival are clinically more meaningful than their

ability to induce a tumor response. However, with the availability of multiple active treatments for metastatic disease, and the likelihood that patients will receive more than one during the course of their treatment, improvements in OS with new therapies will be increasingly difficult to determine.

In the absence of the ability of a specific treatment to demonstrate improved survival, important outcome measures should include the effects of the treatment on patient symptoms, daily activities and performance status, and other quality-of-life indicators, as well as progression-free survival and time to treatment failure. Because most metastatic colorectal cancers are incurable, a specific decision regarding an individual patient’s care ultimately will be required. This decision should be based on a careful assessment of the balance between risks associated with treatment (or lack thereof) and benefits of treatment. Effort should also be made to ensure that the costs of screening, diagnostic tests, treatments, and procedures for colorectal cancer are consistent with their value in improving patient outcomes.

ABBREVIATIONS

- APC: adenomatous polyposis coli (gene)
- ASCO: American Society of Clinical Oncology
- BMI: body mass index
- CAPOX: capecitabine, oxaliplatin
- CEA: carcinoembryonic antigen
- COX: cyclooxygenase
- CT: computed tomography
- CYP: cytochrome P450 isoenzyme
- DFS: disease-free survival
- DPD: dihydropyrimidine dehydrogenase
- EGFR: epidermal growth factor receptor
- FAP: familial adenomatous polyposis
- FIT: fecal immunochemical test
- FOBT: fecal occult blood test
- FOLFIRI: fluorouracil, leucovorin, irinotecan
- FOLFOX: fluorouracil, leucovorin, oxaliplatin
- 5-FU: fluorouracil
- HAI: hepatic artery infusion
- HNPCC: hereditary nonpolyposis colorectal cancer
- HR: hazard ratio
- IFL: irinotecan plus fluorouracil plus leucovorin
- MMR: mismatch-repair (gene)
- MTHFR: methylenetetrahydrofolate reductase
- NCCN: National Comprehensive Cancer Network
- NSAID: nonsteroidal antiinflammatory drug
- OS: overall survival
- PET: positron emission tomography
- PFS: progression-free survival
- RR: relative risk
- TGF-β: transforming growth factor-β
- TS: thymidylate synthase
- UGT1A1: uridine diphosphate-glucuronosyltransferase
- XELOX: capecitabine, oxaliplatin
- XRT: radiation therapy

TABLE 133-13 Major Features of the American Society of Clinical Oncology Postoperative Surveillance Practice Guidelines for Colon and Rectal Cancer

- History and physical examination every 3 to 6 months for the first 3 years, every 6 months during years 4 and 5, and subsequently at the discretion of the physician
- Annual computed tomographic scan of the chest and abdomen for 3 years after primary therapy for patients who are at higher risk of recurrence and who could be candidates for curative-intent surgery
- Colonoscopy at 3 years after operative treatment, and, if results are normal, every 5 years thereafter

JILL M. KOLESAR

KEY CONCEPTS

- 1 Prostate cancer is the most frequent cancer in American men. African American ancestry, family history, and increased age are the primary risk factors for prostate cancer.
- 2 Prostate-specific antigen is a useful marker for detecting prostate cancer at early stages, predicting outcome for localized disease, defining disease-free status, and monitoring response to androgen-deprivation therapy or chemotherapy for advanced-stage disease.
- 3 The prognosis for prostate cancer patients depends on the histologic grade, the tumor size, and disease stage. More than 85% of patients with stage A₁ disease but less than 1% of those with stage D₂ disease can be cured.
- 4 Androgen ablation therapy, with orchiectomy, a luteinizing hormone-releasing hormone (LHRH) agonist alone or a LHRH agonist plus an antiandrogen (combined hormonal blockade), can be used to provide palliation for patients with advanced (stage D₂) prostate cancer. The effects of androgen deprivation are most pronounced in patients with minimal disease at diagnosis.
- 5 Antiandrogen withdrawal, for patients with progressive disease while receiving combined hormonal blockade with an LHRH agonist plus an antiandrogen, can provide additional symptomatic relief. Mutations in the androgen receptor can cause antiandrogen compounds to act like receptor agonists.
- 6 Androgen ablation with a LHRH agonist plus an antiandrogen should be used prior to radiation therapy for patients with locally advanced prostate cancer to improve outcomes over radiation therapy alone.
- 7 Chemotherapy with docetaxel and prednisone improves survival in patients with hormone-refractory prostate cancer. Patients with hormone-refractory prostate cancer should be considered for entry into clinical trials investigating new therapies for prostate cancer.

Prostate cancer is the most commonly diagnosed cancer in American men.¹ Most men with prostate cancer have an indolent course and treatment options for early disease include expectant management, surgery, and radiation. With expectant management, patients

are monitored for disease progression or development of symptoms. Localized prostate cancer can be cured by surgery or radiation therapy, but advanced prostate cancer is not yet curable. Treatment for advanced prostate cancer can provide significant disease palliation for many patients for several years after diagnosis. The endocrine dependence of this tumor is well documented, and hormonal manipulation to decrease circulating androgens remains the basis for the treatment of advanced disease.

EPIDEMIOLOGY

1 In the United States, it is estimated that 218,890 new cases of prostatic carcinoma will be diagnosed and more than 27,050 men will die from this disease in 2007.¹ Between 2000 and 2004 the median age at prostate cancer diagnosis was 68 years and the median age at death caused by prostate cancer was 80 years.² Both prostate cancer incidence and mortality vary with ethnicity. The incidence for all races in the United States is 168 cases diagnosed per 100,000 men. Blacks are at higher than average risk of prostate cancer with an incidence of 256 per 100,000, whereas individuals of Asian and Native American descent are at lower risk with 97 cases per 100,000 and 62 per 100,000, respectively. Whites and Hispanics are at intermediate risk with 161 and 142 cases per 100,000 men, respectively. The number of deaths caused by prostate cancer for all races in the United States is 28 deaths per 100,000 men. Blacks are at the highest risk of prostate cancer death, with a cancer death rate of 62 per 100,000 men, as compared to individuals of Native American descent (22 per 100,000), whites (26 per 100,000), Hispanics (21 per 100,000), and individuals of Asian descent (11 per 100,000 men). Although prostate cancer incidence increased during the late 1980s and early 1990s because of widespread prostate-specific antigen (PSA) screening, deaths from prostate cancer have been continuously declining since 1995.¹

ETIOLOGY

Table 134–1 summarizes the possible factors associated with prostate cancer.^{3,4} The only widely accepted risk factors for prostate cancer are age, race-ethnicity, and family history of prostate cancer.^{3,4} The disease is rare in persons younger than 40 years, but the incidence sharply increases with each subsequent decade, most likely because the individual has had a lifetime exposure to testosterone, a known growth signal for the prostate.⁴

RACE AND ETHNICITY

The incidence of prostate cancer varies across geographic regions. Scandinavian countries and the United States report the highest incidence of prostate cancer, whereas the disease is relatively rare in Japan and other Asian countries.⁵ African American men have the

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

TABLE 134-1 Risk Factors Associated with Prostate Cancer

Factor	Possible relationship
Probable risk factors	
Age	More than 70% of cases are diagnosed in men older than 65 years
Race	African Americans have higher incidence and death rate
Genetic	Familial prostate cancer inherited in an autosomal dominant manner Polymorphisms in the CAG repeat in the androgen receptor (AR) gene, CYP17, SRDA2, MSR1, a deletion of the GSTT1 gene
Possible risk factors	
Environmental	Clinical carcinoma incidence varies worldwide Latent carcinoma similar between regions. Nationalized males adopt intermediate incidence rates between that of the United States and their native country
Occupational	Increased risk associated with cadmium exposure
Diet	Increased risk associated with high-meat and high-fat diets Decreased intake of 1,25-dihydroxyvitamin D, vitamin E, lycopene, and β -carotene increases risk
Hormonal	Does not occur in eunuchs Low incidence in cirrhotic patients. Up to 80% are hormonally dependent. African Americans have 15% increased testosterone Japanese have decreased 5 α -reductase activities Polymorphic expression of the androgen receptor

Compiled from references 2, 4, 5, 6.

highest rate of prostate cancer in the world, and prostate cancer mortality in African Americans is more than twice that seen in white populations in the United States.² Hormonal, dietary, and genetic differences, and differences in access to healthcare may contribute to the altered susceptibility to prostate cancer in these populations.^{3,4} Testosterone, commonly implicated in the pathogenesis of prostate cancer, is 15% higher in African American men as compared with white males. Activity of 5 α -reductase, the enzyme that converts testosterone to its more active form, dihydrotestosterone (DHT), in the prostate, is decreased in Japanese men as compared with African Americans and whites.^{3,4} In addition, genetic variations in the androgen receptor exist. Activation of the androgen receptor is inversely correlated with CAG repeat length. Shorter CAG repeat sequences have been found in African Americans. Therefore the combination of increased testosterone and increased androgen receptor activation may account for the increased risk of prostate cancer for African American men.^{3,4} The Asian diet generally is considered to be low in fat and high in fiber with a high concentration of phytoestrogens, potentially explaining their decreased risk.^{5,6}

FAMILY HISTORY

A familial clustering of prostate cancer is observed and a recent comprehensive linkage analysis of 54 pedigrees identified a region at chromosome 22q12.3 comprised of 11 possible genes likely to be associated with hereditary prostate cancer.⁷

An alternative explanation for the familial clustering may be polymorphisms in genes important for prostate cancer function and development.⁶ Candidate polymorphisms include a polymorphism in the androgen receptor, which has two different nucleotide repeat variants, the CAG and the GCC. The CAG repeat varies in repeat number from 11 to 31 repeats in healthy individuals, and the number of repeats is inversely proportional to the activity of the androgen receptor. Some studies show that shorter CAG repeats are associated with increased prostate cancer risk. Another candidate polymorphism is SRD5A2, which is the gene that codes for 5 α -reductase, the enzyme that converts testosterone to the more active

DHT. A variant in SRD5A2, the Ala49Thr, increases the activity and may increase prostate cancer risk.⁶

A large study performed in the CAPS (Cancer Prostate in Sweden) population, including more than 1,200 subjects with prostate cancer, evaluated a number of polymorphisms previously reported to be associated with prostate cancer risk. Six polymorphisms located in five different genes were significantly associated with risk of prostate cancer, three polymorphisms were in the androgen biosynthesis and response pathway including the CAG repeat in the androgen receptor (AR) gene ($p = 0.03$), one SNP in the CYP17 gene ($p = 0.04$), two SNPs in the SRD5A2 gene ($p = 0.02$ and 0.02 , respectively), a deletion of the GSTT1 gene ($p = 0.006$), and one SNP in the MSR1 gene, IVS5–59C > A ($p = 0.009$).⁸

DIET

A number of epidemiologic studies support an association between high fat intake and risk of prostate cancer. A strong correlation between national per capita fat consumption and prostate cancer mortality has been reported, and prospective case-control studies suggest that a high-fat diet is associated with a two-fold higher risk of prostate cancer.⁹

Other dietary factors implicated in prostate cancer include retinol, carotenoids, lycopene, and vitamin D consumption.⁶ Retinol, or vitamin A, intake, especially in men older than age 70 years, is associated with an increased risk of prostate cancer, whereas intake of its precursor, β -carotene, has a protective or neutral effect. Lycopene, obtained primarily from tomatoes, decreases the risk of prostate cancer in small cohort studies. The antioxidant vitamin E also may decrease the risk of prostate cancer. Men who developed prostate cancer in one cohort study had lower levels of 1,25(OH)₂-vitamin D than did matched controls, although a prospective study did not confirm this finding. Dietary intervention may be promising in prostate cancer prevention.

OTHER FACTORS

Benign prostatic hyperplasia (BPH) is a common problem of elderly men, affecting more than 40% of men older than age 70 years. BPH results in the urinary symptoms of hesitancy and frequency. Since prostate cancer affects a similar age group and often has similar presenting symptoms, the presence of BPH often complicates the diagnosis of prostate cancer, although it does not appear to increase the risk of developing prostate cancer.^{3,10}

Smoking has not been associated with an increased risk of prostate cancer, but smokers with prostate cancer have an increased mortality resulting from the disease when compared with nonsmokers with prostate cancer (relative risk 1.5 to 2), suggesting that although smokers are not more likely to develop prostate cancer, they are at increased risk of death as a consequence of other smoking-related illnesses.³ In a prospective cohort study, alcohol consumption was not associated with the development of prostate cancer.

CHEMOPREVENTION

Currently, the most promising agent for the prevention of prostate cancer is finasteride, a 5 α -reductase inhibitor used for benign prostatic hypertrophy.¹⁰ When compared to placebo, the point prevalence of prostate cancer was reduced for those on finasteride by 25% (95% confidence interval [CI] 18.6 to 30.6%, hazard ratio = 0.75). However, patients in the finasteride group who developed prostate cancer had more high-grade (Gleason grade 7 to 10) tumors than those in the placebo group. Overall, finasteride did reduce the risk of prostate cancer, but the prostate cancers that were diagnosed in the finasteride group were more aggressive. Conse-

quently, the use of finasteride to prevent prostate cancer is controversial.¹¹ Because of its established role in the treatment of BPH, the 20% to 30% of men older than age 50 years with BPH may derive the additional benefit of prostate cancer prevention and should be offered treatment with finasteride. In the 70% to 80% of men without BPH, the benefits, side effects (primarily impotence), and risks of finasteride should be discussed prior to initiating therapy.

Other agents, including selenium, a naturally occurring trace element that is essential in the human diet, vitamin E, vitamin D, lycopene, green tea, nonsteroidal antiinflammatory agents, isoflavones, and statins are being investigated for prevention of prostate cancer. Although the results of these studies are promising, none are currently recommended for routine use outside of a clinical trial.¹²

SCREENING

Early detection of potentially curable prostate cancers is the goal of prostate cancer screening. For cancer screening to be beneficial, it must reliably detect cancer at an early stage, when intervention would decrease mortality. Whether prostate cancer screening fits these criteria has generated considerable controversy.¹³

The common approach to prostate cancer screening, as recommended by the American Cancer Society, is to offer a baseline PSA and digital rectal examination (DRE) beginning at age 50 years to all men of normal risk with a 10-year or greater life expectancy.¹⁴ Men at high risk (African American men and men with a strong family of one or more first-degree relatives), should begin testing at age 45 years. Men at even higher risk, secondary to multiple first-degree relatives affected at an early age, could begin testing at age 40 years. Routine screening of all men is not recommended. Providers should describe the potential benefits and known risks of screening, diagnosis, and treatment, listen to the patient's concerns, and then decide with the patient on an individual's screening method.

The recommendation to *consider*, rather than *perform*, prostate cancer screening is based on the still unproven benefits of prostate cancer screening. A recent Cochrane review identified only two completed randomized clinical trials comparing prostate cancer screening to no intervention.¹⁵ A meta-analysis of the data from these studies indicated that men randomized to screening had prostate cancer detected more often, but did not have a reduction in prostate cancer specific mortality (relative risk 1.01, 95% CI 0.80 to 1.29). Neither study assessed the effect of prostate cancer screening on quality of life, all-cause mortality, or cost-effectiveness. Because PSA measurements can identify small, subclinical prostate cancers, where no intervention may be required, detecting prostate cancer in those not needing therapy not only increases the cost of care through unnecessary screening and workups, but also increases the toxicity of therapy, by subjecting some patients to unnecessary therapy.¹⁶ The ongoing Prostate, Lung, Colon, and Ovarian (PLCO) screening trial is designed to determine if prostate cancer screening is effective in reducing prostate cancer mortality and the results of that trial will help resolve this controversy.¹⁷

The DRE has been recommended since the early 1900s for the detection of prostate cancer. The primary advantage of DRE is its specificity, reported at greater than 85%, for prostate cancer. Other advantages of DRE include low cost, safety, and ease of performance. However, DRE is relatively insensitive and is subject to interobserver variability. DRE as a single screening method has poor compliance and had little effect on preventing metastatic prostate cancer in one large case-control study.¹⁸

② PSA is a glycoprotein produced and secreted by the epithelial cells of the prostate gland. The physiologic function of PSA is to liquefy ejaculate and it is primarily confined to the seminal plasma, although it is also measurable in the plasma.¹⁹ PSA exists as a complex with the proteases α_1 -antichymotrypsin, α_1 -antitrypsin

and α_2 -macroglobulin. Several different assays, measuring free (i.e., unbound) PSA and complexed PSA (PSA bound to α_1 -antichymotrypsin) are available.

Total PSA measurements are used widely for prostate cancer screening in the United States.¹⁹ The normal range for total PSA is ≤ 4 ng/mL and this cut-off is primarily based on a prospective study by Gann et al., which demonstrated that a single PSA level >4 ng/mL had a sensitivity of 73%, with a specificity of 91% in detecting prostate cancer within 4 years.²⁰ The complexed PSA test may also be used for PSA testing (upper level of normal range is 3.4 ng/mL).²¹

PSA may be decreased by approximately 50% after 6 to 12 months of treatment with finasteride, dutasteride and androgen receptor blockers.²² When assessing a PSA value in men on these medications, the clinician should double the actual value. Because both ejaculation and DRE can influence PSA levels, the PSA level should be drawn prior to the DRE and patients should be advised to abstain from ejaculation for 48 hours prior to PSA measurement. Additionally, PSA is influenced by acute urinary retention, acute prostatitis, and prostatic ischemia or infarction, as well as BPH, a nearly universal condition in men who are at risk for prostate cancer. PSA elevations between 4 and 10 ng/mL cannot distinguish between BPH and prostate cancer, which limits the usefulness of PSA alone for the early detection of prostate cancer. The free PSA test is used in men with a total PSA ranging between 4 and 10 ng/mL; those with a free PSA percentage of $<15\%$ are more likely to have prostate cancer and should have a biopsy, whereas those in this range with a free PSA $>25\%$ are most likely have BPH and may not require a biopsy. Individuals with a free PSA between 15% and 25% may have a biopsy or be watched further, depending on other clinical characteristics, such as age.²³

PSA velocity, or the rate of change in PSA levels over time, may be another predictor of prostate cancer risk.²⁴ In a recent report, men with an initial PSA of <4 ng/mL but with a PSA velocity >0.35 ng/mL per year had a higher relative risk of prostate cancer death as compared to men with a PSA velocity of ≤ 0.35 ng/mL per year (relative risk 4.7, 95% CI 1.3 to 16.5; $p = 0.02$).²⁵ Based on these results, some experts recommend further workup for individuals with a PSA less than 4 ng/mL, if their PSA velocity is >0.35 ng/mL per year.

PATHOPHYSIOLOGY

The prostate gland is a solid, rounded, heart-shaped organ positioned between the neck of the bladder and the urogenital diaphragm (Fig. 134-1). Normal growth and differentiation of the prostate depends on the presence of androgens, specifically DHT.^{26,27} The testes and the adrenal glands are the major sources of circulating androgens. Hormonal regulation of androgen synthesis is mediated through a series of biochemical interactions between the hypothalamus, pituitary, adrenal glands, and testes (Fig. 134-2). Luteinizing hormone-releasing hormone (LHRH) released from the hypothalamus stimulates the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the anterior pituitary gland. LH complexes with receptors on the Leydig cell testicular membrane and stimulates the production of testosterone and small amounts of estrogen. FSH acts on the Sertoli cells within the testes to promote the maturation of LH receptors and to produce an androgen-binding protein. Circulating testosterone and estradiol influence the synthesis of LHRH, LH, and FSH by a negative feedback loop operating at the hypothalamic and pituitary level.²⁷⁻²⁹ Prolactin, growth hormone, and estradiol appear to be important accessory regulators for prostatic tissue permeability, receptor binding, and testosterone synthesis.

Testosterone, the major androgenic hormone, accounts for 95% of the androgen concentration. Although the primary source of testosterone is the testes, 3% to 5% of the testosterone concentra-

FIGURE 134-1. The prostate gland.

tion is derived from direct adrenal cortical secretion of testosterone or C19 steroids such as androstenedione.^{26,27,30}

Hormonal manipulations to ablate or reduce circulating androgens can occur through several mechanisms (Table 134–2).^{26,27} The organs responsible for androgen production can be removed surgically (orchiectomy, hypophysectomy, or adrenalectomy). Hormonal pathways that modulate prostatic growth can be interrupted at several steps (see Fig. 134–2). Interference with LHRH or LH can reduce testosterone secretion by the testes (estrogens, LHRH agonists, progestogens, and cyproterone acetate). Estrogen administration reduces androgens by directly inhibiting LH release, by acting directly on the prostate cell, or by decreasing free androgens by increasing steroid-binding globulin levels.^{26,27,30}

Isolation of the naturally occurring hypothalamic decapeptide hormone LHRH has provided another group of effective agents for advanced prostate cancer treatment.²⁸ The physiologic response to

LH, luteinizing hormone; LHRH, luteinizing hormone-releasing hormone.
^aMinor mechanisms of action.
^bInvestigational compounds or uses.

LHRH depends on both the dose and the mode of administration. Intermittent pulsed LHRH administration, which mimics the endogenous release pattern, causes sustained release of both LH and FSH, whereas high-dose or continuous intravenous administration of LHRH inhibits gonadotropin release caused by receptor downregulation.²⁷ Structural modification of the naturally occurring LHRH and innovative delivery have produced a series of LHRH agonists that cause a similar downregulation of pituitary receptors and a decrease in testosterone production.²⁹

Androgen synthesis can be inhibited in the testes or in the adrenal gland. Aminoglutethimide inhibits the desmolase-enzyme complex in the adrenal gland, thereby preventing the conversion of cholesterol to pregnenolone. Pregnenolone is the precursor substrate for all adrenal-derived steroids, including androgens, glucocorticoids, and mineralocorticoids.²⁹ Ketoconazole, an imidazole antifungal agent, causes a dose-related reversible reduction in serum cortisol and testosterone concentration by inhibiting both adrenal and testicular steroidogenesis.^{29,30} As a secondary mechanism to its antiandrogen action, megesterol acetate inhibits the synthesis of androgens. This inhibition appears to occur at the adrenal level, but circulating levels of testosterone also are reduced, which suggests that inhibition at the testicular level also may occur.^{29,30}

Antiandrogens inhibit the formation of the DHT-receptor complex and thereby interfere with androgen-mediated action at the cellular level.³⁰ Megesterol acetate, a progestational agent, also is available and has antiandrogen actions.³⁰ Finally, the conversion of testosterone to DHT may be inhibited by 5 α -reductase inhibitors.¹⁰

PATHOLOGY

The normal prostate is composed of acinar secretory cells arranged in a radial shape and surrounded by a foundation of supporting tissue. The size, shape, or presence of acini is almost always altered in the gland that has been invaded by prostatic carcinoma. Adenocarcinoma, the major pathologic cell type, accounts for more than 95% of prostate cancer cases.^{22,31} Rare tumor types include small cell neuroendocrine cancers, sarcomas, and transitional cell carcinomas.

Prostate cancer can be graded systematically according to the histologic appearance of the malignant cell and then grouped into well, moderately, or poorly differentiated grades.^{31,32} Gland architecture is examined and then rated on a scale of 1 (well differentiated) to 5 (poorly differentiated). Two different specimens are examined, and the score for each specimen is added. Groupings for total Gleason score are 2 to 4 for well-differentiated, 5 or 6 for moderately differentiated, and 7 to 10 for poorly differentiated tumors. Poorly differentiated tumors grow rapidly (poor prognosis), whereas well-differentiated tumors grow slowly (better prognosis).

Metastatic spread can occur by local extension, lymphatic drainage, or hematogenous dissemination.^{26,32} Lymph node metastases are more common in patients with large, undifferentiated tumors that invade the seminal vesicles. The pelvic and abdominal lymph node groups are the most common sites of lymph node involvement (see Fig. 134–1). Skeletal metastases from hematogenous spread are the most common sites of distant spread. The bone lesions are usually osteoblastic or a combination of osteoblastic and osteolytic. The most common site of bone involvement is the lumbar spine. Other sites of bone involvement include the proximal femurs, pelvis, thoracic spine, ribs, sternum, skull, and humerus. The lung, liver, brain, and adrenal glands are the most common sites of visceral involvement, although these organs are usually not involved initially. Approximately 25% to 35% of patients will have evidence of lymphangitic or nodular pulmonary infiltrates at autopsy. The prostate is a rare site for metastatic involvement from other solid tumors.

CLINICAL PRESENTATION

Localized Disease

- Asymptomatic

Locally Invasive Disease

- Ureteral dysfunction, frequency, hesitancy, and dribbling
- Impotence

Advanced Disease

- Back pain
- Cord compression
- Lower-extremity edema
- Pathologic fractures
- Anemia
- Weight loss

The information obtained from the diagnostic tests is used to stage the patient. There are two commonly recognized staging classification systems (Table 134–3). The formal international classification system (tumor, node, metastases [TNM]), adopted by the International Union Against Cancer in 1974, was updated in 1992 in an effort to provide congruence with the classical American Urologic System staging system for prostate cancer.³³ The American Urologic System classification is the most commonly used staging system in the United States (Table 134–3). Patients are assigned to stages A through D and corresponding subcategories based on size of the tumor (T), local or regional extension, presence of involved lymph node groups (N), and presence of metastases (M).³³ Based on men diagnosed with prostate cancer at Walter Reed Army Medical Center from 1988 to 1998, which included more than 2,042 prostate cancer diagnoses, localized prostate cancer (stage T₁ and T₂) was diagnosed more frequently (89% vs. 68%), and advanced disease (stages T₃, T₄, and D) was diagnosed less frequently (11% vs. 32%) when comparing the 1998 to the 1988 incidence rates.

3 The most important prognostic factor appears to be the histologic grade, because the degree of differentiation ultimately determines the stage of disease. Poorly differentiated tumors are highly associated with both regional lymph node involvement and distant metastases.³¹

During 1992 to 1999, 5-year overall survival rates were estimated at 98% for whites and 93% for African Americans.¹ During this same period, the survival rates for localized or regional disease (100%), and distant disease (33%) in white males were about the same as the survival rates for localized or regional disease (100%), and distant disease (26%) in African American males.¹ A 6.3% decline in age-adjusted mortality was documented for the period 1991 to 1995.³⁴ Ten-year cancer-specific survival is approximately 95% for stage A₁,

TABLE 134-3 Staging and Classification Systems for Prostate Cancer

AUS ^a Stage (A–D)	AJC-UICC ^b Classification (TNM)
A (Occult, nonpalpable)	T _x N _x M _x (Cannot be assessed)
A ₁ : Focal	T ₀ N ₀ M ₀ (Nonpalpable)
A ₂ : Diffuse	T ₀ : Focal or diffuse
B (Confined to prostate)	T ₁ N ₀ M ₀ , T ₂ N ₀ M ₀
B ₁ : Single nodule in one lobe, less than 1.5 cm	T ₁ (Clinically inapparent tumor not palpable or visible by imaging)
	T _{1a} : Tumor incidental histologic finding in 5% or less of tissue resected
	T _{1b} : Tumor incidental histologic finding in 5% or more of tissue resected
	T _{1c} : Tumor identified by needle biopsy (e.g., because of elevated prostate-specific antigen)
B ₂ : Diffuse involvement of whole gland, greater than 1.5 cm	T ₂ : (Tumor confined within the prostate ^c)
	T _{2a} : Tumor involves half of a lobe or less
	T _{2b} : Tumor involves more than half a lobe, but not both lobes
	T _{2c} : Tumor involves both lobes
C (Localized to periprostatic area)	T ₃ N ₀ M ₀ , T ₄ N ₀ M ₀
C ₁ : No seminal vesicle involvement, less than 70 g	T ₃ : (Tumor extends through the prostatic capsule ^d)
	T _{3a} : Unilateral extracapsular extension
	T _{3b} : Bilateral extracapsular extension
	T _{3c} : Tumor invades the seminal vesicle(s)
C ₂ : Seminal vesicle involvement, greater than 70 g	T ₄ : (Tumor is fixed or invades adjacent structures other than the seminal vesicles)
	T _{4a} : Tumor invades any of bladder neck, external sphincter, or rectum
	T _{4b} : Tumor invades levator muscles and/or is fixed to the pelvic wall
D (Metastatic disease)	Any T, N _{1–4} , M ₀ , or N _{0–4} , M ₁
D ₁ : Pelvic lymph nodes or ureteral obstruction	N ₁ : Metastasis in a single lymph node, 2 cm or less in greatest dimension
D ₂ : Bone, distant lymph node, organ, or soft tissue metastases	N ₂ : Metastasis in single lymph node more than 2 cm but not more than 5 cm in greatest dimension; or multiple lymph node metastases, none more than 5 cm in greatest dimension
	N ₃ : Metastasis in lymph node more than 5 cm in greatest dimension
	M _{1a} : Nonregional lymph node(s)
	M _{1b} : Bone(s)
	M _{1c} : Other site(s)

^aAmerican Urologic System.

^bAmerican Joint Committee–International Union Against Cancer.

^cTumor found in one or both lobes by needle biopsy, but not palpable or visible by imaging, is classified as T_{1c}.

^dInvasion into the prostatic apex or into (but not beyond) the prostatic capsule is not classified as T₃ but as T₂.

80% for stages A₂ to B₂, 60% for stage C, 40% for stage D₁, and 10% for stage D₂.³⁵ More than 85% of patients with stage A₁ can be cured, whereas fewer than 1% of patients with stage D₂ will be cured.

TREATMENT

Prostate Cancer

■ DESIRED OUTCOME

The desired outcome in early stage prostate cancer is to minimize morbidity and mortality caused by prostate cancer while minimizing toxicity associated with prostate cancer treatments.³⁶ Unfortunately, the most appropriate therapy of early stage prostate cancer is unknown. Early stage disease may be treated with surgery, radiation,

or watchful waiting. Although surgery and radiation are potentially curative, they are associated with significant morbidity and mortality. Because the overall goal is to minimize morbidity and mortality associated with the disease, watchful waiting is appropriate in selected individuals. Advanced prostate cancer (stage D) is not currently curable, and treatment should focus on providing symptom relief and maintaining quality of life.³⁷

■ NONPHARMACOLOGIC THERAPY

Expectant Management

Expectant management, also known as observation or watchful waiting, involves monitoring the course of disease and initiating treatment if the cancer progresses or the patient becomes symptomatic. A PSA and DRE are performed every 6 months, with a repeat biopsy at any sign of disease progression. The advantages of expectant management are avoiding the adverse effects associated with definitive therapies such as radiation and radical prostatectomy, and minimizing the risk of unnecessary therapies. The major disadvantage of expectant management is the risk that the cancer progresses and requires a more intensive therapy.³⁶

Orchiectomy

Bilateral orchiectomy, or removal of the testes, rapidly reduces circulating androgens to castrate levels (<50 ng/dL).²² However, many patients are not surgical candidates because of their advanced age, and other patients find this procedure psychologically unacceptable.²² Orchiectomy is the preferred initial treatment in patients with impending spinal cord compression or ureteral obstruction.

Radiation

The two commonly used methods for radiation therapy are external beam radiotherapy and brachytherapy.³⁶ In external beam radiotherapy, either 3D conformal radiation or intensity-modulated radiotherapy should be used to deliver doses of 70 to 75 Gy in 35 to 41 fractions in patients with low-grade prostate cancer and 75 to 80 Gy for those with intermediate- or high-grade prostate cancer. Brachytherapy involves the permanent implantation of radioactive beads of 145 Gy ¹²⁵Iodine or 124 Gy of ¹⁰³Palladium and is generally reserved for individuals with low-risk cancers.

Radical Prostatectomy

Complications from radical prostatectomy include blood loss, stricture formation, incontinence, lymphocele, fistula formation, anesthetic risk, and impotence. Nerve-sparing radical prostatectomy can be performed in many patients; 50% to 80% regain sexual potency within the first year. Acute complications from radiation therapy include cystitis, proctitis, hematuria, urinary retention, penoscrotal edema, and impotence (30% incidence).²² Chronic complications include proctitis, diarrhea, cystitis, enteritis, impotence, urethral stricture, and incontinence.²² Because radiation and prostatectomy have significant and immediate mortality when compared with observation alone, many patients may elect to postpone therapy until symptoms develop.

■ PHARMACOLOGIC THERAPY

Drug Treatments of First Choice

Luteinizing Hormone-Releasing Hormone Agonists LHRH agonists are a reversible method of androgen ablation and are as effective as orchiectomy in treating prostate cancer.⁴⁰ Currently available LHRH agonists include leuprolide, leuprolide depot, leuprolide implant, triptorelin depot, triptorelin implant, and goserelin

acetate implant.²⁷ Leuprolide acetate is administered once daily, whereas leuprolide depot and goserelin acetate implant can be administered either once monthly, once every 12 weeks, or once every 16 weeks (leuprolide depot, every 4 months). The leuprolide depot formulation contains leuprolide acetate in coated pellets. The dose is administered intramuscularly, and the coating dissolves at different rates to allow sustained leuprolide levels throughout the dosing interval. Goserelin acetate implant contains goserelin acetate dispersed in a plastic matrix of D,L-lactic and glycolic acid copolymer and is administered subcutaneously. Hydrolysis of the copolymer material provides continuous release of goserelin over the dosing period. A recently approved leuprolide implant is a miniosmotic pump that delivers 120 mcg of leuprolide daily for 12 months. After 12 months the implant is removed, and a different implant can be placed. Triptorelin LA is administered as an intramuscular injection of 11.25 mg every 84 days. Triptorelin depot is administered as an intramuscular injection of 3.75 mg once every month.

Several randomized trials have demonstrated that leuprolide, goserelin and triptorelin are effective agents when used alone in patients with advanced prostate cancer.²⁷ Response rates of around 80% have been reported, with a lower incidence of adverse effects compared with estrogens.²⁷ No head-to-head trials have directly compared the currently available LHRH agonists or the dosage formulations, but a meta-analysis reported no difference in efficacy or toxicity between leuprolide and goserelin.⁴¹ Triptorelin is a more recent addition, but is generally considered equally effective.⁴² Consequently, the choice between the three agents is usually made based on cost and patient and physician preference for a dosing schedule.

The most common adverse effects reported with LHRH agonist therapy include a disease flareup during the first week of therapy, hot flashes, erectile impotence, decreased libido, and injection-site reactions.²⁷ The disease flareup is thought to be caused by initial induction of LH and FSH by the LHRH agonist, and manifests clinically as either increased bone pain or increased urinary symptoms.²⁷ This flare reaction usually resolves after 2 weeks and has a similar onset and duration pattern for the depot LHRH products.^{43,44}

LHRH agonist monotherapy can be used as initial therapy, with similar response rates to orchiectomy and estrogen administration expected.⁴⁴ LHRH therapy is associated with a lower incidence of cardiovascular-related adverse effects as compared with estrogen administration. Patients should be counseled to expect worsening symptoms during the first week of therapy, and caution should be exercised when initiating LHRH agonist therapy in patients with widely metastatic disease involving the spinal cord or having the potential for ureteral obstruction because irreversible complications may occur.

Antiandrogens Three antiandrogens—bicalutamide,^{45,46} nilutamide,⁴⁷ and flutamide⁴⁸—are currently available (Table 134-4). Antiandrogens have been used as monotherapy in previously untreated patients, but a recent meta-analysis determined that patients who received monotherapy with antiandrogens have a shorter survival than patients treated with LHRH agonist therapy (hazard ratio 1.13, 95% CI 0.915 to 1.386) or orchiectomy.⁴⁴ Therefore, for advanced prostate cancer, until androgen monotherapy demonstrates at least equivalent survival outcome to LHRH therapy, antiandrogens are indicated only in combination with androgen-ablation therapy; flutamide and bicalutamide are indicated in combination with an LHRH agonist, and nilutamide is indicated in combination with orchiectomy.²⁹

Table 134-4 lists the most common antiandrogen-related adverse effects. In the only randomized comparison of bicalutamide plus an LHRH agonist versus flutamide plus an LHRH agonist, diarrhea was more common in flutamide-treated patients. Antiandrogens can reduce the symptoms from the flare phenomenon associated with LHRH agonist therapy.

TABLE 134-4 Antiandrogens

Antiandrogen	Usual Dose	Adverse Effects
Flutamide	750 mg/day	Gynecomastia Hot flushes Gastrointestinal disturbances (diarrhea) Liver function test abnormalities Breast tenderness Methemoglobinemia
Bicalutamide	50 mg/day	Gynecomastia Hot flushes Gastrointestinal disturbances (diarrhea) Liver function test abnormalities Breast tenderness
Nilutamide	300 mg/day for first month then 150 mg/day	Gynecomastia Hot flushes Gastrointestinal disturbances (nausea or constipation) Liver function test abnormalities Breast tenderness Visual disturbances (impaired dark adaptation) Alcohol intolerance Interstitial pneumonitis

Combined Hormonal Blockade Although up to 80% of patients with advanced prostate cancer will respond to initial hormonal manipulation, nearly all patients will progress within 2 to 4 years after initiating therapy.²² Two mechanisms have been proposed to explain this tumor resistance. The tumor could be heterogeneously composed of cells that are hormone dependent and hormone independent, or the tumor could be stimulated by extratesticular androgens that are converted intracellularly to DHT. The rationale for combination hormonal therapy is to interfere with multiple hormonal pathways to completely eliminate androgen action. In clinical trials, combination hormonal therapy, sometimes also referred to as *maximal androgen deprivation* or total androgen blockade, has been used. The combination of LHRH agonists or orchiectomy with antiandrogens is the most extensively studied combined androgen-deprivation approach.

Many studies have compared combined androgen blockade (CAB) with conventional medical or surgical castration.^{48–50} In studies with LHRH agonists, the results have varied, with no consistent benefit demonstrated for CAB. A recently completed NCI intergroup trial involving 1,387 evaluable stage D₂ prostate cancer patients failed to show any significant survival benefits for the combination of orchiectomy plus flutamide over orchiectomy alone.⁵¹ Like other studies of CAB, overall survival was longest in patients with minimal disease. Diarrhea, elevated liver function tests, and anemia were more common in those patients who received flutamide.

The most recent meta-analysis of 27 randomized trials in 8,275 patients (4,803 treated with flutamide, 1,683 treated with nilutamide, and 1,784 treated with cyproterone) comparing maximal androgen blockade with conventional medical or surgical castration showed a small survival benefit at 5 years for those treated with flutamide or nilutamide (27.6%) compared to those with castration alone (24.7%; $p = 0.0005$).⁵⁰

In one of the few combination androgen-deprivation studies comparing two different antiandrogens (bicalutamide vs. flutamide), the time-to-treatment-failure (the main study end point), time-to-progression (as defined by appearance of new or worsening bone or extraskelatal lesions), and time-to-death were equivalent, suggesting that the two treatments are equally effective.⁵²

Although some experts now consider CAB to be the initial hormonal therapy of choice for newly diagnosed patients, the clinician is left to weigh the costs of combined therapy against potential benefits in light of conflicting results in the randomized trials²⁹ and the

modest benefit seen in the meta-analysis.⁵⁰ For those trials that did show an advantage for CAB, whether these effects are specific to the testosterone-deprivation method (orchiectomy vs. leuprolide vs. goserelin), the antiandrogen, the duration of therapy, or patient selection is not clear. Until further carefully designed studies that use survival, time-to-progression, quality of life, patient preference, and cost as end points are conducted, it is appropriate to use either LHRH agonist monotherapy or CAB as initial therapy for metastatic prostate cancer. CAB may be most beneficial for improving survival in patients with minimal disease and for preventing tumor flare, particularly in those with advanced metastatic disease. All other patients may be started on LHRH monotherapy, and an antiandrogen may be added after several months if androgen ablation is incomplete.

CLINICAL CONTROVERSY

The use of combined androgen blockade is controversial. Meta-analysis shows a small survival advantage when comparing CAB to orchiectomy or LHRH agonist alone. However, this modest benefit is achieved at significant financial cost and with additional toxicities.

There is still considerable debate concerning when to start hormonal-deprivation therapy in patients with advanced prostate cancer.³⁶ The original recommendation to start therapy when symptoms appeared was based on the Veterans Administration Cooperative Urologic Research Group (VACURG) trials, in which no overall survival difference was demonstrated in patients who either started diethylstilbestrol initially or crossed over to active treatment when symptoms appeared.⁵² Because LHRH agonists and antiandrogens are considered suitable alternatives with less cardiovascular toxicity, it is no longer clear whether delaying therapy is justified. Reanalysis of the original VACURG data⁵³ and recent combined androgen-deprivation trials^{54,55} demonstrate a survival advantage for young, good-performance-status, minimal-disease patients treated initially with hormonal therapy, which supports early intervention before symptoms appear.⁵³ The issue of when best to start hormonal therapy is the subject of several ongoing clinical trials.⁵³

CLINICAL CONTROVERSY

Older data with diethylstilbestrol showed that initiation of hormonal therapy at symptom onset yielded equivalent survival to starting hormonal therapy at initial diagnosis. With equivalent survival, decreased costs, and decreased toxicity from diethylstilbestrol, the standard of practice was to delay initiation of hormonal therapy until symptoms developed. The favorable toxicity profile of LHRH agonists led to the re-evaluation of the starting time for therapy; current research shows that younger men with a good performance status may benefit from initiation of hormonal therapy at diagnosis, rather than waiting for symptoms to develop.

Alternative Drug Treatments

The selection of secondary or salvage therapies for patients who progress after their initial therapy depends on what was used for initial management.³⁶ For patients initially diagnosed with localized prostate cancer, radiotherapy can be used in the case of failed radical prostatectomy. Alternatively, androgen ablation can be used in patients who progress after either radiation therapy or radical prostatectomy.

Secondary Hormonal Manipulations Secondary hormonal manipulations, such as the addition of an antiandrogen to a patient

who incompletely suppresses testosterone secretion with an LHRH agonist, or withdrawal of antiandrogens in a patient receiving combination therapy, or use of agents that inhibit androgen synthesis, can be attempted in patients initially treated with one hormonal modality. Supportive care, chemotherapy, or local radiotherapy can be used in patients who have failed all forms of androgen-ablation manipulations because these patients are considered to have androgen-independent disease.

For patients who initially received an LHRH agonist alone, castration testosterone levels should be documented. Patients with inadequate testosterone suppression (plasma testosterone remains >20 ng/dL) can be treated by adding an antiandrogen or performing an orchiectomy. If castration testosterone levels have been achieved, the patient is considered to have androgen-independent disease, and palliative androgen-independent salvage therapy can be used.

④ If the patient initially received combined androgen blockade with an LHRH agonist and an antiandrogen, then androgen withdrawal is the first salvage manipulation.³⁶ Objective and subjective responses have been noted following the discontinuation of flutamide,⁵³ bicalutamide,⁵⁴ or nilutamide⁵⁵ in patients receiving these agents as part of combined androgen ablation with an LHRH agonist. Mutations in the androgen receptor allow antiandrogens such as flutamide, bicalutamide, and nilutamide (or their metabolites) to become agonists and activate the androgen receptor.⁵⁶ Patient responses to androgen withdrawal manifest as significant PSA reductions and improved clinical symptoms. Androgen withdrawal responses lasting 3 to 14 months have been noted in up to 35% of patients, and response seems to be most closely related to longer androgen exposure times.⁵² Incomplete cross-resistance has been noted in some patients who received bicalutamide after they had progressed while receiving flutamide.⁴⁵ The addition of an agent that blocks adrenal androgen synthesis, such as aminoglutethimide, at the time that androgens are withdrawn may produce a better response than androgen withdrawal alone.⁵⁶ Because of the potential for response immediately after antiandrogen withdrawal, a sufficient observation and assessment period (usually 4 to 6 weeks) is usually required before a patient can be enrolled on a clinical trial evaluating a new agent or therapy for advanced prostate cancer.

Androgen synthesis inhibitors, such as aminoglutethimide or ketoconazole, can provide symptomatic relief for a short time in approximately 50% of patients with progressive disease despite previous androgen-ablation therapy.²⁹ Adverse effects during aminoglutethimide therapy occur in approximately 50% of patients.²⁹ Central nervous system effects that include lethargy, ataxia, and dizziness are the major adverse reactions. A generalized morbilliform, pruritic rash has been reported in up to 30% of patients treated. The rash is usually self-limiting and resolves within 5 to 8 days with continued therapy. Adverse effects from ketoconazole include gastrointestinal intolerance, transient rises in liver and renal function tests, and hypoadrenalism.

Supportive Care After all hormonal manipulations are exhausted, the patient is considered to have androgen-independent disease. At this point, either chemotherapy or palliative supportive therapy is appropriate.³⁶ Most patients with advanced prostate cancer have metastatic disease to the bone, which results in pain and skeletal events, such as fractures. Palliation can be achieved by pain management, using radioisotopes such as strontium-89⁵⁷ or samarium-153 lexidronam⁵⁸ for bone-related pain, analgesics, corticosteroids, bisphosphonates,⁵⁹ or local radiotherapy.³⁶

Bisphosphonates have been evaluated in patients with prostate cancer since the 1980s.⁶⁰ A recent Cochrane review that included 1,955 patients from 10 clinical trials evaluated pain response as the primary outcome measure with secondary outcomes including analgesic consumption, skeletal events, prostate cancer death, disease progression, radiologic response, PSA response, adverse events, performance status, and quality of life, and comparisons between different routes, doses,

and types of bisphosphonates. A variety of bisphosphonates have been studied, including clodronate (seven studies), zoledronic acid (one study), pamidronate (one study) and etidronate (one study). In all studies, participants received concurrent hormonal therapy, chemotherapy, or radiation therapy. In the meta-analysis, bisphosphonates did not decrease pain or analgesic consumption, improve disease response, prolong survival, or improve quality of life. However, bisphosphonates are effective overall in decreasing skeletal-related events (odds ratio 0.79, 95% CI 0.62 to 1.00; $P = 0.05$), and toxicity, with the exception of nausea, which was greater in patients receiving bisphosphonates, was similar to placebo.⁶⁰

Zoledronic acid is currently indicated for use in prostate cancer patients with bone metastases after failing one hormonal therapy, based on a study demonstrating that patients receiving zoledronic acid had significantly less skeletal morbidity than those on the placebo arm both by the proportions analysis (33% vs. 44%, respectively; $P = 0.021$) and time-to-first-skeletal-related event analysis ($P = 0.011$) in patients with bone metastases.⁶¹ Zoledronic acid should be avoided in individuals with a serum creatinine >3 mg/dL. Although not approved for this indication, pamidronate is also widely used. The usual dose of pamidronate is 90 mg every month and the usual dose of zoledronic acid is 4 mg every 3 to 4 weeks. Both drugs can cause renal failure, and the risk of renal failure depends on the dose and duration of infusion. To minimize the risk of renal failure, zoledronic acid should be administered as a 4-mg dose over 15 minutes. A trial of pamidronate or zoledronic acid can be initiated in prostate cancer patients with bone pain; if no benefit is observed, the drug may be discontinued.⁵⁹

Bisphosphonates such as pamidronate and zoledronic acid may prevent skeletal morbidity, such as pathologic fractures and spinal cord compression, in men with hormone-refractory metastatic prostate cancer with clinically significant bone loss, as measured by serial bone mineral density testing.⁶² To determine if bisphosphonates can slow metastatic disease progression, the PR05 trial evaluated 311 patients with newly diagnosed bony metastatic disease who received standard hormone therapy and were randomly assigned to receive 3 years of sodium clodronate or placebo.⁶³ The clodronate group did not demonstrate decreased analgesic consumption or improved bone progression free survival or overall survival when compared to the control group, but were less likely to have a worsened World Health Organization performance status (hazard ratio 0.71, 95% CI 0.56 to 0.92; $P = 0.008$).

In a similar trial, the PR04 study randomized 508 men who were within 3 years of initial prostate cancer diagnosis with no evidence of metastases to clodronate or placebo to determine if early intervention with bisphosphonates could prevent development of metastases. The clodronate group received no benefit in bone metastases free survival or overall survival as compared to the placebo group with an increased risk of adverse events.⁶⁴

Chemotherapy ⑤ Historically, hormone refractory prostate cancer has been considered resistant to chemotherapy, with response rates of less than 9% for all regimens evaluated.⁶⁵ In 1996, the combination of mitoxantrone with prednisone was reported to induce a palliative response in 29% of patients with symptomatic disease, compared to 12% receiving prednisone alone, while improving quality of life, and was approved by the FDA despite having no impact on overall survival.⁶⁶

More recently, the combination of docetaxel 75 mg/m² every 3 weeks and prednisone 5 mg twice a day has been shown to prolong survival in hormone-refractory metastatic prostate cancer (Table 134–5).⁶⁷ The most common adverse events reported with this regimen are nausea, alopecia, and bone marrow suppression. In addition, fluid retention and peripheral neuropathy, known effects of docetaxel, are observed. The combination of estramustine (280 mg three times a day, days 1 to 5) and docetaxel (60 mg/m² on day

TABLE 134-5 First-Line Chemotherapy Regimens for Metastatic Hormone-Independent Prostate Cancer

Regimen	Usual Dose	Adverse Effects	Dose Adjustments
Docetaxel	75 mg/m ² every 3 weeks	Fluid retention, alopecia, mucositis, myelosuppression, hypersensitivity	Hepatic Do not administer if AST/ALT greater than 1.5 times the upper limit of normal and alkaline phosphatase greater than 2.5 upper limit of normal Hematologic Assure complete blood count recovered
Estramustine	280 mg three times daily on days 1–5	Edema, gynecomastia, leucopenia, increased risk of thromboembolic events	Hematologic Assure complete blood count recovered

ALT, alanine aminotransferase; AST, aspartate aminotransferase.

2, every 3 weeks) also improves survival in hormone-refractory metastatic prostate cancer.⁶⁸ Estramustine causes a decrease in testosterone and a corresponding increase in estrogen, which results in an increase in thromboembolic events, gynecomastia, and decreased libido. Both docetaxel (in combination with prednisone) and estramustine are FDA-approved for the treatment of metastatic prostate cancer.

Estramustine is an oral capsule and should be refrigerated. Calcium inhibits the absorption of estramustine. Although both the docetaxel-prednisone and the docetaxel-estramustine regimens are effective in hormone-refractory prostate cancer, most clinicians, supported by a recent Cochrane review,⁶⁵ prefer the docetaxel-prednisone regimen because of the cardiovascular adverse effects associated with estramustine. In addition, androgen ablation is usually continued when chemotherapy is initiated.³⁶

■ GENERAL APPROACH TO TREATMENT

The initial treatment for prostate cancer depends primarily on the disease stage, the Gleason score, the presence of symptoms, and the life expectancy of the patient.³⁶ Prostate cancer is usually initially diagnosed by PSA and DRE and confirmed by a biopsy, where the Gleason score is assigned. Asymptomatic patients with a low risk of recurrence, those with a T₁ or T_{2a}, Gleason score of 2 through 6, and a PSA <10 ng/mL can be managed by expectant management, radiation, or radical prostatectomy.³⁶ As patients with asymptomatic early stage disease generally have an excellent 10-year survival, immediate morbidities of treatment must be balanced with the likelihood of dying from prostate cancer. In general, more aggressive treatments of early stage prostate cancer are reserved for younger men, although patient preference is a major consideration in all treatment decisions.

Estimation of life expectancy is an important component for both prostate cancer screening and treatment. Life expectancy may be estimated from social security tables (www.ssa.gov/OACT/STATS/table4c6.html), which reports the life expectancy of the population by age. After determining an approximate life expectancy based on age, the clinician can adjust for individual health status by adding 50% for individuals in the top 25% for overall health, decreasing it by 50% for those in the bottom 25% for overall health and making no adjustment for those in the middle quartiles.³⁶ In a patient with an estimated normal life expectancy of <10 years, expectant management or radiation therapy may be offered. In those with an estimated normal life expectancy of ≥10 years, either expectant management, radiation (external beam or brachytherapy), or radical prostatectomy with a pelvic lymph node dissection may be offered. Radical prostatectomy and radiation therapy generally are considered therapeutically equivalent for localized prostate cancer, although neither has been proven to be better than observation alone.^{36–38} Complications from radical prostatectomy include blood loss, stricture formation, incontinence, lymphocele, fistula formation, anesthetic risk, and impotence. Nerve-sparing radical prostatectomy can be performed in many patients—50% to 80% regain sexual potency within the first year. Acute complications from radiation therapy include

cystitis, proctitis, hematuria, urinary retention, penoscrotal edema, and impotence (30% incidence).¹⁶ Chronic complications include proctitis, diarrhea, cystitis, enteritis, impotence, urethral stricture, and incontinence.³¹ Because radiation and prostatectomy have significant and immediate mortality when compared with expectant management alone, many patients may elect to postpone therapy until symptoms develop.

Individuals with T_{2b} or T_{2c} disease, a Gleason score of 7, or a PSA ranging from 10 to 20 ng/mL are considered at intermediate risk for prostate cancer recurrence.³⁶ Individuals with <10-year expected survival may be offered expectant management, radiation therapy, or radical prostatectomy with or without a pelvic lymph node dissection, and those with a ≥10-year life expectancy may be offered either radical prostatectomy with or without a pelvic lymph node dissection or radiation therapy.

Patients who are at high risk of recurrence (T₃ disease, a Gleason score ranging from 8 to 10, or a PSA value >20 ng/mL) should be treated with androgen ablation for 2 to 3 years combined with radiation therapy.²⁶ Select individuals with a low tumor volume may receive a radical prostatectomy with or without a pelvic lymph node dissection.

⑥ Patients with T_{3b} and T₄ disease have a very high risk of recurrence and are not candidates for radical prostatectomy because of extensive local spread of disease.³⁶ Androgen ablation should be instituted at diagnosis rather than waiting for symptomatic disease or progression to occur. In a clinical trial enrolling 500 men with locally advanced prostate cancer who were randomized to either immediate initiation of androgen ablation with either orchiectomy or androgen ablation, or deferred hormonal therapy, individuals with immediate therapy had a median actuarial cause-specific survival duration of 7.5 years for immediate treatment compared to 5.8 years for deferred treatment.³⁹

⑦ Estrogens were once widely used, but the most widely used estrogen, diethylstilbestrol, was withdrawn from the United States market in 1997 because of increased cardiovascular risk. Secondary hormonal manipulations, cytotoxic chemotherapy, or supportive care is used for the patient who progresses after initial therapy.²⁹

PHARMACOECONOMIC CONSIDERATIONS

The main economic concerns for prostate cancer focus on prostate cancer screening for asymptomatic men, initial therapy of clinically localized disease, surgical versus medical castration, and the use of combined hormonal blockade as treatment for advanced disease.

Prostate cancer screening remains highly controversial because the survival benefits and the associated costs are not well defined.⁶⁹ Krahn et al.⁷⁰ determined that annual screening of all eligible men would cost 45 million Canadian dollars, or 0.15% of total healthcare expenditures. Available cost-utility studies estimate that the cost per crude or quality-adjusted life-year gained from prostate cancer screening ranges from \$3,000 to \$729,000.^{69–72} As the cost-effectiveness of prostate cancer screening cannot be determined until the

benefits are documented, it is important to incorporate economic analysis into the large, ongoing, screening studies.

Treatment options for clinically localized prostate cancer include radiation therapy, surgery, or watchful waiting. There is currently no evidence to suggest which therapy is the most clinically effective, and treatment choice is often made by patient or physician preference. However, there are large economic differences in the therapies, with the cost of a radical prostatectomy \$12,000 more expensive than watchful waiting, and radiation therapy \$15,000 more expensive than watchful waiting.⁷³

Surgical castration (by removal of the testes) and medical castration with LHRH agonists yield similar clinical results, although the majority of patients prefer medical castration. In two economic analyses, the primary cost of the surgical castration was hospital length of stay and medical castration drug costs. Both analyses found that in patients surviving 18 to 24 months, a surgical castration was more cost-effective.⁷⁴

Table 134–6 lists the costs for the initial hormonal therapies for stage D₂ prostate cancer. Using a societal perspective and data from the original leuprolide plus flutamide versus leuprolide alone trial to calculate the incremental cost per life-year gained, Hillner et al.⁷¹ concluded that CAB has an incremental cost-effectiveness of \$25,300 per life-year gained, which is within current accepted benchmarks. The cost dropped to \$13,700 per life-year gained in patients with minimal disease.

In a followup study, this same group used physician focus group estimates to generate quality-of-life factors and incorporated these factors into an economic model.⁷³ The incremental cost per quality-adjusted life-year gained seemed reasonable when data from the original CAB were used: \$25,000 for patients with minimal disease and \$18,000 for patients with severe disease. However, these incremental costs increased dramatically to \$53,700 for patients with minimal disease and to \$41,000 for patients with severe disease when the same model was applied to survival data from a meta-analysis.

Because there is considerable debate about the value of using CAB for advanced prostate cancer, continued economic assessments of this therapy are crucial to help policymakers and clinicians decide on the most appropriate therapy. It also is increasingly important to incorporate economic analyses into chemotherapy trials, particularly those that include clinical benefit response as a main end point.

EVALUATION OF THERAPEUTIC OUTCOMES

Monitoring of prostate cancer depends on the stage of the cancer.³⁶ When definitive, curative therapy is attempted, objective parameters to assess tumor response include assessment of the primary tumor size, evaluation of involved lymph nodes, and the response of tumor markers such as PSA to treatment. Following definitive therapy, the PSA level is checked every 6 months for the first 5 years, then annually. Local recurrence in the absence of a rising PSA may occur, so the DRE is also performed. In the metastatic setting, clinical benefit responses can be documented by evaluating performance status changes, weight changes, quality of life, and analgesic requirements, in addition to the PSA or DRE at 3-month intervals.

ABBREVIATIONS

- BPH: benign prostatic hyperplasia
- CAB: combined androgen blockade
- DHT: dihydrotestosterone
- DRE: digital rectal examination

TABLE 134-6 Comparative Costs of Hormonal Therapy for Advanced Prostate Cancer

Drug	Dose	Annual Cost (Based on AWP)
Leuprolide depot	7.5 mg/month	\$709.20/month for annual cost of \$8,510
Leuprolide depot	22.5 mg/12 weeks	\$2,127.59/12 weeks for annual cost of \$8,510
Leuprolide depot	30 mg/16 weeks	\$2,836.79/16 weeks for annual cost of \$8,510
Goserelin implant	3.6 mg every 28 days	\$469.99/month for annual cost of \$5,640
Goserelin implant	10.8 mg/12 weeks	\$1,409.98/12 weeks for annual cost of \$5,640
Triptorelin depot	3.75mg q 28 days	\$582.00/month for annual cost of \$6,984
Triptorelin LA depot	11.25 mg q 84 days	\$1,746.00/84 days for annual cost of \$6,984
Flutamide	750 mg/day	\$376.60/month for annual cost of \$4,519
Bicalutamide	50 mg/day	\$484.44/month for annual cost of \$5,813
Nilutamide	300 mg/day for first month then 150 mg/day	\$728.80 for first month, then \$364.40/month for annual cost of \$4,373.80 for chronic therapy
Combined Androgen Blockade		Cost Per 3 Months of Therapy (Based on AWP)
Leuprolide depot 22.5 mg/12 weeks		
+ flutamide 750 mg/day		\$3,257
+ bicalutamide 50 mg/day		\$3,581
+ nilutamide 150 mg/day		\$3,221
Goserelin depot 10.8 mg/12 weeks		
+ flutamide 750 mg/day		\$2,540
+ bicalutamide 50 mg/day		\$2,863
+ nilutamide 150 mg/day		\$2,503
Triptorelin LA depot 11.25 mg every 84 days		
+ flutamide 750 mg/day		\$2,876
+ bicalutamide 50 mg/day		\$3,199
+ nilutamide 150 mg/day		\$2,839

AWP, average wholesale price; LA, long acting.

VAL R. ADAMS AND GARY C. YEE

KEY CONCEPTS

- 1 Patients with Hodgkin's lymphoma present with a painless, rubbery lymph node, which most commonly resides in the neck (cervical or supraclavicular nodes).
- 2 Patients with early-stage Hodgkin's lymphoma should be treated with combination chemotherapy with or without involved-field radiation and in special circumstances radiation alone.
- 3 Combination chemotherapy with doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine (ABVD) is the primary treatment for patients with advanced-stage Hodgkin's lymphoma. Patients with advanced unfavorable disease may be treated with more aggressive regimens that have greater activity, but are associated with a higher risk of secondary malignancies.
- 4 Some patients with Hodgkin's lymphoma will be refractory to initial therapy or will have a recurrence following a complete remission. Response to salvage therapy depends on the extent and site of recurrence, previous therapy, and duration of initial remission. High-dose chemotherapy and autologous hematopoietic stem cell transplantation should be considered in patients with refractory or relapsed disease.
- 5 The current classification system for non-Hodgkin's lymphoma is the World Health Organization classification system, which is based on the principle that non-Hodgkin's lymphomas can be classified into specific disease entities, defined by a combination of morphology, immunophenotype, genetic features, and clinical features.
- 6 As compared with Hodgkin's lymphoma, the clinical presentation of non-Hodgkin's lymphoma is more variable because of disease heterogeneity and more frequent extranodal involvement.
- 7 The Ann Arbor staging system correlates poorly with prognosis in non-Hodgkin's lymphoma because the disease does not spread through contiguous lymph nodes and often involves extranodal sites.
- 8 Several prognostic models have been developed to estimate prognosis in patients with non-Hodgkin's lymphoma. The International Prognostic Index (IPI) score is a well-established model for patients with aggressive non-Hodgkin's lymphoma. The Follicular Lymphoma International Prognostic Index (FLIPI) is a similar model used for patients with follicular and other indolent lymphomas.
- 9 The clinical behavior and degree of aggressiveness can be used to categorize non-Hodgkin's lymphoma into indolent and aggressive lymphomas. Patients with an indolent lymphoma usually have a relatively long survival, with or without aggressive chemotherapy. Although these lymphomas respond to a wide range of therapeutic approaches, few if any of these patients are cured of their disease. In contrast, aggressive lymphomas are rapidly growing tumors and patients have a short survival if appropriate therapy is not initiated. Most patients with aggressive lymphomas respond to intensive chemotherapy and many are cured of their disease.
- 10 Patients with localized follicular lymphoma can be cured with radiation therapy alone. Advanced follicular lymphoma is not curable, and there are many treatment options, including watchful waiting, extended-field radiation therapy, single-agent alkylating agents, anthracycline-containing combination chemotherapy, purine analogs, interferon- α , anti-CD20 monoclonal antibodies, and high-dose chemotherapy with hematopoietic stem cell rescue.
- 11 Patients with localized aggressive lymphomas can be cured with several cycles of R-CHOP (rituximab, cyclophosphamide, hydroxydaunorubicin, Oncovin, prednisone) chemotherapy and involved-field irradiation. Patients with bulky stage II, stage III, or stage IV aggressive lymphomas can be cured of their disease with R-CHOP chemotherapy.
- 12 Conventional-dose salvage therapy can induce responses in patients with aggressive lymphomas who relapse, but long-term survival and cure is uncommon. Some patients with aggressive lymphoma who relapse and respond to salvage therapy can be cured with high-dose chemotherapy and autologous hematopoietic stem cell transplantation.

Lymphomas are a heterogeneous group of malignancies that arise from malignant transformation of immune cells that reside predominantly in lymphoid tissues. They most commonly present as a solid tumor, but can sometimes present as circulating tumor cells in peripheral blood. The differing histology of lymphoma cells has led to classification of Hodgkin's lymphoma (Reed-Sternberg cells) or non-Hodgkin's lymphoma (B- or T-cell lymphocyte markers). Non-Hodgkin's lymphomas (NHLs) are further classified into distinct clinical entities, which are defined by a combination of morphology, immunophenotype, genetic features, and clinical features. Chemotherapy is the mainstay of treatment in patients with lymphoma, especially those with widespread disease. Overall cure rates are high for many subtypes of lymphomas, even when patients present with advanced disease.

HODGKIN'S LYMPHOMA

Thomas Hodgkin's first described the mysterious disease of the lymph system that bears his name in 1932. Hodgkin's disease is a form of lymphoma, the cause of which is still unknown, and is fatal in more than 90% of patients untreated for 2 to 3 years. The prognosis with treatment is generally good, but is not well predicted by stage alone. The International Prognostic Index (IPI) was created to better predict an individual's risk of recurrence, which influences treatment decisions. Patients with Hodgkin's lymphoma can be categorized into four prognostic groups: early favorable disease, early unfavorable disease, advanced favorable disease, and advanced unfavorable disease. These groups are defined by patient age, gender, tumor size and spread (stage), presence or absence of systemic symptoms, and laboratory test results. When appropriate therapy is given, more than 75% of all newly diagnosed Hodgkin's lymphoma patients will be cured. This extraordinary success has not been without cost. The treatment programs are intense, technically demanding, and associated with considerable acute toxicity and long-term complications. The long-term effects, particularly secondary malignancies, account for a higher cumulative mortality than Hodgkin's lymphoma 15 to 20 years after treatment. Long-term toxicities with standard chemotherapy regimens have been more fully documented in recent years and are shaping future therapies.¹⁻⁴

EPIDEMIOLOGY AND ETIOLOGY

It is estimated that 8,190 new cases of Hodgkin's lymphoma will be diagnosed in the United States in 2007, which represents less than 1% of all known cancers. It is expected that there will be 1,070 deaths associated with Hodgkin's lymphoma during this same time.⁵ This disease occurs slightly more frequently in males than in females. Once thought to be only a disease of the young, it is now recognized that Hodgkin's lymphoma exhibits a bimodal distribution in industrialized countries. The first peak occurs between the ages of 15 and 44 years (highest from 20 to 29 years of age) and again in those older than 55 years.¹ The 5-year overall survival for all stages according to the Surveillance, Epidemiology, and End Results (SEER) database is approximately 85%.⁶ Death rates as a consequence of recurrent Hodgkin's lymphoma are less than those from other causes 15 years after treatment.^{7,8}

The etiology of Hodgkin's lymphoma is unknown and remains elusive for several reasons. Tissue taken from a Hodgkin's lymphoma mass reveals that only 1% to 2% of the cells are Reed-Sternberg cells (malignant), which has made it difficult to study.¹ The only risk factors that have consistently been associated with the disease include viral exposure and immune function. Infection has been considered a potential cause of Hodgkin's lymphoma since the disease was first described. Studies suggest an increased risk of Hodgkin's lymphoma in patients who have been infected with the Epstein-Barr virus (EBV). Reed-Sternberg cells (large, bilobate, multinuclear cells), the malignant cells in Hodgkin's lymphoma, are linked to EBV, particularly in patients older than age 50 years.^{1,9} The increased risk associated with EBV infection appears to dissipate over about 20 years.¹⁰ Immunosuppressed individuals are also at an increased risk of developing Hodgkin's lymphoma. This includes patients with congenital immunosuppression, solid-organ transplantation recipients, and human immunodeficiency virus (HIV)-infected patients. Although the risk of developing Hodgkin's lymphoma is about sevenfold greater in patients with HIV, the risk is not nearly as great as for non-Hodgkin's lymphoma and does not appear to be correlated with CD4 count.¹¹

Genetic factors also predispose people to Hodgkin's lymphoma. The risk of Hodgkin's lymphoma is increased in people with ataxia telangiectasia. The strongest evidence suggesting that genes are important in the etiology of Hodgkin's lymphoma comes from identical twin

studies, which show that the unaffected identical twin has about a 100-fold increase in risk. Other environmental risk factors are linked with Hodgkin's lymphoma, but only appear to play a minor role.^{1,9}

PATHOPHYSIOLOGY

Hodgkin's lymphoma is a clonal malignant lymphoid disease of transformed lymphocytes. The malignant cell in Hodgkin's lymphoma is known as "Reed-Sternberg" after Drs. Carl Sternberg and Dorothy Reed, who are credited with the first definitive microscopic description of Hodgkin's lymphoma in 1898 and 1902, respectively.¹ The origin of the Reed-Sternberg cell has eluded scientists because of the inability to isolate and analyze these cells to the necessary depth. A typical Hodgkin's lymphoma mass occurs in a lymph node and contains normal reactive and inflammatory cells, fibrosis, and a relatively small percentage (1% to 2%) of Reed-Sternberg cells. In recent years, new laboratory techniques have led to significant progress in identifying the origin of the Reed-Sternberg cell. Single-cell polymerase chain reaction and DNA microarray analysis indicate that nearly all classic Hodgkin's lymphoma cases and all nodular lymphocyte-predominant Hodgkin's lymphomas have immunoglobulin gene rearrangements, which indicates a germinal center or postgerminal center B-cell origin (Table 135-1).^{1,9} Interestingly, nearly all Reed-Sternberg cells fail to express B-cell specific cell surface proteins.

During malignant transformation, B-cell transcriptional processes are disrupted, which prevent B-cell surface marker expression and production of immunoglobulin messenger ribonucleic acid. The normal cellular consequence of failure to express immunoglobulin is apoptosis, but because of alterations in the normal apoptotic pathways, cell survival and proliferation are favored. Reed-Sternberg cells overexpress nuclear factor- κ B, which is associated with cell proliferation and antiapoptotic signals. Infections with viral and bacterial pathogens upregulate nuclear factor- κ B and consequently are hypothesized to be involved with the etiology of Hodgkin's lymphoma.^{1,9} This hypothesis is supported by the finding of EBV in many Hodgkin's lymphoma tumors, but it is important to note that not all tumors are associated with EBV.^{1,12} As molecular techniques continue to improve, our understanding of the pathophysiology of Hodgkin's lymphoma will also improve.

The histopathologic classification of Hodgkin's lymphoma has undergone numerous changes over the last three decades. The current classification system used today is the World Health Organization (WHO) modification of the Revised European-American Classification of Lymphoid Neoplasms (Table 135-2).¹³ This classification divides Hodgkin's lymphoma into two major groups: classical Hodgkin's

TABLE 135-1 B-Cell Development and the Corresponding Neoplasm Derived at Each Stage

		B Cells	Corresponding Neoplasm
Foreign antigen independent	Bone marrow	Stem cell	
		Pro-B cell

lymphoma and nodular lymphocyte-predominant Hodgkin's disease, which constitute approximately 95% and 5% of cases, respectively. Classical Hodgkin's lymphoma is further divided into four subtypes: nodular sclerosis, mixed cellularity, lymphocyte-depletion, and lymphocyte-rich. The subtypes in these classification systems are based on characteristics of the Reed-Sternberg cell, the surrounding cells, and connective tissue. Nodular sclerosis has features that make it distinct from the other three subtypes, which represent a continuum of background cellularity, with lymphocyte-predominance being the most cellular and lymphocyte-depletion being the least cellular. Nodular lymphocyte-predominant Hodgkin's lymphoma is separated because of its distinct immunophenotype: CD15⁻, CD20⁺, CD30⁻, and CD45⁺ (the opposite of classical Hodgkin's disease).¹ With the introduction of extensive staging, sophisticated megavolt radiotherapy, and effective combination chemotherapy, the prognostic value of these subtypes is becoming less clear. The true value of understanding these subtypes is likely tied to the pathogenesis of the disease and potential prevention in the future.

CLINICAL PRESENTATION

1 Approximately 70% of patients with Hodgkin's lymphoma present with a painless, rubbery lymph node and commonly have mediastinal nodal involvement. Hodgkin's lymphoma is occasionally diagnosed in asymptomatic patients who have a mediastinal mass found with chest radiography or other imaging procedure. Asymptomatic adenopathy of the inguinal and axillary regions may be present at diagnosis but is less common, whereas involvement of Waldeyer ring and the epitrochlear nodes rarely occurs (Fig. 135-1).¹⁴ Approximately 25% of patients with Hodgkin's lymphoma present with constitutional symptoms (B symptoms) and pruritus is commonly noted but its presence does not appear to have significant prognostic value.¹

DIAGNOSIS, STAGING, AND PROGNOSTIC FACTORS

Diagnostic and staging procedures are based on recommendations made at the Ann Arbor and Cotswolds conferences and new scientific advances, as described in the National Comprehensive Cancer Network (NCCN) guidelines.¹⁵ The diagnosis and pathologic classifica-

tion of Hodgkin's lymphoma can only be made by review of a biopsy (preferably an excisional biopsy) of the enlarged node by an expert hematopathologist. In addition to a careful physical examination and routine laboratory tests, chest radiography and computed tomography (CT) scans of the chest, abdomen, and pelvis are routinely performed. Positron emission tomography (PET) scanning is more sensitive and specific than CT scanning, but its impact on survival and role staging is unclear.^{1,16} Bone marrow biopsy is recommended in patients with more advanced-stage disease.

Staging can be based on clinical or pathologic findings. Clinical stage is based on all noninvasive procedures (history, physical examination, laboratory tests, and radiologic findings), whereas pathologic stage is based on the biopsy findings of strategic sites (muscle, bone, skin, spleen, and abdominal nodes) with an invasive procedure such as a laparoscopy or laparotomy. Those patients with extranodal disease (muscle, skin, bone, or Waldeyer ring) contiguous to involved nodes are classified with the subscript "E" in the Cotswolds staging system.¹⁵ As a result of improved imaging techniques, pathologic workup and staging that can be associated with toxicity is rarely performed.

The Ann Arbor staging classification, which was developed at the 1970 Ann Arbor conference, has proven to be a good workable scheme. At the Cotswolds meeting in 1989, the Ann Arbor classification was modified to account for new diagnostic techniques (e.g., CT and magnetic resonance imaging), and the understanding that prognosis is associated with the bulk of the disease and the number of involved nodal sites (Table 135-3).^{1,17} After careful staging, about one-half of patients have localized disease (stages I, II, and II_E) and the remainder have advanced disease (stage III or IV). Approximately 10% to 15% present with metastatic disease (stage IV). It is important to note that Hodgkin's lymphoma appears to follow a predictable pattern of nodal spread that is not seen with the NHLs.^{1,15,17}

Patient prognosis is predominately driven by age and stage. Patients who are older than ages 65 to 70 years are about one-half as likely to be cured as younger patients. The difference in cure rates may be related to the high rate of comorbid diseases and decreased organ function, which impairs the patient's ability to tolerate intensive chemotherapy. Stage is the other dominant factor in predicting survival; patients with limited-stage disease (stages I to II) have a 90% to 95% cure rate, whereas those with advanced disease (stages III to IV) have only a 65% to 70% cure rate.^{1,15,17}

Additional risk factors have been identified that improve the prognostic accuracy and impact therapeutic choices. An international collaborative effort identified seven adverse prognostic factors with similar impact on survival (each factor reduced survival by 7% to 8% per year), which can be combined to generate an International Prognostic Score that is used to predict progression-free and overall survival (Table 135-4).¹⁸

TABLE 135-4 The International Prognostic Factors Project Score for Advanced Hodgkin's Lymphoma		
Risk Factors		
Serum albumin (<4 g/dL)		
Hemoglobin (<10.5 g/dL)		
Male gender		
Stage IV disease		
Age (≥45 years)

TREATMENT

Hodgkin's Lymphoma

The current goal in the treatment of Hodgkin's lymphoma is to maximize curability while minimizing short- and long-term treatment-related complications. According to the SEER database, the 5-year age-adjusted relative survival is greater than 80%.⁶ The development of effective therapies for all stages of Hodgkin's lymphoma remains one of the most remarkable achievements in modern cancer care.

Although multiple treatment modalities are used to treat Hodgkin's lymphoma, surgery has a limited therapeutic role regardless of stage. It is, however, important for diagnosis (excisional biopsy), and on some occasions, such as placement of a central line.¹

Combination chemotherapy is the primary treatment modality for most Hodgkin's lymphoma patients. In general, patients with early-stage Hodgkin's lymphoma are treated with combination chemotherapy (and radiation), whereas patients with advanced-stage disease are treated with combination chemotherapy with or without radiation therapy. For patients with refractory or recurrent disease, salvage therapy consists of multiagent chemotherapy with or without high-dose chemotherapy and autologous hematopoietic stem cell transplantation (HSCT), which can be curative.¹

Radiation is often an integral part of the treatment plan. Selected patients with early-stage disease (usually nodular lymphocyte-predominant histology) can receive radiation as the only treatment modality, whereas most patients will receive chemotherapy and radiation. Although radiation is a local therapy, many patients with advanced disease will also receive radiation therapy to residual or bulky disease sites after chemotherapy. The major concern with radiation therapy is its long-term effects, such as cardiovascular disease and secondary malignancies, which commonly occur in the lung, breast, gastrointestinal tract, and connective tissue.^{1,3,19} To avoid these toxicities, several studies have been completed and others are ongoing to maximize efficacy while minimizing the extent of radiation (radiation field) and the dose of radiation.²⁰ Radiation to a single field that contains Hodgkin's lymphoma is called *involved-field radiation*; radiation to the involved field and a second uninvolved area is termed *extended-field radiation* or *subtotal nodal irradiation*; and radiation of all areas is called *total nodal irradiation*.²¹ When given with chemotherapy (the most common scenario), typically only involved-field radiation is used to avoid the increased toxicity associated with extended-field radiation. The following sections review treatment of early-stage favorable disease, early-stage unfavorable disease, advanced-stage favorable disease, advanced-stage unfavorable disease, and salvage therapy.

■ TREATMENT OF EARLY-STAGE FAVORABLE DISEASE

Patients with early-stage favorable disease have stage IA or IIA disease and no adverse risk factors (extranodal disease, bulky disease, three or more sites of nodal involvement, or an erythrocyte sedimentation rate of ≥ 50). Until recently, extended-field radiation was considered to be the treatment of choice for stages IA and IIA disease. This treatment produces disease-free survival rates ranging from 65% to 85% and overall survival rates ranging from 75% to 93%.^{1,22,23}

In an effort to avoid the long-term effects of extended-field radiation and improve treatment results, several studies have evaluated a combined modality approach that involves the use of short-duration chemotherapy and involved-field radiation. Based on favorable results of these studies, most clinicians no longer treat patients with early-stage favorable disease with radiation alone.^{1,15,22,23}

② Clinical trials comparing radiation alone to radiation plus chemotherapy show lower relapse rates in patients treated with combined modality therapy (radiation and chemotherapy), but no change in overall survival.^{1,23,24} Current studies focus on questions such as the optimal number of chemotherapy cycles and the volume of radiation that must be used to obtain optimal patient outcomes. Results of recent studies suggest that as few as two to four cycles of chemotherapy are adequate. Different combination chemotherapy regimens have been used in these studies, and no one regimen is clearly superior to another.^{20,22–24}

The current NCCN guidelines recommend that patients with early-stage favorable disease be treated with two cycles of the Stanford V regimen (doxorubicin, vinblastine, mechlorethamine, etoposide, vincristine, bleomycin, and prednisone) or four cycles of the ABVD (doxorubicin [Adriamycin], bleomycin, vinblastine, and dacarbazine) regimen, followed by consolidative involved-field radiation.¹⁵ With this approach, 5-year progression-free and overall survival rates of $>90\%$ can be achieved.

In selected patients, those with nodular lymphocyte-predominant Hodgkin's lymphoma, who choose to omit chemotherapy, or who cannot tolerate chemotherapy, radiation therapy alone is an option and does not appear to adversely affect survival.^{1,15,22,23} The disadvantage of radiation therapy alone as compared to combination chemotherapy and radiation is the higher relapse rate. The lack of difference in survival rates is a result of the fact that patients who relapse after radiation alone (20% to 25%) can be successfully salvaged with chemotherapy. If the decision is made to use radiation alone, extended-field radiation appears to be superior to involved-field radiation, based on a meta-analysis conducted by Specht et al.²⁵ Results of that analysis showed that more extensive radiation reduces the risk of treatment failure at 10 years (31% vs. 43%), although it does not improve 10-year overall survival (77% vs. 77.1%).

■ TREATMENT OF EARLY-STAGE UNFAVORABLE DISEASE

Patients with early-stage disease who have certain features associated with a poor prognosis (B symptoms, extranodal disease, bulky disease, three or more sites of nodal involvement, or an erythrocyte sedimentation rate >50) are defined as having unfavorable disease. Current guidelines recommend combined modality therapy (combination chemotherapy and involved-field radiation) to reduce the relapse rate and avoid the toxicity associated with extended-field radiation.^{1,15,22,23}

② Although randomized trials show that combined modality therapy reduces the relapse rate in patients with early-stage unfavorable disease, questions concerning the appropriate radiation volume, most effective chemotherapy regimen, and number of chemotherapy cycles remain.²³ A number of studies have compared extended-field radiation to involved-field radiation. In the largest trial (German Hodgkin Study Group [GHSG] HD8 n = 1,204),²⁶ patients with early-stage unfavorable Hodgkin's lymphoma treated with chemotherapy and involved-field radiation had similar outcomes in terms of freedom from treatment failure and overall survival as those treated with the same chemotherapy regimen and extended-field radiation. Because toxicity was greater with extended-field radiation, the accepted standard is chemotherapy and involved-field radiation.

Several ongoing trials compare different chemotherapy regimens or number of chemotherapy cycles.^{1,20,23} Mechlorethamine, vincristine, procarbazine, and prednisone (MOPP) was one of the first highly effective regimens introduced to treat Hodgkin's lymphoma. MOPP or MOPP-like regimens then were given alternately or hybridized with a combination of ABVD. In advanced disease, ABVD was found to be less toxic than alternating MOPP/ABVD, and both were found to be superior to MOPP alone. Consequently,

ABVD has become the standard regimen used to treat patients with early-stage unfavorable disease. It has established effectiveness in patients with advanced-stage disease and a favorable toxicity (both acute and chronic) profile.¹

Despite the excellent results from treatment with ABVD and radiation, approximately 5% of patients will not respond to initial treatment and another 15% of patients will relapse following an initial response. Several ongoing studies are evaluating more aggressive regimens or more cycles of therapy. Two large European trials are evaluating ABVD versus a more intense combination of bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone (BEACOPP), 4 versus 6 cycles of chemotherapy, and 20 versus 30 Gy involved-field radiation.^{1,20,23} Preliminary analysis at 40 and 64 months indicates no difference in treatment failure or overall survival between groups. The current NCCN guideline lists the Stanford V regimen as an acceptable option, which also uses more drugs than the ABVD regimen.¹⁵ However, none of these more aggressive regimens has proven to be more effective than ABVD and each is associated with more toxicity.²⁷ Therefore, ABVD and involved-field radiation remain the standard at this time.

In summary, most patients with early stage disease will be treated with two to four cycles of ABVD chemotherapy and involved-field radiation. The number of cycles administered is based on favorable versus unfavorable disease. When radiation is completely omitted, six cycles of ABVD are recommended.¹⁵ Although this approach results in excellent outcomes, studies are ongoing to maximize efficacy while minimizing acute and long-term toxicity.

■ TREATMENT OF ADVANCED-STAGE DISEASE

Advanced-stage disease consists of stages III and IV disease. In some studies, stage IIB with a large mediastinal mass or extranodal disease is also considered advanced-stage disease (see Table 135–3). By definition, stages III and IV patients have tumor on both sides of the diaphragm, which almost always precludes the use of radiation alone as a therapeutic modality. Intensive combination chemotherapy is the mainstay of treatment, although some patients will benefit from radiation following chemotherapy. The prognosis of advanced-stage disease is excellent with 5-year overall survival rates ranging from less than 56% to 90%. Prognostic factors have been identified and standardized to provide a more accurate individual prognosis (see Table 135–4).^{1,18} Historically, all patients with advanced disease have been treated the same and studies have typically enrolled all advanced-stage patients regardless of prognosis.

Combination Chemotherapy

One of the initial combination chemotherapy regimens introduced in the early 1960s that was shown to produce cures in advanced Hodgkin's lymphoma was the MOPP regimen (Table 135–5).²⁸ MOPP chemotherapy was a mainstay of treatment for patients with stages III and IV advanced Hodgkin's lymphoma. It produced complete remissions in 84% of patients and has a 10-year cure rate of 54%.²⁹

Ever since MOPP therapy was introduced and the efficacy confirmed, researchers tried to modify the regimen in an attempt to improve efficacy and decrease toxicity.²⁸ Some MOPP variations including MVPP (vinblastine substituted for vincristine), CVPP (cyclophosphamide substituted for mechlorethamine), and ChlVPP (chlorambucil substituted for mechlorethamine, and vinblastine substituted for vincristine) were attractive alternatives to MOPP because they offered equal efficacy and differing or less severe toxicities.

③ The development of ABVD by Bonnadonna et al. at the Milan Cancer Institute about a decade later represents the next important

step in the evolution of therapy for Hodgkin's lymphoma (see Table 135–5). ABVD was initially shown to be effective in MOPP failures and was later compared directly to MOPP in advanced disease, where it produced an 82% complete response rate, as compared with a 67% complete response rate with MOPP. Improved failure-free survival was demonstrated with ABVD, but no significant differences in 5-year overall survival were noted.³⁰ Because ABVD was less toxic and provided similar or better outcomes than MOPP, it replaced MOPP as the standard regimen for advanced-stage Hodgkin's lymphoma.

In the early 1980s, the Goldie-Coldman hypothesis proposed that chemotherapy resistance was related to spontaneous mutation rates and the development of resistant clones. To test that hypothesis, researchers designed several clinical trials to evaluate the efficacy of alternating non-cross-resistant drug combinations in patients with Hodgkin's lymphoma.³¹

The initial approach investigators took was to alternate or combine the MOPP and ABVD regimens. When MOPP and ABVD (or ABV) are combined in a monthly cycle, it is referred to as a hybrid regimen. Besides a potential benefit in efficacy, another potential benefit of alternating or hybrid regimens is decreased risk of long-term toxicities. In the alternating MOPP/ABVD regimen, the cumulative doses of procarbazine and mechlorethamine are reduced by 50% and the cumulative doxorubicin dose is reduced by 50%. In the hybrid regimen the cumulative doxorubicin dose is reduced by 33% and the cumulative bleomycin dose is reduced by 50%.

Several clinical trials have been performed to evaluate the efficacy of alternating or hybrid MOPP/ABVD regimens. The results of these trials show that alternating and hybrid regimens are superior to MOPP but not to ABVD.^{1,23,30} Another approach was to administer sequential cycles of MOPP and ABVD (MOPP → ABVD). Results of an intergroup trial showed sequential MOPP and ABVD to be inferior to the MOPP/ABV hybrid regimen in terms of response and survival.³² In another randomized comparison of the MOPP/ABV hybrid regimen and ABVD, the complete remission rate, failure-free survival, and overall survival were similar between the two regimens.³³ However, that trial was closed prematurely because of an increased number of treatment-related deaths and secondary malignancies in the patients who received the MOPP/ABV hybrid regimen.

More aggressive regimens such as Stanford V and BEACOPP have been evaluated as alternatives to MOPP or ABVD. The Stanford V regimen generated significant interest because of the results of phase II trials.²³ However, a randomized controlled trial that compared the Stanford V, ABVD, and a MOPP/ABV hybrid-like regimen (MOPPEBVCAD) found the Stanford V to be inferior in terms of failure-free survival.²⁷ Developed by the GHSG, BEACOPP uses similar drugs as in the COPP/ABVD regimen (a combination of bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone), but rearranges the drugs in a shorter 3-week cycle. Several different versions of BEACOPP have been developed: standard-dose BEACOPP (BEACOPP baseline), higher-dose BEACOPP (BEACOPP-escalated), and dose-dense BEACOPP (BEACOPP-14).²⁰ Granulocyte colony-stimulating factor support is required for the BEACOPP-escalated and BEACOPP-14 regimens. A recent trial randomized 1,201 patients to COPP/ABVD (alternating), BEACOPP, or an increased-dose BEACOPP.³⁴ Most patients had advanced favorable disease and after chemotherapy, all patients received radiation to sites of bulky or residual disease. Freedom from treatment failure at 5 years was 69%, 76%, and 87% for COPP/ABVD, standard-dose BEACOPP, and increased-dose BEACOPP, respectively ($P < 0.001$ for comparison of increased-dose BEACOPP with the COPP/ABVD group and with the BEACOPP group). Five-year overall survival was 83%, 88%, and 91%, for COPP/ABVD, standard-dose BEA-

TABLE 135-5 Combination Chemotherapy Regimens for Hodgkin's Lymphoma

Drug	Dosage (mg/m ²)	Route	Days
MOPP			
Mechlorethamine	6	IV	1, 8
Vincristine	1.4	IV	1, 8

COPP, and increased-dose BEACOPP, respectively ($P = 0.002$ for comparison of COPP/ABVD vs. increased-dose BEACOPP). Although most of these patients had favorable disease, patients with unfavorable disease showed an improvement in 5-year freedom from treatment failure (59%, 74%, and 82%, respectively) and overall survival (67%, 81%, and 82%, respectively), in COPP/ABVD, standard-dose BEACOPP, and increased-dose BEACOPP. Increased-dose BEACOPP appears to be the best regimen from this study, but it was also more toxic. Despite filgrastim support, 90% of patients in the increased-dose BEACOPP group had grade IV leukopenia, as compared to 19% in patients in the COPP/ABVD arm and 37% in the standard-dose BEACOPP arm. The higher rate

of acute toxicity did not translate into a difference in acute treatment-related fatalities (<2% for all three regimens). The improvements in efficacy have been tempered because of a 2.5% leukemia rate at 5 years, which is higher than the 0.4% in the COPP-ABVD arm. These and other long-term complications are a major concern for patients with a good prognosis, and these more aggressive regimens have not been widely adopted.^{22,23} Longer follow-up of this trial is required to determine whether the survival gain with increased-dose BEACOPP is maintained and outweighs the increased risk of long-term toxicities such as secondary malignancies.²³ Because long-term follow-up will take years, some experts recommend that these more intensive regimens be considered in

patients with high-risk disease. Recently, the NCCN guidelines¹⁵ and National Cancer Institute treatment Physician Data Query (PDQ)³⁵ suggest that patients with advanced-stage disease should be divided into favorable and unfavorable disease.

Risk-Adapted Therapy

Advanced-stage favorable disease patients are described based on stage and the presence of 3 or less poor prognostic factors from the international prognostic index (Table 135–4). This group of patients has about a 60% likelihood of being free from treatment failure at 5 years with traditional combination chemotherapy.³⁵ Patients with unfavorable disease are described based on stage and the presence of 4 or more poor prognostic factors from the international prognostic index (Table 135–4).¹⁸ This group of patients has less than a 50% likelihood of being free from treatment failure at 5 years with traditional combination chemotherapy.³⁵ Because of the high treatment failure rate, the therapeutic focus for this group of patients is efficacy rather than long-term toxicity. Until recently, all advanced-stage patients were grouped together. But the current NCCN guidelines¹⁵ and National Cancer Institute PDQ treatment statement³⁵ suggest that escalated-dose BEACOPP be considered for patients with unfavorable disease because of the increase in efficacy. The guidelines recommend that advanced-stage favorable disease patients be treated with ABVD because of less-acute toxicity, no sterility, and a low risk of secondary acute myeloid leukemia/myelodysplastic syndrome.^{15,35}

Radiation

The role of low-dose consolidative radiation when added to chemotherapy for the treatment of advanced-stage Hodgkin's lymphoma is controversial.²³ The rationale for its use is based on the radiosensitivity of Hodgkin's lymphoma, a 20% to 40% relapse rate, and the tendency of Hodgkin's lymphoma to relapse at sites of initial involvement.³⁶ Many clinical trials were conducted to evaluate the benefit of additional radiation in patients who have a complete response to combination chemotherapy. The results of these studies were inconsistent, and a meta-analysis of 14 randomized trials showed a modest improvement in disease control at 10 years, but no difference in overall survival.³⁷ In one study, patients with advanced disease were randomized to receive either involved-field radiation after MOPP/ABV hybrid chemotherapy or no further therapy. Eight-year event-free survival has been reported for patients achieving a complete response randomized to receive radiation or no radiation and a group of partial responders who received radiation (73% vs. 77% and 76%, respectively). These results suggest that radiation provides no benefit for patients who achieve a complete remission with chemotherapy; radiation was also associated with a higher risk of secondary cancers (12.9% vs. 5.6% in the radiation and no radiation arms, respectively). It does, however, show a significant role for consolidative radiation in patients who have a partial response after chemotherapy.³⁸

Summary

In summary, the standard treatment of advanced-stage favorable Hodgkin's lymphoma is six to eight cycles of ABVD chemotherapy. BEACOPP should be considered for patients with unfavorable disease. Although not yet prospectively tested, this risk-adapted approach should result in approximately 70% to >90% of patients achieving a complete remission and approximately 60% to 80% of patients being cured of their disease. No further treatment is needed for patients attaining a complete remission. Patients achieving a partial remission should receive consolidative radiation to residual sites of disease.

CLINICAL CONTROVERSY

Some clinicians believe that increased-dose BEACOPP is superior to ABVD in the treatment of patients with advanced-stage Hodgkin's lymphoma. Increased-dose BEACOPP has been shown to be superior to COPP/ABVD, which is similar to MOPP/ABVD. Other experts believe that ABVD is still the treatment of choice because increased-dose BEACOPP has not been tested directly against it. They also express concern over the long-term toxicity with increased-dose BEACOPP. This controversy will be answered with currently ongoing randomized studies and longer followup of the increased-dose BEACOPP trial.

■ TREATMENT OF REFRACTORY OR RELAPSED DISEASE

4 The goal of salvage therapy is cure regardless of the site(s) of recurrence or primary therapy. With the increasing use of chemotherapy with or without radiation, regardless of disease extent, the rate of primary refractory disease is decreasing. Patients who do not achieve a complete remission with the initial regimen are considered to have primary refractory disease. These patients have a poor prognosis when treated with salvage chemotherapy, and therefore are candidates for high-dose chemotherapy and autologous HSCT.^{1,22,23,39}

Patients who relapse after an initial complete response can be treated with the same regimen, a different potentially non-cross-resistant regimen, radiation, or high-dose chemotherapy and autologous HSCT (often preceded by conventional-dose chemotherapy). The response to salvage therapy depends on the extent and site of recurrence, previous therapy, and duration of initial remission. Patients who relapse after radiation therapy alone have a good chance of being cured with combination chemotherapy, although fewer patients are being treated with radiation alone. Other patient groups who have a favorable prognosis following salvage therapy include patients who experience a local recurrence in a nonirradiated location and those who relapse more than 1 year after completion of their initial chemotherapy. Patients who experience late relapses can be cured with retreatment with the same chemotherapy regimen, treatment with a different, potentially non-cross-resistant regimen, or high-dose chemotherapy and autologous HSCT. The National Cancer Institute has reported on its long-term followup of MOPP-retreated patients. Patients with long initial remissions had a 45% disease-free survival rate at 10 years.⁴⁰

Patients who have an early relapse (less than 1 year after treatment) generally respond poorly to standard-dose salvage chemotherapy, with cure occurring in less than 20% of patients. High-dose chemotherapy and autologous HSCT is more effective, but also produces a higher risk of treatment-related mortality. The choice of salvage treatment should therefore consider the patient's tolerance for a particular set of chemotherapeutic agents and treatment approach (standard-dose chemotherapy vs. high-dose chemotherapy and autologous HSCT).²³

High-dose therapy should be considered in patients who relapse within 12 months of initial remission and in those who are refractory to first-line chemotherapy.²³ Although no one preparative regimen has been shown to be superior to another, most regimens do not include total-body irradiation because of its potential pulmonary toxicity. Most patients are already at higher risk for pulmonary toxicity because of previous exposure to one or more of the following: bleomycin, thoracic radiation, and nitrosoureas. High-dose chemotherapy with autologous HSCT produces long-term progression-free survival rates in patients with refractory and relapsed disease.²³ A recent study on the efficacy of HSCT for relapsed or recurrent Hodgkin's lymphoma reported 5- and 10-year overall

survival rates of 53% and 47%, respectively. They also identified three factors that predicted progression-free survival: chemoresistant disease, residual disease at transplant, and B symptoms at pretransplant relapse. Patients with zero or one risk factor had a 5-year progression-free survival of 67%, those with two risk factors had a 37% progression-free survival, and those with all three risk factors only had a 9% progression-free survival rate.³⁹ Chapter 142 provides more details about high-dose chemotherapy and HSCT.

■ LONG-TERM COMPLICATIONS

A variety of acute and chronic toxicities may occur as a result of treatment for Hodgkin's lymphoma. Long-term complications of radiation therapy, chemotherapy, and combined modality therapy have become more evident as the curability and long-term survival of Hodgkin's lymphoma patients has improved.^{19,23} Gonadal dysfunction, secondary malignancies, and cardiac disease have become important considerations in the treatment of this malignancy. Almost all men and up to 50% of premenopausal women treated with six cycles of regimens containing alkylating agents become sterile. This appears to be a dose-related phenomenon. For men, even a single dose of nitrogen mustard or chlorambucil can cause sterility, so if fertility is a major concern, ABVD may be the best alternative.⁴¹

Now that 10-, 15-, and 20-year survival data are available, evaluation of secondary malignancies can be made. Recent reports show that after treatment for Hodgkin's lymphoma, the relative risk for secondary cancers is increased by about threefold. The risk of developing leukemia carries the highest increase in risk and is seen with radiotherapy, chemotherapy, and chemoradiotherapy. Radiotherapy alone increases the risk modestly, while multimodality therapy increases the risk the most (relative risk = 31.6). The incidence of solid tumors, most commonly gastrointestinal tumors, lung cancer, and breast cancer is also increased. The risk of gastrointestinal tumors is increased the greatest (relative risk = 3.3) by chemoradiotherapy, the risk of lung cancer was also increased with all treatment modalities, with the highest being from chemoradiotherapy (relative risk = 4.3), while the breast cancer risk is increased only after radiotherapy (relative risk = 2.5). The increase in relative risk varies with age and type of treatment. The risks are the highest for patients who are younger than age 25 years at the time of treatment.⁴² The relative risk also varies with specific therapies; for example patients who receive MOPP or increased-dose BEACOPP therapy appear to have a higher risk of secondary acute leukemia as compared with ABVD.²³

Although chemoradiotherapy is associated with a higher risk of secondary malignancies, a meta-analysis of 37 randomized trials showed that its use as first-line therapy in patients with early-stage Hodgkin's lymphoma may actually be associated with a *lower* risk of secondary malignancies as compared with radiotherapy alone (odds ratio = 0.78) by reducing relapse and need for salvage therapy.⁴³ However, first-line chemoradiotherapy was associated with a higher risk of secondary malignancies as compared with chemotherapy alone (odds ratio = 1.38) in patients with Hodgkin's lymphoma, most of whom had advanced-stage disease.

NON-HODGKIN'S LYMPHOMA

The NHLs are a heterogeneous group of lymphoproliferative disorders that affect individuals from early childhood to late adulthood. Advances in molecular biology techniques and our understanding of the human immune system have led to major progress in understanding the pathogenesis and treatment of the lymphomas. NHLs are classified into distinct clinical entities that are defined by a combination of morphology, immunophenotype, genetic features, and clinical features. These differences influence the natural history, and approach and response to treatment. The use of extensive combina-

tion chemotherapeutic regimens shows dramatic improvement in survival and cure in patients with a disease that once was considered incurable. The 5-year survival rate for patients with NHL has increased from 48% to 64% over the past 25 years, and the mortality rate actually *declined* from 1997 to 2004.^{5,6} Further improvement in survival is anticipated with the continued expansion of our therapeutic armamentarium, including high-dose chemotherapy and biologic therapy.

EPIDEMIOLOGY AND ETIOLOGY

NHL is the fifth most common cause of newly diagnosed cancer in the United States and accounts for approximately 4% of all cancers. An estimated 63,190 new cases will be diagnosed in 2007, and it is estimated that 18,660 people will die from NHL during this same period.⁵ Although the average age of patients at the time of diagnosis is about 67 years, NHL can occur at any age. The incidence rate generally increases with age, and is higher in men than in women and in whites than in blacks.⁶ The age-adjusted incidence rate of NHL increased by more than 80% in the United States since the early 1970s, from about 11 cases per 100,000 in 1975 to nearly 20 cases per 100,000 in 2003 and 2004.⁶ The incidence of NHL increased by 3% to 4% from 1975 to 1991, but appears to have stabilized since reaching its peak in 1994. The increase in the incidence of NHL over the past three decades is second only to melanoma and has been referred to as an epidemic of NHL. Although the increased incidence has been particularly noted among the elderly and patients with acquired immune deficiency syndrome (AIDS), much of this increase cannot be explained by known risk factors.

The etiology of NHL is unknown, although several genetic diseases, environmental agents, and infectious agents are associated with the development of NHL.⁴⁴⁻⁴⁶ An increased incidence of NHL is seen in many congenital and acquired immunodeficiency states, supporting the role of immune dysregulation in the etiology of NHL. Patients with congenital immunodeficiency disorders such as Wiskott-Aldrich syndrome, ataxia, and telangiectasia; acquired immunodeficiency disorders such as AIDS, acquired hypogammaglobulinemia, and graft-versus-host disease; and those receiving chronic pharmacologic immunosuppression in the setting of solid-organ transplantation are predisposed to the development of NHL. Autoimmune diseases (Hashimoto thyroiditis, Sjögren's syndrome) cause chronic inflammation in the mucosa-associated lymphoid tissue (MALT), which predisposes patients to subsequent lymphoid malignancies. Other autoimmune diseases, such as systemic lupus erythematosus and rheumatoid arthritis, are also associated with the development of NHL, but the use of immunosuppressive agents in these diseases makes the pathologic cause less clear.

Certain infections are associated with the development of lymphoma.⁴⁴⁻⁴⁶ EBV was discovered in cell lines from tumors of patients with African (endemic) Burkitt's lymphoma, and EBV DNA is associated with nearly all cases of endemic Burkitt's lymphoma. However, EBV is associated with sporadic Burkitt's lymphoma in only approximately 20% to 30% of cases. EBV is also associated with posttransplant lymphoproliferative disorders and some lymphomas in patients with AIDS or congenital immunodeficiencies. The human T-cell lymphotropic virus type 1 was the first human retrovirus associated with a malignancy. Infection with human T-cell lymphotropic virus type 1, especially in early childhood, is strongly associated with an aggressive form of T-cell lymphoma, known as adult T-cell leukemia/lymphoma. Human T-cell lymphotropic virus type 1 is endemic in southern Japan, Africa, and the Caribbean. In endemic areas, more than 50% of all NHL cases are adult T-cell leukemia/lymphoma. A third virus associated with NHL is human herpes virus 8. This virus was originally isolated from Kaposi's sarcoma lesions in AIDS patients. Finally, gastric infection with

Helicobacter pylori, a gram-negative bacteria that leads to chronic gastritis, is associated with gastric MALT lymphomas.

A number of physical agents are also associated with the development of NHL.⁴⁴⁻⁴⁶ Exposure to herbicides, particularly phenoxyl herbicides, is associated with the development of NHL. These observations may explain why certain occupations, such as farmers, forestry workers, and agricultural workers, are associated with a higher risk of NHL. Exposure to lawn-care pesticides is also increasing in the general population. A higher risk of NHL is also associated with exposure to other chemical solvents and dyes, exposure to radiation from nuclear explosions, and high intake of meats and dietary fats. Smoking or alcohol consumption is not strongly associated with an increased risk of NHL.

MOLECULAR ABNORMALITIES

Chromosomal translocations have become a hallmark of many lymphoid malignancies.^{47,48} The presence of these specific translocations can be helpful in the diagnosis and classification of lymphoid malignancies. The mechanisms leading to the translocations are unknown, but they usually involve the antigen receptor loci. In contrast to most myeloid and some lymphoid leukemias, NHLs usually place a structurally intact cellular protooncogene under the regulatory influence of highly expressed immunoglobulin or T-cell receptor genes, leading to effects on cell growth, cellular differentiation, or apoptosis. The most common chromosomal translocations involve t(8;14), t(14;18), and t(11;14); each translocation involves the immunoglobulin heavy-chain gene locus on chromosome 14 at 14q32. The translocation t(8;14) that involves *c-MYC*, a well-characterized oncogene clearly associated with malignancy, is implicated in nearly all cases of Burkitt’s lymphoma. The translocation t(14;18) that involves *BCL-2*, one of several putative B-cell lymphoma-associated oncogenes, is found in approximately 90% of follicular B-cell lymphomas. The translocation t(11;14) that involves *BCL-1*, is found in most patients with mantle cell lymphoma. Another putative B-cell lymphoma-associated oncogene, *BCL-6*, is found in about a third of diffuse large B-cell lymphomas.

Although mutations in the *p53* tumor suppressor gene have been recognized in many human neoplasms, such mutations have not been consistently found in patients with lymphoma, which suggests that it may occur late in malignant evolution.

Detection of oncogenes, such as *BCL-2* in follicular lymphomas, can be used clinically to monitor for minimal residual disease. In patients with follicular lymphoma who received monoclonal antibody-purged autologous bone marrow transplantation, those whose bone marrow was negative by polymerase chain reaction for the *BCL-2* rearrangement after purging had significantly longer freedom from recurrence than those whose bone marrow remained polymerase chain reaction-positive.⁴⁹

Because of their role in the pathogenesis of lymphoma, oncogenes are attractive molecular targets for the development of new and novel therapies.⁵⁰

PATHOLOGY AND CLASSIFICATION

NHLs are neoplasms derived from the monoclonal proliferation of malignant B or T lymphocytes and their precursors. Approximately 85% of NHLs in the United States are of B-cell origin. Proliferation of malignant cells results in the replacement of the normal cells and architecture of lymph nodes or bone marrow with a relatively uniform population of lymphoid cells. The classification of NHLs has evolved over the last five decades, as advances in immunology and genetics have allowed scientists to recognize a number of previously unrecognized subtypes of NHLs (Table 135-6).^{46,51} The current classification schemes characterize the NHLs according to the cell of origin (B cell vs. T cell), clinical features, and morpho-

TABLE 135-6 Evolution in the Classification of Non-Hodgkin’s Lymphomas

logic features. Additional immunohistochemical markers, cytogenetic features, and genotypic characteristics may also be of help to further classify NHL into subtypes.

Morphology

The macroscopic and microscopic appearance of the involved tissue remains one of the most important factors in the diagnosis and classification of NHLs. In the 1950s, Rappaport et al. proposed a morphologic classification of malignant lymphomas based on two features: (a) that the malignant cell would disrupt the nodal architecture in a *nodular* or *diffuse* manner, and (b) that lymphomas of histiocytic origin existed. The Rappaport classification gained rapid acceptance in the United States because of its precision, simplicity, and prognostic significance. Application of the system divided NHLs into those with large (i.e., incorrectly called “histiocytes”) or small cells, with or without a nodular (i.e., follicular) growth pattern.

Immunology

In the 1970s, it became apparent that NHLs were tumors of the immune system and were derived from B or T lymphocytes. The availability of techniques using antibodies to antigens on the surface of lymphoid cells (i.e., immunophenotype) and cytochemical assays led to the following conclusions: (a) most NHLs were of B-cell origin; (b) all follicular or nodular lymphomas were of follicle center cell origin; and (c) most lymphomas previously classified as reticulum cell sarcoma, clasmatocytic lymphoma, or histiocytic lymphoma had the immunologic characteristics of transformed lymphocytes. Using this new information, expert pathologists independently developed new classification schemes for NHL in the 1970s and 1980s.^{46,51} The Kiel classification was based primarily on the work of Lennert and became widely used in Europe. In North America, the Lukes and Collins classification scheme was used briefly, but was soon superseded by the Working Formulation. Like the Rappaport classification, divisions within the Working Formulation were based largely on cell size (large [“histiocytic”] vs. small [lymphocytic]), cell shape (round vs. not round), and growth pattern (follicular [nodular] vs. diffuse). Both the Kiel and Working Formulation classification schemes also considered the histologic grade of the tumor, but only the Working Formulation considered actual survival curves of patients with the various subtypes of NHL. “Low-grade” indicated longer median survival (i.e., indolent) whereas “intermediate-grade” and “high-grade” indicated shorter median survival (i.e., aggressive). In the 1980s and early 1990s, the Working Formulation became the most widely used classification scheme in North America, whereas the Kiel classification was widely used in Europe.⁵¹ It was based on the premise that NHL was a single disease with a range of histologic grade and clinical aggressiveness.

New Disease Entities

In the 1980s and early 1990s, rapid advances in immunology and genetics allowed scientists to recognize a number of previously

unrecognized subtypes of NHLs. Cytogenetic and molecular genetic analyses identified the presence of many chromosomal translocations, oncogenes, and their gene products in patients with NHL (see Molecular Abnormalities section). In addition, diseases that would have been lumped together as “low-grade” or “intermediate/high grade” in the Working Formulation showed marked differences in survival, which prompted scientists to reevaluate lymphoma classification schemes.

Information from these studies allowed scientists to further classify B-cell lymphomas as malignant expansions of cells from either the germinal center, mantle zone, or marginal zone of normal lymph nodes (see Table 135–1).^{48,52} Germinal centers are complex structures that form in spleen and lymph nodes in response to antigenic challenge. In addition to B cells, germinal centers contain antigen-presenting cells and helper T cells that cooperate in mediating the B-cell changes that result in a more potent secondary immune response. Malignant transformation often occurs or is initiated in germinal center B cells. Follicular, Burkitt’s, and most large cell lymphomas are believed to be tumors of germinal center B cells. Three histologically distinct microenvironments have been described within the germinal center: a mantle zone surrounding interior dark, and light zones. The mantle zone contains small resting B cells that have not been exposed to antigen (“naive”). Tumors of cells from the mantle zone are usually clinically indolent and histologically low grade. Antigen-triggered activation of the densely packed B cells of the dark zone causes cells to proliferate and subjects genomic DNA to somatic hypermutation. Surviving clones from within the dark zone then enter the light zone where proliferation slows and affinity selection occurs. During affinity selection, only cells with surface immunoglobulin receptors with high affinity for the antigen survive. Antigen-specific B cells generated in the germinal center reaction leave the follicle and reappear in the outer mantle zone, to form a marginal zone. Marginal zones are particularly prominent in mesenteric lymph nodes, Peyer patches, and the spleen. These postgerminal center B cells include memory B cells of the marginal zone and plasma cells. Marginal cell B-cell lymphomas tend to be indolent and may be either extranodal or nodal; extranodal marginal cell B-cell lymphomas are also referred to as MALT lymphomas.

T-cell lymphomas can be classified on the basis of antigen expression as either precursor (thymic) or mature (peripheral) in origin. These classifications clinically translate to precursor lymphoblastic lymphomas or to a heterogeneous group of peripheral T-cell lymphomas. Tumors of natural killer or natural killer-like T cells are uncommon.

The International Lymphoma Study Group, an informal group of 19 hematopathologists from the United States, Europe, and Asia, adopted a new approach to lymphoma classification in 1993. Because it represented a revision of current or prior European and American lymphoma classifications, it was called the Revised European-American Classification of Lymphoid Neoplasms (REAL). The REAL classification system is based on the principle that a classification is a list of “real” disease entities, which are defined by a combination of morphology, immunophenotype, genetic features, and clinical features.^{51,53} The relative importance of each of these criteria for both definition and diagnosis differs among different diseases. Morphology is always important, and some diseases are primarily defined by morphology alone (e.g., follicular lymphoma), although immunophenotype can be helpful in difficult cases. Some diseases have a specific immunophenotype (e.g., mantle cell lymphoma, small lymphocytic lymphoma) that is virtually diagnostic of that disease. A specific genetic abnormality is important in some lymphomas—t(11;14) in mantle cell lymphoma, t(8;14) in Burkitt’s lymphoma, and t(14;18) in follicular lymphoma—whereas other lymphomas lack specific genetic abnormalities (e.g., MALT lymphoma, diffuse large B-cell lymphoma). Finally, other lymphomas

consider clinical features (e.g., extranodal vs. nodal presentation in marginal zone lymphoma and peripheral T-cell lymphoma). A recent retrospective study of the REAL classification confirmed the clinical relevance of this approach.⁵⁴

Since 1995, members of the European and American Hematopathology societies have worked to develop a new WHO classification of hematologic malignancies. The final classification was published in 2001.¹³ The WHO classification uses an updated version of the REAL classification and expands the principles of the REAL classification to the classification of myeloid and histiocytic malignancies.

5 The WHO classification categorizes lymphoid malignancies into three major categories: B-cell lymphomas, T-cell (and putative natural killer cell) lymphomas, and Hodgkin’s lymphoma (see Table 135–2).^{51,53} Within the B-cell and T-cell neoplasm category there are two major categories: “precursor” neoplasms, which correspond to the earliest stages of differentiation (lymphoblastic), and “peripheral” neoplasms, which correspond to the more differentiated B- and T-cell stages. The WHO classification uses the term *grade* to refer to histologic parameters such as cell and nuclear size, density of chromatin, and proliferation fraction, and the term *aggressiveness* to denote clinical behavior of a tumor. This classification scheme includes both lymphomas and lymphoid leukemias because there is no distinction between the solid and circulating forms of these diseases. The WHO classification includes several previously unrecognized types of lymphomas, including mantle cell lymphoma, monocytoid B-cell lymphoma, extranodal lymphoma of MALT, splenic marginal zone lymphoma, primary mediastinal large B-cell lymphoma, and a variety of T-cell lymphomas. New entities not specifically recognized in the Working Formulation account for approximately 20% to 25% of the cases.

The WHO classification has broad clinical implications. The WHO Clinical Advisory Committee has agreed that clinical groupings of lymphoid neoplasms into prognostic categories are neither necessary nor desirable because such arbitrary groupings are of no practical value and may be misleading.⁵⁵ Treatment of a specific patient should be determined not by the broad prognostic group into which the patient’s neoplasm falls but by the specific type of neoplasm, with the addition of grade *within* the tumor type (if applicable), and clinical prognostic factors.

CLINICAL PRESENTATION

6 Patients with NHL present with a wide variety of symptoms, depending on the site of involvement and whether tumor involvement is nodal or extranodal.⁵⁶ Sites of involvement and dissemination of the malignant cells can sometimes be predicted based on the cell of origin and the tendency of tumors to frequently disseminate to areas where the normal counterparts of the lymphoma cells are located. For example, B-cell lymphomas involve areas of the lymphoid system normally populated by B-lymphocytes, such as lymph nodes, spleen, and bone marrow. T-cell lymphomas commonly disseminate to various extranodal sites, such as the skin and lungs.

PRESENTATION OF NON-HODGKIN’S LYMPHOMA

General

- Patients with NHL present with a wide variety of symptoms, depending on the site of involvement and whether tumor involvement is nodal or extranodal

Symptoms

- Approximately 40% of patients present with fever, night sweats, and weight loss (i.e., B symptoms)
- Fatigue, malaise, and pruritus

Signs

- More than two-thirds of patients present with peripheral lymphadenopathy

Laboratory Tests

- A complete blood count, tests of renal and liver function, and serum electrolytes should be obtained
- Serum β_2 -microglobulin and lactate dehydrogenase levels may be useful as prognostic factors and for monitoring response to therapy

Other Diagnostic Tests

- Varies depending on sites of involvement

Most patients present with peripheral lymphadenopathy. The lymphadenopathy may be either localized or generalized, and the involved nodes are often painless, rubbery, and discrete, and usually located in the cervical and supraclavicular regions as in Hodgkin's lymphoma (see Fig. 135–1). Rapid and progressive lymphadenopathy is more characteristic of aggressive lymphomas. Waxing and waning of lymph nodes, including their complete disappearance and reappearance, is more characteristic of indolent lymphomas. Massive lymphadenopathy can sometimes lead to organ dysfunction. For example, patients with NHL may present with acute renal failure from retroperitoneal adenopathy causing ureteral obstruction or from metabolic abnormalities such as hyperuricemia with uric acid nephropathy.

Approximately 40% of patients with NHL present with fever (temperature $>38^{\circ}\text{C}$ [100.4°F]), weight loss (unexplained weight loss of 10% of body weight over the past 6 months), or night sweats (drenching night sweats). If one of more of these symptoms is present, the patient is noted to have B symptoms, and a B is added to the stage of disease (discussed in Diagnosis, Staging, and Prognostic Factors section in Hodgkin's Lymphoma). B symptoms are more commonly observed in patients with aggressive NHLs.

Patients with Hodgkin's lymphoma rarely present with extranodal (i.e., extralymphatic) disease, but 10% to 35% of patients with NHL have primary extranodal disease at the time of diagnosis.⁵⁶ The frequency of extranodal presentation varies dramatically among different subtypes. The most common extranodal sites are the gastrointestinal tract followed by the skin. The liver or spleen may be enlarged in patients with generalized adenopathy. Patients with mesenteric or gastrointestinal involvement may present with signs and symptoms of nausea, vomiting, obstruction, abdominal pain, a

palpable abdominal mass, or gastrointestinal bleeding. Patients with bone marrow involvement may have symptoms related to anemia, neutropenia, or thrombocytopenia. Other sites of extranodal disease include the testes and bone. The incidence of solitary brain lymphoma is increasing, especially in patients with AIDS.

DIAGNOSIS, STAGING, AND PROGNOSTIC FACTORS

As with Hodgkin's lymphoma, the diagnosis of NHL must be established by pathologic review of tissue obtained by biopsy.⁵⁶ The preferred procedure is an excisional biopsy, where the entire involved lymph node is removed for review by an experienced hematopathologist. This procedure should be done carefully to prevent distortional artifact of the architecture, which could lead to an inaccurate diagnosis. Needle biopsy of the node can sometimes provide adequate tissue for pathologic diagnosis, if an excisional biopsy cannot be performed. When adenopathy is not present, diagnosis may be established by biopsy of cutaneous lesions, bone marrow biopsy and aspiration in patients with unexplained myelosuppression, liver biopsy in patients with hepatomegaly or elevated liver function transaminases, or biopsy of involved extranodal organs, such as bone, Waldeyer ring, lung, and testis.

After the diagnosis is established, further workup is required to determine the extent of involvement.^{46,56,57} Clinical staging always begins with a thorough history and physical examination. Patients should be questioned about the presence or absence and extent of fever, night sweats, and weight loss. A detailed history of lymphadenopathy should also be obtained, including when and where the lymph nodes were first noted, and their rate of growth. A complete physical examination is performed to assess the extent of disease involvement, with special attention given to all nodal areas (see Fig. 135–1). All patients should have a complete blood count, serum chemistries including liver and renal profiles, a chest radiograph, and bone marrow aspiration and biopsy. The likelihood of bone marrow involvement varies among the different histologic types of lymphoma (Table 135–7). Lumbar puncture to evaluate the cerebrospinal fluid is recommended in patients who have histologic types of lymphoma that often spread to the CNS.

Imaging studies are usually important in the staging workup.^{56,57} CT scanning can identify both nodal and extranodal sites of disease, and has largely replaced lymphangiography for the evaluation of retroperitoneal lymphadenopathy. The abdominal and pelvic CT

scan can identify mesenteric and retrocrural node involvement. CT scans can also detect tumor involvement of organs, including the kidneys, ovary, spleen, and liver. PET is strongly recommended in patients with potentially curable aggressive NHLs, but it is expensive and not available at all centers.⁵⁸ Magnetic resonance imaging is of limited usefulness in the staging of NHL. Gallium scans are sometimes used as part of the staging work up. Other tests, such as liver–spleen scan, bone scan, upper gastrointestinal series, and intravenous pyelogram, are sometimes useful in patients with organ symptomatology or serum chemistry abnormalities.

Although staging laparotomy was widely used in the late 1960s and 1970s as part of the staging workup in patients with lymphoma, it is rarely used today because of technical improvements in imaging studies and the morbidity and potential mortality associated with the procedure.

The Ann Arbor staging classification developed for the clinical staging of Hodgkin's lymphoma is also used to stage patients with NHL (see Table 135–3). After completion of the staging workup, most patients will be found to have advanced disease (stages III and IV). The frequency of localized disease at the time of diagnosis varies depending on the histologic type of lymphoma (see Table 135–7). Stage is a more important prognostic factor in Hodgkin's lymphoma than in NHL.

7 The Ann Arbor system emphasizes the distribution of nodal disease sites because Hodgkin's lymphoma usually spreads through contiguous lymph nodes and does not involve extranodal sites. But NHL is a disease with tremendous heterogeneity that does not spread through contiguous lymph nodes and that often involves extranodal sites. As a result of these clinical differences between Hodgkin's lymphoma and NHL, Ann Arbor stage correlates poorly with prognosis.

8 This lack of accuracy with the Ann Arbor staging system in NHL has led to several international projects to develop prognostic models for the most common types of NHLs—diffuse large B-cell lymphomas and follicular lymphomas. The International Non-Hodgkin's Lymphoma Prognostic Factors Project was based on more than 2,000 patients with diffuse aggressive lymphomas treated with an anthracycline-containing combination chemotherapy regimen in the United States, Europe, and Canada.⁵⁹ The Project identified five risk factors that correlated with low response to chemotherapy and poor survival: (a) age >60 years, (b) reduced performance status ≥ 2 , (c) abnormal serum lactate dehydrogenase (LDH) levels, (d) two or more extranodal sites of disease, and (e) advanced tumor stage (Ann Arbor stages III or IV; Table 135–8). In patients ≤ 60 years old, three risk factors correlated with low response to chemotherapy and poor survival: (a) reduced performance status, (b) abnormal serum LDH levels, and (c) Ann Arbor stage. It is unclear whether the effect of serum LDH level is related to a tumor or a host event. LDH likely measures cellular catabolism (the enzyme is released from injured cells), or the product of tumor burden and proliferation. Because each of the factors has about the same impact (e.g., relative risk) on prognosis, the number of adverse risk factors is summed to provide the IPI. Patients could, therefore, have a score of 0 to 5. Table 135–8 shows the correlation between four risk groups based on the IPI score and complete response rate and 5-year survival. For patients ≤ 60 years old, a simplified IPI score can be developed based on Ann Arbor stage, serum LDH, and performance status.

As prognosis improves as a result of more effective therapy, it is important to reevaluate prognostic factors. The IPI was based on patients treated from 1982 to 1987 with anthracycline-based combination chemotherapy; none of the patients received rituximab. In a reexamination of the IPI in a cohort of patients treated with rituximab-containing chemotherapy, Sehn et al. found that the IPI remained predictive but it only identified two, rather than four, risk groups.⁶⁰ When the number of risk factors is redistributed, three

Data from The International Non-Hodgkin's Lymphoma Prognostic Factors Project. A predictive model for aggressive non-Hodgkin's lymphoma. *N Engl J Med* 1993;329:987–994. Copyright © 1993 Massachusetts Medical Society.

risk groups are identified that correlate with prognosis. This revised IPI score may more accurately predict prognosis in patients treated with rituximab-containing combination chemotherapy, but needs to be validated in a larger group of patients.

Although the IPI is often used to predict prognosis in patients with other NHL subtypes, the IPI has several shortcomings when applied to patients with indolent lymphomas. Because only patients with diffuse aggressive lymphomas were used to develop the IPI system, some important prognostic factors may have been missed. Furthermore, the IPI system has limited discriminating power in follicular lymphoma because only approximately 10% of patients are categorized as high-risk in the IPI system. To address these concerns, an international cooperative study was designed to develop a prognostic model similar to the IPI in patients with follicular lymphoma. The results of that study, which was based on more than 4,000 patients with follicular lymphoma diagnosed between 1985 and 1992, was recently published.⁶¹ Five factors were identified that correlated with poor survival: (a) age >60 years, (b) advanced tumor stage (Ann Arbor stage III or IV), (c) low hemoglobin level (<12 g/dL), (d) five or more nodal sites of disease (see Fig. 135–1), and (e) an abnormal serum LDH level. Analogous to the IPI, the number of adverse risk factors is summed to provide the Follicular Lymphoma International Prognostic Index (FLIPI). Three prognostic groups were identified: low-risk (0 to 1 factors), intermediate-risk (2 factors), and high-risk (≥ 3 factors). The new system appeared to have higher discriminating power among groups as compared with the IPI system. Table 135–9 shows the correlation between the FLIPI score and overall survival.

Although IPI and FLIPI are clinically useful tools to estimate prognosis, the factors used to calculate these scores probably represent clinical surrogates for the biologic heterogeneity among NHLs and many researchers are interested in determining the prognostic importance of certain phenotypic and molecular characteristics of NHLs. For example, markers of apoptosis, cell-cycle regulation, cell lineage, and cell proliferation are being evaluated as potentially clinically useful prognostic factors.⁶² Gene expression profiling with microarrays may also correlate with survival. Using gene expression profiling, investigators identified at least two molecularly distinct

forms of diffuse aggressive lymphomas based on gene expression patterns indicative of different stages of B-cell differentiation: germinal center B-cell and activated peripheral blood B-cell.⁶³ Patients with the germinal center B-cell profile had significantly better overall survival independent of IPI score after treatment with CHOP (cyclophosphamide, hydroxydaunorubicin, Oncovin, prednisone) or CHOP-like chemotherapy. The investigators used 17 genes to construct a model that correlated with overall survival after chemotherapy. In another study of diffuse aggressive lymphomas, investigators were able to develop a predictive model based on only six genes.⁶⁴ Two molecularly distinct profiles of follicular lymphoma also have been identified; the first included genes encoding for T-cell markers and genes highly expressed in macrophages, and the second included genes that are preferentially expressed in macrophages, dendritic cells, or both.⁶⁵ Patients with the first molecular signature had a more favorable outcome than those with the second signature. These results suggest that molecular classification of tumors on the basis of gene expression may allow identification of clinically significant subtypes of cancer.

TREATMENT

Non-Hodgkin’s Lymphoma

■ GENERAL TREATMENT PRINCIPLES

The primary goals in the treatment of NHL are to relieve symptoms, cure the patient of their disease whenever possible, and minimize the risk of serious toxicities. The treatment strategy depends on many factors, including patient’s age, concomitant disease, disease type, stage of disease, site of disease, and patient preference.

9 Historically, both the clinical behavior and degree of aggressiveness are often used to describe NHLs. Indolent lymphomas, which make up approximately 25% to 40% of all NHLs, are characterized by their slow-growth behavior. Patients with an indolent lymphoma usually have a relatively long survival (measured in years), with or without aggressive chemotherapy. Although these lymphomas respond to a wide range of therapeutic approaches, there is no convincing evidence of a survival plateau, which indicates that patients are rarely cured of their disease. In contrast, aggressive lymphomas, which make up approximately 60% to 75% of all NHLs, are characterized by rapid growth rate and short survival (measured in weeks to months), if appropriate therapy is not initiated. Despite their more aggressive nature, many patients with aggressive lymphomas who respond to chemotherapy can experience prolonged disease-free survival and some are cured of their disease. Therefore, the terminology for the NHLs represents a paradox, where “indolent” is bad and “aggressive” is good in terms of the likelihood for cure.

Therapeutic approaches to NHL include radiation therapy, chemotherapy, and biologic agents.⁴⁶ The role of radiation therapy in the treatment of NHL differs from its role in the treatment of Hodgkin’s lymphoma. Although the disease responds to radiation therapy, only a small percentage of patients with NHL present with truly localized disease that can be treated with local or regional radiation therapy. Radiation therapy is used more commonly in advanced disease, primarily as a palliative measure to control local bulky disease.

Effective chemotherapy for NHL ranges from single-agent therapy in indolent lymphomas to aggressive, complex chemotherapy regimens in aggressive lymphomas. The most active agents used in the treatment of NHL include the alkylating agents (e.g., cyclophosphamide, chlorambucil), bleomycin, doxorubicin, purine analogs, etoposide, methotrexate, vincristine, and corticosteroids (e.g., prednisone, dexamethasone). The most aggressive chemotherapy approaches are dose-dense chemotherapy or high-dose chemotherapy followed by autologous or allogeneic HSCT.

B-cell lymphomas have served as a model for immunotherapy with monoclonal antibodies for more than 20 years, beginning with the successful use of custom-made monoclonal antibodies targeted against the idiotype present on the patient’s cancer cells.⁶⁶ These encouraging results lead to the development of monoclonal antibodies against a more “generic” target, a molecule on the surface of B cells that would be present on tumor cells.⁶⁶ One potential target, the CD20 molecule, is present only on cells in the B-lymphocyte lineage. It is expressed on the surface of both normal and malignant B cells, but not on other normal tissues. Rituximab (Rituxan) is a chimeric monoclonal antibody directed at the CD20 molecule.⁶⁶ Since rituximab was approved in November 1997 to treat relapsed or refractory indolent or follicular CD20⁺ lymphomas, it has become one of the most widely used therapies for NHL. More recently, two radiolabeled monoclonal antibodies (i.e., radioimmunoconjugates) targeted against the CD20 antigen were approved. With the availability of monoclonal antibodies and radioimmunoconjugates for the therapy of lymphoma, nearly all patients with NHL will receive one or more biologic agents during the course of their disease.

Objective response to therapy for NHL should be defined according to the International Workshop to Standardize Response Criteria for Non-Hodgkin’s Lymphoma, which was recently updated to incorporate the results of newer tests to monitor response such as PET, immunohistochemistry, and flow cytometry.⁵⁸ The revised guidelines describe criteria for response (e.g., complete response, partial response, and stable disease) and survival (e.g., overall, disease-free, event-free, progression-free).

Appropriate therapy for NHL depends on the patient’s age, histologic type, stage of disease, site of disease, and presence of adverse prognostic factors (as measured by IPI or FLIPI score), and patient preferences. In general, treatment of lymphoma can be divided into limited disease and advanced disease. Limited disease includes those patients with localized disease (Ann Arbor stages I and II). Advanced disease is defined as all Ann Arbor stage III or IV patients, and also frequently includes Ann Arbor stage II patients with poor prognostic features (see Tables 135–8 and 135–9).^{59,61}

The following section discusses the clinical characteristics and therapy of the most common disease entities.

■ INDOLENT LYMPHOMAS

Follicular Lymphomas

The combined group of follicular lymphomas makes up the second most common histologic type of NHL in the United States, comprising approximately 20% of all NHLs worldwide and up to 70% of indolent lymphomas reported in American and European clinical trials.^{54,67} These lymphomas are classified as *follicular small cleaved cell*, *follicular mixed cell*, and *follicular large cell lymphoma* in the

Working Formulation.⁵¹ The WHO classification includes criteria for grading follicular lymphoma based on the number of centroblasts per high-power field: grade 1 (0 to 5 centroblasts/high-power field), grade 2 (6 to 15 centroblasts/high-power field), and grade 3 (>15 centroblasts/high-power field).¹³ The clinical behavior and treatment outcome of grades 1 and 2 follicular lymphoma are similar, and they are usually treated as indolent lymphomas. In contrast, grade 3 follicular lymphoma is synonymous with what is often referred to as follicular large cell lymphoma and is usually treated as an aggressive lymphoma.

Follicular lymphomas tend to occur in older adults, with a slight female predominance (see Table 135–7). Most patients have advanced disease at diagnosis, but approximately 25% to 33% of patients have localized disease (clinical stage I or II) at diagnosis.⁵⁴ Extranodal disease, bulky disease, and B symptoms are uncommon features at diagnosis. Most patients with follicular lymphoma have the chromosomal translocation t(14;18) at the time of diagnosis.

The clinical course is generally indolent, with median survivals of 8 to 10 years. But the natural history of follicular lymphoma can be unpredictable. Spontaneous regression of objective disease has been noted in as many as 20% to 30% of patients.⁶⁸ There is also a high conversion rate of follicular lymphoma to a more aggressive histology over time that steadily increases after diagnosis and reaches 40% to 70% at 8 to 10 years.^{46,68} At autopsy, 95% of patients with follicular lymphoma have some evidence of diffuse large B-cell lymphoma. Patients with transformed indolent lymphoma should be treated in the same way as an aggressive lymphoma.

Most patients have dramatic responses to initial therapy, and their disease course is characterized by multiple relapses, with responses to salvage therapy becoming progressively shorter after every relapse, eventually leading to death from disease-related causes.⁶⁸ This pattern of constant relapses over time without evidence of a survival plateau and the failure of randomized controlled trials to show a survival benefit with aggressive chemotherapy led to the conclusion that therapy does not prolong overall survival and patients are not cured of their disease. However, several recently published studies suggest that the use of biologic agents, particularly rituximab, has changed the natural history of the follicular lymphoma. In a study of patients enrolled in Southwest Oncology Group (SWOG) trials over a period of more than 20 years, patients treated with CHOP and a monoclonal antibody had a significantly longer 4-year overall survival than those treated with CHOP alone (91% vs. 69%).⁶⁹ Similar results were reported in patients treated over a 30-year period at the M.D. Anderson Cancer Center.⁷⁰ That study also showed an apparent plateau in the failure-free survival curve.

Certain subsets of patients with follicular lymphoma have a much better or worse prognosis.⁶² Some studies suggest that the natural history of follicular large cell lymphoma (i.e., grade 3 follicular lymphoma) is similar to that of other aggressive lymphomas and that treatment with intensive combination chemotherapy regimens may result in long-term disease-free survival, including a possible plateau in the survival curve.^{67,71} The recent development of the FLIPI prognostic model should help clinicians to identify patients in different prognostic groups based on disease characteristics at the time of diagnosis.⁶¹ Patients who are predicted to have a poor prognosis (i.e., high-risk) could then be offered aggressive or experimental therapy, whereas those who are predicted to have a good prognosis (i.e., low-risk) would be treated with standard therapy, avoiding unnecessary toxicity.

Treatment of Localized Disease (Stages I and II) Radiation therapy is the standard treatment for early stage follicular lymphoma. Involved-field, extended-field, and total nodal irradiation have been used. Carefully staged patients with either stage I or contiguous stage II disease treated with radiation therapy alone can achieve disease-free survival rates of 40% to 50% and overall survival

rates of 60% to 70% at 10 years.^{67,72} Late relapses are uncommon; only 10% of patients who reached 10 years without relapse subsequently experienced a recurrence.

Chemotherapy is not usually given in most patients with localized follicular lymphoma, but it may be helpful in some patients with high-risk stage II disease (e.g., multiple sites of involvement or bulky disease).⁷³

⑩ Approximately 40% to 60% of patients with clinical stage I or II follicular lymphoma are cured of their disease with radiation therapy alone.^{67,72} Most centers use radiation at a dose of 30 to 40 Gy to either involved (i.e., local) or regional fields, which would consist of irradiation to the involved nodal region plus one additional uninvolved region on each side of the involved nodes. Extended-field irradiation is not usually used because of the absence of a survival benefit and possible increased risk of secondary malignancies. In addition, previous use of extended-field irradiation compromises the ability of that patient to receive subsequent chemotherapy. The current NCCN guidelines state that locoregional radiation therapy, chemotherapy followed by radiation therapy, or extended-field radiation therapy are appropriate options for patients with early-stage follicular lymphoma.⁵⁷

Treatment of Advanced Disease (Stages III and IV) ⑩ The management of stages III and IV indolent lymphomas remains controversial because until recently, no therapeutic approaches had been shown to prolong overall survival despite the high complete remission rates to initial therapy. However, the results of recently published studies suggest that the initial use of biologic therapy such as rituximab is associated with longer overall survival.^{69,70} More than 80% of patients with stage III or IV follicular lymphoma are alive at 5 years, and the median survival ranges between 7 and 10 years.

Therapeutic options for these patients are diverse and include watchful waiting, radiation therapy, single-agent chemotherapy, combination chemotherapy, biologic therapy, radioimmunotherapy, and combined-modality therapy.^{46,67,72,74} Although complete remission can be achieved in 50% to 80% of patients with various treatments, the median time to relapse is usually only 18 to 36 months. Approximately 20% of patients who have a complete response remain in remission for longer than 10 years. After relapse, patients are retreated and, again, high remission rates can be achieved. Unfortunately, response rates and duration of response both decrease with each retreatment.

Two different initial treatment approaches exist and are described as conservative or aggressive. Patients treated with the conservative approach receive no initial therapy followed by single-agent chemotherapy, rituximab, or radiation therapy when treatment is needed. Candidates for the conservative approach are usually older, asymptomatic, and have minimal tumor burden. Patients with symptoms, extensive extranodal involvement, bulky disease, or impaired end-organ function at the time of diagnosis are not candidates for conservative treatment. With the aggressive approach, patients usually receive combination chemotherapy, with or without rituximab, or radioimmunotherapy early in the disease course. Both conservative and aggressive approaches are listed as possible options in the current NCCN guidelines, but the guidelines recommend that initial therapy should include rituximab unless contraindicated.⁵⁷ Patients who respond to induction therapy may receive maintenance therapy with single-agent rituximab.

At the time of relapse, many treatment options are available,^{57,67,75} and the following factors must be considered: age, symptomatic status of the patient, tumor burden, rate of regrowth (based on previous assessment of active disease sites), presence or absence of characteristics suggesting transformation or biologic progression, prior therapy, degree and duration of response to prior therapy, availability of clinical trials, and patient preferences.

No Initial Therapy. Because there are no convincing data that standard treatment approaches have improved survival, some clinicians have adopted a “watch-and-wait” approach for asymptomatic patients where therapy is delayed until the patient experiences systemic symptoms or disease progression such as rapidly progressive or bulky adenopathy, anemia, thrombocytopenia, or disease in threatening sites such as the orbit or spinal cord.^{74,76} The median time until treatment was required is 3 to 5 years, and approximately 20% of patients do not require therapy for up to 10 years. The 10-year survival is 73%, which is not significantly different from patients who received therapy at the time of diagnosis. In a randomized study of asymptomatic patients with indolent lymphomas (mostly follicular), patients who underwent watchful waiting had similar cause-specific and overall survival as compared with those who received immediate chlorambucil.⁷⁷ With a median length of followup of 16 years, approximately 17% of patients who were randomized to the watchful waiting group died of other causes without receiving chemotherapy and an additional 9% are alive and have not yet had chemotherapy. As described above, patients with follicular lymphoma who are followed without therapy sometimes have spontaneous regressions that can be complete while the disease in other patients can convert to a more aggressive histology. If the watchful waiting approach is chosen, the patient should be evaluated at least every 2 months for the first year and quarterly thereafter, so that intervention can occur before serious problems occur.

Radiation. Follicular lymphoma is sensitive to radiation therapy, and total lymphoid irradiation or whole-body irradiation has been used to treat patients with advanced follicular lymphoma. Although the results with total lymphoid irradiation have been excellent in selected patients with limited-stage III follicular lymphoma,⁶⁷ extensive radiation therapy is rarely used for patients with advanced follicular lymphoma requiring systemic therapy because of concerns regarding prolonged myelosuppression and difficulties in administering future treatments. Total lymphoid irradiation has been given in combination with chemotherapy, but studies fail to show a survival advantage for combined modality treatment.⁶⁷ As a result, new high-dose chemotherapy regimens usually do not include the use of total lymphoid irradiation.

Chemotherapy. Oral alkylating agents, given either alone or combined with prednisone, have been the mainstay of treatment for follicular lymphoma. More intensive chemotherapy has not been shown to improve patient outcome. In a randomized trial of oral chlorambucil (0.1 to 0.2 mg/kg/day), oral cyclophosphamide (1.5 to 2.5 mg/kg/day), or CVP (cyclophosphamide, vincristine, and prednisone) in patients with indolent lymphoma, no significant difference in overall survival or freedom-from-relapse between the three groups was observed.⁶⁸ In a more recently published randomized trial of single-agent cyclophosphamide (100 mg/m²/day) versus CHOP-B (cyclophosphamide, doxorubicin, vincristine, prednisone, and bleomycin), no significant difference in overall time to failure or overall survival was observed at 10 years.⁷⁸ The dosage of single-agent chlorambucil or cyclophosphamide is usually adjusted to maintain a platelet count above 100,000 cells/mm³ and a white blood cell count above 3,000 cells/mm³. Although single-agent alkylating agents have a high initial complete remission rate, the time required to achieve a complete response is slow (median time is 9 to 12 months). Complete responses occur more rapidly with combination chemotherapy, particularly with doxorubicin-containing regimens. Many clinicians will therefore give CHOP or CHOP-like chemotherapy when a rapid response is necessary. The development of the CHOP regimen is described in more detail in Aggressive Lymphomas below. Table 135–10 shows the CHOP regimen that is widely used in the treatment of NHL. In those who achieve a complete response, the duration of response is relatively

TABLE 135-10 CHOP Regimen

Drug	Dose (mg/m ²)	Route	Treatment Days
Cyclophosphamide	750	IV	1
Doxorubicin	50	IV	1
Vincristine	1.4	IV	1
Prednisone	100	Oral	1–5
One cycle is 21 days			

Another name for doxorubicin is hydroxydaunorubicin.

short (about 2.5 years). There is no benefit of maintenance therapy with chemotherapy. After the “best” response is achieved, many experts will discontinue therapy and observe.

Both single-agent alkylating agents and CVP are well tolerated by most patients. The advantages of oral chlorambucil are no hair loss, little or no nausea, and minimal myelosuppression. Because of its mild side effect profile, oral chlorambucil is usually recommended for older patients who are minimally symptomatic or who have other comorbidities. There are some concerns with the risk of secondary acute leukemia in patients receiving continuous exposure to alkylating agents.

Purine Analogs. Several studies report encouraging results with two adenosine analogs, fludarabine phosphate and cladribine (2-chlorodeoxyadenosine), in previously untreated and relapsed advanced follicular lymphoma.⁷⁹ The mechanism of action for both drugs is not well understood, but both agents accumulate in lymphocytes and are resistant to adenosine deaminase. In patients with relapsed or refractory indolent lymphoma, single-agent fludarabine has an overall response rate of almost 50% and a complete response rate of 10% to 15%. Response rates are higher in previously untreated patients, with overall and complete response rates of 70% and almost 40%, respectively. The median time to progression is less than 6 months for relapsed disease and more than 12 months for previously untreated patients. Although the response rates to 2-chlorodeoxyadenosine in previously untreated patients is similar to those with fludarabine, the duration of response appears to be shorter with 2-chlorodeoxyadenosine.

Combination regimens that include one of these purine analogs are also being investigated.⁷⁹ Fludarabine and mitoxantrone (FN) and fludarabine, mitoxantrone, and dexamethasone (FND), given with or without rituximab, are examples of fludarabine-containing regimens that show encouraging results in patients with indolent lymphoma.

Purine analogs usually do not cause nausea and vomiting or hair loss, but they are associated with cumulative and prolonged myelosuppression and profound immunosuppression, which increases the risk of opportunistic infections, such as fungal infections, *Pneumocystis jiroveci* pneumonia, and viral infections. Because the use of fludarabine-based regimens may impair stem cell mobilization and collection, some experts avoid fludarabine-based regimens for patients who are potential candidates for autologous HSCT.

Interferon Alfa. Single-agent interferon- α (IFN- α) is active in the treatment of follicular lymphoma, but is not curative.⁸⁰ Several randomized controlled trials have evaluated the potential benefit of adding IFN- α to combination chemotherapy. Based on the results of one of these trials, IFN- α_{2b} (Intron A) was granted FDA approval as initial treatment for patients with clinically aggressive follicular lymphoma and a large tumor burden, in combination with an anthracycline-containing regimen. Its approval was based on the Groupe d’Etude des Lymphomes Folliculaires (GELF) trial, which compared CHVP (cyclophosphamide, doxorubicin, teniposide, and prednisone) to CHVP and IFN- α_{2b} .⁸¹ CHVP was given monthly for six cycles, then every 2 months for six more cycles, whereas IFN- α_{2b} was given at a dose of 5 million units three times a week for 18

months. Patients who received concurrent IFN- α_{2b} had a significantly higher response rate (85% vs. 69%), which translated into significant differences in median progression-free survival (2.9 years vs. 1.5 years) and overall survival (not reached vs. 5.6 years).

At least 10 randomized controlled trials in the United States and Europe have evaluated the role of IFN- α either during induction, as maintenance therapy, or in both settings. The results of these trials have been inconsistent.⁸² In a meta-analysis of more than 1,500 newly diagnosed patients from the various randomized trials, the efficacy of IFN- α depended on the intensity of the initial chemotherapy regimen and the IFN- α dose.⁸³ The major conclusion of the meta-analysis was that IFN- α was probably beneficial in patients receiving relatively intensive initial chemotherapy (anthracycline- or anthracene-containing regimen) and at a dose of ≥ 5 million units ($\geq 36 \times 10^6$ units per month).

In the most recent randomized controlled trial, 571 patients with stage III or IV indolent NHL (mostly follicular) were studied as part of a SWOG trial. Patients who responded to intensive chemotherapy that consisted of six to eight cycles of prednisone, methotrexate, doxorubicin, cyclophosphamide, and etoposide/mechlorethamine, vincristine, procarbazine, and prednisone (ProMACE-MOPP) or chemotherapy plus irradiation therapy were randomized to receive either consolidation IFN- α_{2b} (2 million units/m² given subcutaneously three times weekly) for 2 years or observation.⁸⁴ With a median follow-up of more than 6 years, no difference in progression-free or overall survival was observed.

The reasons for the divergent results cannot be easily explained.⁸² Based on these negative results, the significant cost and toxicities associated with this agent and the recent availability of other treatment options, most clinicians no longer use IFN- α in patients with indolent lymphomas.

Rituximab. The approval of rituximab is arguably the most important recent development in the treatment of NHL. Its initial approval in 1997 was based on an open-label multicenter study that enrolled 166 patients with relapsed or recurrent indolent lymphoma.⁸⁵ Rituximab, given intravenously at a dose of 375 mg/m² weekly for 4 weeks, resulted in an overall response of 48% (complete response: 6%, partial response: 42%). Median time to progression for responders was 13.2 months and median duration of response was 11.6 months. Other studies of single-agent rituximab in patients with relapsed or refractory indolent NHL have reported overall response rates of 40% to 60% and complete response rates of 5% to 10%.⁸⁶

Based on the activity of rituximab in relapsed or refractory patients, it is increasingly being used as first-line therapy, either alone or in combination with chemotherapy.^{86,87} When given as a single-agent to patients with previously untreated indolent NHL, the overall response rate is 60% to 70% and the complete response rate is 20% to 30%. It is interesting to note that many of these patients remain in molecular remission (i.e., polymerase chain reaction-negative) at 12 months.

The rationale for the use of rituximab in combination with conventional agents is based on clinical activity of both agents/regimens, non-cross-resistant mechanisms of action, nonoverlapping toxicities, and synergistic antitumor activity in vitro. Many clinical trials have evaluated the use of rituximab in combination with other chemotherapy agents.^{86,87} In a phase II trial of six courses of rituximab and CHOP chemotherapy (R-CHOP), the overall and complete response rate in 40 patients with previously untreated or relapsed indolent lymphoma was 95% and 55%, respectively.⁸⁸ More than 70% of patients were progression-free after 4 years of followup. In an updated analysis, median time-to-progression was reached at 82 months.⁸⁹ Based on these encouraging results, several randomized controlled trials have evaluated rituximab in combination with various chemotherapy regimens in first-line therapy for follicular or other indolent lymphomas.^{72,87} In the R-CHOP versus CHOP trial,

patients who were randomized to receive R-CHOP as initial therapy had significantly higher overall response rates (96% vs. 90%), reduced risk for treatment failure (relative risk = 0.4), and longer time-to-treatment-failure and overall survival.⁹⁰ In another randomized trial of R-CHOP versus CHOP in relapsed or resistant follicular lymphoma, patients treated with R-CHOP had higher overall and complete response rates (85% vs. 72% and 30% vs. 16%, respectively) and lower risk of treatment failure (hazard ratio = 0.65), but no significant difference in overall survival was observed.⁹¹ Similar results were reported when rituximab was added to other combination regimens.^{72,87} In a meta-analysis of all randomized controlled trials, patients with indolent lymphoma treated with rituximab and chemotherapy had a significantly higher overall response rate and reduced risk of treatment failure (hazard ratio [HR] = 0.62) and death (HR = 0.65).⁹² In 2006, rituximab was FDA-approved for first-line therapy for follicular lymphoma in combination with CVP chemotherapy.

Rituximab and CHOP chemotherapy can be combined in many different ways.⁹³ In the R-CHOP regimen developed by Czuczman et al., two doses of rituximab are given before the start of CHOP therapy; two more doses are given in the middle of the six cycles of CHOP; and two additional doses are given at the end of CHOP therapy.⁸⁸ However, in most NHL protocols and in clinical practice, rituximab is given on day 1 of CHOP chemotherapy.⁹³ In some protocols, rituximab is given on the day before chemotherapy (i.e., day 0) or rituximab is given on day 1 and the other drugs are given on day 3.

In patients who respond to rituximab, either alone or combined with chemotherapy, maintenance therapy with single-agent rituximab is often given to prolong the duration of remission. In a phase II study, patients with indolent lymphoma who responded to first-line single-agent rituximab received maintenance rituximab, given at a dose of 375 mg/m² weekly for 4 weeks every 6 months, in an attempt to improve the initial therapeutic response and prolong duration of remission.⁹⁴ With continued maintenance therapy, the final response rate increased to 73%, with 37% complete responses. Median progression-free survival was 34 months. Based on these encouraging results, several randomized controlled trials were initiated in previously untreated or chemotherapy-treated patients with indolent lymphoma.^{74,87} Patients in these trials received induction therapy with either single-agent rituximab or combination chemotherapy with or without rituximab. Several different maintenance rituximab schedules have been used: 375 mg/m² weekly for 4 weeks every 6 months for 2 years or 375 mg/m² every 2 to 3 months for 1 to 2 years.^{87,93} Administration every 2 to 3 months is supported by the observation that therapeutic rituximab levels are maintained for about 3 months.⁹³ The results of these trials show that maintenance single-agent rituximab significantly prolongs progression-free and overall survival as compared with observation or rituximab retreatment at the time of disease progression.⁸⁷ In 2006, rituximab was FDA-approved as maintenance therapy for patients with stable disease or who achieve a partial or complete response following induction chemotherapy.

Most of the adverse effects of rituximab are infusion-related, particularly after the first infusion, and consist of fever, chills, respiratory symptoms, fatigue, headache, pruritus, and angioedema.⁸⁷ Pre-medication with oral acetaminophen 650 mg and diphenhydramine 50 mg is usually given 30 minutes before rituximab infusion.

Radioimmunotherapy. The recent approval of the anti-CD20 radioimmunoconjugates—¹³¹I-tositumomab (Bexxar) and ⁹⁰Y-ibritumomab tiuxetan (Zevalin)—has provided clinicians with a novel treatment option for patients with indolent NHLs.^{72,95,96} Both ¹³¹I-tositumomab and ⁹⁰Y-ibritumomab tiuxetan are mouse antibodies linked to a radioisotope, either iodine-131 (¹³¹I) or yttrium-90 (⁹⁰Y). Indolent lymphomas are known to be responsive to radiation therapy (i.e., radiosensitive), and the rationale of radioimmuno-

therapy is that the antibody will act as a “guided missile” to deliver its payload (i.e., radiation) to its target (i.e., lymphoma cells that express the CD20 antigen). The specificity of the monoclonal antibody allows delivery of the radiation selectively to the tumor (and adjacent normal tissues).

Radioimmunoconjugates have some advantages and disadvantages over unlabeled (“naked”) monoclonal antibodies such as rituximab. Tumor cell kill following rituximab depends on binding of the antibody to the tumor cell and the host immune system. Therefore, tumor cells that do not express the target antigen are not accessible to the antibody, or those that are resistant to immune-mediated attacks may escape treatment. Radioimmunoconjugates, because of their ability to deliver radiation over a distance from a source, can not only kill tumor cells that are in contact with the antibody, but also adjacent tumor cells which may not have been in contact with the antibody or may not express the target antigen. This effect is sometimes referred to as the relevant bystander or “crossfire” effect. However, one disadvantage of radioimmunotherapy is that it can also damage adjacent normal tissues, such as bone marrow cells.

Both ^{131}I -tositumomab and ^{90}Y -ibritumomab tiuxetan have shown activity in relapsed and refractory patients with indolent or transformed lymphomas.^{72,95,96} In patients who respond to radioimmunotherapy, the duration of remission can be more than several years. Based on these encouraging results, some clinicians consider radioimmunotherapy earlier in the disease course, including patients with previously untreated disease. In a phase II study, patients with previously untreated follicular lymphoma were treated with six cycles of CHOP chemotherapy followed 4 to 8 weeks later by ^{131}I -tositumomab.⁹⁷ The overall response rate to the entire treatment regimen was 91%, including 69% complete remissions, and the 5-year progression-free survival is estimated to be 67%. Similar results were reported in a phase II trial of ^{131}I -tositumomab given without induction CHOP chemotherapy in previously untreated patients with advanced-stage follicular lymphoma.⁹⁸ A current multicenter cooperative group study (SWOG S0016) randomizes previously untreated patients with advanced indolent lymphomas to either CHOP or rituximab (given concurrently, based on the Czuczman regimen⁸⁸) or CHOP and ^{131}I -tositumomab (given sequentially).

Radioimmunotherapy is generally well-tolerated. The major acute toxicities with both radioimmunoconjugates are infusion-related reactions and myelosuppression. ^{131}I -tositumomab can also cause thyroid dysfunction. The primary concern with radioimmunotherapy is the development of treatment-related myelodysplastic syndrome or acute myelogenous leukemia.⁹⁹

The decision to use radioimmunotherapy must be made carefully because of the complexity, risks, and costs of the treatment regimen. Because of safety concerns related to delivery of radiation to bone marrow, candidates for radioimmunotherapy usually have limited bone marrow involvement and adequate absolute neutrophil and platelet counts. Although medical oncologists usually select patients for therapy, the radioimmunotherapy regimen must be administered at a radiation oncology or nuclear medicine facility.

Hematopoietic Stem Cell Transplantation. High-dose chemotherapy, followed by autologous or allogeneic HSCT, is another option for patients with relapsed follicular lymphoma.^{72,75,100} In patients who are transplanted at the time of initial treatment failure, 5-year event-free survival is approximately 40% to 50%. Although the rate of recurrence is lower after allogeneic HSCT as compared with autologous HSCT, that benefit is offset by increased treatment-related mortality after allogeneic HSCT.¹⁰⁰ The presence of a survival plateau after allogeneic HSCT suggests that some patients may be cured of their disease. In a recently published randomized trial, patients with relapsed follicular lymphoma who received autologous HSCT had significantly longer progression-free and overall survival than those who received additional courses of combination chemotherapy.¹⁰¹

Based on these encouraging results, some studies have evaluated autologous HSCT as consolidation therapy after CHOP or CHOP-like chemotherapy in patients with poor-risk follicular lymphoma.⁷² Preliminary results of several randomized controlled trials show that autologous HSCT does not consistently prolong progression-free or overall survival. None of the induction regimens in these trials included rituximab, which further complicates interpretation of these results. Based on these results, autologous HSCT cannot be recommended as first-line consolidation therapy.

Rituximab is being evaluated in the setting of autologous HSCT.^{86,102} It is given pretransplant as an *in vivo* purging agent prior to stem cell collection. In other studies, rituximab is given as posttransplant consolidation.

High-dose myeloablative transplants are usually reserved for younger patients without serious comorbidities, but nonmyeloablative allogeneic transplants may be an option for older patients who would not otherwise be eligible for autologous or allogeneic HSCT.

Investigational Therapies. As discussed above, the idiotype present on the patient's tumor cells serves as a potential target for immunotherapy. This idiotype can be used to manufacture a patient-specific vaccine.¹⁰³ Vaccines would potentially produce both humoral and cellular immune responses, and would also be longer acting than passive immunotherapy. Several vaccines are being evaluated in clinical trials.⁶⁶

Other Indolent Lymphomas

Marginal zone B-cell lymphomas, MALT (extranodal) and nodal types, are two of the new forms of NHL not previously recognized in the Working Formulation.¹⁰⁴ Extranodal and nodal types of marginal zone B-cell lymphomas represent approximately 7.6% and 1.8%, respectively, of new cases of NHLs.⁵⁴ Clinically, MALT lymphomas tend to be indolent. Most patients present with localized disease involving extranodal sites, which involves glandular epithelial tissues of various sites, such as the stomach, lungs, parotid gland, thyroid, and orbit. The stomach is the most frequent site and gastric MALT lymphomas are frequently associated with chronic gastritis and *H. pylori* infection. Because MALT lymphomas tend to remain localized for long periods, local treatment (surgery or local/regional radiation therapy) is effective and offers the opportunity for cure. Patients with gastric MALT lymphomas who are positive for *H. pylori* should be treated for their infection (e.g., antibiotics). Patients with disseminated MALT lymphoma should be treated with the same type of chemotherapy used in patients with follicular lymphoma.

■ AGGRESSIVE LYMPHOMAS

Diffuse Large B-Cell Lymphoma

Diffuse large B-cell lymphomas (DLBCLs) are the most common lymphoma in the International NHL Classification Project, accounting for approximately 30% of all NHLs.⁵⁴ Most DLBCLs are classified as *diffuse large cell cleaved*, *noncleaved*, or *immunoblastic* or *diffuse mixed cell* in the Working Formulation.⁵¹ DLBCLs are characterized by the presence of large cells, which are similar in size to or larger than tissue macrophages and usually more than twice the size of normal lymphocytes. The median age at the time of diagnosis is in the seventh decade, but DLBCL can affect individuals of all ages, from children to the elderly. Patients often present with a rapidly enlarging symptomatic mass, with B symptoms in approximately 30% to 40% of the cases.^{56,105} Approximately 30% to 40% of patients with DLBCL present with extranodal disease; common sites include the head and neck, gastrointestinal tract, skin, bone, testis, and CNS. DLBCL is the most common type of diffuse aggressive lymphomas, which share in common an aggressive clinical behavior that leads to death within weeks to months if the tumor is not treated. Diffuse

aggressive lymphomas are also sensitive to many chemotherapeutic agents, and some patients treated with chemotherapy can be cured of their disease.

Several factors have been shown to correlate with response to chemotherapy and survival in patients with aggressive lymphoma.⁶² Because the IPI was originally developed based on patients with aggressive lymphoma, IPI score correlates with prognosis (see Table 135–8).⁵⁹ As described above, the revised IPI score may more accurately predict prognosis in patients receiving rituximab-containing combination chemotherapy.⁶⁰

Therapy of DLBCL is based on the Ann Arbor stage, IPI (or revised IPI) score, and other prognostic factors.^{46,105,106} About one-half of patients present with localized (stage I or II) disease. However, many patients present with large bulky masses (i.e., larger than 10 cm), and patients with bulky stage II disease are treated with the same approach as that used with those with advanced disease (stage III or IV).

Treatment of Localized Disease (Stages I and II) Before 1980, radiation therapy was the primary treatment for patients with localized DLBCL. Five-year disease-free survival with radiation therapy alone was approximately 50% and 20% in patients with stage I and stage II disease, respectively.^{105,107} Randomized trials in the 1980s showed that radiation therapy followed by chemotherapy resulted in significantly longer disease-free and overall survival as compared with radiation therapy alone. Other studies reported excellent results with a short course of chemotherapy (three cycles) followed by involved-field radiotherapy or six to eight cycles of CHOP chemotherapy, with or without consolidation radiotherapy. With either of these approaches, 5-year progression-free survival was >90% for patients with stage I disease and approximately 70% for patients with stage II disease.^{105,107}

⑪ Because it was not clear which approach was more effective, the SWOG performed a randomized trial that compared three cycles of CHOP and involved-field radiotherapy or eight cycles of CHOP in patients with stage I and nonbulky stage II aggressive lymphoma.¹⁰⁸ Patients treated with three cycles of CHOP plus radiotherapy had significantly better 5-year progression-free (77% vs. 64%) and overall (82% vs. 72%) survival than did patients treated with CHOP alone. The incidence of life-threatening toxicity was higher in patients who received CHOP alone. But with longer followup, more patients who received abbreviated chemotherapy experienced late relapses and the differences in progression-free or overall survival were no longer significant between the two arms. Further subgroup analysis of that trial identified several prognostic factors that led to the development of the stage-modified IPI score.¹⁰⁷ Four adverse risk factors comprise the score: nonbulky stage II disease (bulky stage II disease is considered advanced disease), age >60 years, elevated LDH levels, or performance status ≥ 2 .

The stage-modified IPI score is often used to identify patients with localized aggressive NHL who may have a poor prognosis. Based on the results of this trial, the current standard for therapy of most patients with localized nonbulky aggressive lymphoma without any adverse risk factors is three to four cycles of R-CHOP followed by locoregional radiation therapy (30 to 40 Gy).^{57,105} Five-year median survival in this favorable group of patients exceeds 90%.¹⁰⁷

Five-year median survival is reduced to approximately 70% in patients with at least one adverse risk factor in the stage-modified IPI score.¹⁰⁷ Patients in this high-risk subgroup may benefit from more aggressive chemotherapy (six to eight cycles of R-CHOP) followed by locoregional radiation therapy.⁵⁷

Treatment of Advanced Disease (Bulky Stage II, Stages III and IV) It has been known since the late 1970s that intensive combination chemotherapy can cure some patients with disseminated DLBCL.^{46,105} Initial studies with COP (same as CVP) produced a plateau on the survival curve of just 10%, with a median

survival of less than 1 year. Based on the activity of single-agent doxorubicin, McKelvey et al. developed the CHOP regimen (see Table 135–10).¹⁰⁹ A few years later, a SWOG study showed that CHOP was more active than COP, and CHOP chemotherapy rapidly became the treatment of choice for patients with aggressive lymphomas.¹¹⁰ Studies in larger numbers of patients showed that approximately 50% of patients had a complete remission to CHOP chemotherapy, and 50% to 75% of the patients who had a complete response (about one-third of all patients) experienced long-term disease-free survival and cure of their disease.

In an effort to improve these results, many investigators used several general approaches to develop second- and third-generation regimens in the 1980s and early 1990s.^{46,105} Results of phase II trials suggested that these second- and third-generation regimens were more active than CHOP, with slightly higher complete response rates and improved disease-free survival rates. However, they were also more difficult to administer, more toxic, and more expensive. Based on these results, many oncologists adopted one of these second- or third-generation combination regimens as their standard regimen for patients with advanced aggressive lymphomas.

Many randomized studies have compared different combination regimens in patients with aggressive lymphoma.^{46,105} Although the results of these studies show that no one regimen is clearly superior to another, they show the superiority of anthracycline-containing regimens over those that do not contain an anthracycline. In the largest and most widely quoted study, the SWOG initiated a randomized trial in 1986 that compared CHOP to three of the most commonly used third-generation regimens in nearly 900 patients with bulky stage II, stage III, or stage IV aggressive NHL. At the time of the initial publication (median followup: 35 months), no differences in disease-free and overall survival were observed between the four groups.¹¹¹ Furthermore, no significant differences in disease-free or overall survival were observed in any subgroup of patients. But the risk of treatment-related mortality was higher in patients receiving one of the third-generation regimens. Extended followup of that trial shows that approximately 35% of patients who participated in that trial are probably cured of their disease, regardless of the initial combination chemotherapy regimen.¹⁰⁷ Interestingly, the overall survival is approximately 10% higher than the disease-free survival, which probably reflects the effectiveness of salvage high-dose chemotherapy with autologous HSCT (see Treatment of Refractory or Relapsed Disease section below).

Based on the lack of survival benefit with the newer combination chemotherapy regimens, the less complicated and less expensive CHOP regimen was considered as the treatment of choice for most patients with DLBCL and other aggressive NHLs for many years. Even with CHOP chemotherapy, however, less than 50% of patients with DLBCL were cured of their disease and most patients who relapse after an initial response do so in the first 2 years. New treatment approaches were clearly needed.

Several studies attempted to improve treatment results by increasing chemotherapy dose (i.e., dose-intensity), shortening the interval between chemotherapy cycles (i.e., dose-density), or both. Because of the increased risk of severe neutropenia, these approaches require growth factor support. Although results of these studies have not consistently shown improved survival, encouraging results from several recently published studies suggest that these approaches be evaluated in future randomized trials.^{112,113}

Based on the encouraging results of R-CHOP in indolent lymphomas, several studies evaluated this combination in aggressive lymphomas.^{87,106,107} The first randomized controlled trial that established the efficacy of R-CHOP in advanced-stage DLBCL showed that R-CHOP significantly increased complete response rates and overall survival in elderly (≥ 60 years old) patients as compared with CHOP alone (discussed in Treatment of Elderly Patients with Advanced Disease

section later).¹¹⁴ Although the results of that study established R-CHOP as standard therapy in older patients, the role of R-CHOP in the treatment of younger patients was not clear. That issue was recently addressed in the MabThera International Trial, which enrolled younger (18 to 60 years old) patients with good-prognosis DLBCL.¹¹⁵ Patients randomized to receive rituximab plus CHOP-like chemotherapy had significantly higher complete response rates (86% vs. 68%) and longer 3-year event-free and overall survival (79% vs. 59% [HR = 0.44] and 93% vs. 84% [HR = 0.40], respectively). Furthermore, in a population-based study conducted in British Columbia, institution of a policy recommending R-CHOP for all patients with newly diagnosed advanced-stage DLBCL resulted in significant improvements in progression-free and overall survival.¹¹⁶ Based on these trial results, rituximab received FDA approval for first-line treatment in combination with CHOP or CHOP-like chemotherapy and R-CHOP is recommended for most patients with advanced-stage DLBCL in the current NCCN Guideline.

Treatment outcomes for high-risk patients according to the IPI (or revised IPI) score are unsatisfactory. High-risk groups generally include all patients older than 60 years and those with an IPI score of ≥ 3 (or an age-adjusted IPI score of ≥ 2). Because progression-free survival is only approximately 50% in these high-risk patients treated with R-CHOP,^{60,117} other more aggressive treatments, preferably as part of a clinical trial, should be considered in these patients. Examples of more aggressive approaches include dose-intense or dose-dense chemotherapy with growth factor support, usually combined with rituximab, or high-dose chemotherapy with autologous HSCT.^{105–107,118}

One approach is to give high-dose chemotherapy with autologous HSCT as intensive consolidation in high-risk patients with DLBCL who achieve a remission with standard chemotherapy.¹¹⁹ Several randomized controlled trials have been conducted in patients with aggressive NHLs, and the results of these trials have been critically reviewed by two independent panels of experts.^{120,121} Based on a review of the available evidence, it was concluded that high-dose chemotherapy with autologous HSCT is effective in high-risk (based on IPI score) patients who have a complete remission to conventional therapy (first complete remission in high-risk patients) and in untreated high-risk patients (high-dose sequential therapy in untreated high-risk patients).¹²¹ There was inadequate evidence to make a treatment recommendation for the other possible clinical situations, such as in patients who do not respond to standard induction therapy (primary refractory disease) or in patients who have a partial remission to standard induction therapy (first partial remission after full-course induction therapy). A recently published meta-analysis of all randomized controlled trials of autologous HSCT as intensive consolidation in aggressive NHL concluded that there was no evidence that autologous HSCT improved outcomes in good-risk patients.¹²² The evidence for high-risk patients was inconclusive.

CLINICAL CONTROVERSY

Because of high relapse rate in patients who have a complete response to R-CHOP, some experts believe that high-dose chemotherapy with autologous HSCT should be considered as consolidation therapy in high-risk patients with aggressive NHLs who have a complete remission to R-CHOP chemotherapy. Other experts, however, believe that the evidence supporting high-dose chemotherapy with autologous HSCT in this setting is inconclusive and that autologous HSCT should be reserved for patients who relapse.

11 In summary, all patients with bulky stage II, stage III, or stage IV disease should be treated with R-CHOP or rituximab and CHOP-

like chemotherapy until a complete response is achieved (usually four cycles).⁵⁷ Clinicians are encouraged to adopt the revised response criteria proposed by the International Working Group.⁵⁸ In patients who have a positive pretreatment PET scan, PET scanning can be useful in response assessment. A rapid response to chemotherapy (i.e., a complete response achieved in the first three treatment cycles) is associated with a more durable remission compared with patients requiring longer treatment cycles. Two or more cycles of chemotherapy should be given following attainment of a complete response (total of six to eight cycles). The use of long-term maintenance therapy following a complete response has not been shown to improve survival. Treatment outcomes for high-risk patients according to the IPI (or revised IPI) score are unsatisfactory and alternative treatment approaches, preferably as part of a clinical trial, should be considered in these patients.⁵⁷ High-dose chemotherapy with autologous HSCT should be considered in high-risk patients who respond to standard chemotherapy and are candidates for autologous HSCT.

Treatment of Elderly Patients with Advanced Disease More than one-half of patients with NHL are older than 60 years of age at diagnosis, and about one-third are older than age 70 years. The International Non-Hodgkin's Lymphoma Prognostic Factors Project showed that patients older than 60 years of age had a significantly lower complete response rate and overall survival.⁵⁹ The reasons for the poorer outcome in elderly patients are not clear. Older patients do not tolerate intensive chemotherapy as well as younger patients, and some studies report that older patients have a higher risk of treatment-related mortality. As a result, many clinicians treat elderly patients with reduced dose or less-aggressive chemotherapy regimens. In general, these less-intensive regimens have used anthracyclines with less cardiotoxicity than doxorubicin, have substituted mitoxantrone for doxorubicin, or have used short-duration weekly therapy.¹⁰⁵

Over the past few years, several nonrandomized and randomized trials have evaluated different treatment approaches in older patients with aggressive NHL.¹⁰⁵ The results of these studies suggest that carefully selected elderly patients with good performance status and without significant comorbidities can tolerate aggressive anthracycline-containing regimens as well as younger patients. These patients should be treated initially with full-dose R-CHOP or similar regimens; dosages can be reduced later if severe toxicity occurs. Hematopoietic growth factors may allow elderly patients to maintain dose intensity.

The combination of rituximab and CHOP (R-CHOP) has replaced CHOP as standard treatment for elderly patients with aggressive lymphoma, based on the results of the Groupe d'Etude des Lymphomes de l'Adulte (GELA) study.¹¹⁴ In that study of 399 elderly patients with DLBCL, patients who were randomized to receive R-CHOP had a significantly higher complete response rate (76% vs. 63%) and longer event-free and overall survival as compared with those who received CHOP. In an updated analysis of that trial, significant differences in 5-year event-free survival (47% vs. 29%) and overall survival (58% vs. 45%) were observed between the two treatment groups.¹¹⁷ In another randomized controlled trial conducted primarily in the United States (Eastern Cooperative Group 4494), elderly (≥ 60 years old) patients who received rituximab, either as induction or maintenance with CHOP chemotherapy, had significantly longer failure-free survival as compared to those not given rituximab during their treatment course.¹²³ Maintenance therapy with single-agent rituximab did not provide any additional benefit in patients who received R-CHOP as induction therapy. It is important to note that rituximab is given differently in the two studies. In the GELA study, rituximab is given on day 1 (the same day that cyclophosphamide, doxorubicin, and vincristine are administered) with each cycle of CHOP chemotherapy.¹¹⁴ In the Eastern Cooperative

Group 4494 study, R-CHOP was modeled after the regimen developed by Czuczman et al.⁸⁸ two doses of rituximab are given before cycle 1, and one dose is given before cycles 3, 5, and 7 (if administered).¹²³ In most NHL protocols and in clinical practice, rituximab is given on day 1 of CHOP chemotherapy.⁹³

Treatment of Refractory or Relapsed Disease Although many patients with aggressive NHL experience long-term survival and cure with intensive chemotherapy, approximately 20% to 30% of patients fail to achieve a complete remission and, of those patients who do achieve a complete remission, approximately 20% to 30% subsequently relapse. Therefore, approximately 30% to 40% of all patients with aggressive NHL will require salvage therapy at some point during their disease course. Response to salvage therapy depends on the initial responsiveness of the tumor to chemotherapy. Patients who achieve an initial complete remission and then relapse generally have a better response to salvage therapy than those who are primarily or partially resistant to chemotherapy.

Many conventional-dose salvage chemotherapy regimens have been used in patients with relapsed or refractory NHL. Many patients who respond to salvage therapy (i.e., chemosensitive relapse) will then receive high-dose chemotherapy with autologous HSCT. In an effort to avoid cross-resistance, most salvage regimens incorporate drugs not used in the initial therapy. Some of the more commonly used salvage regimens include DHAP (dexamethasone, cytarabine, cisplatin), ESHAP (etoposide, methylprednisolone, cytarabine, cisplatin), and MINE (mesna, ifosfamide, mitoxantrone, etoposide), and no one regimen appears to be clearly superior to any other regimen.^{105,124} Rituximab is sometimes added to these salvage regimens. With these salvage regimens, approximately 25% to 35% of patients achieve a complete response, with a median duration of remission of 1 to 2 years. Only approximately 5% to 10% of patients will have long-term disease-free survival.

ICE (ifosfamide, carboplatin, and etoposide) chemotherapy is a newer regimen that has been used in patients with refractory disease. Some clinicians believe that ICE is better tolerated than older cisplatin-based regimens, particularly in older patients. The combination of ICE and rituximab (RICE) is currently being evaluated as a salvage regimen, and early results are encouraging.¹²⁵ Rituximab is given before the first dose of ICE and then weekly during the regimen.

12 To improve the cure rate, many studies have evaluated high-dose chemotherapy with autologous HSCT as intensive consolidation therapy in patients who respond to salvage therapy.^{119–121} In the PARMA study, 215 patients with relapsed aggressive NHL who had a response to DHAP salvage therapy were randomized to receive either high-dose chemotherapy or continued DHAP therapy.¹²⁶ Patients who received high-dose chemotherapy had significantly longer 5-year disease-free survival (46% vs. 12%) and overall survival (53% vs. 32%) than did those treated with conventional salvage therapy. Further analysis of that study showed that patients who relapsed within 12 months of their initial diagnosis were less likely to benefit from high-dose chemotherapy than were patients who relapsed after 12 months. Based on a review of the available evidence, including the PARMA study, it was concluded that high-dose chemotherapy with autologous HSCT is effective in patients who relapse for the first time and who have responded to salvage therapy (first chemotherapy-sensitive relapse).^{120,121} Unfortunately, there was inadequate evidence to make a treatment recommendation for patients who relapse and have not responded to salvage therapy (chemotherapy-resistant relapse). Based on these studies, high-dose chemotherapy with autologous HSCT is considered to be the treatment of choice in younger patients with chemotherapy-sensitive relapse.^{57,105} High-dose chemotherapy with autologous HSCT is not recommended in patients with untested or chemotherapy-refractory relapse.

Rituximab is being evaluated in the setting of autologous HSCT.^{86,102,119} It is given pretransplant as an in vivo purging agent prior to stem cell collection. In one study of patients with aggressive lymphoma, two courses of rituximab (starting at day 42 and 6 months after transplantation) were given as posttransplant consolidation.¹⁰²

Other Aggressive Lymphomas

Mantle cell lymphoma (MCL) is one of the new disease entities that was previously unrecognized by other classification systems.^{107,127,128} This histologic type was found in 6% of cases in the International Lymphoma Classification Project.⁵⁴ The chromosomal translocation t(11;14) occurs in most cases of MCL. MCL usually occurs in older adults, particularly in men, and most patients have advanced disease at the time of diagnosis (see Table 135–7). Extranodal involvement is found in approximately 90% of cases. The course of the disease is moderately aggressive; the median overall survival is about 3 years, with no evidence of a survival plateau.

Patients with disseminated MCL are usually treated with the same intensive combination chemotherapy regimens that are used in diffuse aggressive lymphomas. One widely used combination regimen is HyperCVAD (cyclophosphamide, vincristine, doxorubicin, dexamethasone) alternating with methotrexate and cytarabine. Overall response rates to these regimens is approximately 80%, with about one-half of patients achieving a complete response.^{107,127,128} Median progression-free and overall survival was 20 and 36 months, respectively. Because MCL usually expresses CD20, rituximab, either alone or combined with CHOP, has been used with some success in patients with newly diagnosed and relapsed MCL.^{87,107,127,128} In a meta-analysis of randomized controlled trials, the addition of rituximab to combination chemotherapy was associated with improved overall survival (HR = 0.60).⁹² Despite the high response rates, MCL is not considered curable with standard chemotherapy. Consequently, younger patients who have an initial response to chemotherapy often undergo autologous or allogeneic HSCT as consolidation therapy.^{127,128} The NCCN Guideline recommends that patients with advanced-stage MCL be treated initially with rituximab and combination chemotherapy, followed by autologous or allogeneic HSCT as first-line consolidation therapy.⁵⁷ Unfortunately, most patients with MCL eventually relapse and are treated with salvage therapy or enrolled in trials of investigational agents, some of which are aimed at molecular targets.^{50,107} Bortezomib (Velcade) received FDA approval in 2006 for treatment of relapsed or refractory MCL based on the results of a phase II study that showed a 33% response rate.¹²⁹

Primary mediastinal large B-cell lymphoma is a distinct clinicopathologic entity, accounting for approximately 7% of all DLBCLs and 2.4% of all NHLs in the International NHL Classification Project.⁵⁴ This type of lymphoma tends to occur in younger patients (median age at presentation is 30 years old) and has a female predominance (see Table 135–7).¹³⁰ Patients present with a locally invasive mediastinal mass originating in the thymus, with frequent airway compromise and superior vena cava syndrome. Although the disease course is similar to that of other aggressive lymphomas, the biologic features of primary mediastinal large B-cell lymphoma clearly differentiate it from other types of DLBCL.¹³⁰ Patients with primary mediastinal large B-cell lymphoma should be treated similar to other patients with localized DLBCL.

■ NON-HODGKIN'S LYMPHOMA IN ACQUIRED IMMUNE DEFICIENCY SYNDROME

The risk of NHL for patients with AIDS is increased more than 100-fold as compared to the general population.^{131,132} AIDS-related lymphoma arises as a consequence of long-term stimulation and proliferation of B lymphocytes from HIV and the reactivation of

prior EBV infection as a consequence of HIV-induced immunosuppression. AIDS-related lymphoma usually occurs late in the course of HIV infection and is the cause of death in approximately 15% of HIV-infected individuals. Although HIV infects T cells, more than 95% of AIDS-related lymphomas are B-cell neoplasms. Most cases of AIDS-related lymphomas are classified as Burkitt's or DLBCL.

The clinical presentation is similar to that observed in other immunocompromised states. Most patients with AIDS-related lymphoma present with B symptoms and have advanced-stage (III or IV) disease at the time of diagnosis.¹³¹ Involvement of extranodal sites is common. The clinical course of AIDS-related lymphoma is usually aggressive and has improved with the availability of highly active antiretroviral therapy (HAART). Improved survival has been observed, primarily in patients with DLBCL. Patients with AIDS-related lymphoma treated with intensive therapy have a median survival that is similar to the survival of patients with HIV-negative NHLs.¹³² In the post-HAART era, many of the prognostic factors have also changed and only lymphoma-related factors such as the IPI remain as independent predictors of prognosis.

The treatment of patients with AIDS-associated lymphomas is difficult because the immunocompromised state of these patients increases their risk of significant toxicity as a consequence of myelosuppressive therapy. Except for primary CNS lymphoma, AIDS-related lymphoma is never considered truly localized and systemic chemotherapy is indicated. For patients with adequate immune function and without a history of an opportunistic infection, chemotherapy regimens similar to that used for aggressive lymphomas may be used.^{46,131,132} However, many patients with AIDS-related lymphoma were previously treated with less-intensive regimens because of the increased risk of treatment-related toxicity. In the post-HAART era, however, most clinicians believe that standard doses of chemotherapy can be safely administered to patients who achieve a virologic response to HAART.

The results of treatment with standard chemotherapy regimens have been disappointing, particularly in patients with Burkitt's lymphoma. In patients with DLBCL, the complete response rate with combination chemotherapy is approximately 40% to 50%, with 5-year overall survival rates of approximately 20% to 30%. Newer approaches, such as the dose-adjusted EPOCH (etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin) regimen developed at the National Cancer Institute and rituximab-containing combination chemotherapy, appear promising.¹³²

The optimal timing for HAART is not clear in patients with AIDS-related lymphoma.¹³² If HAART is given concurrently with chemotherapy, patients should be monitored closely for possible pharmacokinetic interactions between HAART and chemotherapy. Some experts suggest that HAART should be withheld until the completion of chemotherapy to allow administration of full chemotherapy doses and to avoid the risk of pharmacokinetic interactions. Prophylactic antibiotics should be continued during chemotherapy and intrathecal chemotherapy should be administered to prevent CNS relapses.

EVALUATION OF THERAPEUTIC OUTCOMES

Hodgkin's and non-Hodgkin's lymphomas tend to respond well to radiation, chemotherapy, and biologic therapy. The goal of therapy for patients with Hodgkin's and aggressive non-Hodgkin's lymphoma is long-term survival and cure. The therapeutic goal in patients with indolent NHLs is less clear because of the indolent nature of the disease and the lack of convincing evidence showing that therapy prolongs survival. Therapeutic responses should be evaluated based on physical examination, radiologic evidence, PET scanning, and other positive findings at baseline.⁵⁸ Patients with Hodgkin's and aggressive non-Hodgkin's lymphomas are usually

evaluated for response at the end of four cycles of therapy or at the end of treatment if fewer than four cycles of therapy are planned. If patients are treated with chemotherapy alone, two additional cycles of chemotherapy are given after the patient has achieved a complete remission. The rapidity of response to therapy in patients with indolent NHL depends on the choice of therapy. Responses occur slowly with therapy with oral alkylating agents, but occur much more rapidly with aggressive therapies such as combination chemotherapy with or without rituximab. If radiation alone is used, then a therapeutic evaluation should occur at the end of treatment.

CONCLUSIONS

Several decades ago, lymphomas were considered a fatal disease. Today, most patients with Hodgkin's lymphoma and many patients with aggressive NHLs can be cured with radiation therapy, chemotherapy, or a combination of radiation and chemotherapy. Our ability to achieve long-term survival and cure in these patients is the result of many factors, including development of accurate and reproducible classification systems; a more uniform approach to the staging of lymphoma; and advances in treatment strategies, especially the use of intensive combination chemotherapy. The routine use of hematopoietic growth factors allows oncologists to maintain dose intensity, which may be important for the treatment of aggressive lymphomas. The use of high-dose chemotherapy with autologous HSCT as intensive consolidation therapy for selected patients with aggressive NHLs who respond to initial induction therapy or as salvage therapy after relapse for patients with Hodgkin's lymphoma or aggressive NHLs has also contributed to increased cure rates.

New treatment approaches are needed, particularly for indolent NHLs. One of the most exciting therapies is biologic therapy with anti-CD20 monoclonal antibodies. The recent approval of radiolabeled anti-CD20 antibodies (i.e., radioimmunoconjugates) provides another therapeutic option for these patients. There is some evidence that these new therapies have changed the natural history of the disease. It is important to better understand how to use these new agents, either alone or combined with standard chemotherapy. Although about one-third of patients with aggressive lymphomas can be cured of their disease, most patients will relapse and eventually die of their disease. More effective induction chemotherapy regimens are needed for newly diagnosed patients, and more active salvage therapy is needed for patients with relapsed aggressive NHLs.

The goal for the future is to develop treatment modalities to achieve cure in a larger number of patients. But the acute and chronic toxicities associated with treatment must also be considered, particularly in elderly patients and those with significant comorbidities. Consideration of long-term toxicities is of particular concern to patients with Hodgkin's lymphoma because of the high cure rate.

Finally, a better understanding of the pathogenesis of NHL through continued research in molecular biology and immunology will hopefully lead to the development of specific therapies aimed at molecular targets. In addition, gene expression profiling may also allow researchers to identify new clinically important subtypes of NHL and to identify subgroups of patients who do respond poorly to standard therapy.

JUDITH A. SMITH AND JUDITH K. WOLF

KEY CONCEPTS

- 1 Ovarian cancer is denoted “the Silent Killer” because of the nonspecific signs and symptoms that contribute to the delay in diagnosis. The few patients who present with disease still confined to the ovary will have a 5-year survival rate greater than 90%, but most patients present with advanced disease and have a 5-year survival rate of 10% to 30%.
- 2 Ovarian cancer is a sporadic disease with less than 10% of cases of ovarian cancer attributed to heredity. However, a history of two or more first-degree relatives with ovarian cancer increases a woman’s risk of developing ovarian cancer by more than 50%.
- 3 CA-125 is a nonspecific inflammatory antigen used as a tumor marker for diagnosis and monitoring epithelial ovarian carcinoma. If CA-125 is elevated at the time of diagnosis, changes in CA-125 titers correlate with disease response and progression.
- 4 Ovarian cancer is staged surgically according to the International Federation of Gynecology and Obstetrics (FIGO) staging algorithm. Tumor debulking and total abdominal hysterectomy-bilateral oophorectomy surgery are the primary surgical interventions for ovarian cancer. After the completion of the staging and primary surgical treatment, the current standard of care is six cycles of a taxane-platinum-containing chemotherapy regimen.
- 5 Although most patients will achieve a complete response to initial treatment, more than 50% will have recurrence within the first 2 years. If recurrence occurs less than 6 months after completion of chemotherapy, the tumor is considered to be platinum-resistant. The antitumor activity of second-line chemotherapy regimens is similar and the choice of treatment for recurrent platinum-resistant ovarian cancer depends on residual toxicities, physician preference, and patient convenience. Participation in a clinical trial is also a reasonable option for these patients.

Ovarian cancer is a gynecologic cancer that usually arises from disruption or mutations in the epithelium of the ovary.¹ It is associated with the highest mortality among the gynecologic cancers, primarily because most patients present with advanced disease. 1 Ovarian cancer is denoted “the Silent Killer” because of the nonspecific signs and symptoms that often lead to a delay in diagnosis. The

few patients who present with disease still confined to the ovary will have a 5-year survival rate greater than 90%, but most patients present with advanced disease and have a 5-year survival rate of 10% to 30%. Primary treatment includes tumor-debulking surgery followed by six cycles of a taxane-platinum chemotherapy regimen. Although 70% of patients achieve an initial complete response to chemotherapy, more than 50% of these patients will have recurrence within the first 2 years from diagnosis.² Ovarian cancers often metastasize via the lymphatic and blood systems to the liver and/or lungs. Common complications of advanced and progressive ovarian cancer include ascites and small bowel obstruction.

ETIOLOGY AND EPIDEMIOLOGY

It is estimated that 22,430 new cases of ovarian cancer will be diagnosed and 15,280 women will die of the disease in 2007.³ Ovarian cancer is associated with the highest mortality rate among the gynecologic cancers and is the fifth leading cause of cancer-related deaths in woman. The mortality rate associated with ovarian cancer has not changed significantly over the past three decades. The high mortality rate is related to the insidious onset of nonspecific symptoms and the lack of adequate screening tools, which allows the disease to go undiagnosed until it has progressed beyond the pelvic cavity.

As with many other cancers, the risk of ovarian cancer increases with increasing age. A woman’s risk increases from 15.7 to 54 per 100,000 as her age advances from 40 to 79 years, and the median age at diagnosis is 59.³ Most cases of ovarian cancer present during the peri- and postmenopausal phase of women’s reproductive life span.⁴

2 Hereditary accounts for less than 10% of all ovarian cancer cases. Family history is an important risk factor in the development of ovarian cancer. If one family member has a diagnosis of ovarian cancer, the associated lifetime risk is 9%, but this risk increases to greater than 50% if there are two or more first-degree relatives (e.g., her mother and sister) with a diagnosis of ovarian cancer or multiple cases of ovarian and breast cancer within the same family.^{1,2}

BRCA1 and *BRCA2* are the tumor suppressor genes thought to be involved in one or more pathways of DNA damage recognition and repair. The *BRCA1* gene is located on chromosome 17q12–21 and the *BRCA2* gene is located on chromosome 13q12–13. Both *BRCA1* and *BRCA2* mutations are associated with ovarian cancer. However, *BRCA1* is more prevalent, being associated with 90% of inherited and 10% of sporadic cases of ovarian cancer.⁵ Patients with *BRCA1*-associated ovarian cancer are usually considerably younger than patients with *BRCA2* mutations, with a mean age of 54 years.⁶ Patients usually present with advanced stage at diagnosis, and the *BRCA1*-linked ovarian cancers are more aggressive tumors that typically are serous histology, moderate to high grade. As *BRCA1* and *BRCA2* are thought to be involved in DNA damage or repair, their inactivation/mutations may be associated with an increased

Learning objectives, review questions,
and other resources can be found at
www.pharmacotherapyonline.com.

resistance of ovarian cancer cells to cytotoxic agents with mechanisms of action involving induction DNA damage.

Hereditary breast and ovarian cancer syndrome is one of the two different forms of hereditary ovarian cancer and is associated with germ-line mutations in *BRCA1* and *BRCA2*.^{5,7} The hereditary non-polyposis colorectal cancer or Lynch's syndrome is a familial syndrome with germ-line mutations causing defects in enzymes involved in DNA mismatch repair, which is associated with up to 12% of hereditary ovarian cancer cases.⁵

Hormone exposure, specifically estrogen, and reproductive history also are associated with the risk of developing ovarian cancer. Conditions that increase the total number of ovulations in women's reproductive history, such as nulliparity, early menarche, or late menopause, are associated with an increasing risk for epithelial ovarian cancers.^{8,9} Conversely, those conditions that limit ovulations are associated with a protective effect. Each time ovulation occurs, the ovarian epithelium is broken, followed by cellular repair. According to the *incessant ovulation hypothesis*, the risk of mutations and, ultimately, cancer increases each time the ovarian epithelium undergoes cell repair.

Finally, ovarian cancer is associated with certain dietary and environmental factors. A diet that is high in galactose, animal fat, and meat may increase the risk of ovarian cancer, whereas a vegetable-rich diet may decrease the risk of ovarian cancer.^{7,10} Although controversial, exogenous factors such as asbestos and talcum powder use in the perineal area also are associated with an increased risk of ovarian cancer.^{7,10}

PATHOLOGY AND CLASSIFICATION

Ovarian carcinomas can be separated into three major entities: epithelial carcinomas, germ cell tumors, and stromal carcinomas. Most ovarian tumors (85% to 90%) are derived from the epithelial surface of the ovary.¹¹ The classification of common epithelial tumors has been developed by the World Health Organization and the International Federation of Gynecology and Obstetrics.¹² The nomenclature considers cell type, location of the tumor, and the degree of the malignancy, which ranges from benign tumors to tumors of low malignancy to invasive carcinomas. Epithelial tumors classified as low malignancy ("borderline malignancy") are characterized by epithelial papillae with atypical cell clusters, cellular stratification, nuclear atypia, and increased mitotic activity, and have a much better prognosis than those classified as invasive carcinomas. Malignant tumors are characterized by an infiltrative destructive growth pattern with malignant cells growing in a disorganized manner and dissection into stromal planes.

Invasive epithelial adenocarcinomas are characterized by histologic subtype and grade, which measures the degree of cellular differentiation. Although the histologic type of the tumor is not a significant prognostic factor, with the exception of clear cell, the histopathologic grade is an important prognostic factor. Undifferentiated tumors are associated with a poorer prognosis than those lesions that are considered to be well or moderately differentiated. A universal grading system for ovarian cancer was established that combines mitotic score, nuclear atypia score, and architectural score based on the histologic pattern.¹³

The histologic subtypes of adenocarcinomas include papillary serous, mucinous, endometrioid, clear cell, mixed epithelial, transition-cell, and undifferentiated.^{2,4,13} Papillary serous adenocarcinoma is the most common type of epithelial ovarian cancer and accounts for approximately 46% of cases. The peak age of diagnosis ranges from 45 to 65 years with 63 years as the median age of diagnosis.¹⁴ Serous carcinomas typically display complex papillary and solid patterns and qualify as high-grade carcinomas. Endometrioid carcinomas are seen in women 40 to 50 years of age

and comprise approximately 8% of ovarian carcinomas, of which approximately 6% are surface epithelial neoplasms.¹⁴ Endometrioid tumors are usually diagnosed as stage I disease and have a better prognosis than tumors with serous histology. Mucinous carcinomas occur in women between 40 and 70 years of age and account for approximately 36% of all ovarian cancers. The overall prognosis for mucinous carcinoma is better than for serous carcinoma because most patients present with stage I disease. Clear cell carcinoma comprises approximately 3% of ovarian carcinomas in women, with a mean age of 57 years. Although clear cell carcinoma is the least-common ovarian neoplasm, it is most commonly associated with paraneoplastic-related hypercalcemia.¹⁴

Germ cell tumors of the ovary, including malignant teratoma and dysgerminomas, are rare, comprising approximately 2% to 3% of all ovarian cancers in Western countries with an increased incidence in black and Asian women.^{15,16} These tumors are highly curable and affect primarily young women. In contrast to epithelial tumors, approximately 60% to 70% of germ cell tumors are stage I at diagnosis, which is related to earlier detection and response to symptoms in this younger patient population.¹⁶ Serum markers (human β -chorionic gonadotropin and alpha-fetoprotein) are helpful to confirm the diagnosis and monitor response to treatment.

Finally, ovarian sex cord-stromal tumors account for 7% of all ovarian cancers and tend to be diagnosed at stage I.¹² Sex cord-stromal tumors are associated with hormonal effects, such as precocious puberty, amenorrhea, and postmenopausal bleeding. Because these tumors are rare, the optimal treatment of ovarian sex cord-stromal tumors is not clear. The current recommended standard of care is surgery followed by treatment with a platinum-based chemotherapy regimen.

Ovarian cancer is usually confined to the abdominal cavity, but spread can occur to the lung, liver, and, less commonly, to the bone or brain. Disease is spread by direct extension, peritoneal seeding, lymphatic dissemination, or by blood-borne metastasis. Lymphatic seeding is the most common pathway and frequently causes ascites.

SCREENING AND PREVENTION

SCREENING

Ovarian cancer is an uncommon disease with no known preinvasive component, which has made it difficult to screen patients to detect early disease. In addition, the risk factors for developing ovarian cancer are not well understood, which also makes it difficult to identify a high-risk group of individuals. At the present time, there are no effective screening tools for early detection of ovarian cancer.

Pelvic examinations are noninvasive and well accepted, and can detect large tumors with a sensitivity of 67% for detecting all tumors.¹⁵ However, because pelvic examinations cannot detect minimal or microscopic disease, they do not usually detect ovarian cancer until it is in advanced stage. As a result of these limitations, routine pelvic examinations are not an effective screening tool and do not decrease overall mortality.¹⁵

Transvaginal ultrasound (TVUS) creates an image of the ovary by releasing sonic sound waves and can be used to evaluate the size and shape and to detect the presence of cystic or solid masses or abdominal fluid. TVUS can also evaluate blood flow within ovarian mass. Normal ovarian size cutoff parameters range from 1.25 cm² for women 55 to 59 years of age to 1.0 cm² for women older than age 65 to 69 years.^{17,18} TVUS is sensitive in identifying ovarian lesions and abnormalities, but its use as a routine screening test is limited by a lack of specificity and an inability to detect peritoneal cancer or cancer in normal size ovaries.^{19,20}

Serum cancer antigen-125 (CA-125) is a nonspecific inflammatory antigen that can be elevated in numerous conditions associated

with inflammation in the abdominal cavity. CA-125 has been extensively studied as a potential tumor marker for ovarian cancer based on the observation that CA-125 levels in a woman without ovarian cancer tend to stay the same or decrease over time, whereas levels associated with malignancy tend to gradually increase over time.¹⁹ However, CA-125 is a nonspecific test that can be elevated in number of benign conditions, including other gynecologic conditions, such as endometriosis, and many nongynecologic conditions, such as diverticulitis and peptic ulcer disease. CA-125 levels are an unreliable predictor of the presence or absence of disease. Because of these limitations, CA-125 levels are not recommended as a routine screening test for detection of ovarian cancer. Numerous other serologic markers such as carcinoembryonic antigen and lipid-associated sialic acid have been evaluated but cannot be recommended for routine screening for ovarian cancer.

The United States Preventive Services Task Force found fair evidence to support screening with CA-125 or TVUS and concluded that earlier detection would likely have a small effect, at best, on mortality from ovarian cancer.²¹ Unfortunately, because of the low prevalence of ovarian cancer and the invasive nature of diagnostic testing after a positive screening test, the United States Preventive Services Task Force also found fair evidence that screening could likely lead to important harms. The United States Preventive Services Task Force concluded that the potential harms outweigh the potential benefits and recommended against any form of routine screening with CA-125 or TVUS for ovarian cancer.

In high-risk women, as defined by family history, most clinicians use a multimodality approach for ovarian cancer screening that includes an annual TVUS in combination with CA-125 blood test every 6 months. Changes in CA-125 are monitored over time and changes such as a persistent elevation or consistent increases in CA-125 levels in conjunction with TVUS abnormalities are evaluated further.

PREVENTION

As with most cancers, it is difficult to make recommendations for prevention for the general population because ovarian cancer is a sporadic disease with no established risk factors. Noninvasive measures, such as chemoprevention, have demonstrated some benefit in decreasing the risk of developing ovarian cancer. Ovulation itself is considered a potential insult to the ovarian epithelium, increasing its susceptibility to damage and, ultimately, to cancer. Interventions or reproductive conditions associated with decreasing the number of ovulations, including multiparity, may have a protective effect for the prevention of ovarian cancer. However, the more invasive prevention interventions, such as prophylactic surgery and genetic screening, should be reserved for those women identified to be at high risk for developing ovarian cancer.

Chemoprevention

Although a number of agents have been investigated as chemoprevention of ovarian cancer, including oral contraceptives, aspirin, nonsteroidal antiinflammatory agents, and retinoids, none of these agents is currently accepted as standard treatment for the prevention of ovarian cancer. Oral contraceptives inhibit ovulation, which reduces the opportunity for potential for damage to the ovarian epithelium. Oral contraceptives decrease the relative risk to less than 0.4 in women who used oral contraceptives for longer than 10 years.^{22,23} Because oral contraceptive use is associated with an increased risk of breast cancer, women with a family history of breast cancer are not candidates for this use of oral contraceptives as chemoprevention of ovarian cancer.^{22,23}

Nonsteroidal antiinflammatory drugs, aspirin, and acetaminophen also have been suggested for use in the chemoprevention of

different cancers, especially hereditary nonpolyposis colon cancer.²⁴ Although the results of observational studies show that the use of nonsteroidal antiinflammatory drugs, aspirin, and acetaminophen reduces the risk of ovarian cancer, these findings have not been confirmed in prospective clinical studies. The proposed mechanism of these agents is the antiinflammatory effect on normal ovulation and inhibition of ovulation.^{24,25}

Prophylactic Surgery

Prophylactic surgical interventions for the prevention of ovarian cancer are reserved for patients with a significant family history and/or with known genetic mutations such as *BRCA1* and should be postponed until after childbearing is completed. The goal is to remove healthy, at-risk organs before any carcinogenic activity is initiated, ultimately reducing the risk of developing cancer. These surgeries include prophylactic oophorectomy or bilateral salpingo-oophorectomy and tubal ligation. These procedures will cause surgical menopause which can be associated with severe hot flashes, vaginal dryness, sexual dysfunction and increased risk for development of osteoporosis and heart disease in these women. Because of the potential impact on quality of life and increased health risks, prophylactic surgery is not recommended as a general prevention intervention for the general population.

Although prophylactic surgical interventions are associated with significant reduction in risk of developing ovarian cancer, patients who choose to have a prophylactic oophorectomy/bilateral salpingo-oophorectomy completed need to be informed that complete protection is not guaranteed.^{15,23,26} Although a 67% risk reduction has been shown, a potential 2% to 5% risk of primary peritoneal cancer remains.^{27,28} Primary peritoneal cancers have identical histology of ovarian tumors with diffuse involvement of peritoneal surfaces. Often primary peritoneal cancers can result from “seeding” during the prophylactic surgery. It is recommended for peritoneal washings to be completed during the prophylactic surgery to check for presence of peritoneal surfaces. If positive, then prophylactic surgery would change to staging and treatment surgery to determine extent of disease and remove any other possible lesions.

Tubal ligation is another procedure that can potentially reduce the risk for developing ovarian cancer. In a case-control study, Narod et al. reported that tubal ligation in *BRCA*-positive women was associated with a 63% reduction in risk of developing ovarian cancer.²⁹ However, it is not recommended as a sole procedure in prophylaxis. The mechanism for its protective effect is not clear but it has been proposed that tubal ligation may limit exposure of the ovary to environmental carcinogens.

GENETIC SCREENING

Genetic screening should be considered for those women with a significant family history of ovarian cancer. Patients should be evaluated for the presence of genes such as *BRCA1*, *BRCA2*, or other genes such as those associated with hereditary nonpolyposis colorectal cancer or the hereditary breast ovarian cancer (hereditary breast and ovarian cancer syndrome) syndrome.^{29–32} Prior to genetic screening, appropriate patient/family counseling and genetic counseling should be available to help women prepare and deal with the health and psychosocial implications of the genetic screening results.

CLINICAL PRESENTATION

Patients with early ovarian cancer are often asymptomatic and the ovarian mass is often detected incidentally during their annual pelvic examinations. Patients with ovarian cancer often present with nonspecific, vague symptoms.^{2,4,33} These symptoms can easily be

confused with symptoms of common benign gastrointestinal disorders. Patients will often not seek medical attention until these symptoms become unrelenting and bothersome, which allows the disease to progress. Patients with advanced disease may report symptoms such as pain, abdominal distension, and ascites.^{2,33}

Several groups have partnered together to educate women about early signs and symptoms of ovarian cancer. Goff et al. recently developed a symptom index total, based on a comparison of symptoms experienced in patients with ovarian cancer and a matched control group.³⁴ Symptoms that were correlated with ovarian cancer were persistent or recurrent bloating, pelvic or abdominal pain, difficulty eating or feeling full quickly, and urinary symptoms (either urgency or frequency). The Gynecologic Cancer Foundation, Society of Gynecologic Oncologists, and American Cancer Society recommend that women who have any of those problems nearly every day for more than 2 or 3 weeks should see a gynecologist, especially if the symptoms are new and quite different from her usual state of health.

CLINICAL PRESENTATION OF OVARIAN CANCER

General

- Ovarian cancer is sometimes referred to as “the Silent Killer” because of the vague nonspecific signs and symptoms that contribute to the delay in diagnosis.

Symptoms

- The patient may complain of abdominal discomfort, nausea, dyspepsia, flatulence, bloating, fullness, early satiety, urinary frequency, change in bowel function (diarrhea or constipation), weight change, and digestive disturbances.
- Several oncology groups have partnered to educate women about the following early symptoms: bloating, pelvic or abdominal pain, difficulty eating or feeling full quickly, and feeling a frequent or urgent need to urinate.

Signs

- Abdominal or pelvic mass may be palpable.
- Lymphadenopathy may be present.
- Vaginal bleeding may be irregular.
- Patient may have signs of ascites (abdominal distension, shifting, and dullness to percussion—may present like a “pregnant abdomen”).

Laboratory Tests

- CA-125 may be elevated (normal level is less than 35 units/mL).
- Abnormalities in liver function tests may suggest hepatic involvement.
- Abnormalities in renal function tests may suggest compression of the renal system by the tumor.

DIAGNOSIS

The diagnostic workup for suspected ovarian cancer includes a careful physical examination including a Papanicolaou (Pap) smear, pelvic and a rectovaginal examination.⁷ The presence of a pelvic mass that is unilateral or bilateral, solid, irregular, fixed, or nodular is highly suggestive of ovarian cancer. Unfortunately, by the time pelvic mass can be palpitated on physical exam, the disease is already advanced beyond pelvic cavity. A detailed family history should be taken, especially noting the number and pattern of first degree relatives with malignancies.

A complete blood count, chemistry profile (including liver and renal function tests), and CA-125, carcinoembryonic antigen, and CA19 levels should be performed. ③ Although CA-125 is a nonspe-

cific antigen, it is the best current tumor marker for epithelial ovarian carcinoma. A normal CA-125 value is less than 35 units/mL. If CA-125 is elevated at the time of diagnosis, changes in CA-125 titers correlate with tumor burden. Rising CA-125 titers are often associated with disease progression, but CA-125 can be elevated in various other conditions such as different phases of the menstrual cycle, diverticulitis, endometriosis, as well as other non-gynecologic cancers. When patient presents with an abdominal mass, it is important to rule out other cancers in the abdominal cavity. Carcinoembryonic antigen and CA19-9 are markers for other gastrointestinal cancers and may be helpful in the differential diagnosis.

Other diagnostic tests should include a transvaginal or abdominal ultrasonography, chest radiography, computed tomography, magnetic resonance imaging, or positron emission tomography scan. An upper GI series, intravenous pyelogram, cystoscopy, proctoscopy, or barium enema is sometimes indicated to confirm diagnosis and extent of disease.

TREATMENT

Ovarian Cancer

■ GENERAL APPROACH TO TREATMENT

⑤ A multimodality approach that includes comprehensive surgery and chemotherapy is used for the initial treatment of ovarian cancer with curative intent. Although most patients will initially achieve a complete response, more than 50% will recur within the first 2 years.^{2,35} A clinical complete response to treatment is defined as no evidence of disease by physical examination or diagnostic tests and a normal CA-125 titer.

Chemotherapy regimens for ovarian cancer have evolved over the past four decades. Treatment regimens began with single-agent melphalan followed by single-agent cyclophosphamide. Shortly after cisplatin was introduced into clinical practice, it was added to cyclophosphamide and this combination was the “standard of care” for over a decade until the introduction of paclitaxel in the 1980s. Paclitaxel soon replaced cyclophosphamide and paclitaxel plus cisplatin became the standard of care. Carboplatin was then substituted for cisplatin because of its improved toxicity profile and paclitaxel plus carboplatin was adopted. During this same period, many researchers have conducted numerous clinical trials of intraperitoneal (IP) chemotherapy. These advances in chemotherapy for the treatment of ovarian cancer have not translated into major changes in overall 5-year survival, which remains less than 20%.

Certain subgroups of patients have a better or worse response to chemotherapy. The histologic subtype of the tumor is a prognostic factor; clear cell histology is more likely to be poorly differentiated, faster growing, and have intrinsic drug resistance.^{2,37} However the extent of residual disease, size larger than 1 cm, and tumor grade are better predictors of response to chemotherapy and overall survival.²

In general, younger patients have a better performance status and tolerate chemotherapy better than elderly patients. For unknown reasons, white women tend to have a worse prognosis and response to therapy as compared to other ethnic backgrounds.^{2,6,7}

In patients with recurrent ovarian cancer, the goals of treatment are to relieve symptoms such as pain or discomfort from ascites, slow disease progression, and prevent serious complications such as small bowel obstructions.

■ SURGERY

Surgery is the primary treatment intervention for ovarian cancer.³⁷⁻⁴¹ Surgery may be curative for selected patients with limited stage IA disease.

FIGURE 136-1. Staging laparotomy for ovarian cancer with diagram of female reproductive tract (uterus, fallopian tubes, ovaries, vagina). Dash line box outlines what is removed during the total abdominal hysterectomy with bilateral salpingo-oophorectomy.

Primary surgical treatment includes a total abdominal hysterectomy with bilateral salpingo-oophorectomy, omentectomy, and lymph node dissection (Fig. 136-1).^{37,41} The primary objective of the surgery is to optimally debulk the tumor to less than 1 cm of residual disease.⁴² Long-term followup studies confirm that residual disease smaller than 1 cm correlates with higher complete response rates to chemotherapy and longer overall survival as compared to patients with bulky residual disease (larger than 1 cm).^{40,41}

A comprehensive exploratory laparotomy is vital for the accurate confirmation of diagnosis and staging of ovarian cancer.³⁷⁻³⁹

4 Unlike other cancers that are typically diagnosed by biopsy and/or laboratory results and clinically staged by results from imaging tests, gynecologic cancers, such as ovarian cancer, are surgically diagnosed and then staged according to the International Federation of Gynecology and Obstetrics (FIGO) staging algorithm (Fig. 136-2). The FIGO staging system requires a fairly extensive surgery by an experienced gynecologic oncologist. The skill of the surgeon has a significant impact on prognosis, with definitive benefit of a trained gynecologic oncologist performing surgery as compared to a gynecologist or general surgeon.⁴³ The reasons for this approach include (a) pelvic tumors cannot be readily biopsied without risk of “tumor seeding,” which can increase the risk of recurrence, and (b) surgical staging takes into account the presence of microscopic disease in samples obtained by pelvic washing and lymph node dissection and read by a pathologist during the surgical procedure. It is recommended that the initial surgical staging and tumor-debulking surgery be completed by a trained gynecologic oncology surgeon when ovarian cancer is suspected to prevent understaging and to optimize overall outcome.⁴⁴

Secondary cytoreduction or interval debulking is when surgery is performed after completion of some or all chemotherapy to remove residual disease. Some protocols include additional cycles of chemotherapy after the surgical procedure. The importance of cytore-

duction before, during or after chemotherapy is still controversial but it has been recommended to facilitate response to chemotherapy and improve overall survival. Randomized trials of secondary surgical cytoreduction have reported conflicting results. In an older randomized trial, van der Burg et al. performed interval debulking surgery on 140 stage IIB to stage IV suboptimally debulked (less than 1 cm of residual disease) ovarian cancer patients after receiving three cycles of cisplatin plus cyclophosphamide.⁴⁵ Patients then received an additional three cycles of these same drugs after surgery. Patients randomized to the nonsurgical treatment arm received six cycles of chemotherapy. Interval debulking surgery significantly prolonged overall and progression-free survival and reduced the risk of death by 33%. However, in a recently published study of 550 women with stage III or IV disease treated with primary cytoreductive surgery and three cycles of paclitaxel and cisplatin, patients randomized to receive secondary cytoreductive surgery followed by three more cycles of chemotherapy had similar progression-free survival and overall survival as compared with those randomized to receive three more cycles of chemotherapy alone.⁴⁶

The overall effect of interval debulking is influenced by several factors including initial response to chemotherapy, the amount of residual disease before and after second-look surgery, and the presence of microscopic residual disease. The results of recent trials suggest that secondary surgical cytoreduction does not prolong survival in patients who are treated with maximal primary cytoreductive surgery followed by appropriate postoperative chemotherapy.

“Second-look surgery” is an elective surgical procedure performed in patients who achieve a clinical complete response after primary chemotherapy to determine if any visible or microscopic disease is present in the peritoneal cavity. The benefit of “second-look laparotomy” to evaluate residual disease after completing chemotherapy remains controversial because it has been difficult to establish any impact on overall survival. It has questionable benefit

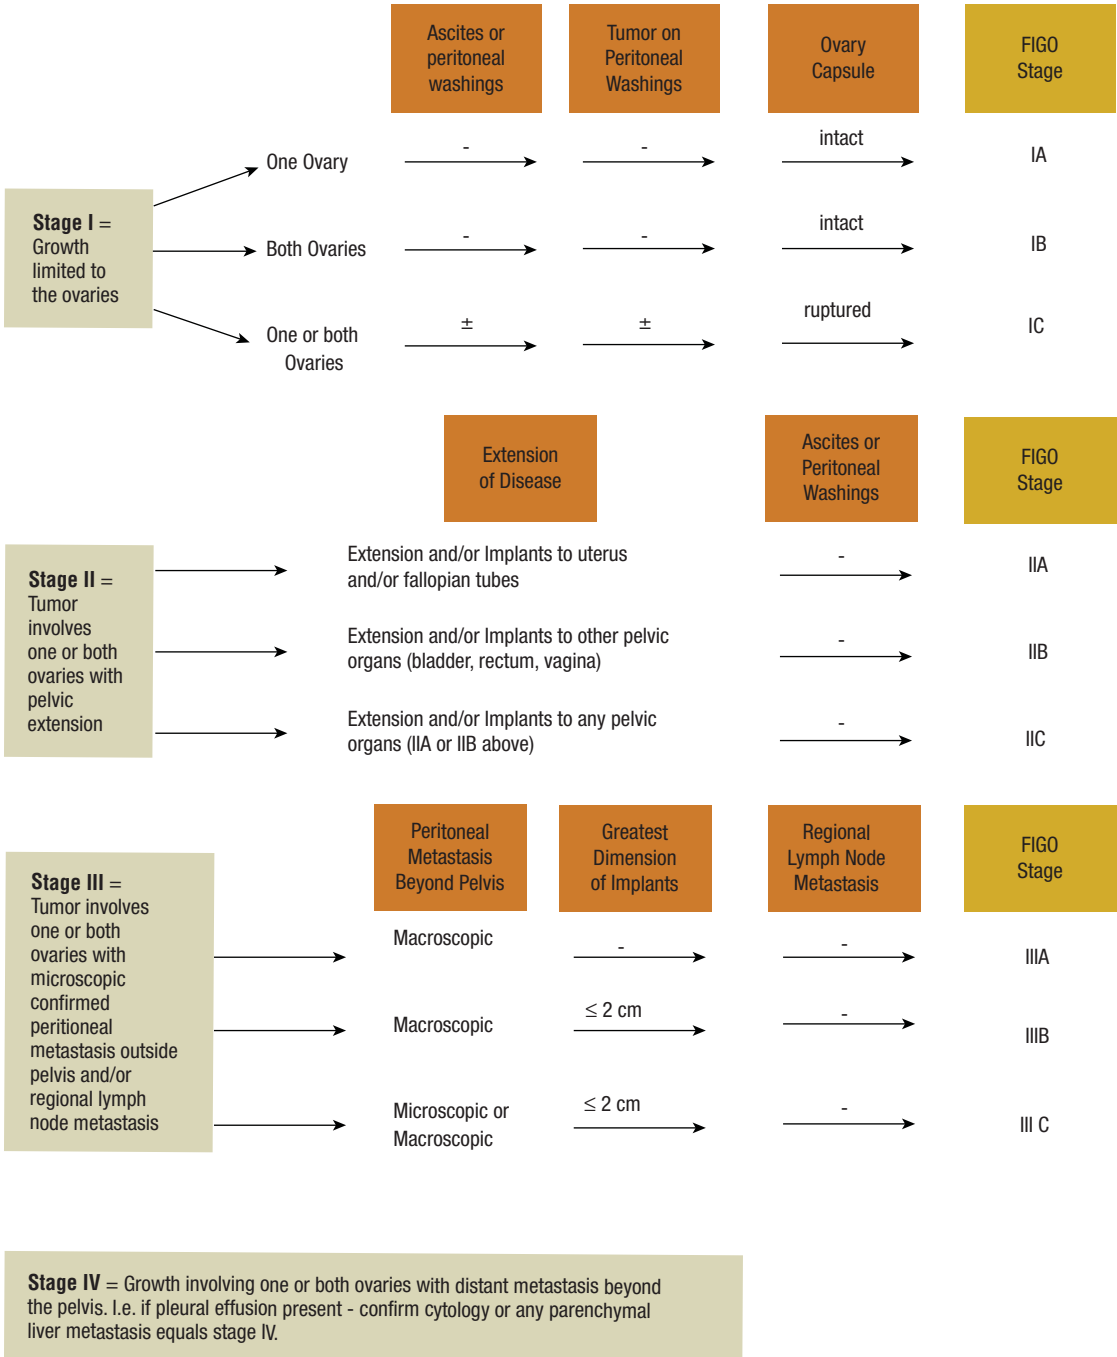

FIGURE 136-2. International Federation of Gynecology and Obstetrics (FIGO) staging algorithm.

because approximately 50% of those with a negative second look still relapsed.³ If visible or microscopic disease is detected during second look, then the clinician may decide to give additional chemotherapy. But if no visible or microscopic disease is detected during second look, the clinician may decide to observe and monitor the patient. Use of laparoscopic surgical techniques is controversial for initial surgery but is sometimes considered in debulking of recurrent or advanced disease when the intent is palliative rather than curative.⁴⁰ In patients with recurrent disease, the goal of debulking surgery is to relieve symptoms associated with complications such as small bowel obstructions and help improve the patient's quality of life.

■ RADIATION

Radiation has a limited role in the management of ovarian cancer. Use of radiation for treatment of early stage disease has had no

benefit or impact on overall survival.⁴⁷ Radiation therapy is most beneficial for palliation of symptoms in patients with recurrent pelvic disease, often associated with small bowel obstructions. The two forms of radiation therapy used in ovarian cancer are external beam whole-abdominal irradiation and intraperitoneal isotopes such as ³²P. Alleviation of symptoms with external beam whole-abdominal irradiation is associated with a significant improvement in the patient's quality of life. The recommended dose ranges from 35 to 45 Gy, depending on the treatment history and ability to tolerate radiation treatments.

■ CHEMOTHERAPY

First-Line Treatment

Systemic chemotherapy with a taxane-platinum regimen following optimal surgical debulking is the standard of care for treatment of

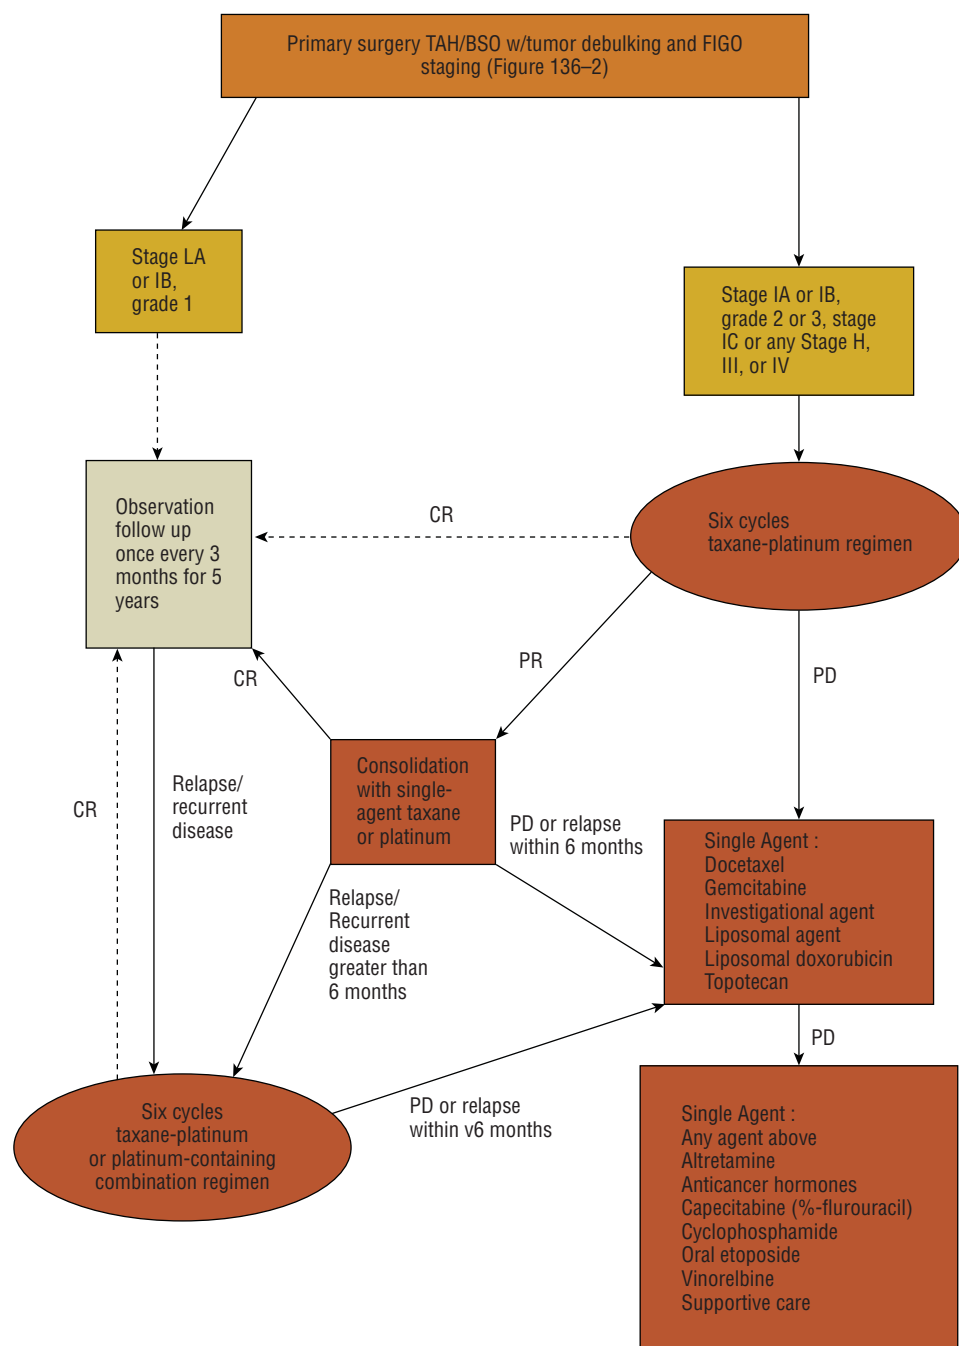

FIGURE 136-3. Management of newly diagnosed, refractory and progressive epithelial ovarian cancer. All recommendations are category 2A unless otherwise indicated. (BSO, bilateral salpingo-oophorectomy; CR, complete response; PD, progression of disease; PR, partial response; TAH, total abdominal hysterectomy; USO, unilateral salpingo-oophorectomy.)

epithelial ovarian cancer (Fig. 136-3). Table 136-1 summarizes the chemotherapeutic regimens used as the initial treatment of newly diagnosed epithelial ovarian cancer. More than 60 randomized, controlled clinical trials have evaluated combination chemotherapy regimens for the treatment of advanced ovarian cancer and a meta-analysis of these trials confirmed the efficacy of platinum/taxane regimens over other regimens.^{48,49}

Historically, single-agent alkylating agents such as melphalan, and later cyclophosphamide, were used for the treatment of advanced ovarian cancer until the introduction of cisplatin in the 1970s. Combination chemotherapy regimens containing cisplatin and cyclophosphamide achieved higher response rates and overall survival than regimens without cisplatin in patients with advanced ovarian cancer.⁵⁰ Based on the results of these trials, the combination of cisplatin plus cyclophosphamide remained the standard of care for the treatment of ovarian cancer until the early 1990s.

The next major advance in the therapy of advanced ovarian cancer occurred with the introduction of paclitaxel into chemother-

apy regimens. McGuire et al. reported the results of Gynecologic Oncology Group (GOG)-111 study that found the combination of paclitaxel 135 mg/m² over 24 hours and cisplatin 75 mg/m² achieved higher response rates and longer survival than did cyclophosphamide 750 mg/m² and cisplatin 75 mg/m² in patients with newly diagnosed, suboptimally debulked, stages III and IV ovarian cancer.⁵¹ Survival improved significantly in the paclitaxel arm, with an increase in median progression-free survival (18 months vs. 13 months) and overall survival (38 months vs. 24 months). Neutropenia, alopecia, and peripheral neuropathy were more severe in the paclitaxel/cisplatin group. Similar results were reported in a large European-Canadian Intergroup Phase III randomized trial study (OV10) that also confirmed superior response rates with the paclitaxel 135 mg/m² over 24 hours with cisplatin 75 mg/m² regimen as compared to cyclophosphamide 750 mg/m² with cisplatin 75 mg/m² regimen.⁵² Based on the results of these studies, paclitaxel plus cisplatin was widely adopted and became the accepted standard of care.

TABLE 136-1 Chemotherapeutic Regimens for the Initial Treatment of Epithelial Ovarian Cancer

Drug(s)	Dose(s)	Cycle Frequency
Paclitaxel + carboplatin	175 mg/m ² IV (3-hour infusion) day 1 Dosed to AUC 5–7.5 IV day 1	Every 21 days
Paclitaxel + cisplatin (IV)	135 mg/m ² IV (24-hour infusion) day 1 75 mg/m ² IV day 1	Every 21 days
Paclitaxel + cisplatin (IP)	Day 1: paclitaxel 135 mg/m ² IV infused over 24 hours + Day 2: cisplatin 100 mg/m ² IP infused over 1 hour + Day 8: paclitaxel 60 mg/m ² IP infused over 1 hour. Regimen is given once every 21 days × six cycles.	Every 21 days
Cisplatin + cyclophosphamide	50–100 mg/m ² IV day 1 500–1,000 mg/m ² IV day 1	Every 21–28 days
Docetaxel + carboplatin	75 mg/m ² IV day 1 Dosed to AUC 5 IV day 1	Every 21 days

AUC, area-under-the-curve; IP, intraperitoneal.

The availability of carboplatin lead to clinical trials to evaluate whether carboplatin could be substituted for cisplatin, which would spare patients from the significant neurotoxicity and nephrotoxicity associated with cisplatin. Several prospective randomized comparisons of carboplatin plus paclitaxel versus cisplatin plus paclitaxel in patients with advanced ovarian cancer have been conducted.^{53–56} The results of these trials show that carboplatin plus paclitaxel is equally efficacious and better tolerated than cisplatin and paclitaxel. In the GOG-158 study, 840 previously untreated patients with optimally resected stage III disease (no residual tumor nodule >1 cm) were randomized to carboplatin (area-under-the-curve = 7.5) plus paclitaxel 175 mg/m² over 3 hours, or cisplatin 75 mg/m² plus paclitaxel 135 mg/m² over 24 hours administered every 21 days for six cycles.^{53,55} The results of that trial showed no difference in progression-free survival between the two treatment arms with a median time to progression of 19.4 months in the paclitaxel plus cisplatin arm versus 20.7 months in the paclitaxel plus carboplatin arm. As expected, the incidence of leukopenia, fever, gastrointestinal toxicity, and metabolic toxicity was higher in patients in the cisplatin arm, whereas patients in the carboplatin arm experienced more thrombocytopenia and pain. Although the incidence of neurotoxicity was similar in the two treatment arms, it was more severe in the paclitaxel plus cisplatin arm. The results of this study showed that the substitution of carboplatin for cisplatin in the regimen does not compromise efficacy and improves tolerability. These findings were confirmed in two other large randomized controlled studies.^{55,56} Based on these results, paclitaxel plus carboplatin became the accepted standard of care.

Other clinical trials have evaluated the use of docetaxel as a substitute for paclitaxel. In the Scottish Randomized Trial in Ovarian Cancer trial, Vasey et al. compared carboplatin (area-under-the-curve = 5) combined with either docetaxel (75 mg/m² over 1 hour) or paclitaxel (175 mg/m² over 3 hours) administered every 21 days for six cycles as first-line chemotherapy for stages IC to IV epithelial ovarian cancer.⁵⁷ The results of this study showed that the substitution of docetaxel for paclitaxel does not compromise efficacy and improves tolerability, particularly neurotoxicity. These findings have not yet been confirmed in another randomized control trial. Based on the results of this study, the combination of docetaxel plus carboplatin is considered a reasonable treatment option for patients with advanced ovarian cancer. Six cycles of paclitaxel plus carboplatin following tumor debulking surgery remains the current standard of care for treatment of advanced ovarian cancer.

CLINICAL CONTROVERSY

The use of IP chemotherapy as first-line treatment of advanced ovarian cancer has been recommended by the National Comprehensive Cancer Network (NCCN) guidelines. However, appropriate patient selection is critical for success of this treatment approach. Many clinicians are hesitant to use IP chemotherapy because of the increased risk of toxicity and complications. Additional studies are ongoing to determine the optimal IP chemotherapy regimen.

Intraperitoneal chemotherapy was initially employed as palliative care in the management of ascites and uncontrolled intraabdominal tumors. In the late 1970s, intraperitoneal chemotherapy administration at a primary treatment intervention was initiated based on the rationale that exposure of the tumor to high drug concentrations would increase tumor drug uptake by passive diffusion and ultimately cancer cell death.⁵⁸ The increase in area-under-the-curve exposure in the peritoneal cavity was demonstrated but the correlative increase in drug uptake in tumor tissue has yet to be validated in any preclinical or clinical study.

IP chemotherapy has demonstrated a benefit in the first-line treatment of patients with optimally debulked advanced stage ovarian cancer.^{49,59–62} In the most recent trial, Armstrong et al. reported the results of the GOG-172 study, which evaluated 415 patients randomized to receive either the combination regimen of paclitaxel 135 mg/m² over 24 hours and cisplatin 75 mg/m² or a new combination regimen that included paclitaxel 135 mg/m² IV infused over 24 hours followed by cisplatin 100 mg/m² IP infused over 1 hour on day 2, and then paclitaxel 60 mg/m² IP infused over 1 hour on day 8.⁵⁷ Both treatment regimens were given once every 21 days for total of six cycles. Patients randomized to the IP chemotherapy arm had a 5.5-month increase in the median progression-free survival and a 15.9-month increase in overall survival.⁵⁹

Since the publication of this study, there has been a resurgence of interest in use of IP chemotherapy despite the limitation that only 42% of the patients on the IP treatment arm were able to complete the planned six cycles as a result of significantly more toxicity, including pain, fatigue, myelosuppression, gastrointestinal, metabolic, and neurotoxicity.^{59,60,63,64} Because only 42% of patients were able to complete the planned six courses of IP chemotherapy, there is some controversy regarding whether the route of administration was the contributing factor in the observed differences in overall survival.⁵⁹ The significant increase in systemic toxicity, primarily neurotoxicity, has led to the question of whether carboplatin IP could be substituted for cisplatin. Although these platinum agents have demonstrated equal efficacy when administered IV to ovarian cancer patients, based on the concept that drug passively diffuses into the tumor, the difference in molecular size of cisplatin versus carboplatin makes it difficult to extrapolate IP activity of cisplatin to carboplatin.

The NCCN 2007 guidelines recommend that IP chemotherapy be considered and offered to patients as appropriate first-line treatment of optimally debulked, ≥1 cm residual disease, ovarian cancer.⁶⁵ The National Cancer Institute also released a position statement in January 2006 supporting the role of IP chemotherapy as first-line treatment for advanced ovarian cancer.⁶⁶ Because of the significant toxicities associated with IP therapy, only carefully selected patients should receive IP therapy. Ideal candidates for IP therapy are younger patients with good performance status, minimal comorbidities, adequate renal and liver function, and optimally debulked disease without significant bowel resection.^{59,64}

In patients who are poor surgical candidates because of comorbidities or bulky tumors, neoadjuvant chemotherapy can be given prior to any surgical interventions.⁶⁷ In patients with bulky disease,

the goal of neoadjuvant chemotherapy is to reduce tumor burden to make surgery more feasible and optimal tumor debulking more likely. The typical regimen used in neoadjuvant chemotherapy is three cycles of a taxane combined with a platinum agent followed by surgery. After surgery, patients usually receive another three to six cycles, depending on their response to chemotherapy. In patients who are poor candidates for surgery because of comorbidities, the primary intent of neoadjuvant chemotherapy is to relieve symptoms and slow disease progression. In this setting, palliative chemotherapy alone has not been curative for patients with advanced ovarian cancer.⁶⁷ If tolerated, these patients will receive the standard taxane-platinum chemotherapy regimen once every 3 to 4 weeks. Another option for palliative neoadjuvant chemotherapy, especially in elderly patients, is single-agent carboplatin once every 4 weeks.

Consolidation Therapy

If patients do not achieve a clinical complete response after completion of six cycles of taxane-platinum regimen, then consolidation chemotherapy should be considered in an attempt to achieve a complete response (see Fig. 136–3). If the patient has a partial response to first-line chemotherapy, as measured by a greater than 50% decline in CA-125 (as compared with the presurgery level) or tumor regression, the cancer is still considered taxane-platinum sensitive. The typical regimens for consolidation chemotherapy are the taxane-platinum regimen or single-agent therapy with either a taxane or platinum agent.⁶⁸ If the patient had a poor response to taxane and/or platinum agents, then alternative second-line agents can be considered.⁶⁵ Additional cycles of chemotherapy are given until complete response is achieved. Another alternative in the setting of no or minimal measurable disease after completion of primary chemotherapy is to just observe the patient and provide supportive care as indicated until disease progresses then reinstitute chemotherapy at that time.⁶⁵

Because the initial clinical complete response observed in first-line treatment has not been durable, optimization of first-line therapy is under investigation. Numerous options have been evaluated, including the use of additional cycles or maintenance chemotherapy and dose intensity.

CLINICAL CONTROVERSY

GOG-178 evaluated 3 versus 12 cycles of paclitaxel maintenance chemotherapy after completion of first-line chemotherapy. This study was closed early after the interim analysis reported a significant improvement in progression-free survival. Because most patients who were randomized to receive 3 cycles of maintenance therapy crossed over to the 12-cycle arm after the interim analysis, the impact on overall survival is unknown. The benefit of maintenance chemotherapy after achieving a complete response has led to much debate among gynecologic oncology clinicians.

Maintenance Chemotherapy Maintenance chemotherapy is similar to consolidation chemotherapy except it is given to those patients who have achieved a clinically complete response. The goal of maintenance chemotherapy is to eradicate any residual microscopic disease that may be present to extend progression-free and, ultimately, overall survival.

Maintenance chemotherapy has gained popularity after the publication of the results of the collaborative Southwest Oncology Group and GOG 178 study that compared single-agent paclitaxel 175 mg/m² over 3 hours once every 21 days for 3 additional cycles versus an additional 12 cycles.^{69,70} Eligible patients had to have been in complete clinical remission after at least five to six cycles of a taxane-

platinum regimen. This study was closed after the interim analysis by the Southwest Oncology Group Safety Monitoring Committee because patients receiving the additional 12 cycles had 7-month longer progression-free survival than those receiving 3 cycles of single-agent paclitaxel (28 vs. 21 months). After the results were reported, many patients randomized to the three-cycle arm chose to receive nine additional cycles of paclitaxel, which reduced the ability of the trial to show a difference in overall survival.⁷¹ Because this study was closed early and did not demonstrate an overall survival benefit, another randomized, controlled trial through the GOG was initiated to confirm the improvement in progression-free survival and to attempt to determine the impact on overall survival. Until these confirmatory trials are completed, the role of maintenance chemotherapy is controversial in the management of advanced ovarian cancer patients. Maintenance chemotherapy is listed as an option in the 2007 NCCN guidelines (2B recommendation).⁶⁵

High-Dose Chemotherapy with Hematopoietic Stem Cell Rescue High-dose chemotherapy with autologous or allogeneic hematopoietic stem cell transplantation (HSCT) is an option for selected patients with chemosensitive disease, few comorbidities, and good performance status. Although high response rates have been reported in patients with recurrent ovarian cancer treated with autologous HSCT, the duration of response is usually short and few patients have experienced long-term progression-free survival.^{72,73} Allogeneic HSCT has been also been evaluated in recurrent ovarian cancer to induce an immune response against the tumor (“graft-versus-tumor” effect).

Based on the activity of autologous HSCT in recurrent ovarian cancer, Goncalves et al. evaluated the modality for first-line treatment of patients with optimally debulked ovarian cancer. In this multicenter phase II study, 34 patients received two cycles of high-dose cyclophosphamide-epirubicin once every 21 days followed by two cycles of high-dose carboplatin (days 42 and 98).⁷⁴ Each dose of high-dose carboplatin was followed by hematopoietic stem cell infusion. The results of this study failed to show an improvement in the rate of pathologic complete response with upfront autologous HSCT as compared to standard taxane-platinum chemotherapy. Additional studies are ongoing to determine the role of autologous or allogeneic HSCT in the treatment of advanced ovarian cancer.

Treatment of Recurrent Disease

5 Although most patients will achieve a complete response to initial treatment, most patients will eventually have recurrence of their disease. When a patient relapses, the prognostic factors are similar to the factors after initial surgery except that the disease-free interval—defined as the length of time that has lapsed since the completion of chemotherapy—should be considered to determine if the tumor is likely to be drug resistant. If recurrence occurs less than 6 months after completion of chemotherapy, or if the patient progresses during platinum-based chemotherapy, the tumor is defined as platinum-resistant. Patients with platinum-sensitive disease generally have a better prognosis than platinum-resistant patients.

Because the chemotherapy agents used for second-line treatment of recurrent or refractory platinum-resistant disease have similar response rates that average less than 30%, the selection of the agent depends on the toxicity profile of the agent, physician preference, patient performance status, residual toxicities, and patient convenience (see Fig. 136–3). Participation in a clinical trial of an investigational agent is also a reasonable option for these patients. If the patient has a clinical complete response to first-line chemotherapy and the recurrence occurs more than 6 months after chemotherapy is completed, the tumor is considered platinum-sensitive. Table 136–2 summarizes some of the chemotherapeutic regimens used in the treatment of recurrent or refractory ovarian cancer.

TABLE 136-2 Chemotherapeutic Regimens for Recurrent or Refractory Ovarian Cancer

Drug(s)	Dose(s)	Cycle Frequency
Docetaxel	75 mg/m ² IV day 1	Every 21 days
Pegylated-liposomal doxorubicin	40 mg/m ² IV day 1	Every 28 days
Gemcitabine	800–1,000 mg/m ² IV days 1, 8, and 15	Every 28 days
Paclitaxel	60–80 mg/m ² IV (1-h infusion) day 1	Every week
Paclitaxel	135–175 mg/m ² IV day 1	Every 21 days
Carboplatin	AUC 5 IV day 1	Every 21–28 days
Cisplatin	75 mg/m ² IV day 1	Every 21–28 days
Topotecan	1.3–1.5 mg/m ² IV once daily for 5 days	Every 21 days
Topotecan	4 mg/m ² IV once a week × 3 weeks, then 1 week off	Every 21 days
Etoposide	50 mg/m ² orally once daily days 1–10 repeat every 21 days	Every 28 days
Capecitabine	1,800–2,000 mg/m ² in divided doses twice a daily for 2 weeks on, 1 week off	Every 21 days
Altretamine	260 mg/m ² orally (total daily dose divided in four doses) for 14–21 days	Every 28 days
Tamoxifen	20 mg orally twice a day	Continuous
Letrozole	2.5 mg orally once daily	Continuous

AUC, area-under-the-curve.

CLINICAL CONTROVERSY

In patients with recurrent ovarian cancer that is platinum-sensitive, some clinicians recommend retreatment with a chemotherapy regimen that includes a platinum agent. Other clinicians suggest that the platinum-free interval for these patients should be extended and recommend that recurrent disease first be treated with a nonplatinum regimen (i.e., pegylated-liposomal doxorubicin), reserving the platinum agent until the next relapse.

Platinum-Sensitive Disease Retreatment with a platinum-containing regimen should be considered in patients with platinum-sensitive disease. The International Collaborative Ovarian Neoplasm 4 and Arbeitsgemeinschaft Gynaekologische randomized 802 patients with recurrent platinum-sensitive ovarian cancer to either single-agent platinum, a non-taxane-platinum combination, or a taxane-platinum combination.⁷⁵ Patients treated with the paclitaxel plus platinum regimen had significantly longer progression-free (29 vs. 24 months) and overall survival (hazard ratio = 0.82 [95% CI 0.69 to 0.97]) as compared to the other two treatment arms.⁷⁵ Although the combination taxane-platinum was clearly superior in this European study, it is difficult to extrapolate these results to patients treated in the United States because of differences in first-line treatment. At the time that International Collaborative Ovarian Neoplasm 4 was conducted, the standard of care in Europe for first-line treatment was single-agent carboplatin, so most patients enrolled on this study had no prior exposure to a taxane agent. However, the standard of care in the United States has been combination taxane-platinum since the early 1990s. Confirmatory data is needed to evaluate if combination regimens would also be more beneficial in these patients for treatment of recurrent ovarian cancer.

The 2007 NCCN guidelines recommend the combination of carboplatin with either gemcitabine or paclitaxel for treatment of platinum-sensitive recurrent ovarian cancer.⁶⁵ Carboplatin alone or any of the second-line agents is recommended for patients with platinum-sensitive disease who are unable to tolerate additional combination chemotherapy regimens because of residual toxicity or poor performance status.^{65,76}

Platinum-Resistant Disease Unfortunately many patients develop recurrent drug-resistant disease after initial platinum-based therapy and cytoreductive surgery.^{77,78} Patients who progress on a platinum agent or have no response are considered “platinum-refractory,” whereas those patients who have recurrence within 6 months of completing a platinum-containing regimen are considered “platinum-resistant.”⁷⁹ The 2007 NCCN guidelines list many possible treatment options for recurrent platinum-resistant/-refractory ovarian carcinoma.⁶⁵ The optimal chemotherapeutic agent or regimen in the treatment of platinum-resistant disease is currently unclear. Ideally, the agent should be active in ovarian cancer and non-cross-resistant with taxanes or platinum agents. Unfortunately, the response rate is low for all of the agents in platinum-refractory/-resistant ovarian cancer. Patients should usually be evaluated for response after treatment with at least three cycles of the chemotherapy agent or regimen. Because partial responses are rare, stable disease is considered a treatment success. If no response is observed, then an alternative chemotherapy regimen may be selected.

Topotecan, an analog of the plant alkaloid 20(S)-camptothecin, is active in patients with metastatic ovarian cancer and is non-cross-resistant with platinum-based chemotherapy.⁸⁰ Preclinical studies suggest that protracted schedules of administration with low doses achieve the greatest antitumor response.⁸¹ Topotecan has demonstrated activity in phase II trials as second-line and salvage therapy in patients who have relapsed after, or progressed during, platinum-based therapy.^{80,81,83} A randomized phase III trial compared topotecan and paclitaxel in patients with advanced ovarian cancer who had failed one platinum-based regimen.⁸² Patients were randomized to receive topotecan 1.5 mg/m² per day as a 30-minute infusion for 5 days repeated every 21 days or paclitaxel 175 mg/m² as a 3-hour infusion every 21 days. The overall response rate was 20.5% and 13.2% for the topotecan- and paclitaxel-treated groups, respectively. The median time to progression for topotecan-treated patients (32 weeks) was not significantly different than for paclitaxel-treated patients (20 weeks). Median survival was 61 weeks in the topotecan-treated group and 43 weeks in the paclitaxel-treated group. Topotecan was well tolerated with minimal nonhematologic toxicities.^{80,82,83}

Pegylated liposomal doxorubicin is one of the primary agents used for second-line therapy of recurrent ovarian cancer.^{84–86} The drug tends to be better tolerated than topotecan, which is important for heavily pretreated patients with advanced disease. A large, randomized phase III study compared pegylated liposomal doxorubicin 50 mg/m² every 4 weeks to topotecan 1.5 mg/m² per day for 5 days repeated every 21 days in patients who failed first-line platinum therapy.⁸⁶ A total of 474 patients were randomized, 239 to pegylated liposomal doxorubicin and 235 to topotecan. The overall confirmed response rates for the pegylated liposomal doxorubicin and topotecan groups were 20% and 17%, respectively. Overall survival tended to favor pegylated liposomal doxorubicin, with a median of 108 weeks versus 71.1 weeks for topotecan. Differences in toxicity were observed between the arms, with more hematologic toxicity occurring in the topotecan arm and more palmar-plantar erythrodysesthesia (PPE) in the pegylated liposomal doxorubicin arm. However, the incidence of PPE has decreased in current clinical practice because the standard dose of pegylated liposomal doxorubicin used currently, 40 mg/m², is less than the dose that was used in the initial clinical trials and approved by the FDA.^{87,88}

Gemcitabine, a novel pyrimidine antimetabolite, is also a widely used agent used in the treatment of recurrent platinum-resistant ovarian cancer. Although the overall response rate is only approximately 13% to 22% with single-agent gemcitabine in patients with platinum-refractory recurrent ovarian cancer, an additional 16% to 50% of patients have stable disease for a median of 7 months.^{89,90} The main toxicities include myelosuppression, fatigue, myalgia, and skin rash. Because of its non-cross-resistant activity and in vivo synergy

with platinum agents, gemcitabine is being evaluated in doublet regimens in patients with refractory disease and with carboplatin/taxane regimens in previously untreated patients.⁹⁰ The combination of gemcitabine with taxanes have demonstrated response rates from 36% to 90%, which if confirmed, is extremely encouraging.⁹⁰

Other agents that have shown an overall response rate of 10% to 25% in patients with recurrent ovarian cancer include altretamine, etoposide, capecitabine, tamoxifen, letrozole, vinorelbine, and oxaliplatin.⁹¹ Response rates tend to be higher in the platinum-sensitive subgroups. Most of these agents are available in oral formulations, which allows for outpatient administration in the palliative care setting.

Although there are no guidelines for the selection of agents for the treatment of recurrent platinum-resistant ovarian cancer, the three most commonly used agents in clinical practice include pegylated liposomal doxorubicin, gemcitabine, and topotecan. These agents have demonstrated efficacy when used as a single agent and in combination with other agents. A phase II GOG study is ongoing to help define the optimal chemotherapy combination for treatment of recurrent or refractory platinum-resistant ovarian cancer.

Additional research continues to identify new agents and new targets for the treatment of ovarian cancer. Because platinum agents and taxanes have been identified as the most active classes of agents for treatment of ovarian cancer, drug development has focused on new platinum derivatives, taxanes and taxane analogs, and agents that exert cytotoxic activity by interacting with DNA directly. Specifically, new cytotoxic agents such as Yondelis, TLK-286, pemetrexed, and epothilones; monoclonal antibodies such as bevacizumab and cetuximab; and small molecule tyrosine inhibitors such as erlotinib, gefitinib, and lapatinib, are being evaluated in patients with ovarian cancer.^{92–94}

PHARMACOECONOMIC CONSIDERATIONS

Healthcare at the end of life is associated with higher costs than at any other time, and, unfortunately, most patients with ovarian cancer will eventually die from the disease.⁹⁵ In the past, cost-to-benefit analyses have demonstrated palliative care, despite the limited benefit, is cost-effective based on patients' expectations and "willingness to pay."^{96,97} Economic analyses of new chemotherapy agents usually measure cost-effectiveness, where effectiveness is measured as changes in survival (i.e. overall survival, progression-free survival) or quality-adjusted life-years.⁹⁸

The paclitaxel plus platinum regimen is the current accepted standard of care for first-line treatment of advanced ovarian cancer. When paclitaxel was initially evaluated as first-line treatment, several economic analyses showed that the cost-effectiveness ratio of paclitaxel and cisplatin was within the range of other accepted medical interventions and supported its adoption as first-line treatment of advanced ovarian cancer.^{98,99} In another cost-benefit study, Dranitsaris et al. reported that patients were willing to pay a mean of \$64 which was marginally lower than the incremental cost of \$87 to receive docetaxel rather than paclitaxel to reduce their risk of toxicity, primarily neuropathy.¹⁰⁰

In the setting of recurrent ovarian cancer, Smith et al. performed a retrospective cost minimization analysis of pegylated liposomal doxorubicin versus topotecan.¹⁰¹ The results of that analysis showed that pegylated liposomal doxorubicin was the preferred second-line agent, based on lower costs because of reduced toxicities as compared to topotecan.¹⁰¹

EVALUATION OF THERAPEUTIC OUTCOMES

Patients receiving a taxane or platinum chemotherapy regimen should be monitored for signs of hypersensitivity or infusion-related reac-

tions. Patients treated with paclitaxel often experience infusion-related reactions which have been attributed to the Cremophor diluent. Premedications including an H₁-blocker, H₂-blocker, and steroid should be administered prior to each chemotherapy administration to prevent hypersensitivity reactions. If a patient has a reaction, paclitaxel desensitization can be attempted with 24 hours of premedications (H₁-blocker, H₂-blocker, and steroids) followed by paclitaxel given as a titrated infusion (1:1000 → 1:100 → 1:10 → full dose) over 8 hours. With repeated exposure (i.e., seven cycles or more) to carboplatin, patients can develop a delayed hypersensitivity reaction. A similar protocol can be used for carboplatin desensitization.

Ovarian cancer patients receive multiple courses of chemotherapy that can have varying effects on kidney and liver function. Appropriate laboratory tests should be ordered to assess organ function so that chemotherapy doses can be adjusted as indicated. Patients on platinum-containing regimens often can experience electrolyte wasting, so patients should be monitored for electrolytes intravenous or oral replacement is indicated. The use of myeloid growth factors should be considered to prevent treatment delays and/or dose reductions. Prevention of nausea and vomiting, both acute and delayed, is critical for patients receiving emetogenic chemotherapy regimens such as paclitaxel-carboplatin.

During initial taxane-platinum chemotherapy, a CA-125 level should be obtained with each cycle and monitored for at least a 50% reduction in CA-125 after completion of four cycles, which is related to an improved prognosis. Patients who achieve a complete response after completion of first-line treatment should have followup once every 3 months, including CA-125, physical examination, pelvic examination, and appropriate diagnostic scans (i.e., computed tomography, magnetic resonance imaging, or positron emission tomography), which should be evaluated for presence of disease. In addition to routine followup examinations, clinicians should monitor for resolution of any residual chemotherapy-related side effects, including neuropathies, nephrotoxicity, ototoxicity, myelosuppression, and nausea/vomiting.

In the progressive disease or recurrent setting, CA-125 levels can still be used to monitor for response and should be checked with each cycle, although no change in therapy is recommended until after completion of at least three cycles of the second-line chemotherapy. In addition to laboratory monitoring, appropriate diagnostic scans (i.e., computed tomography, magnetic resonance imaging, or positron emission tomography) should be done once every three cycles. Again, patients need to be monitored with each cycle of chemotherapy to evaluate for new or persistent of toxicities such as neuropathies, fluid retention, PPE, myelosuppression, and nausea/vomiting.

Eventually most ovarian cancer patients will progress through all chemotherapy regimens and investigational treatment options, after which the best supportive care measures should be provided to maintain patient comfort and quality of life. Develop a plan for treatment of common complications of advanced/progressive ovarian cancer, including thrombosis, ascites, uncontrollable pain, and small bowel obstruction. The primary goal at the end of life for patients with progressive ovarian cancer is to provide any measures necessary to maintain patient comfort and quality of life.

CONCLUSIONS

Ovarian cancer remains one of the major challenges in gynecologic oncology. Key issues for improving outcome are patient education and awareness of the signs and symptoms of ovarian cancer. Earlier diagnosis is associated with a significant improvement in prognosis and overall survival. Although some milestones have been reached in extending progression-free and overall survival over the past few decades, there are still many unresolved issues. More data is needed to determine the optimal agents to be used for IP chemotherapy and the usefulness of maintenance chemotherapy and their impact on overall

survival. Research needs to identify and develop new approaches to the prevention of recurrence and new options for the treatment of advanced primary as well as recurrent and refractory ovarian cancer, such as agents to modulate or overcome drug resistance, new molecular targets and optimize chemotherapy regimens.

HELEN L. LEATHER AND BETSY BICKERT POON

KEY CONCEPTS

- 1 Acute leukemias are the most common malignancies in children and the leading cause of cancer-related death in patients younger than age 35 years.
- 2 The World Health Organization recently developed a new classification system for myeloid neoplasms, but the French-American-British (FAB) classification remains the most widely used.
- 3 To establish a definitive diagnosis of acute leukemia, the following diagnostic components are required: bone marrow biopsy and aspirate (with >20% blasts), cytogenetics, and immunophenotyping.
- 4 Several risk factors correlate with prognosis for acute lymphoblastic leukemia (ALL). Poor prognostic factors include high white blood cell count at presentation, very young or very old age at diagnosis, delayed remission induction and presence of certain cytogenetic abnormalities (e.g., Philadelphia [Ph⁺] chromosome).
- 5 For children with ALL, remission induction therapy includes vincristine, a corticosteroid, and asparaginase, with or without an anthracycline. For adults with ALL, vincristine, prednisone, and an anthracycline are given, and asparaginase is sometimes added.
- 6 All patients with ALL require prophylactic therapy to prevent CNS disease because of the high risk of central nervous system relapse. The choice for therapy includes a combination of the following: cranial irradiation, intrathecal chemotherapy, or high-dose systemic chemotherapy with drugs that cross the blood-brain barrier.
- 7 Long-term maintenance therapy for 2 to 3 years is essential to eradicate residual leukemia cells and prolong the duration of remission. Maintenance therapy consists of oral methotrexate and mercaptopurine, with or without monthly pulses of vincristine and a corticosteroid.
- 8 Disease-free survival is lower in adults with ALL and has been attributed to greater drug resistance, poor side-effect tolerance with subsequent nonadherence, and possibly less-effective therapy. This population is also more likely to have Ph⁺ ALL, which is associated with a worse outcome.
- 9 Colony-stimulating factors can be safely and effectively used with myelosuppressive chemotherapy for acute leukemias. The benefits can include reduced incidence of serious infections, re-

duced hospital stays, and fewer treatment delays, but do not include prolonged disease-free survival or overall survival.

- 10 There are several poor prognostic factors for adult acute myeloid leukemia (AML): older age, organ impairment, certain FAB subtypes, presence of extramedullary disease, and presence of certain cytogenetic and molecular abnormalities.
- 11 Therapy of AML usually includes induction therapy with an anthracycline and cytarabine. Postremission therapy is required in all patients and can include either consolidation chemotherapy with or without maintenance therapy, or hematopoietic stem cell transplantation.
- 12 It is estimated that up to 10⁸ to 10⁹ malignant cells remain following attainment of a complete remission. Postremission therapy with either chemotherapy or hematopoietic stem cell transplantation is essential in AML.
- 13 Treatment of acute promyelocytic leukemia consists of induction therapy, followed by consolidation and maintenance therapy. Induction includes tretinoin and an anthracycline; consolidation therapy consists of two to three cycles of anthracycline-based therapy; maintenance consists of pulse doses of tretinoin, mercaptopurine, and methotrexate for 2 years.

The leukemias are heterogeneous hematologic malignancies characterized by unregulated proliferation of the blood-forming cells in the bone marrow. These immature proliferating leukemia cells (blasts) physically “crowd out” or inhibit normal cellular maturation in bone marrow, resulting in anemia, neutropenia, and thrombocytopenia. Leukemic blasts may also infiltrate a variety of tissues such as lymph nodes, skin, liver, spleen, kidney, testes, and the central nervous system.

The term *leukemia* was coined by Virchow to describe the “white blood” of some patients that he saw under the microscope in 1845.¹ Historically, leukemia has been classified as acute or chronic based on differences in cell of origin and cell line maturation, clinical presentation, rapidity of progression of the untreated disease, and response to therapy. Four major leukemias are recognized: acute lymphoblastic (or lymphocytic) leukemia (ALL), acute myeloid leukemia (AML), chronic lymphocytic leukemia, and chronic myeloid leukemia. Undifferentiated immature cells that proliferate autonomously characterize acute leukemias. Chronic leukemias also proliferate autonomously, but the cells are more differentiated and mature.¹ Untreated, the acute leukemias are rapidly progressive, resulting in death within 2 to 3 months.

EPIDEMIOLOGY

- 1 It is estimated that 18,610 new cases of acute leukemias—13,410 cases of AML and 5,200 cases of ALL—will be diagnosed in the

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

United States in 2007, accounting for 1.3% of the total cancer incidence.² The incidence has been relatively stable for two decades. An estimated 10,410 deaths per year, representing approximately 2% of all cancer deaths, are caused by acute leukemias. The acute leukemias are the leading cause of cancer-related deaths in persons younger than age 35 years, but an uncommon cause of cancer-related death after age 35 years.^{1,2} Among adults, acute and chronic leukemias occur at equal rates. More than 90% of the cases of acute and chronic leukemia occur in adults. AML accounts for most cases of acute leukemia in adults, and occurs with increasing frequency in elderly patients. There are about 4 cases of AML and 1.4 cases of ALL per 100,000 individuals.³ The median age at diagnosis of patients with AML is about 65 years, whereas the median age for ALL patients is about 10 years.¹⁻³ The incidence of AML rises with age from 1.8 per 100,000 in individuals younger than age 65 years to 17.9 per 100,000 in those 65 years or older.^{3,4} Acute leukemia is slightly more common in males than in females. In the United States, acute leukemia is more common among whites than among African Americans, American Indians, and Hispanic ethnicities.^{1,3}

Despite the low incidence rate, the acute leukemias are the most common malignancy in persons younger than 15 years of age, accounting for approximately 30% of all childhood malignancies.³ In the United States, 9,850 persons younger than 15 years of age are diagnosed with cancer each year; approximately 2,500 of them have ALL.⁴ AML accounts for approximately 20% of all childhood leukemias, and the chronic leukemias account for less than 5%.³ Childhood ALL is 30% more common in males than in females, peaks at 2 to 5 years of age, and is twice as likely to affect white children as African American children.^{3,5} The incidence of childhood AML is highest in the Hispanic population and occurs throughout childhood without any peak age period. Acute leukemia during the first year of life (infant leukemia) is twice as likely to be ALL as AML.³

Chemotherapy has dramatically improved the outlook of patients with acute leukemia. More than 85% of children and young adults with acute leukemia achieve an initial complete remission (CR) of their disease. Overall, 65% to 85% of adults achieve an initial CR.^{1,4} For persons younger than 20 years of age, the 5-year survival rate is 83% for ALL and 50% for AML.³ The prognosis of adult acute leukemia is generally worse than that of childhood leukemia, with only 30% to 40% of patients becoming long-term survivors.^{1,4}

ETIOLOGY

The exact cause of the acute leukemias is unknown. A multifactorial process involving genetics, environmental and socioeconomic factors, toxins, immunologic status, and viral exposures is likely. Table 137-1 summarizes the major factors that have been linked to acute leukemias. Infectious and genetic factors have the strongest associations to date.^{1,6-8} In pediatric ALL, a number of environmental factors are inconsistently linked to the diseases: exposure to ionizing radiation, toxic chemicals, herbicides and pesticides; maternal use of contraceptives, diethylstilbestrol, or cigarettes; parental exposure to drugs (amphetamines, diet pills, and mind-altering medications), diagnostic radiographs, alcohol consumption, or chemicals before and during pregnancy; and chemical contamination of groundwater.^{6,8} Ionizing radiation and benzene exposure are the only environmental risk factors strongly associated with ALL or AML.⁸ A few studies have reported a possible link between electromagnetic fields of high-voltage power lines and the development of leukemia, but larger studies could not confirm this association. In most patients who develop leukemia, a causative agent cannot be identified.

Childhood AML is associated with Hispanic ethnicity, prior exposure to alkylating agents or epidophyllotoxins, and in utero exposure to ionizing radiation.^{1,8} Maternal alcohol consumption,

parental and child pesticide exposure, and parental benzene exposure are also associated with childhood AML.

PATHOPHYSIOLOGY

A basic understanding of normal hematopoiesis is needed before one can understand the pathogenesis of leukemia. Chapter 103 has a detailed discussion of hematopoiesis. Normal hematopoiesis consists of multiple well-orchestrated steps of cellular development. A pool of pluripotent stem cells undergoes differentiation, proliferation, and maturation, to form the mature blood cells seen in the peripheral circulation. These pluripotent stem cells initially differentiate to form two distinct stem cell pools. The myeloid stem cell gives rise to six types of blood cells (erythrocytes, platelets, monocytes, basophils, neutrophils, and eosinophils), while the lymphoid stem cell differentiates to form circulating B and T lymphocytes. Leukemia may develop at any stage and within any cell line.

Two features are common to both AML and ALL: first, both arise from a single leukemic cell that expands and acquires additional mutations, culminating in a monoclonal population of leukemia cells. Second, there is a failure to maintain a relative balance between proliferation and differentiation, so that the cells do not differentiate past a particular stage of hematopoiesis. Cells (lymphoblasts or myeloblasts) then proliferate uncontrollably. Proliferation, differentiation, and apoptosis are under genetic control, and leukemia can occur when the balance between these processes is altered. New antileukemia drug therapies are being developed that are specifically targeted to the biologic processes involved in proliferation and differentiation.

AML probably arises from a defect in the pluripotent stem cell or a more committed myeloid precursor, resulting in partial differentiation and proliferation of immature precursors of the myeloid blood-forming cells. In older patients, trilineage leukemic involvement is common, suggesting that the cell of origin is probably a stem or very early progenitor cell. In younger patients, a more differentiated progenitor becomes malignant, allowing maturation of some granulocytic and erythroid populations. These two forms of AML exhibit different patterns of resistance to chemotherapy, with resistance more evident in the older adults with AML. ALL is a disease characterized by proliferation of immature lymphoblasts. In this type of acute leukemia, the defect is probably at the level of the lymphopoietic stem cell or a very early lymphoid precursor.¹

Leukemic cells have growth and/or survival advantages over normal cells, leading to a "crowding out" phenomenon in the bone marrow. This growth advantage is not caused by more rapid prolifer-

^aPercentages should be compared vertically, not horizontally.

eration as compared with normal cells. Some studies suggest that it is caused by factors produced by leukemic cells that either inhibit normal cellular proliferation and differentiation, or reduce apoptosis as compared with normal blood cells.

The types of genetic alterations that lead to leukemia have only recently become evident. The genetic defects may include (a) activation of a normally suppressed gene (protooncogene) to create an oncogene that produces a protein product that signals increased proliferation; (b) loss of signals for the blood cell to differentiate; (c) loss of tumor suppressor genes that control normal proliferation; and (d) loss of signals for apoptosis. Most normal cells are programmed to die eventually through apoptosis, but the appropriate programmed signal is often interrupted in cancer cells, leading to continued survival, replication, and drug resistance. Signal transduction, RNA transcription, cell-cycle control factors, cell differentiation, and programmed cell death may all be affected.

LEUKEMIA CLASSIFICATION

2 The French-American-British (FAB) classification system identifies eight different subtypes of AML based on granulocytic differentiation and maturation (Table 137–2), and this system is used to determine prognosis and choice of therapy. However, it does not consider clinical characteristics, clonal cytogenetic abnormalities, immunophenotyping, or response to therapy. The World Health Organization and the Society of Hematopathology have proposed a new classification system for myeloid neoplasms (Table 137–3).⁹ This new classification system incorporates not only morphologic findings, but also genetic, immunophenotypic, biologic, and clinical features. It has long been known that certain cytogenetic abnormalities have prognostic significance, but did not always correlate well with the FAB classification system.¹⁰ In addition, this new classification attempts to formally incorporate the relationship between AML and myelodysplastic syndrome (MDS). A limitation of the World Health Organization classification is that it does not account for some of the myeloid disorders of childhood. There are recommendations to expand the myelodysplastic/myeloproliferative disorders to include additional subclasses such as juvenile myelomonocytic leukemia and patients with Down syndrome.¹¹

Lymphoid leukemias are not addressed in the current World Health Organization classification system. Markers on the cell surface or membrane of the lymphoblast can be used to classify ALL. ALL may also be described by cytogenetic abnormalities. Chromosome alterations include numerical (hyperdiploidy and hypodiploidy), and structural abnormalities due to exchanges of genetic information within (inversion) or between (translocation) chromosomes.¹² ALL is also subclassified based on cell type into mature B-cell, precursor B-cell, and T-cell disease. Eighty percent of

childhood ALL derives from precursor B cells and approximately 15% from T cells. The remainder is either mixed lineage or from mature B cells.

ACUTE LYMPHOBLASTIC LEUKEMIA

CLINICAL PRESENTATION

3 Common signs and symptoms at presentation result from malignant cells replacing and suppressing normal hematopoietic progenitor cells and infiltration into extramedullary spaces. In addition to clinical presentation, laboratory and pathology evaluations are required for a definitive diagnosis of leukemia. An abnormal complete blood count is usually the diagnostic test that initiates a leukemia diagnostic workup. The most important test is a bone marrow biopsy and aspirate, which is submitted to hematopathology for numerous evaluations. A lumbar puncture is performed to determine if there are blasts in the central nervous system (CNS). A

TABLE 137-3 World Health Organization Classification of Acute Myeloid Leukemia

Acute myeloid leukemia (AML) with recurrent genetic abnormalities
AML with t(8;21)(q22;q22), (AML1/ETO)
AML with abnormal bone marrow eosinophils and inv(16)(p13;q22) or t(16;16)(p13;q22), (CBFβ/MYH11)
Acute promyelocytic leukemia with t(15;17)(q22;q12), (PML/RARα) and variants
AML with 11q23 (MLL) abnormalities
Acute myeloid leukemia with multilineage dysplasia
Following MDS or MDS/MPD disorder
Without antecedent MDS or MDS/MPD, but with dysplasia in at least 50% of cells or two or more lineages
Acute myeloid leukemia and MDS, therapy-related
Alkylating agent/radiation-related type
Topoisomerase II inhibitor-related type (some may be lymphoid)
Others
Acute myeloid leukemia, not otherwise categorized, classify as
Acute myeloid leukemia, minimally differentiated
Acute myeloid leukemia without maturation
Acute myeloid leukemia with maturation
Acute myelomonocytic leukemia
Acute monoblastic/acute monocytic leukemia
Acute erythroid leukemia (erythroid/myeloid and pure erythroleukemia)
Acute megakaryocytic leukemia
Acute basophilic leukemia
Acute panmyelosis with myelofibrosis
Myeloid sarcoma

MDS, myelodysplastic syndrome; MLL, mixed lineage leukemia; MPD, myeloproliferative disease; PML, promyelocytic leukemia; RAR, retinoic acid receptor-α.

From Vardiman et al.⁹

chest radiograph is performed to screen for a mediastinal mass (most common in T-cell disease).

Leukemia is suspected if the bone marrow contains greater than 5% blasts. Cytochemical stains are helpful to determine if the acute leukemia is of myeloid or lymphoid lineage. Immunophenotyping analyzes specific antigens, known as clusters of differentiation, often abbreviated “CD,” present on the surface of hematopoietic cells. Although no leukemia-specific antigens have been identified, the pattern of cell-surface antigen expression reliably distinguishes between lymphoid and myeloid leukemia.¹ Cytogenetic analysis of the marrow to determine the presence of nonrandom numerical and structural chromosomal abnormalities in leukemic cells is also helpful for diagnosis, establishing prognosis, and evaluating response to therapy.^{1,5,6,12} Chromosome translocations can result in abnormal expression and/or function of cellular oncogenes. Unique translocations can identify specific subtypes of acute leukemia. Recently, technically difficult cytogenetic analysis has been supplemented with fluorescent in situ hybridization, which allows for quick, sensitive analysis of samples that might be inadequate for karyotyping. Fluorescent in situ hybridization is a process in which specific genes in an intact cell are visualized with fluorescent-labeled probes. Molecular tests may be used to identify products of specific translocations.

CLINICAL PRESENTATION^{1,5,6}

General

- Recent history of vague symptoms such as tiredness, lack of exercise tolerance, and “feeling unwell,” but in no obvious distress.

Symptoms

- Patient’s commonly report fever, pallor, weight loss, malaise, fatigue, palpitations, and bone pain. Other possible symptoms include epistaxis, palpitations, dyspnea on exertion, seizures, headache, or diplopia.

Signs

- Temperature is often elevated and may be caused by disease or infection; ecchymoses or petechiae; painless testicular enlargement; splenomegaly, hepatomegaly, and/or lymphadenopathy; and, rarely, small, blue-green collections of leukemia cells under the skin (chloromas).

Laboratory Tests

- Complete blood count with differential. Anemia (43% <7 g/dL) is normochromic and normocytic (without a compensatory increase in reticulocytes). Thrombocytopenia (severe, <20,000 cells/mm³) is present in 28% of cases. Leukopenia/leukocytosis: 17% of patients will present with a white blood cell (WBC) count ≥50,000 cells/mm³ and 53% with a WBC <10,000 cells/mm³.
- Uric acid may be elevated because of rapid cellular turnover and is more common in patients presenting with elevated WBC count.
- Electrolytes: potassium and phosphate may be elevated with a compensatory decrease in calcium.

Other Diagnostic Tests

- Bone marrow aspirate and biopsy: send for morphologic examination, cytochemical staining, immunophenotyping, and cytogenetic (chromosome) analysis. All patients should have a screening lumbar puncture performed to assess CNS involvement.

RISK CLASSIFICATION

4 Many clinical and laboratory features at diagnosis are associated with response to treatment, as measured by the CR rate, duration of

remission, and long-term survival. Identification of these risk factors allows the clinician to better understand the disease and to tailor treatment according to risk of disease recurrence (i.e., risk-adapted therapy). For example, if a patient has many clinical and laboratory features that are associated with a good response to chemotherapy (“standard-risk”), then the clinician may choose to give less-intensive therapy to reduce the risk of long-term side effects. Conversely, if a patient is unlikely to respond well to standard therapy (“high-risk” or “very-high-risk”), then the clinician may choose to give more-intensive chemotherapy.

The National Cancer Institute developed an ALL risk stratification to create a standard for comparison in children.¹³ Remission induction therapy is initially selected based on this classification, which divides children into standard- or high-risk categories based on age, WBC count, and karyotype (Fig. 137–1). Recently, more sophisticated biologic studies have allowed more refined risk stratification.¹⁴ For example, it incorporates treatment response through the measurement of subclinical minimal residual disease by either flow cytometry or polymerase chain reaction.

The strongest prognostic factor for outcome for ALL is response to therapy. Traditionally this was measured morphologically in bone marrow specimens. More recently molecular measurement of minimal residual disease has enabled detection of leukemic cells not visible on morphologic examination.¹⁵ This technique allows detection of 1 leukemia cell in 10,000 normal cells, which is about 100-fold more sensitive than morphologic examination. If minimal residual disease is detected at the end of induction therapy, the clinician may decide to give more-intensive therapy to decrease the risk of relapse.

The Children’s Oncology Group has proposed a risk- and response-based classification of childhood ALL (see Fig. 137–1).¹⁴ That classification system uses the National Cancer Institute risk assignment to initially categorize patients into standard- or high-risk groups. Patients with T-cell ALL are automatically categorized as very-high-risk, regardless of age, WBC count, or other factors. Following remission induction therapy, risk is reclassified based on the rapidity and completeness of response to therapy, the presence or absence of cytogenetic abnormalities, testicular involvement, or CNS involvement (see Fig. 137–1). Children may have their therapy augmented if the bone marrow has more than 5% blasts on day 15 of therapy. Children will have therapy reduced if they have either triple trisomies (chromosomes 4, 10, and 17) or TEL-AML1 (translocation ETS leukemia-acute myeloid leukemia-1) fusions and have less than 5% blasts by day 8 or 15 or 29 of induction in conjunction with less than 0.1% minimal residual disease on day 29. Children who have the Philadelphia chromosome [Ph⁺ disease, t(9;22)], hypodiploidy, T-cell disease, induction failures, mixed lineage leukemia (MLL), or a slow response to induction therapy are considered very high-risk.

Other prognostic factors have been identified but are not the basis for therapy changes. Females have a better prognosis than males. Race is controversial, with older studies indicating worse outcomes for minorities. Hepatosplenomegaly and mediastinal mass are both associated with worse outcomes.

TREATMENT

Acute Lymphoblastic Leukemia

TREATMENT GOALS

The short-term goal of treatment for acute leukemia is to rapidly achieve a complete clinical and hematologic remission. CR is defined as the disappearance of all physical and bone marrow

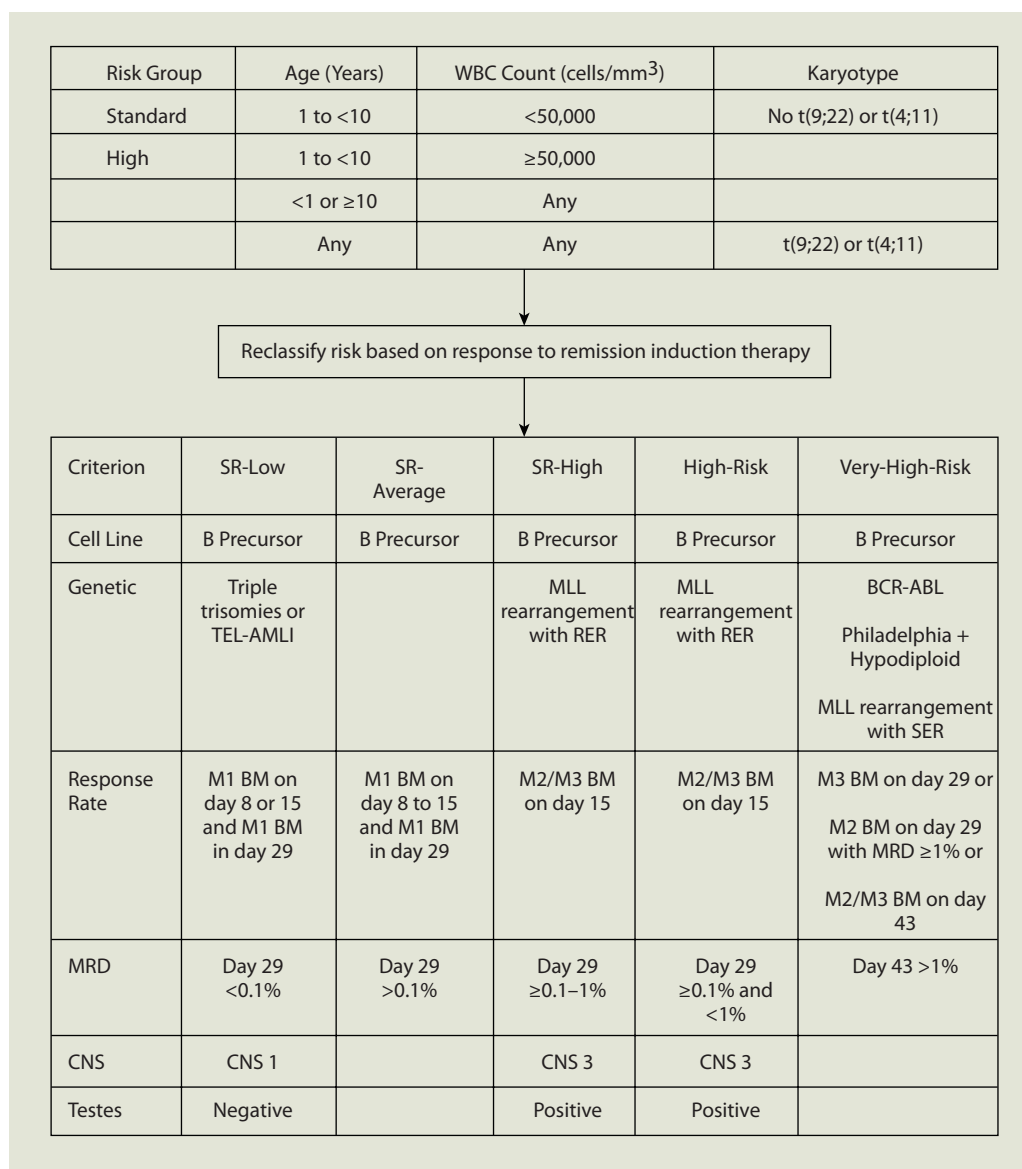

FIGURE 137-1. Risk- and response-based classification of childhood ALL. *Note:* Patients with T-cell ALL are automatically categorized as very-high-risk regardless of other factors. (BM, bone marrow; CNS 1, no lymphoblasts; CNS 3, lymphoblasts with ≥5 WBC/mm³ or clinical signs of CNS disease; M1, <5% blasts, M2, 5–25% blasts, M3, >25% blasts; MLL, mixed lineage leukemia; MRD, minimal residual disease; RER, rapid early response; SER, slow early response; SR, standard risk; TEL-AMLI, translocation ETS leukemia-acute myeloid leukemia-1; WBC, white blood cell.)

evidence (normal cellularity with <5% blasts) of leukemia, with restoration of normal hematopoiesis (neutrophils ≥1,500 cells/mm³ and platelets >100,000 cells/mm³). After a CR is achieved, the goal is to maintain the patient in continuous CR. In general, a child is considered to be “cured” after being in continuous CR for 5 to 10 years.

Successful treatment of ALL was first developed in children. Current regimens induce CR in 98% of children with ALL.¹² Children who do not achieve a CR by the end of induction have an overall event-free survival (EFS) of 16%.⁵ Cure rates in children have risen from less than 5% with treatments used in the 1960s to approximately 90% by 2005.¹² The reason for this improvement lies largely in improved scheduling of existing drugs, as relatively few new drugs have come to the market since the 1960s.

Although treatment results with adult ALL are worse than those with childhood ALL, recent use of aggressive chemotherapy in adult ALL has increased the CR rate to 60% to 85%. Long-term disease-free survival (DFS) in this population, however, remains low

(between 30% and 40%) because of the higher proportion of adults presenting with poor-risk disease. CR rates and DFS vary according to a number of poor prognostic factors and certain types of ALL are associated with a very poor outcome.

Therapy for childhood ALL is divided into five phases: (a) remission induction; (b) consolidation therapy; (c) interim maintenance; (d) delayed intensification; and (e) maintenance therapy (Fig. 137–2). CNS prophylaxis is a mandatory component of ALL treatment regimens and is administered longitudinally during all phases of treatment.

■ TREATMENT PHASES

Remission Induction

5 The goal of remission induction is to rapidly induce a complete clinical and hematologic remission, where hematologic remission is defined as reducing the leukemia cell burden below morphologic detection following recovery of normal blood counts. The CR rate

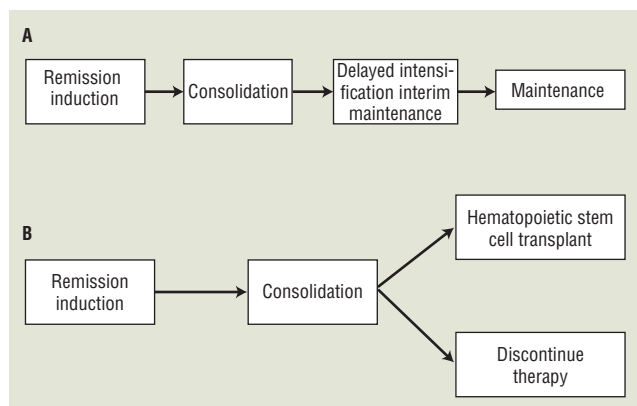

FIGURE 137-2. Treatment algorithm for (A) acute lymphoblastic leukemia and (B) acute myeloid leukemia.

is 98% in children treated with vincristine, dexamethasone or prednisone, and asparaginase or pegaspargase.^{1,12} Most treatment protocols add daunorubicin to induction (four-drug induction) for high-risk ALL, and some also add other agents, such as cyclophosphamide, methotrexate, or cytarabine.

The rate of clearance of blasts is an important prognostic factor. Children with a slow rate of clearance of blasts from the bone marrow in the first 8 (high-risk) or 15 (standard-risk) days of therapy have an eventual outcome that is inferior to those with rapid clearance of blasts (see Fig. 137-1 for definitions of risk).¹⁶ Additional intensified therapy significantly improves outcome of children with a slow early response.¹⁶ Historically, prednisone has been the primary glucocorticoid used in pediatric ALL regimens. Dexamethasone is now being used in some standard-risk protocols because of its longer duration of action and higher cerebrospinal fluid penetration compared to prednisone.¹² Dexamethasone, when used in place of prednisone during induction, consolidation, and maintenance, also improves EFS and decreases the risk of CNS relapse.¹⁷ However, dexamethasone increases the risk of side effects such as osteonecrosis, steroid myopathy, hyperglycemia, and infections.^{17,18} Patients older than 10 years of age are particularly prone to osteonecrosis and receive dexamethasone intermittently (7 days on, 7 days off) to minimize these effects. Because patients with Down syndrome have increased infections and mortality with dexamethasone, prednisone is substituted in these patients.

Asparaginase is available in three forms. Asparaginase and pegaspargase are isolated from *Escherichia coli* while cristaspase (investigational agent available if allergic to the other products) is isolated from *Erwinia chrysanthemi*. Pegaspargase is pegylated *E. coli* asparaginase; pegylation prolongs its duration of activity and allows it to be given less frequently. Pegaspargase is preferred over asparaginase because of fewer intramuscular injections, decreased antibody formation, and superior response rates. Asparaginase products are the chemotherapeutic agents most likely to cause hypersensitivity reactions (10% to 40%). The reaction is delayed with pegaspargase and usually occurs 6 to 12 hours following a dose. The hypersensitivity reaction to pegaspargase may also be prolonged and frequently requires hospitalization for 5 to 7 days.

Ph⁺ ALL is associated with a poor long-term outcome and is treated as very-high-risk disease. This includes a four-drug induction and a matched related-donor allogeneic hematopoietic stem cell transplant (HSCT) if available. The availability of imatinib mesylate, a signal transduction inhibitor that inhibits BCR-ABL kinase, has stimulated much research to try and improve responses in the 10% to 20% of children who are Ph⁺ and refractory to a four-drug induction.¹⁹ Imatinib is currently incorporated into childhood treatment trials for Ph⁺ ALL in Europe and the United States.

CLINICAL CONTROVERSY

Which is the superior corticosteroid for the treatment of ALL? Prednisone/prednisolone has been the steroid of choice for many years. Dexamethasone was recently shown to have better CNS penetration than prednisone with a consequent decrease in CNS relapse rate. However, the incidence of debilitating side effects such as osteonecrosis is higher with dexamethasone. Many investigators have difficulty weighing the quality-of-life decrease from the side effects against the small increase in survival.

Central Nervous System Prophylaxis

6 CNS prophylaxis is incorporated throughout all phases of therapy. The rationale for CNS prophylaxis is based on two observations. First, many chemotherapeutic agents do not readily cross the blood-brain barrier. Second, results from early clinical trials of ALL showed that 50% to 85% of patients with ALL and no CNS involvement at diagnosis experienced a CNS relapse.^{5,6} These observations indicate that the CNS is a potential sanctuary for leukemic cells and that undetectable leukemic cells are present in the CNS in many patients at the time of diagnosis. Detectable CNS involvement at the time of diagnosis is relatively uncommon (<5%) in ALL.⁵ Factors that are associated with an increased risk of CNS involvement at diagnosis in children include a high initial WBC count, T-cell phenotype, mature B-cell phenotype, age ≤1 year, African American race, thrombocytopenia, lymphadenopathy, and hepatomegaly or splenomegaly.^{5,12}

The goal of CNS prophylaxis is to eradicate undetectable leukemic cells from the CNS. Leukemic meningitis is more easily prevented than treated. Once CNS relapse has occurred, patients are at increased risk of bone marrow relapse and death from refractory leukemia. Initial trials of childhood ALL in the 1960s established craniospinal irradiation as the standard for prevention of CNS relapse.¹² However, this approach was associated with long-term sequelae including neuropsychological deficits, precocious puberty, osteoporosis, decreased intellect, thyroid dysfunction, an increased risk of brain tumors, short stature, and obesity. Subsequent trials have demonstrated that irradiation may be replaced by frequent administration of intrathecal chemotherapy in most children with ALL.¹² Only patients with very-high-risk disease still receive prophylactic cranial radiation in the United States as a consequence of the long-term sequelae.

The selection of a CNS prophylaxis regimen must consider efficacy, toxicity, and risk of CNS disease. Intrathecal chemotherapy, cranial irradiation, and high-dose intravenous methotrexate or cytarabine can be used to treat or prevent CNS disease. Current treatment approaches have reduced isolated CNS relapses to less than 5% among children.^{5,20} Risk factors for CNS relapse include male sex, hepatomegaly, CNS2 disease (the presence of leukemic blasts in a cerebrospinal fluid sample that contains <5 WBC/mm³), age younger than 2 years or older than 6 years, and a bloody diagnostic lumbar puncture.^{5,20} Intrathecal therapy consists of methotrexate and cytarabine, given either alone or in combination. When given together, hydrocortisone is commonly added (triple intrathecal therapy) to decrease the incidence of arachnoiditis. For standard-risk ALL, triple intrathecal therapy reduces CNS relapse rates by 2.5% in comparison to intrathecal methotrexate, but has no effect on overall survival.²⁰ The doses of intrathecal chemotherapy used in pediatric ALL patients must be individualized based on age because of differences in the volume of cerebrospinal fluid at various ages. Liposomal cytarabine induces CNS remission in 57% of relapsed patients, but is associated with a high incidence of arachnoiditis and other CNS-related side effects.²¹ Currently its use is limited to refractory or relapsed CNS disease.

Consolidation Therapy

Consolidation therapy in ALL is started after a CR has been achieved, and refers to continued intensive chemotherapy in an attempt to eradicate clinically undetectable disease in order to secure (consolidate) the remission. Regimens usually incorporate either non-cross-resistant drugs that are different from the induction regimen, or more dose-intensive use of the same drugs.

Randomized trials show that consolidation therapy clearly improves patient outcome in children, but its benefit in adults is less clear.^{1,12} The relative benefit of individual components of treatment regimens is difficult to demonstrate because of the overall complexity of therapy in ALL. Standard consolidation lasts 4 weeks and usually consists of vincristine, mercaptopurine, and intrathecal methotrexate. Children with testicular disease usually receive radiation during this phase of therapy if a complete clinical response in the testes is not achieved by the end of induction. In children, the intensity of consolidation therapy is based on the child's risk classification and rate of cyto-reduction during induction. Patients who respond slowly to induction therapy are at higher risk of relapse if they are not treated on more aggressive regimens. Consolidation may be intensified for slow early responders or high-risk patients to include cyclophosphamide, low-dose cytarabine, and pegaspargase. Children with Ph⁺ ALL or infants with t(4;11) mixed lineage leukemia (MLL), or children who only achieve a partial remission may receive a HSCT in first remission if a suitable donor is available.¹ Imatinib has been incorporated into consolidation for children with Ph⁺ disease.

Delayed Intensification/Interim Maintenance

One or two delayed intensification phases separated by low-intensity interim maintenance cycles have been added to maintain remission and to decrease cumulative toxicity. Delayed intensification usually consists of dexamethasone, vincristine, doxorubicin, pegaspargase, cyclophosphamide, thioguanine or mercaptopurine, low-dose cytarabine, and intrathecal methotrexate. Interim maintenance usually consists of dexamethasone, vincristine, weekly methotrexate, mercaptopurine, and intrathecal methotrexate. The addition of these delayed intensified cycles improved results with a 6-year 76% EFS for a single delayed intensification and 83% for two cycles in intermediate-risk patients.²² A single delayed intensification improved 7-year EFS by 6% in low-risk patients.²³ Current studies are testing similar regimens in standard-risk patients. The antimetabolite-based regimens may have a reduced risk of late toxicities, but the more intensive regimens appear to result in better survival for some patients, especially those with higher-risk disease.

Maintenance Therapy

7 Maintenance therapy allows long-term drug exposure to slowly dividing cells, allows the immune system time to eradicate leukemia cells, and promotes apoptosis (programmed cell death). The goal of maintenance therapy is to further eradicate residual leukemic cells and prolong remission duration. Although maintenance therapy is clearly beneficial in childhood ALL, the possible benefit in adults has only recently been demonstrated.

Maintenance therapy usually consists of daily mercaptopurine and weekly methotrexate for 12-week courses, at doses that produce relatively little myelosuppression, with monthly "pulses" of vincristine and a steroid for 5 days per month. In an effort to determine the long-term outcome of the duration and intensity of maintenance therapy, the Childhood ALL Collaborative Group published findings from a large meta-analysis involving 12,000 randomized children from 42 trials initiated prior to 1987.²⁴ That analysis revealed that longer maintenance, pulses of vincristine and prednisone, and the inclusion of one or two intensive reinduction courses signifi-

cantly reduced the total number of deaths or relapse. However, only intensive reinduction improved survival.

Based on the results of studies that show a trend toward an increase in late relapse (excluding isolated testicular relapse) among male children treated for 2 years versus 3 years, some centers treat female children for 2 years while males receive maintenance to complete a total of 3 years of therapy. Interpatient variability in the pharmacokinetics of oral methotrexate and mercaptopurine may also be an important determinant of the effectiveness and toxicity of maintenance therapy. Patients who take their oral methotrexate and mercaptopurine on an evening versus a morning schedule appear to have a superior outcome. Mercaptopurine cannot be given with milk or milk products because of the presence of xanthine oxidase. To account for the interpatient variability, most clinicians will titrate the dose of either agent to maintain an absolute neutrophil count of 750 to 1,500 cells/mm³. Some protocols circumvent bioavailability and poor adherence issues by administering methotrexate intravenously or intramuscularly. The importance of these pharmacokinetic issues in adults is less-well defined.

Genetic polymorphisms may affect drug metabolism, receptor expression, drug transportation, drug disposition, and pharmacologic response. These alterations may contribute to acute and chronic toxicity from ALL therapy as well as differences in treatment outcome. The most studied polymorphism involves thiopurine metabolism. Thiopurines are inactivated by S-methylation by cellular thiopurine S-methyltransferase (TPMT). Approximately 10% of the population has intermediate TPMT activity as a result of heterozygous polymorphisms in the gene encoding for TPMT, and 1 in 300 has extremely low activity as a result of homozygous presence of this TPMT polymorphism.²⁵ Deficiency of TPMT activity results in excessive myelosuppression from mercaptopurine and thioguanine. Patients with low activity (homozygous mutant TPMT genotype) may require 85% to 90% dose reductions.²⁵ Prospective evaluation of TPMT status was complicated in the past, as many ALL patients receive transfusions prior to definitive diagnosis. TPMT status can now be determined directly by DNA-based testing, which may become a standard of care in the near future.

■ T-CELL DISEASE

Patients with T-cell leukemia have an inferior response rate to standard-risk therapy and are automatically categorized as very-high-risk (see Fig. 137-1). Patients with T-cell leukemia have an increased incidence of CNS disease and benefit from systemic therapy that penetrates the CNS such as high-dose methotrexate.¹⁸ Patients with T-cell disease have lower methotrexate polyglutamate accumulation and seem to benefit from these higher doses.

Nelarabine is a prodrug of ara-G that preferentially accumulates in T-lymphoblasts as ara-GTP. Children and young adults in first bone marrow relapse had a 55% complete or partial response in the phase II trial.²⁶ Nelarabine is currently incorporated into a high-risk backbone for initial therapy of childhood T-cell ALL.

■ ACUTE LYMPHOBLASTIC LEUKEMIA IN INFANTS

ALL and AML in infants younger than 1 year of age accounts for less than 5% of the reported acute leukemias in childhood, but they are associated with poor outcomes. EFS in infant ALL is 20% to 40%.²⁷ Sixty percent to 70% of infants with acute leukemia have a translocation that involves the MLL gene located at 11q23.²⁷ In infant ALL, the t(4;11) is most common and has been associated with an extremely poor outcome in the past, with only 10% to 20% EFS.²⁷ Other poor prognostic factors in infant ALL include age less than 6 months, a high WBC count, hepatosplenomegaly, and CNS disease. These factors are also closely associated with MLL translocations.

Patients with infant ALL may have greater drug resistance to asparaginase and prednisone, but increased sensitivity to cytarabine.²⁷ Although intensive regimens such as high-dose methotrexate and high-dose cytarabine have improved survival rates, unacceptably high mortality rates have also been observed with some regimens. Lack of pharmacokinetic data for chemotherapy in infants has contributed to toxicity from inappropriate dosing of doxorubicin and vincristine. To reduce neuropsychological complications, most protocols avoid cranial irradiation. The use of allogeneic HSCT for infants with ALL remains controversial due to a lack of donors, concerns over the long-term toxicity of total body irradiation, and excessive mortality in some series.

■ ACUTE LYMPHOBLASTIC LEUKEMIA IN ADULTS

8 Because most adults are considered high-risk, adults usually receive more-intensive remission induction regimens. Complete remission is achieved in 70% to 90% of adults with a four-drug regimen containing daunorubicin or doxorubicin, vincristine, L-asparaginase, and prednisone.^{1,6} DFS is considerably lower and is achieved in 30% to 40% of patients. The value of adding more drugs to the basic three- or four-drug induction regimen is unclear. Equally unclear is the value of higher doses of standard combinations of drugs for remission induction. Some studies suggest that high-dose methotrexate and cytarabine alternating with fractionated cyclophosphamide plus vincristine, doxorubicin, and dexamethasone (hyperCVAD) may improve response and survival in adults with ALL.²⁸ Poorer outcomes in adults have been attributed to greater drug resistance, poor side-effect tolerance with subsequent nonadherence, and possibly less-effective therapy.

A considerable number of ALL cases occur in patients older than age 60 years, and treatment of this group of patients is an even greater challenge. The response to therapy and durability of response seem less than in younger adults or children. Treatment-related mortality rates during remission induction therapy are also higher in this population. Older patients are more likely to be Ph⁺ positive, with the Ph⁺ present in more than 50% patients age 55 years and older. Older patients are less likely to have T-cell ALL.⁶ Based on data demonstrating improved and sustained responses in Ph⁺ chronic myeloid leukemia with the tyrosine kinase inhibitor imatinib, several groups have evaluated the addition of imatinib to conventional chemotherapy in Ph⁺ ALL patients.^{29–32} Although no randomized trials have compared imatinib and conventional chemotherapy versus conventional chemotherapy alone, several single-center uncontrolled trials have reported improved overall survival (OS) with the addition of imatinib.^{29,30} This approach also appears to be tolerated in the elderly.³¹ Two other tyrosine kinase inhibitors, dasatinib and nilotinib, have also been evaluated in imatinib-resistant Ph⁺ leukemias. Responses are achieved, although are short-lived, with relapses occurring within 6 months.^{33,34} A primary concern with the tyrosine kinase inhibitors is the emergence of resistance, specifically T315I mutations.

■ TREATMENT OF RELAPSED ACUTE LYMPHOBLASTIC LEUKEMIA

The most common site for relapse is the bone marrow, although isolated relapses can occur in the CNS or testicles. Because marrow relapse usually follows isolated CNS or testicular relapses, patients with isolated extramedullary relapses are treated with localized radiation (cranial or testicular) and aggressive systemic chemotherapy similar to that given to patients with a marrow relapse.^{5,35}

Patients who have completed treatment and who have stayed in remission for longer periods are more likely to be reinduced into remission again. Patients with more favorable risk factors initially,

and those who received less intensive initial treatments, are more likely to respond well to reinduction/salvage regimens. Although 80% to 90% of children can achieve a second remission with anthracycline, corticosteroid, vincristine, and asparaginase/pegasparase, the 3-year OS following bone marrow (28%), CNS (60%), and testicular relapse (60%) is not optimal.³⁵ Survival is only 8% for children achieving a third remission after a second bone marrow relapse.³⁵ Clofarabine, a purine antimetabolite, achieves a 12.5% complete response rate, but the duration of response is less than 6 months.

Allogeneic HSCT (alloHSCT) is the treatment of choice for early bone marrow relapse (first CR [CR1] less than 36 months).³⁵ Children who relapse more than 36 months after completion of initial therapy have reasonable outcomes with chemotherapy alone.^{12,35} For patients with initial remissions less than 36 months, alloHSCT performed while in second CR (CR2) is associated with a 8-year DFS of 41%, versus 23% with chemotherapy.³⁶ Patients who undergo alloHSCT are less likely to relapse, but are more likely to experience treatment-related morbidity and mortality if total-body irradiation is included in the conditioning regimen.³⁷

Historically high-risk adult patients with a human leukocyte antigen (HLA)-matched sibling have been offered alloHSCT, but recent data suggest that there is no benefit to alloHSCT in this population (with the exception of Ph⁺ ALL). High treatment-related mortality in this group may offset any benefit from a lower relapse rate.³⁸ Most elderly patients are not candidates for standard alloHSCT but are candidates for nonmyeloablative alloHSCT. Whether this approach will reduce treatment-related mortality and result in more favorable outcomes is currently unknown. The National Marrow Donor Program and the American Society for Blood and Marrow Transplantation have developed guidelines for transplant consultation based on current clinical practice and evidence-based medicine. The following groups of ALL patients are at risk for progression and should be referred for transplant evaluation: high-risk ALL, including patients with high-risk cytogenetics (i.e., Ph⁺), high WBC count (>30,000 to 50,000 cells/mm³) at diagnosis, CNS or testicular leukemia, no CR within 4 weeks of initial treatment, remission induction failures, and those patients in CR2 and beyond.^{39,40}

■ ROLE OF COLONY-STIMULATING FACTORS IN ACUTE LYMPHOBLASTIC LEUKEMIA

9 The use of granulocyte colony-stimulating factor colony-stimulating factor in children and adults administered during, after, or between courses has been shown to shorten the duration of neutropenia by 2 to 10 days.^{41,42} Standard-risk ALL therapy in children is not myelosuppressive and does not warrant the use of colony-stimulating factors. In the adult ALL population, one trial has demonstrated an improved CR rate, but this has not been confirmed in other large randomized studies.⁴² No trial has shown improved EFS or OS in either the pediatric or adult populations. Several studies reported a decrease in the incidence of febrile neutropenia, duration of hospitalization, and duration of antibiotic use, although the effects on these end points are inconsistent among trials.⁴²

The current American Society of Clinical Oncology guidelines recommend the initiation of colony-stimulating factors after completion of the first few days of chemotherapy of either the initial induction or first remission course to shorten the duration of neutropenia by at least a week.⁴²

■ LATE EFFECTS OF ACUTE LYMPHOBLASTIC LEUKEMIA

Certain late effects associated with cranial or craniospinal irradiation and/or corticosteroids were discussed earlier. The Childhood Cancer Survivor Study tracks the health status of adults treated for childhood cancer between 1970 and 1986 and has yielded invaluable

information on how to monitor adult survivors.⁴³ Leukemia survivors have a relative risk of 2.2 for developing a chronic health condition as compared with healthy siblings, and a relative risk of 4.1 for severe or disabling chronic conditions. Former ALL regimens that incorporated intensive use of topoisomerase II inhibitors (etoposide and teniposide) are associated with unacceptably high risks of development of secondary leukemia.¹² High cumulative doses of anthracyclines used in high-risk or relapsed patients can cause cardiomyopathy. Cranial irradiation has also been found to cause learning deficits, especially in patients younger than 5 years of age at the time of treatment. Patients who received cranial radiation as children also have higher unemployment rates and lower marital rates among females two decades after diagnosis.⁴⁴ The Children's Oncology Group has recently developed long-term followup guidelines for survivors of childhood, adolescent, and young adult cancers (www.survivorshipguidelines.org).

ACUTE MYELOID LEUKEMIA

CLINICAL PRESENTATION

3 Common signs and symptoms at presentation are described below. In addition to clinical presentation, laboratory and pathology evaluations are required for a definitive diagnosis of leukemia. The most important test is a bone marrow aspirate and biopsy, which is submitted to hematopathology for testing and evaluation. Cytochemical stains are helpful to determine if the acute leukemia is of myeloid or lymphoid lineage. Immunophenotyping is necessary and was described in the ALL clinical presentation above. Cytogenetic analysis of the marrow to determine the presence of nonrandom numerical and structural chromosomal abnormalities in leukemic cells is also helpful for diagnosis, establishing prognosis, and evaluating response to therapy.¹⁰ Chromosome translocations can result in abnormal expression and/or function of cellular oncogenes. Unique translocations can identify specific subtypes of acute leukemia. For example, acute promyelocytic leukemia (APL) is characterized by a specific translocation between chromosomes 15 and 17: t(15;17). Recently, technically difficult cytogenetic analysis has been supplemented with fluorescent in situ hybridization that allows for quick, sensitive analysis of samples that might be inadequate for karyotyping. Molecular tests may be used to identify products of specific translocations, such as promyelocytic leukemia (PML) retinoic acid receptor- α (RAR α) in APL and AML1-ETO and CBF β /MYH 11 in other subtypes of AML. The results of some of these molecular tests correlate with prognosis and are discussed in Risk Classification below.

CLINICAL PRESENTATION^{1,4}

General

- Recent history of vague symptoms such as tiredness, lack of exercise tolerance, chest pain, and “feeling unwell” but in no obvious distress.

Symptoms

- The patient may report weight loss, malaise, fatigue, and palpitations and dyspnea on exertion. They may also present with fever, chills, and rigors suggestive of infection; bruising (excessive vaginal bleeding, epistaxis, ecchymoses, and petechiae); gum hypertrophy (AML M4 and AML M5 subtypes); bone pain; seizures; headache; and diplopia.

Signs

- Temperature may be elevated because of low neutrophil count; petechiae.

Laboratory Tests

- Complete blood cell count (with differential). Anemia is usually present and is normochromic and normocytic (without a compensatory increase in reticulocytes). Thrombocytopenia (severe, $<50,000$ cells/mm³) is present in approximately 50% of cases. Leukopenia/leukocytosis: approximately 20% of patients will present with an elevated WBC count, 20% with a low WBC count, and the rest with normal counts. Even patients with elevated counts can be considered functionally neutropenic.
- Uric acid may be elevated as a result of rapid cellular turnover (more common in patients presenting with elevated WBC counts).
- Electrolytes: potassium and phosphate are usually elevated.
- Coagulation: elevated prothrombin time, partial thromboplastin time, D-dimers; hypofibrinogenemia.

Other Diagnostic Tests

- Bone marrow biopsy and aspirate: send for morphologic examination, cytochemical staining, immunophenotyping, and cytogenetic (chromosome) analysis. At diagnosis the marrow is typically hypercellular, with normal erythropoiesis being replaced by leukemic blasts. To be diagnosed with AML, there needs to be more than 20% blasts. Molecular testing for FMS-like tyrosine kinase 3 (FLT3) mutations is warranted.
- For patients presenting with CNS signs, a diagnostic lumbar puncture should be performed. This is typically performed once there is clearance of blasts from the peripheral blood. CNS involvement is common with AML M4 and M5 subtypes.

RISK CLASSIFICATION

10 Many clinical and laboratory features at diagnosis are associated with response to treatment, as measured by the CR rate, duration of remission, and long-term survival. Identification of these risk factors may allow the clinician to better understand the disease and to tailor treatment according to risk of disease recurrence. For example, if a patient has many clinical and laboratory features that are associated with a good response to chemotherapy (“good-risk”), then the clinician may choose to give less-intensive therapy to reduce the risk of long-term toxic effects. Conversely, if a patient is unlikely to respond well to therapy (“high-risk”), then the clinician may choose to give more intensive chemotherapy that might include HSCT.

Several prognostic factors have been identified for adults with AML. The most important patient factor is age, with younger patients more likely to achieve a CR than older patients (older than age 60 years).^{1,4,7} The lower CR rate in older patients results from an increased frequency of fatal infection and bleeding complications and resistance to conventional chemotherapy. The duration of remission is also shorter in older patients as compared to younger patients. Other patient-specific prognostic factors include concurrent infection and any major organ impairment.⁴ FAB morphologic subtype may be important, with some subtypes associated with a worse outcome. Patients with extramedullary disease, CNS involvement, or underlying MDS have a worse prognosis. Certain cytogenetic abnormalities are also known to worsen the response rate and survival of patients with AML (Table 137–4).^{1,4,10} In addition, patients who develop a “secondary” leukemia after treatment of another malignancy usually have a very poor response to antileukemic chemotherapy.

Prognostic factors associated with pediatric AML have been reported but few have been shown to consistently predict treatment outcome. Historically, poor prognostic factors include an initial WBC count greater than 100,000 cells/mm³, FAB subtype M1 without Auer

TABLE 137-4 Risk Category According to Cytogenetic Abnormalities Present

Disease	Risk Category		
	Good-Risk	Intermediate-Risk	High-Risk
AML	t(8;21)(q22;q22); inv(16); t(15;17); t(9;11) trisomy 21	Normal karyotype; trisomy 8; 11q23; del(7q); del(9q); trisomy 22	Complex karyotype; -5; -7; del(5q); inv(3p)
Probability of relapse	≤25%	50%	>70%
4-Year survival	≥70%	40–50%	≤20%
ALL	Hyperdiploidy; t(10;14); or 6q		t(9;22); t(8;14); t(4;11); t(1;9)

ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia.
Data from Hasle et al.¹¹ and Thomas et al.²⁹

rods, certain chromosomal abnormalities (see Table 137–4), age younger than 5 years, and having AML secondary to prior chemotherapy or radiation therapy. A recent report from the Children’s Cancer Group identified both poor and favorable prognostic factors. Poor prognostic factors at diagnosis included male gender, platelet count ≤20,000 cells/mm³, hepatomegaly, MDS, FAB subtype M5, greater than 15% bone marrow blasts at day 14 of induction therapy, and trisomy 8.⁴⁵ Abnormal chromosome 16 was associated with a higher rate of CR.⁴⁵

More recently, several genetic molecular abnormalities have been identified in adults with AML that have prognostic significance. Abnormalities that are associated with a poor outcome include FLT3 abnormalities; MLL; brain and acute leukemia gene, cytoplasmic (BAALC) and Wilms tumor gene (WT-1).⁴⁶ Nucleophosmin mutations, member1 (NPM1) (in the absence of FLT3 abnormalities) are associated with an improved relapse-free survival and OS.⁴⁶ The future of AML treatment may lie in a prognostically prioritized molecular classification. There are proposed algorithms for patient management based on the presence or absence of these abnormalities but they are not currently incorporated into standard practice.⁴⁶

TREATMENT

Acute Myeloid Leukemia

TREATMENT GOALS

11 The short-term goal of treatment for AML is to rapidly achieve a complete clinical and hematologic remission. In the absence of a CR, a rapid and fatal outcome is inevitable. CR is defined as the disappearance of all clinical and bone marrow evidence (normal cellularity >20% with <5% blasts) of leukemia, with restoration of normal hematopoiesis (neutrophils ≥1,000 cells/mm³ and platelets >100,000 cells/mm³).⁴⁷ Partial remission is a significant response to treatment (a decrease of at least 50% of blasts), but evidence of residual disease in the bone marrow remains (5% to 25% blasts) and is considered a treatment failure requiring additional therapy. The definition of response for adult AML was reevaluated in 2003, and changes in the definition of response were proposed to include not only CR, but also morphologic CR (patient independent of transfusion), CR with incomplete count recovery, cytogenetic CR (patient with normal cytogenetics in which cytogenetics were previously abnormal), and molecular CR (molecular studies negative).⁴⁷

After a CR is achieved, the goal is to maintain the patient in continuous CR. As discussed later, the occurrence of leukemic relapse in the bone marrow significantly reduces the likelihood of curing the disease. Most patients who will die from acute leukemia die within the first 6 years; the survival curve (percentage alive versus time) beyond the sixth year after therapy does not continue to decline as rapidly (“survival plateau”), and at this time patients can be considered “cured.”¹

With recent advances in chemotherapy and supportive care, 65% to 85% of all patients with AML achieve a CR, and 20% to 40% become long-term survivors.^{1,4} Overall, the median duration of remission is 1 to 2 years. In patients older than 60 years of age, the percentage of patients achieving a CR is lower (39% to 64%), and the median duration of remission is shorter than 1 year.⁴⁸ In contrast to ALL, effective therapies used in AML cause severe and often prolonged myelosuppression, with the exception of tretinoin. As a result, patients with AML, particularly patients older than 60 years of age, are at greater risk for treatment-related fatal infectious and bleeding complications.

The 5-year survival in children with AML has increased from 17% in 1976 to 50% in 2000.³ Children with Down syndrome and AML receive less-intense therapy and have an EFS of 68% to 100%.⁴⁹ Treatment of AML, unlike that of ALL, usually only consists of induction and intensive postremission therapy (see Fig. 137–2). CNS prophylaxis is not routinely given in adult AML, but is generally administered to pediatric patients.

TREATMENT PHASES

Remission Induction

11 As with ALL, the goal of remission induction for AML is to rapidly induce a CR with associated restoration of normal hematopoiesis. Compared to ALL, however, fewer patients with AML achieve CR. Because the CR rate in AML is related to the intensity of the remission induction regimen, the drugs used in AML are given at doses that uniformly cause severe marrow hypoplasia (except tretinoin). One reason for the lower CR rate in AML as compared to ALL is the inability to give optimal doses of chemotherapy because of marrow toxicity. With continued improvement of supportive care for patients undergoing chemotherapy, more intensive treatment regimens are being given in an effort to reduce the high rate of leukemic relapse and increase the proportion of long-term survivors. Most patients achieve a CR after one or two courses of chemotherapy. Patients who require additional chemotherapy to achieve a CR have been reported to have a poor prognosis, even if remission is ultimately achieved.¹

The most active single agents in AML are the anthracycline antibiotics (daunorubicin, doxorubicin, and idarubicin), anthracenediones (mitoxantrone), and the antimetabolite cytarabine. The most common regimen (“7+3”) combines daunorubicin administered as a short infusion of 45 to 60 mg/m² per day on days 1 to 3, along with cytarabine administered as a continuous 24-hour infusion of 100 mg/m² per day on days 1 to 7.^{4,50,51} The CR rate with the 7+3 regimen is 65% to 75% in patients ages 18 to 60 years. The remission rate decreases to 40% to 50% in patients older than 60 years of age.

Several trials have attempted to improve upon conventional 7+3 therapy, but have shown no improvement by (a) increasing cytarabine to 10 days, (b) shortening cytarabine to 5 days, (c) substituting doxorubicin for daunorubicin, (d) adding thioguanine, or (e) increasing cytarabine dosage to 200 mg/m² per day (given by continuous

infusion).⁴ Other clinical trials have evaluated idarubicin or mitoxantrone as alternatives to daunorubicin in combination with standard continuous infusion cytarabine. Trials in younger patients reported improved CR rates with these newer anthracyclines/anthracenediones and one trial demonstrated prolonged survival. Among older adults the CR rate and OS does not appear to be different among the different anthracyclines/anthracenediones.^{50,51} In a review of long-term followup results from randomized trials evaluating idarubicin versus daunorubicin, only one trial maintained a significant difference favoring idarubicin. The effect of anthracycline choice on the CR rates in the elderly was studied by the Eastern Cooperative Oncology Group (ECOG).⁵² Elderly AML patients were randomized to standard doses of cytarabine combined with either daunorubicin (45 mg/m² for 3 days), idarubicin (12 mg/m² for 3 days), or mitoxantrone (12 mg/m² for 3 days). No difference in DFS, OS, or toxicity was seen between the three induction regimens.⁵²

CLINICAL CONTROVERSY

Is there a superior anthracycline to use as part of the induction regimen for AML? Some clinicians believe that idarubicin is superior in attaining a complete remission following one cycle of induction compared to alternative anthracyclines or anthracenediones. Randomized trials in the elderly show similar remission rates with all anthracyclines and anthracenediones. Whether there is a difference in younger patient's remains to be seen.

Thus the anthracycline of choice for the standard 7+3 regimen remains controversial, with many centers adopting idarubicin into the induction regimen in younger AML patients, and the choice in the elderly is based on individual clinician preference and institutional acquisition costs.

Other strategies that have been evaluated include adding another agent such as etoposide to the induction regimen.^{4,50,51} A comparison of the standard 7+3 regimen with or without etoposide on days 1 to 7 ("7+3+7") in newly diagnosed AML patients ages 15 to 70 years demonstrated no difference in CR rates or OS. A subset analysis of patients younger than 55 years of age demonstrated a doubling of the duration of remission and OS in the etoposide-containing arm. The 7+3+7 regimen was more toxic in patients older than 55 years of age. These results have been confirmed in other studies, but as yet are to be adopted in the United States as part of standard therapy. Based on experimental tumor models that showed a steep dose-response curve for cytarabine, higher doses of cytarabine have also been evaluated as a means to enhance the outcome of remission induction therapy. Several groups, including the Southwest Oncology Group and the Australian Leukemia Study Group, have evaluated the impact of adding high-dose cytarabine to induction therapy. This strategy does not improve the CR rate or OS, but does improve DFS. A retrospective study conducted by the European Group for Blood and Marrow Transplantation demonstrated that the cytarabine dose administered during induction and/or consolidation did not influence the outcome in patients who ultimately went on to receive allogeneic or autologous HSCT.⁵³ These data suggest that high doses of cytarabine during induction may not be needed in patients scheduled to receive a HSCT as postremission therapy. In summary, the role of high-dose cytarabine during induction remains controversial. If used during induction, high-dose cytarabine is more appropriate in younger patients than in elderly patients because of poor tolerance by elderly patients.

The National Comprehensive Cancer Network (NCCN) has published guidelines for the treatment of AML.⁵⁴ The classic 7+3 regimen may be inadequate in adults younger than 60 years of age because the duration of remission is less than that reported in some studies that employed high-dose cytarabine in induction.⁵⁴ The

NCCN guideline recommends that adults younger than 60 years of age without an antecedent hematologic disorder (i.e., no preexisting hematologic malignancy such as MDS) be treated with either the 7+3 regimen or more aggressive chemotherapy including high-dose cytarabine with an anthracycline or anthracenedione. In patients 60 years of age and older with good performance status, the conventional 7+3 regimen should be used or the patient should be enrolled in available clinical trials. The approach in patients with an antecedent hematologic disorder differs, and younger patients (<60 years) should be offered available clinical trials or proceed to alloHSCT (provided a suitable donor is available). Older patients (≥60 years) with an antecedent hematologic disorder or those with significant comorbidities unrelated to leukemia should be offered a clinical trial or best supportive care because of the dismal outcomes associated with conventional chemotherapy. All adult patients who present with CNS symptoms, and all AML M4 and AML M5 patients who are not symptomatic, should have a diagnostic lumbar puncture, and if it is positive, should be treated for disease. Methotrexate 12 to 15 mg, with or without cytarabine, should be administered intrathecally twice a week until clearance of leukemic blasts from the cerebrospinal fluid, and then monthly for about 6 months.

Intensive Postremission Therapy

12 Although most adults with AML achieve a CR, the duration of remission is short (4 to 8 months) if no further treatment is given. Relapse is presumably a consequence of the presence of residual, but clinically undetectable, leukemic cells after remission induction therapy. The goal of intensive postremission therapy is to eradicate these residual leukemic cells and to prevent the emergence of drug-resistant disease. The need for postremission therapy is based on postmortem analysis and cell kinetic data suggesting that nearly 10⁹ residual leukemic cells remain after effective remission induction therapy. Strategies evaluated as postremission therapy include (a) low-dose, prolonged maintenance therapy, (b) short-course intensive chemotherapy-alone regimens, and (c) high-dose chemotherapy with or without radiation therapy followed by alloHSCT or autologous HSCT (autoHSCT).

Chemotherapy In the treatment of AML, postremission therapy is often referred to as consolidation therapy. Results of randomized trials in adults clearly show that postremission therapy following remission induction therapy prolongs survival versus no therapy, although the exact duration of postremission therapy is controversial.^{4,50,51}

The intensity of postremission therapy is important.⁵⁵ In a large Cancer and Leukemia Group B (CALGB) trial, all patients received standard 7+3 induction, and once a CR was achieved, were randomized to receive one of three cytarabine-based consolidation regimens: 100 mg/m² per day or 400 mg/m² per day as a continuous 24-hour infusion, or 3,000 mg/m² every 12 hours on days 1, 3, and 5.⁵⁶ For adults younger than age 60 years, the probability of remaining in CR after 4 years was significantly higher in patients who received high-dose cytarabine (25% vs. 29% vs. 44%, respectively).⁵⁶ Elderly patients had lower response rates in all arms and did not benefit from the administration of higher doses of cytarabine, probably because they were unable to tolerate the high-dose regimen. Dose-limiting neurotoxicity in the high-dose arm was greater in elderly patients.⁵⁶

It is not clear whether the same agents (cytarabine and an anthracycline) given for remission induction should be used for postremission therapy in higher doses, or whether different agents should be given. If leukemic relapse is caused by a resistant cell line, then the use of different agents that are non-cross-resistant with drugs used in induction might be beneficial.

High-dose cytarabine appears to be a key part of postremission therapy, particularly if not used in induction therapy. However,

many questions remain, such as the optimal dose (g/m²), number of doses per cycle, and number of cycles of high-dose cytarabine. Among patients with core-binding factor AML, defined as the presence of either t(8;21) or inv(16), it is clear that multiple cycles are beneficial, generally three to four cycles.^{57,58} The NCCN guideline recommends four cycles of high-dose cytarabine for adults younger than 60 years of age and with good cytogenetics or, alternatively, one cycle of high-dose cytarabine followed by autoHSCT.⁵⁴ Patients with intermediate-risk cytogenetics should receive 4 cycles of high-dose cytarabine or undergo either an autoHSCT or an allogeneic (sibling) HSCT.⁵⁴ If a patient is 60 years of age or older, standard-dose cytarabine with or without anthracycline for one to two cycles, a reduced-dose high-dose cytarabine regimen (1 to 1.5 g/m² per day for four to six doses) for one to two cycles, or enrollment in a clinical trial is recommended. Patients with high-risk cytogenetics, underlying MDS, or secondary AML should either be enrolled in a clinical trial or be referred for either a matched sibling or alternative donor alloHSCT.⁵⁴

CLINICAL CONTROVERSY

Intensive postremission therapy is clearly necessary to prevent relapse and those regimens containing high-dose cytarabine appear to be a key part of postremission therapy. However, the optimal dose of high-dose cytarabine, the number of doses per cycle, and the number of cycles to give remain unknown.

Allogeneic Hematopoietic Stem Cell Transplantation

AlloHSCT represents the most aggressive approach to postremission therapy in the management of AML. Much controversy surrounds this treatment approach, specifically the appropriateness, timing, treatment design, and donor selection.

The antileukemic activity of alloHSCT is based on the administration of pretransplant high-dose chemotherapy (or chemoradiotherapy) and the development of a posttransplant immune-based antileukemic response. The immune-based response, referred to as a graft-versus-leukemia (GVL) effect, often accompanies the graft-versus-host disease (GVHD) reaction. The immune-based benefit of alloHSCT has been demonstrated through the observation of consistently lower relapse rates with alloHSCT as compared to autologous or syngeneic HSCT. This potential benefit of alloHSCT can be offset by the risk of posttransplant complications such as GVHD, venoocclusive disease, graft failure, and infections.

AlloHSCT was first evaluated as a treatment modality for AML in refractory patients, but because of initial success in small numbers of patients, it has also been evaluated as intensive postremission therapy in AML patients in first or subsequent remission. Nonrandomized trials of HLA-identical sibling alloHSCT performed in AML patients in CR1 reported 5-year survival rates of 45% to 60% with relapse rates of 10% to 20%.^{4,50,51} Transplant-related mortality following HLA-

matched sibling alloHSCT is 15% to 25% in most series. As clinicians have gained more experience in this intensive form of therapy and been provided with more effective immunosuppressive and antibiotic regimens, transplant-related mortality rates have decreased and survival rates have increased. Bone marrow registry data indicate that long-term survival rates in AML patients who receive a matched sibling alloHSCT while in first remission have increased from approximately 45% in the early 1980s to approximately 60% in the mid-1990s.¹

Table 137-5 presents the results of randomized comparisons of alloHSCT to autoHSCT or intensive consolidation chemotherapy alone.^{4,51} AlloHSCT from an HLA-matched sibling donor for AML patients in CR1 results in long-term DFS in 43% to 55% of patients. Although the results vary, some of the studies show longer DFS and lower relapse rates with alloHSCT in AML in CR1 as compared to chemotherapy-alone postremission regimens.

AlloHSCT is still generally restricted to patients younger than 60 years of age, which limits the number of patients eligible for treatment of a disease that primarily affects older adults. One new approach, termed nonmyeloablative stem cell transplant (NST), uses less-toxic nonmyeloablative preparative regimens and is now being evaluated in AML patients, particularly in older patients and those with comorbid illnesses that would limit their eligibility for conventional alloHSCT. NST is designed to provide enough immunosuppression in the preparative regimen to allow for engraftment of donor cells, and depends heavily on the development of a GVL effect as a means to treat and prevent relapse of AML. Initial results of NST in AML indicate that the procedure is well tolerated in a wide age range of patients, and that it is associated with low rates of regimen-related toxicity.^{59,60} Evaluations in larger numbers of patients are necessary to determine the comparative impact of NST on GVHD, DFS, and OS. Because only 30% of patients have an HLA-matched sibling donor, alloHSCT is further restricted as a treatment alternative for AML patients.⁶¹ Matched unrelated donor transplantation with a phenotypically HLA-matched donor identified from bone marrow registries is also a treatment option in young adults and pediatric AML patients. This approach is associated with long-term DFS rates of 30% to 40%, which are slightly lower than in AML patients undergoing HLA-matched sibling alloHSCT because of a higher risk of treatment-related mortality with the procedure.^{4,51,62}

The decision to transplant a patient depends a great deal on which biological risk group the patient belongs. Among patients with favorable risk AML, alloHSCT does not result in better outcomes as compared to high-dose cytarabine-based therapy. All patients with high-risk AML, including those with an antecedent hematologic disorder, treatment-related MDS, or induction failure, should undergo evaluation for HSCT. Similarly patients in CR1 with high-risk cytogenetics and patients in CR2 and beyond should undergo evaluation for alloHSCT.³⁹

Autologous Hematopoietic Stem Cell Transplantation

Compared to alloHSCT, autoHSCT has the advantage of a lower risk of posttransplant complications because of lack of immunosup-

TABLE 137-5 Comparative Trials of Allogeneic HSCT (AlloHSCT) or Autologous HSCT (AutoHSCT) or Chemotherapy (Chemo) Alone as Postremission Therapy for AML in First Complete Remission

	Disease-Free Survival at 4 Years (%)			Overall Survival at 4 Years (%)

pression and GVHD, and more broad applicability because of a lack of donor limitations and fewer age restrictions. Although the preparative regimen still provides antileukemic activity, autoHSCT is associated with a higher risk of relapse because of a lack of a GVL effect and potential tumor contamination with autologous stem cells. DFS following autoHSCT for AML in CR1 ranges from 40% to 60%, with treatment-related mortality of 5% to 15% and relapse rates of 30% to 50%.⁶³ Long-term response rates decrease proportionally as autoHSCT is employed in second or subsequent CR.

Controversies in autoHSCT include the optimal timing of therapy, the amount of consolidation therapy needed prior to HSCT, the dose of stem cells needed, and the impact of posttransplant therapy.⁶³ Table 137–5 compares autoHSCT versus other postremission therapies.

Comparisons of Postremission Therapy Options Several randomized trials in AML patients in CR1 have compared outcomes following alloHSCT, autoHSCT, and/or intensive consolidation chemotherapy (see Table 137–5).⁵¹ In most trials, eligible patients based on age and donor availability received an alloHSCT and the remaining patients were randomized between autoHSCT and chemotherapy alone. The European Organization for Research and Treatment of Cancer-GIMEMA (Gruppo Italiano Malattie Ematologiche Maligne dell'Adulto) trial observed a DFS advantage and reduced relapse risk for alloHSCT or autoHSCT as compared to chemotherapy alone, but no differences in OS.^{4,51} Survival rates were comparable because of a higher relapse rate in the chemotherapy group as compared to a higher treatment-related mortality rate in the alloHSCT group. This is the only trial that has demonstrated superior 4-year DFS with transplantation versus chemotherapy. Interestingly, the response rates in the conventional chemotherapy arm in this trial were lower than those reported in other studies, which may account for the survival benefit in the transplant group. Several other trials have shown no difference in DFS or OS between autoHSCT, alloHSCT, and conventional chemotherapy. In aggregate, these trials show that either autoHSCT or alloHSCT can reduce the risk of relapse, although this has not translated into a survival benefit. One trial design issue that might explain this lack of survival benefit was the low percentage of patients who progressed to transplantation when randomized, thus diluting the effect of transplantation. The effect of stem cell source on DFS and OS is controversial. Several comparative trials of bone marrow versus peripheral blood have been completed in patients with hematologic malignancies, and a meta-analysis of nine randomized trials demonstrated a lower relapse rate for those patients receiving peripheral blood stem cells.⁶⁴

Most transplant centers base their decision to transplant on cytogenetic risk category.⁴ Patients with high-risk cytogenetics do poorly with conventional chemotherapy or autoHSCT (DFS <15%), making alloHSCT the treatment of choice in this population. Patients with good-risk cytogenetics should not proceed to transplant in CR1, as neither auto- nor alloHSCT is superior to conventional chemotherapy. The optimal treatment of choice in patients with intermediate-risk cytogenetics is not clear and is based on clinician preference. Many centers consider a relapse probability of 40% to 50% sufficiently high so as to warrant the risk of transplantation-related mortality. The decision to proceed with HSCT in this group may rest on the results of molecular testing. As discussed in Risk Classification above, several genetic molecular abnormalities have been identified in adults with AML that have prognostic significance. Abnormalities that are associated with a poor outcome include FLT3 abnormalities; myeloid/lymphoid or MLL abnormalities; BAALC; and WT-1.

According to the NCCN guidelines, the decision to proceed to HSCT depends on cytogenetics.⁵⁴ If the patient has a good-risk cytogenetic profile and is younger than age 60 years, then high-dose cytarabine for four cycles or one cycle of high-dose cytarabine-based

therapy followed by autoHSCT is preferred over alloHSCT. If the patient has a high-risk cytogenetic profile and is younger than 60 years of age, then alloHSCT transplantation should be considered early after remission induction. Patients with intermediate-risk cytogenetics should be entered into a clinical trial, but if a clinical trial is not available, either a matched sibling alloHSCT or an autoHSCT should be considered. AutoHSCT can be used if a hematologic and cytogenetic remission is achieved. For patients 60 years and older, the NCCN guidelines do not favor HSCT and recommend either enrollment into a clinical trial, or consideration of conventional dose cytarabine with or without an anthracycline or intermediate dose cytarabine. Clinicians increasingly consider autoHSCT as a treatment option, and for selected patients older than 60 years of age, NST is being used more frequently.^{59,60} For the AML patient who relapses early after induction therapy, if a sibling or matched related donor is available, then alloHSCT is the primary reinduction therapy because conventional chemotherapy offers little benefit. If the relapse occurs late, then HSCT can be used as postremission consolidation after conventional induction therapy.⁵⁴

■ CHILDHOOD ACUTE MYELOID LEUKEMIA

The most effective remission induction regimens for children include an anthracycline plus cytarabine, and either thioguanine or etoposide, yielding a remission rate of 75% to 85%.⁶⁵ Intensified therapy regimens, which include more antileukemic agents or compress the time in which the agents are delivered, improve survival rates. In compressed or intensified treatment regimens, the second course of therapy is given 6 days after the first, without waiting for marrow recovery to occur. Although intensive therapy is associated with an increased mortality rate as compared with standard chemotherapy in children with AML, the long-term EFS is significantly better in the intensive-therapy group (49% vs. 35%).^{65,66} The Children's Oncology Group is assessing the benefit of adding gemtuzumab to current therapy.

Following induction therapy, patients should be evaluated for a response. A proportion of children will not achieve a CR, and will require additional chemotherapy called *reinduction*. Typically a bone marrow biopsy is performed 7 to 10 days after the completion of chemotherapy (or day 14 from the start of chemotherapy) to document disease eradication. If there is persistent disease, a second course of therapy is administered. The second course may be identical to the initial induction regimen, or include high-dose cytarabine and asparaginase, or mitoxantrone and cytarabine. If the marrow is aplastic, a repeat marrow biopsy should be performed upon hematologic recovery to document a CR.

An evidence-based review of the role of HSCT in the treatment of pediatric AML concluded that HSCT was indicated in the following settings: (a) CR1: alloHSCT is superior to autoHSCT and chemotherapy; (b) CR2: alloHSCT is preferable to chemotherapy and autoHSCT.⁶⁷ Children with no suitable stem cell donor should receive consolidation chemotherapy, with which survival results are similar to those seen with autoHSCT.⁶⁸

Infant AML is usually myelomonoblastic or monoblastic in morphology. Poor prognostic factors include t(1;22), high WBC count, and CNS disease. Neonates with Down syndrome may develop transient myeloproliferative disease that usually spontaneously resolves without treatment within a few months. Infants with AML receive the same therapy as children of other ages, with the dosing per kilogram and not per body surface area.

■ ACUTE MYELOID LEUKEMIA IN THE ELDERLY

As the median age at diagnosis is in the range of 65 to 70 years, AML is a disease of the elderly. Unfortunately, long-term DFS is lower in

older patients, ranging from 5% to 15%, as compared to 40% in younger patients.⁴⁸ In patients older than age 55 years, a review of ECOG studies reported the median duration of survival to be 6 to 9 months, as compared to 11 months in patients younger than age 55 years. The actual response and survival rates may be even lower, as many elderly patients with AML are not included in clinical trials because of a lack of eligibility and poor performance status.^{4,48}

Elderly patients with AML have a poor outcome as a result of the frequent presence of unfavorable prognostic factors, including high-risk cytogenetic features, preceding myelodysplasia, and a higher incidence of inherent drug resistance.⁴ Greater than 70% of de novo AML patients older than age 55 years will express the multidrug resistance phenotype associated with chemotherapy resistance, including resistance to the leukemia-active anthracyclines and etoposide.⁴⁸ Older patients with AML may also have poor outcome because of the inability to withstand aggressive therapy as a result of poor organ function, poor performance status, or existing comorbidities. Although older patients with AML may be able to tolerate aggressive remission induction therapy, they often cannot tolerate intensive postremission therapy, which increases their likelihood of leukemic relapse.

The potential therapeutic strategies in elderly AML patients include (a) no chemotherapy (i.e., best supportive care or palliative care therapy), (b) attenuated chemotherapy, (c) investigational therapy, or (d) standard-dose chemotherapy.⁴ The palliative approach is most appropriate in patients with slowly progressive leukemia ("smoldering leukemia"). The difficulty lies in the ability to reliably identify these patients at diagnosis. Although initially accepted in older patients, palliative care approaches in older patients with AML with moderate-to-good performance status and organ function are now considered inappropriate. An ECOG-CALGB study randomized patients to either conventional chemotherapy or to observation in which patients could receive modest doses of chemotherapy for symptom palliation. Survival was twice as long in the chemotherapy group. The quality-of-life of each group was similar, with patients in each group spending approximately 50% of the study time in the hospital.⁶⁹

These results show that chemotherapy prolongs survival without significantly decreasing the quality-of-life for elderly patients. Thus chemotherapy is a viable treatment option for elderly patients, although the best chemotherapy regimen and overall treatment approach are controversial. One approach is to attenuate the dose of chemotherapy, preferably with oral agents where possible, or lower doses of intravenous agents. Agents used in this strategy include oral etoposide, low-dose subcutaneous cytarabine, and other oral agents such as thioguanine and idarubicin (oral idarubicin is not currently commercially available in the United States). The United Kingdom AML Study Group recently published a comparative trial of low-dose subcutaneous cytarabine twice daily versus hydroxyurea. Low-dose cytarabine produced a greater number of complete remissions compared to placebo, and prolonged 1-year survival.⁷⁰

Another approach is to use the same remission induction regimens that would be used in younger adults. With this approach, the complete remission rate in older AML patients ranges from 41% to 62%, as compared with 65% to 73% in adults younger than 60 years of age, and are very short-lived (5 to 10 months). Treatment-related mortality ranges from 15% to 20%. More elderly patients than younger patients will require two courses of remission induction therapy to achieve a complete remission. In an effort to improve response rates, some trials have attempted to determine the optimal anthracycline and the appropriate dose. Unlike younger patients, comparative data in elderly patients do not suggest any efficacy or toxicity advantages of idarubicin or mitoxantrone over daunorubicin for AML induction therapy.⁷¹ Mitoxantrone in combination with etoposide results in worse survival compared to daunorubicin and

cytarabine.⁷² Early uncontrolled trials reported high morbidity and mortality rates during remission induction in elderly AML patients who received aggressive doses of daunorubicin (>45 mg/m² per day for 3 days), but more recent trials suggest that older AML patients can safely tolerate higher doses of daunorubicin (60 to 90 mg/m² per day), which may be a result of improvements in supportive care.^{69,73} Older patients with AML also do not experience added benefit when etoposide is incorporated into an anthracycline and cytarabine-containing regimen, or when etoposide is substituted for cytarabine in induction.^{74,75}

Postremission strategies in elderly AML patients are less-well defined.⁴ Although high-dose cytarabine is a standard component of postremission therapy in younger patients, it has not been shown to be beneficial in elderly AML patients. In the elderly, attenuated-dose cytarabine during remission induction decreases remission and survival rates while decreasing treatment-related mortality rates, which raises the concern that attenuated-dose cytarabine during postremission therapy may cause similar outcomes. In the CALGB trial that compared postremission cytarabine doses, higher doses of cytarabine (3,000 mg/m²) was not as effective in patients older than age 60 years as it was in younger patients.⁵⁶ Serious toxicities, particularly neurotoxicity, were more frequent in elderly patients, and these toxicities limited the ability to deliver the planned four courses of therapy. A recent ECOG review concluded that lower doses of cytarabine (1,500 mg/m² for 6 to 12 doses) in older AML patients are well tolerated, with a treatment-related mortality rate of only 2% and median survival at 2 years of 30%.⁷³ Based on these data, some clinicians suggest that attenuated high-dose regimens (such as 1,500 mg/m²) may be sufficient for elderly AML patients. The appropriate number of cycles of postremission consolidation therapy is unknown and currently under investigation in a randomized ECOG trial. An alternative approach to intensive postconsolidation therapy is the administration of multiple courses of chemotherapy in the ambulatory setting. The Acute Leukemia French Association recently demonstrated improved overall survival among patients receiving six monthly courses of outpatient chemotherapy (daunorubicin or idarubicin day 1; low-dose subcutaneous cytarabine for 5 days) compared to intensive consolidation (daunorubicin or idarubicin days 1 to 4; cytarabine continuous infusion).⁷⁶

Although maintenance therapy is considered inferior to intensive consolidation chemotherapy in younger patients, its role in older patients with AML is still undefined. Some studies suggest that maintenance therapy following consolidation prolongs DFS but not OS as compared to no maintenance therapy.⁷⁷ Because older patients may not be able to tolerate more aggressive postremission strategies such as HSCT, maintenance therapy may play an important role in improving outcomes.

More novel immunomodulatory approaches to postremission therapy have been evaluated in elderly patients with AML. Results with interleukin-2 as a means to enhance the antileukemic activity of immune cells are promising. A recently completed randomized trial of interleukin-2/histamine hydrochloride versus control as postconsolidation immunotherapy resulted in increased DFS.⁷⁸ The CALGB is currently conducting a randomized trial in the elderly comparing 90 days of postremission low-dose, subcutaneous interleukin-2 versus observation. FLT3 ligand is another immunomodulatory cytokine that enhances recovery and activity of hematopoietic and dendritic cells and is currently under investigation as postremission therapy in elderly AML patients.

Several FLT3 inhibitors are in clinical development, including ABT-869, lestaurtinib (CEP-701), and midostaurin (PKC 412). Inhibition of farnesyl transferase is another treatment target. Tipifarnib has been the most extensively evaluated, demonstrating CR rates of 14%.⁷⁹ Other approaches include antiangiogenic therapies (e.g., lenalidomide, semaxanib [SU5416], axitinib [AG013736], bevaciz-

umab, arsenic trioxide), proteasome inhibition and antiapoptotic therapies (e.g., bortezomib, oblimersen), epigenetic therapies (e.g., azacitidine, decitabine), and novel alkylating agents such as cloretazine.⁸⁰ Response rates with these new approaches in the elderly range from 0% to 59%. Whether they can modify the course of disease resulting in prolonged survival is unclear. Gemtuzumab ozogamicin is an immunoconjugate that consists of a monoclonal antibody linked to calicheamicin, a potent antineoplastic agent. Based on its activity in relapsed and refractory AML, it is being evaluated in combination with chemotherapy in untreated patients. It is unknown whether these improved CR rates will translate into longer DFS and OS.

NST is another therapeutic option in elderly patients with AML and MDS. Two small studies suggest this is a feasible option, with actuarial OS and EFS rates of 44% to 69% and 37% to 56%, respectively.^{59,60} The advantage of this approach is less toxicity as a result of less-intensive chemotherapy, with the immune system providing the major antileukemic effect via GVHD/GVL mechanisms (see Chap. 142).

■ TREATMENT OF RELAPSED OR REFRACTORY ACUTE MYELOID LEUKEMIA

The most common cause of treatment failure in AML patients receiving chemotherapy alone or undergoing HSCT is relapse. In addition, many patients, particularly elderly patients, have refractory disease as defined by the inability to achieve a CR after two courses of induction therapy. In most cases, the preferred method of treatment for relapsed or refractory disease is HSCT. Prolonged DFS is observed in 30% to 40% of patients receiving allo- or autoHSCT in first relapse or CR2. Unfortunately, only a small percentage of relapsed or refractory adult patients will be eligible for HSCT, particularly alloHSCT, because of age and donor restrictions. The role of NST is also being evaluated in this setting.

The timing of HSCT to treat relapse is controversial. Some studies suggest that outcomes of HLA-matched, related alloHSCT are similar regardless of whether the transplant is performed at the time of early first relapse or in CR2. The difficulty with this approach is identifying a patient in “early relapse,” as often the patient will present in a florid relapse. While performing the alloHSCT in first relapse eliminates the need for and toxicity of salvage chemotherapy, the feasibility of this approach is limited by the lead time required to activate a donor search. An International Bone Marrow Transplant Registry study demonstrated that alloHSCT was superior to chemotherapy for treatment of relapse occurring 1 to 2 years following induction.⁸¹ Prolonged leukemia-free survival occurred in at least twofold more alloHSCT recipients as compared to patients receiving chemotherapy. In the treatment of refractory disease, alloHSCT is superior to autoHSCT in adults younger than age 55 years.

Patients who relapse following alloHSCT have a poor outcome, with a median survival of about 3 to 4 months.^{1,82} In this setting, treatment options depend on performance status, clinical condition, and the time since alloHSCT. Patients relapsing less than 100 days following alloHSCT are unlikely to respond to current therapies, and salvage attempts are often associated with a high treatment-related mortality. For selected patients relapsing more than 1 year after alloHSCT, a second alloHSCT may be an alternative, but the likelihood of prolonged survival is generally less than 10% with a second transplant.¹ Other strategies being investigated for the treatment of relapse after alloHSCT include immune manipulation to stimulate a GVL effect through donor lymphocyte infusions, and premature discontinuation of calcineurin inhibitors and other immunosuppressants.

AutoHSCT is an option at the time of first relapse if cells have been previously collected and stored during first remission. If such cells were not collected, then it is necessary to achieve a second CR

in order to proceed to autoHSCT. Prolonged DFS of 30% and 20% are reported when autoHSCT is performed in CR2 and CR3, respectively. The advantages of autoHSCT are the lack of donor limitations and fewer age-based restrictions; the disadvantage is the need to achieve a CR, which requires exposure to more cytotoxic chemotherapy. If patients relapse following autoHSCT, alloHSCT from a related or unrelated donor is preferred in selected younger patients. NST or other investigational therapies can be considered for older patients who relapse after autoHSCT.

If patients with relapsed or refractory disease are not candidates for HSCT, until recently the primary mode of treatment was salvage chemotherapy. The ability to achieve a second CR with salvage chemotherapy is related to the duration of the first remission. Approximately 50% to 60% of patients who relapse longer than 2 years after induction therapy will achieve a second CR, often with the same induction regimen.^{4,51} If the patient relapses 1 to 2 years after induction therapy, the second CR rate decreases to 40%, and only 10% to 20% of patients who relapse within 6 to 12 months following induction are able to achieve a second CR with alternate salvage chemotherapy regimens. Long-term survival at 3 years ranges from zero in patients who relapse early to 20% to 25% in those who experience a prolonged duration of initial remission. Based on these data, a risk-adapted approach should be taken when considering treatment options.

The most commonly used salvage regimens include high-dose cytarabine given at doses of 2,000 to 3,000 mg/m² every 12 hours for 8 to 12 doses. High-dose cytarabine schedules that use once-daily doses or alternate-day doses have also been used in an attempt to minimize toxicity.^{1,51} Cytarabine has been administered alone or in combination with various agents, including etoposide, fludarabine, topotecan, clofarabine, and an anthracycline, as treatment of relapsed or refractory AML. Response rates to such salvage regimens range from 30% to 50%, but are often short-lived. Patients who received high-dose cytarabine during remission induction may be less likely to benefit from such a regimen for treatment of relapse, and thus require alternate salvage strategies. Patients with remission duration of longer than 1 year appear to benefit most from high-dose cytarabine regimens.^{4,51}

Approximately 70% of relapsed or refractory AML express the multidrug resistance phenotype, which confers a high degree of chemotherapy resistance because of its encoding and overexpression of P-glycoprotein. P-glycoprotein is a membrane protein capable of removing certain antineoplastics from the intracellular to extracellular space. Antagonists of P-glycoprotein, such as cyclosporine, the cyclosporine analog valspodar (formerly PSC 833), and zosuquidar, have been investigated as a strategy to overcome resistance in these patients.^{83–85} In addition to inhibiting P-glycoprotein, cyclosporine may also affect the disposition of agents such as anthracyclines, and thus increase the exposure to cytotoxic agents. Valsopodar is 10-fold more effective in inhibiting P-glycoprotein than cyclosporine and lacks cyclosporine's renal toxicity. Unfortunately, randomized trials in previously untreated or relapsed/refractory patients have shown no advantages and more regimen-related deaths in patients older than age 60 years receiving the multidrug resistance modulator.^{83,84} Similarly zosuquidar did not result in improvements in OS, although more patients with a poor performance score were randomized to the intervention group and may in part be the reason for the adverse outcome.⁸⁵

Monoclonal antibodies have the potential to deliver targeted therapy to the malignant cell. Gemtuzumab ozogamicin is an anti-CD33 antibody complexed to the antitumor antibiotic calicheamicin. Because CD33 is expressed in 90% of leukemic blasts, this anti-CD33-directed product provides targeted cell kill to leukemic cells. Patients with AML in first untreated relapse treated with gemtuzumab (9 mg/m² for two doses separated by 14 days) attained a CR in 16% of patients, with an additional 13% of patients having normalization of blood counts with the exception of persistent platelet counts <100,000 cells/mm³.⁸⁶ Toxic-

ity can be problematic with gemtuzumab. Common adverse effects include infusion-related reactions (fever and chills), prolonged neutropenia and thrombocytopenia, and transient elevations in hepatic enzymes. A more serious adverse event associated with gemtuzumab therapy is venoocclusive disease. It was initially thought that this only occurred in patients receiving gemtuzumab following HSCT, but has now been described in several patients who never underwent HSCT. Patients treated with gemtuzumab should have their weight and liver function tests, particularly bilirubin, monitored. Because gemtuzumab lacks specific dose-limiting organ toxicities, it has also been investigated in combination with other chemotherapy agents.⁸⁷ The United Kingdom Medical Research Council AML15 trial evaluated the benefit of adding gemtuzumab to remission induction chemotherapy (i.e., cytarabine-daunorubicin-etoposide or daunorubicin-cytarabine or fludarabine-cytarabine-filgrastim-idarubicin). Although the CR rates were similar, the combination of gemtuzumab plus conventional chemotherapy was associated with an improved DFS.⁸⁷ Gemtuzumab therapy in pediatric patients has been limited by the high risk of venoocclusive disease of the liver when given prior to HSCT. Other antibodies are under investigation in salvage regimens and high-dose preparative regimens for AML.

Several classes of new agents are being investigated as alternate treatment approaches for relapsed or refractory AML, including the ubiquitin-proteasome pathway inhibitors (bortezomib), new novel nucleoside analogs (troxacitabine), hypomethylating agents (decitabine and 5-azacitidine), histone deacetylase inhibitors (phenylbutyrate, vorinostat), and angiogenesis modulators (bevacizumab and thalidomide).⁸⁸ Arsenic trioxide, which is effective in the treatment of APL, is being investigated for the treatment of AML via its modulation of apoptotic and chromatin remodeling pathways. Imatinib mesylate, the tyrosine kinase inhibitor used in the treatment of chronic myeloid leukemia, also inhibits AML cell lines and is currently undergoing clinical trials in AML.⁸⁹

In children with AML, the duration of CR1 predicts response to salvage chemotherapy. The BFM (Berlin-Frankfurt-Munster) group reported that patients who relapse within 1.5 years of initial diagnosis have a 5-year survival of 10%, versus 40% for those who relapse later than 1.5 years after initial diagnosis.⁹⁰ In children with relapsed or refractory AML, a regimen of mitoxantrone 12 mg/m² per day for 4 days starting on the third day of treatment and cytarabine 1,000 mg/m² per dose every 12 hours for eight doses can achieve a second CR rate of 76% with only a 3% mortality rate.⁹¹ However, the 2-year OS rate was only 24%. Patients were eligible to receive intensification with high-dose cytarabine and etoposide at the investigator's discretion, and this arm was closed as a consequence of a toxic death rate of 10%. Currently, most pediatric patients in CR2 receive alloHSCT if a suitable donor is available.

■ LATE EFFECTS OF THERAPY FOR ACUTE MYELOID LEUKEMIA

Because of the intense therapy received by children with AML, they are at risk for a variety of long-term sequelae. A recent study reported that more than 50% of survivors have growth abnormalities.⁹² Other findings include neurocognitive deficits, transfusion-associated hepatitis, endocrine disorders, cataracts, and cardiomyopathy (median cumulative anthracycline dose 335 mg/m²). The 20-year cumulative risk for a second malignancy is estimated to be 1.8%.

TREATMENT

Acute Promyelocytic Leukemia

13 APL is a subclass of AML (FAB M3) that accounts for approximately 10% of all cases, and is the most curable of the AML

subtypes. Most patients are diagnosed between the ages of 15 and 60 years. Five-year DFS rates of 70% to 80% are reported with APL.⁹³ APL is clinically unique from the other subclasses because of the common occurrence of severe coagulopathy (characterized by disseminated intravascular coagulation) at diagnosis and during remission induction therapy. In APL, differentiation and maturation arrest are caused by alterations in the RAR because of the translocation of chromosomes 15 and 17. The discovery of t(15;17) now provides a cytogenetic marker of the disease and is predictive of response to differentiation therapy with tretinoin (commonly referred to as all-*trans* retinoic acid). This translocation leads to a fusion protein of the PML gene on chromosome 15 and the RAR α on chromosome 17.

Prior to the availability of tretinoin, treatment of APL consisted of the same combination chemotherapy regimens used in the treatment of other subclasses of AML. Such standard regimens produced CR rates of 50% to 60%, but were associated with a high treatment-related mortality rate caused by hemorrhagic complications. The introduction of molecularly targeted therapy with tretinoin allows for high CR rates with a significant reduction in life-threatening bleeding complications.

■ TREATMENT PHASES

Remission Induction

Tretinoin, an oral vitamin A analog, is usually given orally in a dose of 45 mg/m² per day, as a single dose or divided into two doses, given after a meal. Tretinoin-based regimens achieve CR rates as high as 95% in APL patients within 1 to 3 months. Because tretinoin does not cross the blood-brain barrier, leukemic meningitis should be treated with conventional intrathecal chemotherapy.

Although devoid of myelosuppressive effects, tretinoin therapy is associated with headache, skin and mucous membrane reactions, bone pain, nausea, and the retinoic acid syndrome. When tretinoin is started, rapid onset of differentiation of promyelocytes occurs, which can lead to leukocytosis and retinoic acid syndrome. The retinoic acid syndrome (fever, respiratory distress, interstitial pulmonary infiltrates, pleural effusions, and weight gain) is now referred to as the APL differentiation syndrome or APL hyperleukocytosis syndrome, because it is associated with other treatment modalities in the management of APL. Among tretinoin-treated patients, this syndrome is fatal in 5% to 29% of cases. A combination of chemotherapy with tretinoin induction decreases the risk of APL differentiation syndrome, and rapid initiation of dexamethasone 10 mg (0.2 mg/kg per dose in children) twice daily for 3 days upon development of symptoms decreases associated mortality.⁹³

A number of clinical trials have evaluated treatment regimens for APL since the discovery of tretinoin.⁹³ These trials demonstrated that tretinoin induction therapy, followed by consolidation chemotherapy, produced similar CR rates but decreased relapse and increased EFS and OS as compared to chemotherapy alone for remission induction and consolidation. However, a significant proportion of patients receiving tretinoin in that study relapsed by 4 years, and 25% of patients experienced the APL differentiation syndrome. In an effort to extend the duration of remission and decrease tretinoin-associated toxicity, other trials have evaluated the sequential and concurrent administration of tretinoin with chemotherapy during remission induction therapy. The United Kingdom Medical Research Council trial compared concurrent administration of tretinoin with chemotherapy to sequential tretinoin during induction (given 5 days before anthracycline-based remission induction chemotherapy) with the hope of reducing coagulopathy-related complications. Concurrent administration was superior in terms of CR rates, early death, and EFS and OS at 3 years. The French study demonstrated similar CR rates with concurrent or

sequential tretinoin and standard induction chemotherapy, but noted a better DFS and EFS at 2 years in the concurrent administration group (suggesting a synergistic or additive effect for the combination).⁹³ Based on these data, the current recommendations for induction therapy for newly diagnosed APL patients include tretinoin 45 mg/m² per day until a CR is achieved, in combination with an anthracycline (either daunorubicin 50 to 60 mg/m² per dose for 3 days, or idarubicin 12 mg/m² per dose every other day for four doses).⁹³ Similar CR rates are observed with daunorubicin or idarubicin. APL cells appear to be more sensitive to anthracyclines, perhaps as a consequence of decreased P-glycoprotein expression.

It is important to note that chemotherapy regimens used in combination with tretinoin differ from standard AML regimens, primarily as a result of the lack of a cytarabine backbone. Several studies have evaluated the role of cytarabine in remission induction regimens for APL. In earlier trials, the addition of cytarabine did not improve the CR rate.⁹³ Children should also be treated with tretinoin and an anthracycline, with results similar to those achieved in adults.

Arsenic trioxide is a compound with demonstrated efficacy in relapsed APL. It has been evaluated as part of remission induction therapy in several small studies. The concept of a “chemotherapy-free” regimen in this disease is attractive. Administration of arsenic trioxide with or without tretinoin (\pm chemotherapy) results in high initial CR rates and molecular response rates.^{94–96} Larger studies are needed before this can be adopted as a standard of care.

Intensive Postremission Therapy

Consolidation chemotherapy should be administered to patients with APL because of the high relapse rate. Consolidation therapy usually consists of an anthracycline-based regimen in combination with tretinoin. The role of high-dose cytarabine in consolidation is still controversial. Although one European trial has demonstrated increased relapse risk if cytarabine is not incorporated,⁹³ these results have not been confirmed by other groups. Current recommendations reserve high-dose cytarabine regimens for patients who remain polymerase chain reaction-positive after consolidation with an anthracycline-containing regimen.⁹³

Arsenic trioxide has also been evaluated in consolidation therapy. The CALGB recently released the results of a randomized trial that compared standard chemotherapy plus tretinoin followed by arsenic trioxide to standard chemotherapy plus tretinoin followed by standard postremission therapy. The addition of arsenic trioxide resulted in longer EFS and OS.⁹⁷

Maintenance Therapy

Unlike other subtypes of AML, maintenance therapy is an important component of therapy for APL. Before the advent of tretinoin, nonrandomized trials suggested a benefit of continuous low-dose methotrexate and mercaptopurine in prevention of relapse of APL. Larger prospective randomized trials have demonstrated decreased relapse rates in patients who received maintenance therapy (either tretinoin or combination chemotherapy), and some trials have demonstrated increased EFS and OS.⁹³ In a study that compared maintenance with tretinoin, chemotherapy, or tretinoin plus chemotherapy versus observation, observation was associated with the highest relapse rate and tretinoin plus chemotherapy with the lowest relapse rate.⁹³ Current recommendations for maintenance therapy in adult APL patients include tretinoin 45 mg/m² per day for 15 days every 3 months, in addition to mercaptopurine 100 mg/m² orally daily and methotrexate 10 mg/m² per week, for 2 years in all patients.⁹³ The NCCN guidelines similarly recommend tretinoin maintenance therapy with or without 6-mercaptopurine and methotrexate.⁵⁴

TREATMENT OF RELAPSED ACUTE PROMYELOCYTIC LEUKEMIA

Relapsed APL can also be effectively treated with tretinoin therapy. Patients relapsing after tretinoin-based therapy can achieve a second CR with tretinoin-based reinduction. For patients resistant to induction or reinduction with tretinoin-based regimens, alternative strategies include arsenic trioxide, and allo- or autoHSCT. Outcomes with autoHSCT depend on the disease status of the patient at the time of transplant. AutoHSCT in CR2 (versus CR1) is associated with a lower OS, leukemia-free survival, and increased treatment-related mortality. Based on the sensitive nature of patients to chemotherapy, autoHSCT in CR1 is currently not warranted, but offers an excellent option for polymerase chain reaction PML/RAR α -negative patients in CR2. AlloHSCT should not be offered to patients in CR1, as the mortality associated with alloHSCT outweighs the risks of conventional chemotherapy. However, it is an appropriate choice in CR2 as consolidation after reinduction with either arsenic trioxide or tretinoin.⁹⁸

Arsenic trioxide has induced clinical remissions in relapsed APL through its induction of apoptosis and differentiation.^{99,100} The recommended dose is 0.15 mg/kg per day IV until bone marrow remission, not to exceed 60 doses, followed by consolidation beginning 3 to 6 weeks after completion of induction at the same dose for a total of 25 doses over a period up to 5 weeks. Arsenic trioxide therapy is associated with two specific toxicities. First, it can cause the APL hyperleukocytosis syndrome, similar to that seen with tretinoin. Management is similar: corticosteroids at first signs of pulmonary distress or a rapidly rising WBC count. The second toxicity is a prolongation of the QT_c interval. Consequently, it is important to obtain a baseline 12-lead electrocardiogram prior to starting therapy with arsenic trioxide, and correct any electrolyte abnormalities, including potassium, calcium, and magnesium. Other medications known to prolong the QT_c interval should be avoided, if possible, during arsenic trioxide therapy. The QT_c interval should not exceed 500 milliseconds at baseline, and if it increases to >500 milliseconds during therapy, the patient should be reevaluated. Do not reintroduce the arsenic trioxide until the QT_c is <460 milliseconds. Following induction of a second CR with arsenic trioxide in relapsed patients, postremission therapy with combination arsenic trioxide and chemotherapy can result in molecular remissions and improved DFS, as compared to chemotherapy or arsenic trioxide alone following remission.¹⁰⁰ Additional investigations are underway to evaluate the role of arsenic trioxide in multidrug postremission regimens.

PATIENT MONITORING

In comparison to non-APL AML, molecular and cytogenetic testing at the end of remission induction therapy in APL has no prognostic value. Clinicians should not make decisions based on the presence or absence of any genetic abnormalities at this time. Because terminal differentiation of blasts in APL requires more than 40 days, results of a bone marrow biopsy obtained at the end of remission induction can be misleading because insufficient time has elapsed to determine response. Molecular and cytogenetic response assessment should occur after the completion of consolidation treatment.

Detection of residual PML/RAR α transcripts in the bone marrow at the end of consolidation therapy is strongly associated with subsequent hematologic relapse. Achievement of PML/RAR α -negative status is associated with a higher probability of cure. The use of this molecular technique allows the clinician to assess response to therapy and also detect relapse earlier, which might prevent the development of overt disease recurrence and is associated with improved outcome compared with delaying treatment until overt morphologic relapse.⁹³ Most experts recommend that APL patients

should be routinely evaluated for continuous remission status. Suggested followup includes polymerase chain reaction for PML/RAR α every 3 to 6 months for 2 years, and then every 6 months for 2 years.⁹³

■ ROLE OF COLONY-STIMULATING FACTORS IN ACUTE MYELOID LEUKEMIA

9 Colony-stimulating factors have been evaluated in AML patients to enhance chemotherapy cytotoxicity, shorten the duration of neutropenia, and reduce the incidence and severity of infection following induction and consolidation chemotherapy. Most studies show limited benefit with the use of colony-stimulating factors as “priming” agents administered during remission induction therapy in an effort to recruit leukemia cells into the cycle to enhance susceptibility to cell-cycle-specific chemotherapy agents, leading to increased cell kill. A recent trial demonstrated similar response rates, but those patients in CR following remission induction chemotherapy had a higher DFS if they received filgrastim.¹⁰¹ No effect on OS was observed. Subgroup analysis demonstrated improved OS and DFS for patients with standard-risk AML receiving filgrastim. Results from the French Association (ALFA)-9000 trial were recently published. In that trial, the addition of sargramostim to induction and consolidation courses resulted in higher CR rates and EFS, but no effect on OS was observed.¹⁰² Use of colony-stimulating factors concurrently during chemotherapy administration is discouraged outside the setting of a clinical trial and is not recommended for this use in the American Society of Clinical Oncology guidelines.⁴²

CLINICAL CONTROVERSY

Colony-stimulating factors were investigated a decade ago as “priming agents” to recruit cells into the cycle, so theoretically there was a greater leukemia cell kill. Although most studies showed no difference in the CR rate, recent data suggest this approach may improve DFS in certain subgroups of patients.

Both filgrastim and sargramostim are FDA approved to prevent neutropenic complications in adult AML patients receiving intensive chemotherapy. The original package inserts listed myeloid malignancies as a contraindication to the use of filgrastim or sargramostim. Myeloid blast cells have receptors for granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor, and there was initial concern that the use of these factors would stimulate regrowth of the myeloid leukemia. Although subsequent studies have addressed these concerns, many pediatric clinicians do not initiate filgrastim until an initial remission is achieved.

A number of randomized trials, primarily in elderly patients, consistently demonstrate that filgrastim or sargramostim reduces the duration of neutropenia following AML induction chemotherapy.⁴² While neutropenia can be reduced from 2 to 12 days depending on the trial, results vary in terms of improvements in infectious morbidity and mortality, resource use, and disease response rates. The American Society of Clinical Oncology Guidelines for the Use of White Blood Cell Growth Factors considers the use of colony-stimulating factors after initial induction therapy reasonable, with the understanding that the effects on length of hospitalization and incidence of severe infection are modest.⁴² Patients older than age 55 years appear to derive the greatest benefit, and use is appropriate in this population where more rapid marrow recovery might decrease the duration of hospitalization.⁴² Following consolidation therapy, patients receiving colony-stimulating factors have a more profound shortening of the duration of severe neutropenia resulting in a reduction in infection rates and an associated reduction in the

use of antibiotic therapy.⁴² Use of growth factors after consolidation do not affect CR duration or OS. Further pharmacoeconomic data are required in this setting, but the body of evidence supports their use following consolidation therapy in adults. Other controversial issues surrounding colony-stimulating factor use in AML include which colony-stimulating factor to use, what dose, which day to start after chemotherapy, how long to continue, and should the marrow be examined for leukemia prior to starting a colony-stimulating factor. All growth factors have been evaluated in patients with AML, including sargramostim, filgrastim, and pegfilgrastim. Although pegfilgrastim is not FDA approved for this indication, preliminary results show that it can be used in this setting.^{103,104} The use of colony-stimulating factors can also interfere with the interpretation of the day 14 bone marrow examination. Growth factors should be discontinued at least 7 days prior to a bone marrow aspirate and biopsy to avoid interfering with the interpretation of the results (i.e., may see immature myeloid forms that would suggest residual disease).

SUPPORTIVE CARE

The most common and significant toxic effect of antileukemic agents is marrow suppression. With the exception of corticosteroids, tretinoin, asparaginase/pegasparase, and vincristine, antineoplastic agents used to treat acute leukemia cause myelosuppression. During AML remission induction and postremission therapy, daily monitoring of the complete blood count and the absolute neutrophil count is necessary to determine when red cell and platelet transfusions are needed and when neutropenia is achieved. Less-frequent monitoring may be sufficient during ALL induction. Marrow hypoplasia from the myelosuppressive regimens usually reaches its lowest point (nadir) after 1 to 2 weeks of therapy and lasts for another 1 to 2 weeks. During this period of hypoplasia, infectious and bleeding complications are major causes of death in leukemic patients. As typical signs and symptoms of infection may be absent in the neutropenic host, frequent monitoring of vital signs (especially fever) and daily physical examination are important.¹⁰⁵ Infection control strategies often include routine hand washing; dietary restrictions; reverse isolation and laminar-air flow rooms; fungal, *Pneumocystis*, and bacterial prophylaxis; and the empiric use of broad-spectrum antibiotics when fever occurs (see Chap. 126).¹⁰⁵ In contrast to the practice at many institutions, the NCCN guidelines do not recommend prophylactic antimicrobials or gut decontamination during induction or consolidation, and leave the choice to the discretion of the treating facility based on local infection patterns and concerns.⁵⁴ Several groups have analyzed the literature surrounding the use of prophylactic antibacterials. In general, prophylactic antibacterials should be reserved for patients who are expected to have prolonged (more than 7 days) and profound (absolute neutrophil count <100 cells/mm³) neutropenia. Based on these criteria, prophylaxis following induction chemotherapy is warranted and postconsolidation therapy is warranted on a case-by-case basis.

In children, prophylactic antibiotics have not proven useful and have resulted in increased resistance. Pediatric ALL patients on standard induction regimens, which generally are minimally myelosuppressive, often have recovered blood counts earlier and do not require very aggressive measures. However, they do require close monitoring of vital signs and blood counts until their counts recover. Pediatric AML patients are usually admitted for at least 1 month during induction and again for consolidation. Regardless of therapy, children with AML have a 10% to 20% induction mortality rate caused by infection and bleeding complications.¹⁰⁶ The incidence of viridans streptococci has increased with the intensity of therapy and is most associated with high-dose cytarabine. These

infections can lead to meningitis or delayed acute respiratory distress syndrome.

Pneumocystis jiroveci prophylaxis (usually trimethoprim-sulfamethoxazole) is begun in all adults and children with ALL by the end of induction and continues until 6 months after therapy is discontinued.

Acute leukemia patients, particularly those patients with an initial elevated WBC count, are at risk for tumor lysis syndrome. Preventive measures include allopurinol or rasburicase, and adequate hydration (with or without sodium bicarbonate) prior to and during chemotherapy to prevent the development of urate nephropathy from rapid destruction of WBCs. In adults, 300 mg of allopurinol once daily, started 1 to 2 days prior to chemotherapy, is usually adequate. Children should receive 10 mg/kg per day of allopurinol in three divided doses. Rasburicase, a recombinant urate-oxidase enzyme produced by genetic modification of *Saccharomyces cerevisiae*, catalyzes the enzymatic oxidation of uric acid into the inactive soluble metabolite, allantoin. In children, rasburicase 0.15 to 0.2 mg/kg per day more rapidly reduces uric acid levels in patients with aggressive malignancies compared to allopurinol, and reduces the need for dialysis.^{107–109} Rasburicase has been evaluated in adults, and some studies in adults show that fixed dosing produces equivalent outcomes to a mg/kg dosing strategy.¹¹⁰ Because of its cost, this product is usually limited to patients with ALL who have a high WBC count or bulky extramedullary disease, aggressive lymphoma, or patients with AML with a high presenting WBC. Most institutions also include an elevated uric acid as part of the criteria for use. Because of the rapid onset of action and long duration of action of rasburicase, many institutions also limit its use to a single dose and allow repeat doses when the criteria for use are met again. Rasburicase is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency.

Tumor lysis syndrome may lead not only to hyperuricemia, but also to hyperkalemia, hyperphosphatemia, and hypocalcemia. Hematologic support consists primarily of platelet and packed red blood cell transfusions. Platelet transfusions are often given for peripheral counts below 5,000 to 10,000 cells/mm³ or clinical signs of bleeding. Transfusions of packed red cells may also be indicated for a hematocrit less than 25%, profound fatigue, shortness of breath, tachycardia, or chest pain. APL can release procoagulants that can cause disseminated intravascular coagulation, necessitating close monitoring and replacement of coagulation factors with cryoprecipitate. Because of the gastrointestinal toxic effects of chemotherapy, parenteral nutrition may be required. Patients are frequently receiving infusions of antibiotics, fluids, hyperalimentation, and blood prod-

ucts simultaneously. To provide the total support needed for these patients, a multiple-lumen central venous access device such as a Hickman catheter can be placed at the start of therapy.

EVALUATION OF THERAPEUTIC OUTCOMES

Appropriate development of a pharmaceutical care plan for the acute leukemia patient begins with establishing the diagnosis and prognosis for the patient. Long-term therapeutic goals for the patient may include long-term DFS, although palliative care is a possibility in some patients. The desired short-term outcome is the establishment of remission. The return of hematologic values to normal and a repeat bone marrow biopsy that demonstrates no evidence of disease serve as documentation that remission has been achieved. Monitoring guidelines for induction or consolidation are similar (Table 137–6). After the appropriate postremission therapy has been completed, the patient may return monthly for 1 year, and then every 3 months, to check hematologic values. If no evidence of disease exists after 5 years from the diagnosis and the patient has been in continuous CR, the patient is considered cured.

Intense monitoring of fevers, hematologic and chemistry laboratory values, microbiology reports, and the patient's physical condition are necessary to identify infection, risk of bleeding, and tumor lysis syndrome early. A coagulation screening panel will identify patients with ongoing disseminated intravascular coagulation, a particular risk with APL.

During therapy, the pharmacist can be an important provider of patient education. Patients should receive information regarding acute and chronic toxicities of the chemotherapy being administered, as well as possible treatments for those toxicities. The pharmacist can also be an important resource for information regarding antibiotics, antiemetics, nutritional support, colony-stimulating factors, and other supportive care issues.

Pharmacists need to be involved in checking drug doses and any dose modifications for organ dysfunction or prior toxicity. Pharmacists are often in the best position to recognize the potential for medication errors and drug interaction and to help avoid them. Similarly, pharmacists are often able to identify the possibility that patient problems are secondary to drug treatments.

Numerous late sequelae from leukemia therapy have been recognized and should be included in the monitoring plan after therapy is completed. Chapter 142 discusses the long-term consequences of HSCT.

TABLE 137-6 Acute Myeloid Leukemia Assessment and Monitoring

Baseline Workup	Monitoring during Therapy	Postremission Monitoring
History and physical examination	Daily physical examination	Routine physical examination at clinic visit
CBC with differential, platelets	CBC with differential, platelets	CBC with differential, platelets
Serum chemistries (creatinine, bilirubin, AST, ALT to assess organ function)	Serum chemistries (including uric acid, K ⁺ , Ca ²⁺ , PO ₄ , S _{cr} during tumor lysis syndrome risk period ^a)	Bone marrow biopsy and aspirate at set intervals to evaluate ongoing remission and if peripheral blood counts are abnormal or if they fail to recover within 5 weeks of treatment
Coagulation (PT, PTT, D-dimers, fibrinogen)	Coagulation (PT, PTT, D-dimers, fibrinogen [if APL])	PML/RAR α monitoring [if APL]
Bone marrow biopsy and aspirate with cytogenetics	Bone marrow biopsy and aspirate 7–10 days after end of chemotherapy. Repeat bone marrow biopsy and aspirate upon hematologic recovery to document complete response (with cytogenetics if initially abnormal)	
Immunophenotyping and cytochemistry	Temperature curve (initiate antibiotics when febrile)	
Human leukocyte antigen (HLA) typing	Lumbar puncture (with intrathecal chemotherapy) if initial lumbar puncture was positive for leukemia	
Cardiac workup (MUGA or echocardiogram; ECG)		
Intravascular access		
Lumbar puncture (if symptomatic or AML M4 or M5)		
Chest radiography		
Height and weight		
Molecular testing for genetic aberrations (FLT3, NPM1)		

ALT, alanine aminotransferase; APL, acute promyelocytic leukemia; AST, aspartate aminotransferase; CBC, complete blood cell count; ECG, electrocardiogram; FLT3, FMS-related tyrosine kinase 3; MUGA, multiple-gated acquisition (blood pool scan); NPM1, nucleophosmin; PML/RAR α , promyelocytic-leukemia retinoic acid receptor- α ; PT, prothrombin time; PTT, partial thromboplastin time; S_{cr}, serum creatinine.

^aRisk for tumor lysis syndrome during induction therapy only.

ABBREVIATIONS

autoHSCT: autologous hematopoietic stem cell transplantation
 BAALC: brain and acute leukemia gene, cytoplasmic
 CALGB: Cancer and Leukemia Group B
 CR: complete remission
 CR1: first complete remission
 CR2: second complete remission
 CR3: third complete remission
 DFS: disease-free survival
 ECOG: Eastern Cooperative Oncology Group
 EFS: event-free survival
 FAB: French–American–British classification system
 GVHD: graft-versus-host disease
 GVL: graft-versus-leukemia (effect)
 HLA: human leukocyte antigen
 HSCT: hematopoietic stem cell transplantation
 MDS: myelodysplastic syndrome
 MLL: mixed lineage leukemia
 NCCN: National Comprehensive Cancer Network
 NPM1: nucleophosmin mutations, member 1
 NST: nonmyeloablative stem cell transplant
 OS: overall survival
 Ph⁺: Philadelphia chromosome
 PML: promyelocytic leukemia (gene)
 RAR: retinoic acid receptor- α
 TPMT: thiopurine methyltransferase
 WBC: white blood cell

AMY M. PICK, MARCEL DEVETTEN, AND TIMOTHY R. MCGUIRE

KEY CONCEPTS

- 1 Chronic myelogenous leukemia (CML) is characterized by the presence of the Philadelphia chromosome (Ph), a translocation between chromosomes 9 and 22. The resulting abnormal fusion protein, p210 *BCR-ABL*, phosphorylates tyrosine kinase residues and is constitutively active, resulting in uncontrolled cell proliferation.
- 2 Three phases of CML have been identified: chronic phase, accelerated phase, and blast crisis. At the time of diagnosis, most patients have chronic phase CML.
- 3 Imatinib is a tyrosine kinase inhibitor and is the most commonly used therapy in the treatment of chronic phase CML. Most patients on imatinib achieve a complete cytogenetic response within 9 to 12 months of initiation.
- 4 Interferon alfa (IFN- α) plays a minor role in the current treatment of CML and is reserved for patients who fail tyrosine kinase inhibitors and are ineligible for transplant.
- 5 Allogeneic hematopoietic stem cell transplantation is the only curative treatment for CML and is most often used when patients have suboptimal responses to imatinib therapy.
- 6 The management of CLL is highly variable and includes observation in asymptomatic older patients, the use of well-tolerated single agent chemotherapy in symptomatic older patients, and more aggressive therapy in younger patients.
- 7 Alemtuzumab may be used in patients who fail fludarabine and alkylator-based therapy. Its role in combination therapy is currently under investigation.
- 8 The combination of fludarabine, cyclophosphamide, and rituximab in CLL achieves higher response rates than single-agent chemotherapy.
- 9 Allogeneic hematopoietic stem cell transplantation in patients with CLL appears to achieve long-term disease-free survival in some patients, but late relapses occur and its role remains controversial.

Chronic leukemia includes chronic myelogenous leukemia (CML), chronic lymphocytic leukemia (CLL), hairy cell leukemia, and prolymphocytic leukemia. Chronic leukemia differs from acute

leukemia in that its clinical course is indolent. Most patients with chronic leukemia survive for several years after their initial diagnosis, even without treatment. Conversely, most patients with acute leukemia die of their disease within weeks to months if not treated. This chapter focuses on the two most common types of chronic leukemia, CML and CLL.

CHRONIC MYELOGENOUS LEUKEMIA

CML is a myeloproliferative disease that results from a malignant transformation of an early hematopoietic progenitor cell. This leads to abnormal proliferation and accumulation of progenitor and mature myeloid cells in the bone marrow and peripheral blood.¹ The clinical course of CML has three phases: chronic phase, accelerated phase, and blast crisis. The disease begins in the chronic phase in which signs and symptoms can be controlled with chemotherapy. CML then progresses to a transition phase, known as accelerated phase, in which blast counts in the bone marrow and peripheral blood increase despite ongoing therapy. Finally, there is blast crisis, a terminal phase that is similar to acute leukemia that can lead to rapid clinical deterioration and death.

EPIDEMIOLOGY AND ETIOLOGY

It is estimated that 4,570 new cases of CML will be diagnosed in the United States in 2007, representing 15% of all leukemias.² CML patients have a median age at diagnosis of 67 years.³ This age, collected from the Surveillance, Epidemiology, and End Results database, is higher than the median age of 45 to 55 years reported from most institutional studies.¹

For most newly diagnosed cases of CML, the etiology is unclear. Ionizing radiation and heavy occupational exposure to benzene are known risk factors. The increased risk of CML from radiation exposure was evident in atomic bomb survivors and in patients who received radiation therapy for ankylosing spondylitis.¹ CML is not associated with any known oncogenic viruses.

PATHOPHYSIOLOGY

CML was first described in 1845, but extensive research into the genetic and molecular characteristics of the disease began with the discovery of the Philadelphia chromosome (Ph) in 1960 by Nowell and Hungerford. Research in the 1980s identified the molecular changes that occur as a result of the Ph when an oncogenic protein was identified and implicated in the pathophysiology of CML.⁴⁻⁶

Ph is the first karyotypic abnormality specifically implicated in the pathogenesis of cancer, and its discovery has resulted in extensive research into the molecular biology of CML.¹ This chromosomal abnormality is characteristic of CML and is present in approximately 95% of patients with a presumptive diagnosis of the disease. It can also occur in

FIGURE 138-1. Diagram of the chromosomal translocation that results in the Philadelphia chromosome. (Fishleder AK. *Oncogenes and cancer: Clinical applications*. *Cleve Clin J Med* 1990;57:721–726. Reprinted with permission. Copyright ©1990. Cleveland Clinic. All rights reserved.)

as many as 20% of adults and 5% of children with acute lymphoblastic leukemia, and in rare cases of acute myelogenous leukemia.^{1,7}

① Ph, identified as a shortened long arm of chromosome 22, is found in granulocyte and erythrocyte progenitors, macrophages, megakaryocytes, and, occasionally, lymphocytes.¹ The Ph is the consequence of breaks in chromosomes 9 and 22, resulting in a transposition that relocates the 3' end of *abl*, the Abelson protooncogene, from its normal site on chromosome 9 at band 34 to the 5' end of the breakpoint cluster region (*bcr*) on chromosome 22 at band 11.^{1,7} This reciprocal translocation is symbolized as t(9;22)(q34;q11) and results in the formation of the hybrid *bcr-abl* fusion gene (Fig. 138–1). Through this chromosomal translocation, the *abl* protooncogene is able to escape the normal genetic controls on its expression and is activated into a functional oncogene, directing the transcription of an 8.5-kilobase messenger ribonucleic acid (mRNA) molecule. The translated 210-kilodalton protein, known as p210BCR-ABL, is unique and has higher tyrosine phosphokinase activity than the 145-kilodalton protein translated by the mRNA of the normal *abl* gene. The enzymatic activities of normal tyrosine kinases are under tight control and become activated only with physiologic activating signals. But p210BCR-ABL is constitutively (i.e., constantly) active, and this unregulated activity results in cell proliferation, inhibition of programmed cell death, and accumulation of the malignant clone.^{4,6} Although p210BCR-ABL is the most common tyrosine kinase found in CML, variations in the breakpoints in the *abl* gene encode different size proteins. For example, a smaller protein, p190BCR-ABL, is involved in two-thirds of adults with Ph-positive acute lymphoblastic leukemia, although rarely found in CML patients.^{1,7,8}

Because CML begins with the malignant transformation of a single cell, it is considered a clonal disease. This alteration gives the transformed progenitor cell an inheritable growth advantage, leading to the proliferation of a neoplastic, monoclonal population of pluripotent stem cells.^{1,4} The Ph can be found in both myeloid and lymphoid cells, which suggests that the transformed cell of CML is a pluripotent stem cell. Granulocytosis, usually present in CML, results from the increased growth rate of the transformed clone and disruption of normal hematopoietic cell maturation. Disrupted maturation leads to additional divisions by CML progenitor cells before reaching a nonproliferative stage; the resulting number of circulating granulocytes may be many times higher than normal. Later in the clinical course of CML, cytopenias may occur in association with fibrotic changes in the bone marrow.^{1,4}

The *bcr-abl* fusion gene encodes for a mutant tyrosine kinase that is involved in both the increased proliferation of the CML clone and the reduction in FAS-mediated apoptosis.^{1,4} Characterization of the adenosine triphosphate binding site on the tyrosine kinase has led to the development of tyrosine kinase inhibitors. The first of these inhibitors, imatinib mesylate (Gleevec), was approved by the FDA in 2001 for patients in chronic phase who had failed interferon- α (IFN- α) or who were in accelerated phase or blast crisis. It received

additional FDA approval in 2002 for first-line treatment in newly diagnosed CML. More potent inhibitors with a higher binding affinity and selectivity for *abl* kinase have been developed, including dasatinib (Sprycel) and nilotinib (Tasigna), and are likely to be used in imatinib-resistant CML.^{9–12} The clinical results associated with the newer generation tyrosine kinase inhibitors are discussed in more detail in Treatment below.

CLINICAL PRESENTATION

CLINICAL PRESENTATION OF CML¹

General

- 90% of patients are diagnosed in chronic phase
- 50% are asymptomatic in chronic phase and often diagnosed following abnormal complete blood count¹

Signs and Symptoms

- Fatigue
- Left upper quadrant pain
- Abdominal pain or distension
- Weight loss
- Night sweats

Physical Examination

- Splenomegaly
- Hepatomegaly

Laboratory Tests

- Peripheral blood
 - Leukocytosis
 - Thrombocytosis
 - Basophilia
 - Low or undetectable leukocyte alkaline phosphatase
 - Elevated uric acid and lactate dehydrogenase
- Molecular testing
 - Presence of *bcr-abl* by reverse-transcription polymerase chain reaction
- Bone marrow
 - Hypercellular
 - Fully mature myeloid cells
 - Increased megakaryocytes
 - <10% blasts in chronic phase
- Cytogenetics
 - Presence of the Ph chromosome
 - Additional abnormalities

CLINICAL COURSE

② Three clinical phases of CML have been identified: chronic phase, accelerated phase, and blast crisis. Nearly all patients are in chronic phase at the time of diagnosis.¹³ In chronic phase CML, nontransplant therapies suppress the CML clone and normalize the white blood cell (WBC) count. As the disease progresses, other mutations develop and treatment becomes less effective. Clinical evidence of disease progression, the accelerated phase of CML, begins to emerge as the patient's WBC count becomes increasingly difficult to control with therapy. Physical symptoms of acceleration include a resurgence of splenic enlargement, unexplained fever, and persistent bone pain. The rate of progression of CML is variable. In about one-third of patients, blast crisis occurs without

an apparent accelerated phase.^{14,15} Blast crisis is the final stage of CML and is marked by the presence of rapidly proliferating blast cells that have lost the ability to differentiate into mature cells.^{1,16} The proliferative advantage of blast cells over normal hematopoietic cells is much greater than that of chronic phase leukemic cells. A poor response to treatment is seen, which is not exclusively a result of drug resistance but also from the high proliferative rate of the blastic clone.¹⁷ The increased proliferative rate in blast crisis CML is the consequence of a number of factors in addition to *bcr-abl*, such as the activation of the RAC- and RAS-signaling pathways and loss of tumor suppressors such as p53.^{1,14} In blast crisis, about two-thirds of patients experience myeloid leukemia and the other third transform to a lymphoid leukemia.

Although the three phases of CML are well recognized, the criteria used to define them varies greatly. Clinical trials of imatinib have used different classification criteria for the various phases, with all staging criteria developed prior to the development of imatinib. In 2001, the World Health Organization proposed a new classification system that included new criteria for accelerated phase and blast crisis.¹⁸ In a comparison of the World Health Organization criteria with that used in imatinib trials, approximately 10% of patients had to be reclassified to a different phase.¹⁹ Based on that analysis, a new classification system was proposed to distinguish the phases of CML (Table 138–1).

PROGNOSIS

The overall survival of the patient depends on the phase of CML at the time of diagnosis. Most patients with CML are diagnosed in chronic phase and can be maintained on imatinib for many years. The duration of accelerated phase is shorter than chronic phase and typically lasts a few months before progression to blast crisis. The median survival for patients in blast crisis is 7 to 10 months, with most treatment options providing modest or no survival advantage.^{4,20}

There are currently no biomarkers available to predict disease progression for CML. Important poor prognostic factors include older age, splenomegaly, high platelet count, and a high percentage of circulating blasts at diagnosis. These features have been used to categorize patients into three risk groups: low, intermediate, and high. This scoring system, known as the Sokal score, was developed in the 1970s and is able to predict disease progression based on specified risk factors.¹ Although the scoring system was developed prior to the use of imatinib, the Sokal score predicted the likelihood of success with imatinib (Treatment).

TREATMENT

Chronic Myelogenous Leukemia

The ultimate goal in the treatment of CML is eradication of the Ph clone. Most, if not all, patients will initially be placed on imatinib therapy following a diagnosis of CML. More than 85% of patients will achieve a complete cytogenetic response on imatinib and will remain on imatinib until disease progression.^{13,21,22} A small percentage of patients will choose allogeneic hematopoietic stem cell transplantation (HSCT), which is the only treatment shown to permanently eliminate the Ph-positive malignant clone. Table 138–2 shows the effect of various treatment modalities on survival in chronic-phase CML.

Three types of treatment responses have been described: hematologic, cytogenetic, and molecular (see Fig. 138–2). *Hematologic* response is defined as the normalization of peripheral blood counts and is the earliest type of response. *Cytogenetic* responses are based on the percentage of cells positive for Ph in the bone marrow, with *complete* cytogenetic remission defined as the elimination of Ph and *major* cytogenetic response defined as fewer than 35% Ph-positive cells. Patients who have a major or complete cytogenetic response have an improved survival compared to those who fail to achieve a cytogenetic response.^{1,23}

Because most patients on imatinib achieve a complete cytogenetic response, more sensitive tests to monitor disease status are increasingly used. *Molecular* responses are determined by quantitative reverse-transcriptase polymerase chain reaction (RT-PCR), which is several logs more sensitive than methods used to measure cytogenetic remissions. A complete molecular response is the absence of *bcr-abl* transcripts by RT-PCR. Caution must be used as RT-PCR assays have various sensitivities and may show a complete molecular remission even when low levels of *bcr-abl* transcripts are present.²³ Quantitative RT-PCR should be performed on every patient prior to initiating therapy and throughout therapy to monitor residual disease. Because there is good correlation between bone marrow and peripheral blood *bcr-abl* mRNA levels, peripheral blood can often be used for this analysis.^{13,23,24} Figure 138–2 illustrates the residual disease that remains after various types of responses and the response rates obtained with the common therapies for CML.

CONVENTIONAL CHEMOTHERAPY

Conventional cytotoxic chemotherapy can be used in chronic-phase CML to reduce high circulating WBCs, but has only modest effects on median survival.¹ Historically, the two agents used to normalize WBCs are busulfan (Myleran) and hydroxyurea (Hydrea). Busulfan is rarely used because randomized trials show that hydroxyurea treatment provides a significant survival advantage over busulfan.²⁵

Hydroxyurea rapidly lowers high circulating WBCs in chronic-phase CML. Hydroxyurea inhibits the enzyme ribonucleotide reduc-

Minimal residual disease in chronic myeloid leukemia. *N Engl J Med* 2003;349(15):1399–1401. Copyright © 2003 Massachusetts Medical Society. All rights reserved.)

tase, which inhibits DNA synthesis, eliminates cells in the S phase of the cell cycle, and synchronizes cells in the G₁ or pre-DNA synthesis phase.¹ The drug is usually administered daily and can be initiated at 40 to 50 mg/kg/day in divided doses until the WBC count falls below 10,000 cells/mm³. At this point, the dose can be decreased to a maintenance level of 20 mg/kg/day but is usually discontinued as imatinib alone can maintain WBC count. Imatinib is often the sole agent used if rapid reduction in WBCs is not required. Unlike hydroxyurea, imatinib suppresses the malignant clone in the bone marrow and has a direct impact on long-term disease-free survival.^{25–27}

■ IMATINIB MESYLATE (GLEEVEC)

The development of imatinib has revolutionized the treatment of CML. The pivotal discovery in imatinib’s development was the characterization of the adenosine triphosphate binding site on the *bcr-abl* tyrosine kinase. From the numerous tyrosine kinase inhibitors developed in the 1990s, STI571 (STI stands for signal transduction inhibitor), better known as imatinib, emerged as the drug with the best oral bioavailability and selectivity for the *bcr-abl* tyrosine kinase.^{28,29} In 2001, imatinib mesylate (Gleevec) received FDA approval for patients in chronic phase who had failed IFN-α and in accelerated phase or blast crisis. In 2002, it received FDA approval for first-line treatment in newly diagnosed CML.

Imatinib inhibits several tyrosine kinases including *bcr-abl*, KIT, and platelet-derived growth factor receptor. It is the inhibition of the *bcr-abl* tyrosine kinase that leads to differentiation and apoptosis of the CML clone. Imatinib competitively binds to the adenosine triphosphate-binding site on *bcr-abl*, which inhibits the phosphorylation of proteins involved with CML clone proliferation.^{27,30} Table 138-3 summarizes the clinical results of imatinib in CML patients in chronic phase, accelerated phase, and blast crisis. Early phase I and phase II studies of imatinib, designed to determine maximum tolerated dose and safety, showed higher-than-expected response rates in all CML patient populations.^{27,31} The impressive activity in these early trials led to FDA approval of imatinib, prior to the completion of a large phase III trial, for patients with previously treated CML. Subsequent trials examined imatinib in newly diagnosed CML patients. Today, imatinib is the treatment of choice for nearly all patients with chronic-phase CML.^{10,12,22,32}

Chronic Phase

A large phase III randomized trial, known as the International Randomized Study of Interferon vs. STI571 (IRIS) study compared

400 mg imatinib to IFN-α plus low-dose subcutaneous cytarabine. After a median followup of 19 months, patients who received imatinib had a significantly higher rate of complete hematologic remissions, as well as of complete and major cytogenetic remissions. Additionally, a significantly lower percentage of patients had progressed to blast crisis or were intolerant to therapy.³³ The study was designed so that patients could crossover to the other arm for lack of activity or intolerance. After 60 months of followup, only 3% of patients who were originally randomized to receive IFN-α remained on their initial regimen.²¹ Because of this nearly complete crossover to the imatinib arm, it is not possible to determine the relative survival benefit of imatinib when compared to IFN-α.

The 5-year followup data from the IRIS trial was recently published.²¹ The estimated 5-year overall survival of the 553 patients who were originally randomized to receive imatinib was 89%. Eighty-seven percent of patients achieved a complete cytogenetic response while on imatinib. There were differences in the rate of complete cytogenetic responses among risk groups when the Sokal scoring system was used. The complete cytogenetic response rates were 89%, 82%, and 69% in low-risk, intermediate-risk, and high-risk patients, respectively. The risk of disease progression while on imatinib has remained fairly constant and quite low, ranging between 1.5% and 2.8% during the first 3 years to less than 1% in years 4 and 5. The risk of disease progression was associated with the Sokal score; the rates of progression were 3%, 8%, and 17% in low-risk, intermediate-risk, and high-risk patients, respectively. However, the Sokal score was not associated with disease progression in patients who had a complete cytogenetic response. Indicators for disease progression include a lack of a major cytogenetic response at 12 months and lack of complete cytogenetic response at 18 months.²¹

TABLE 138-3 Cytogetic Response Associated with Imatinib in Chronic Myelogenous Leukemia				
Disease Status	Daily Dose	MCR	CCR	Median Followup

③ Imatinib effectively reduces WBC count in chronic-phase CML. Declines in the WBC count are usually observed after 1 to 2 weeks and complete hematologic responses are achieved in the first 6 weeks. More time is required to achieve a cytogenetic response, with many patients requiring 9 to 12 months to obtain a complete cytogenetic response.^{13,22} Although most patients on imatinib achieve a complete cytogenetic response, very few patients achieve a complete molecular remission. In a study by Hughes et al., less than 5% of patients on imatinib have undetectable levels of *bcr-abl* when analyzed by RT-PCR.³⁴ Recent studies suggest that the level of residual disease is predictive of progression-free survival. A decline in *bcr-abl* mRNA by 2 logs within 3 months after achieving a complete cytogenetic response is reported to be a predictor of longer progression-free survival.³⁵ Consequently, careful monitoring of *bcr-abl* levels by RT-PCR is required to help clinicians determine modifications in therapy. The 2008 National Comprehensive Cancer Network (NCCN) guidelines suggest that *bcr-abl* levels should be measured at baseline and then every 3 months to assess response.²² If patients fail to achieve a decline in *bcr-abl* transcripts, other interventions should be considered, such as increasing the imatinib dose, dasatinib, nilotinib, or clinical trial. The lack of a complete and permanent molecular remission is the primary reason why imatinib is not considered a cure in CML.

The imatinib dose depends on the phase of CML. The NCCN guidelines and the European Leukemia Network recommend imatinib as the preferred treatment for most patients in chronic phase.^{22,32} Most, if not all, newly diagnosed patients in chronic phase will be started on imatinib 400 mg daily and nearly 90% of these patients will achieve a complete cytogenetic response (see Table 138-3). Because most patients fail to achieve a complete molecular response with 400 mg daily, studies are evaluating the role of higher doses of imatinib. Historical data suggests that higher cytogenetic responses can be seen with 800 mg daily versus 400 mg daily in newly diagnosed chronic-phase CML.³⁶ This dosing issue remains unsettled. The 2008 NCCN guidelines suggests that newly diagnosed patients with poor prognostic factors or high-risk Sokal scores may consider starting on higher doses of imatinib.²² The European Leukemia Network does not recommend starting on higher doses of imatinib for any patient until prospective randomized studies confirm there is a response or survival benefit over imatinib 400 mg.³²

Accelerated Phase/Blast Crisis

The response rate of imatinib is lower in accelerated phase or blast crisis as compared with chronic phase. In a phase II study, the complete hematologic and cytogenetic response rates for imatinib in accelerated phase were reported to be 82% and 43%, respectively, and patients treated with imatinib had a significantly improved survival when compared to historical controls.^{37,38} In blast crisis, 24% of patients treated with imatinib have a hematologic response and 16% a major cytogenetic response.³⁹ Unlike the long duration of response seen with imatinib in chronic phase, the duration in accelerated phase and blast crisis is much shorter. In the studies mentioned above, the estimated median duration of response for patients receiving imatinib in accelerated phase was 13.4 months.³⁸ In blast crisis, the estimated median duration of response with imatinib was 10 months.³⁹ Although clinical responses are seen, many patients cannot tolerate the side effects of higher doses of imatinib required for response in patients not in chronic phase.^{26,40} Several ongoing clinical trials are investigating the use of imatinib in combination with other therapies.^{32,40}

The maximum dose tolerated of imatinib in phase I trials was 1,000 mg, but doses as high as 1,200 mg are being evaluated in resistant patients.^{26,40} Studies have examined these higher doses in this population. Higher response rates have been reported with 600

mg of imatinib compared to 400 mg in advanced disease.^{27,37} Because of the lack of prospective data, the dosing for advanced phases is not specifically addressed by the NCCN guidelines or the European Leukemia Network.^{22,32} Typically, higher doses of 600 to 800 mg daily are used in patients with accelerated phase or blast crisis CML.^{11,13,20,22,37}

Imatinib Resistance

Some patients will experience disease progression despite imatinib therapy. Imatinib resistance is categorized based on the time to onset of nonresponsive disease. Intrinsic or primary resistance occurs when patients fail to achieve a hematologic response to therapeutic doses of imatinib (lack of efficacy). Acquired or secondary resistance occurs when there is a loss of efficacy over time.^{17,40} Mutations in *bcr-abl* are the most common mechanism of resistance, occurring in 42% to 90% of cases and are typically found in advanced disease.^{32,40} The most common mutations are *bcr-abl* domain point mutations that impair imatinib binding. It is estimated that 89% of patients with *bcr-abl* mutations will relapse in chronic phase.^{40,41} Approximately 10% of imatinib resistance is associated with overproduction of *bcr-abl*.¹ The overproduction of *bcr-abl* is caused by genomic amplification of additional *bcr-abl* transcripts.⁴² In the case of *bcr-abl* over-expression, dose escalation may be the best approach. Higher doses of imatinib may be the optimal approach for avoiding imatinib resistance.^{40,41} Therefore, clinical trials are evaluating the role of imatinib 800 mg in unresponsive or advanced disease CML.^{1,17} The use of more potent *bcr-abl* tyrosine kinase inhibitors such as dasatinib or nilotinib may effectively overcome imatinib resistance.^{11,40}

Imatinib Monitoring

Imatinib therapy should be frequently monitored to assess response or disease progression. Recommendations for monitoring include baseline molecular and cytogenetic assessment. A complete hematologic response is expected within 3 months of starting imatinib in chronic phase patients. If patients appear to be responding to treatment, then *bcr-abl* transcripts should be evaluated by RT-PCR every 3 months and bone marrow cytogenetics performed every 6 to 12 months.^{16,22-24} Most patients will achieve a cytogenetic response and will remain on imatinib therapy. Treatment options for patients who have disease progression include imatinib dose escalation, dasatinib, nilotinib, allogeneic HSCT, and a clinical trial.^{22,32}

Side Effects and Drug Interactions

Imatinib is associated with hematologic and nonhematologic side effects. Myelosuppression is one of the most common side effects. Moderate-to-severe (grade 3 or 4) myelosuppression occurs in approximately 5% to 10% of patients with chronic-phase CML and in 50% to 60% of patients in accelerated phase or blast crisis.^{1,14,27} The myelosuppression usually occurs during the first 2 to 4 weeks of therapy and is more common in patients with advanced disease (i.e., high blastic involvement of the bone marrow) and those with low hemoglobins.⁴³ Because hematopoiesis in patients with CML depends on the Ph-positive progenitors, some degree of myelosuppression should be expected when the clone is suppressed. However, a recent study reported that imatinib also suppresses normal hematopoiesis, which suggests that myelosuppression associated with imatinib is probably related to effects on the Ph clone and normal progenitors.^{26,44} During imatinib therapy, patients should have blood work drawn every 1 to 2 weeks to monitor for severe myelosuppression. Appropriate initial management of myelosuppression is to interrupt imatinib treatment, not dose reduce, as dose reductions below 300 mg daily do not fully inhibit *bcr-abl* and may lead to the emergence of imatinib resistance.^{1,14,22,27}

Imatinib is also associated with nonhematologic toxicities.^{10,22,26,27} Dose-related nausea and vomiting is the most common side effect and can be managed by taking the drug with a meal. Higher doses of imatinib should be split in half and taken twice daily to reduce GI side effects. Diarrhea is another common side effect that is dose-related and can be controlled with antidiarrheal medications. Dose-related edema and fluid retention often manifests as periorbital edema. Rarely, fluid retention can be severe, leading to pulmonary and cerebral edema. Risk factors for edema include female gender, age older than 65 years and a history of heart and kidney disease. Approximately 20% to 40% of patients complain of musculoskeletal symptoms, which tend to occur during the first month of therapy and decline in severity over time. Calcium and magnesium supplements may provide symptomatic relief. Drug rash can frequently occur but is usually mild and can be managed with antihistamines or topical steroids. Severe rash, while uncommon, has been reported as an important cause for discontinuation of therapy. Hepatotoxicity can occur with imatinib, and the drug should be withheld if liver function tests exceed five times normal. After the tests normalize, imatinib can be restarted at a reduced dose of not less than 300 mg per day. The drug is then escalated upward to the prior dose if the liver function tests do not rise during 6 to 12 weeks of treatment at the reduced dose.²⁶ One death as a consequence of liver failure has been reported in a patient receiving large doses of acetaminophen and imatinib. It is recommended that patients on imatinib limit their use of acetaminophen to 1,300 mg daily.²² Clinicians should evaluate the patient's medication history for all drugs that may contribute to hepatotoxicity.

Imatinib is metabolized by CYP3A4 and inducers of this enzyme may decrease imatinib concentrations. For example, a patient in the original phase I trial of imatinib who was also on phenytoin had a suboptimal response and was found to have a 75% reduction in plasma imatinib concentrations as compared to patients not on phenytoin. The clinical significance of this interaction was confirmed by rapid disease response when phenytoin therapy was withdrawn.³¹ Imatinib may increase the concentrations of other drugs metabolized by CYP3A4. For example, imatinib has been reported to increase blood levels of cyclosporine and simvastatin. Other agents that should be closely monitored include aprepitant, dexamethasone, St. John's wort, and warfarin.²²

■ OTHER TYROSINE KINASE INHIBITORS

Dasatinib (Sprycel) and nilotinib (Tasigna) are two recently approved tyrosine kinase inhibitors used to overcome resistance in CML. Dasatinib is an oral *bcr-abl* tyrosine kinase inhibitor that was FDA approved in 2006 for the treatment of imatinib-resistant CML. Dasatinib is an oral tyrosine kinase inhibitor of five critical oncogenic enzymes, including *bcr-abl*. Unlike imatinib, dasatinib binds to both the active and inactive forms of *bcr-abl* kinase and can overcome most *bcr-abl* mutations responsible for imatinib resistance. Preclinical data show that dasatinib is 300 times more potent than imatinib and has been active in all imatinib-resistant clones studied to date except for the T315I mutant.^{11,41} The drug received accelerated approval based on hematologic and cytogenetic responses seen in imatinib-resistant or imatinib-intolerant patients.⁴⁵ In a phase II study of 186 patients with imatinib-resistant or -intolerant chronic phase CML, 90% and 52% of patients achieved a complete hematologic response and major cytogenetic response, respectively.⁴⁶ Responses were also observed in patients with more advanced disease.⁴⁵ In another phase II trial, patients with imatinib-resistant chronic phase CML were randomized to receive either dasatinib or high-dose (800 mg) imatinib.⁴⁷ Dasatinib-treated patients had a significantly higher major and complete cytogenetic response rate than those treated with high-dose imatinib (52% vs. 33%). The complete cytogenetic response rate was

also significantly higher with dasatinib (40% vs. 16%). The dose used in those trials was 70 mg twice daily. A phase III dose-optimization study showed that dasatinib 100 mg once daily was equivalent to dasatinib 70 mg twice daily in patients with chronic-phase CML.⁴⁵ Patients with more advanced disease should be treated with dasatinib at a dose of 70 mg twice daily.

Nilotinib is an oral tyrosine kinase inhibitor of the inactive form of *bcr-abl* that was FDA approved in 2007 for the treatment of imatinib-resistant CML. Nilotinib is 10 to 30 times more potent in inhibiting *bcr-abl* than imatinib as a result of a modification of the methylpiperazinyl group of imatinib.^{11,41} In clinical trials, nilotinib inhibited 32 of the 33 imatinib-resistant *bcr-abl* mutations. Like imatinib and dasatinib, nilotinib does not inhibit the kinase activity of the T315I *bcr-abl* mutation. The drug received accelerated approval based on hematologic and cytogenetic responses in imatinib-resistant and imatinib-intolerant patients.⁴⁸ In a phase II trial of 280 patients with imatinib-resistant or -intolerant chronic phase CML, 48% of patients achieved a major cytogenetic response.⁴⁹ Responses were also observed in patients with accelerated phase CML.⁵⁰ The nilotinib dose used in these trials was 400 mg twice daily; the drug should not be given with food. The dosing in clinical trials has been 400 to 600 mg twice daily for imatinib-resistant CML.

The side-effect profile of other tyrosine kinase inhibitors is similar to imatinib. Reversible myelosuppression is the most common side effect seen with dasatinib and nilotinib, and sometimes requires temporary interruption of therapy. Other side effects for dasatinib include nausea, vomiting, diarrhea, edema, and pleural effusions.^{11,45-47} Edema or pleural effusions has not been reported in early clinical trials with nilotinib, but elevations in indirect bilirubin has been noted in 10% to 15% of patients.^{11,48-50} Future studies and longer followup time will be needed to examine additional side effects of these two drugs.

Like imatinib, dasatinib and nilotinib are metabolized by CYP3A4. Clinicians need to be aware of possible drug interactions with inducers and inhibitors of the CYP3A4 pathway.²² Dasatinib and nilotinib may prolong the QT interval. Until further data is available, patients should avoid concomitant therapy with other drugs that are known to prolong the QT interval, such as antiarrhythmics, macrolide antibiotics, and phenothiazines. In vitro data also suggest that long-term suppression of gastric acid decreases dasatinib absorption. Patients should refrain from taking concomitant H₂-blockers or proton pump inhibitors while on dasatinib until further studies can determine the clinical relevance.⁴⁵ The bioavailability of nilotinib is increased when given with a meal.⁴⁸

The precise role of dasatinib and nilotinib in the treatment of CML needs to be fully elucidated. The 2008 NCCN guidelines recommend that dasatinib or nilotinib be considered when patients do not achieve a complete hematologic response in 3 months or no cytogenetic response in 6 months. If patients continue to have a partial response or have disease progression while on imatinib, then a change in therapy to dasatinib or nilotinib should be considered.²²

The results from the early studies of dasatinib and nilotinib are quite promising for those who have imatinib-resistant CML. The development of the new generation tyrosine kinase inhibitors may further improve the prognosis of CML. Ongoing studies are investigating their use as frontline therapy and in combination with other therapies.

■ INTERFERON ALFA

Prior to the introduction of imatinib, IFN- α was the preferred agent in the treatment of CML. Today it is reserved for patients who fail tyrosine kinase inhibitor therapies and are not candidates for HSCT.

The interferons are a family of glycoproteins involved in many of the functional aspects of the hematopoietic system. Two recombinant forms of IFN- α are currently marketed: IFN- α_{2a} (Roferon

A) and IFN- α_{2b} (Intron A). In addition, two polyethylene glycol-conjugated products were developed in an attempt to improve the toxicity profile and decrease the frequency of injections of IFN- α (PEG-IFN- α_{2b} and PEG-IFN- α_{2a}). Although PEG-IFN- α_{2b} is not more effective and has a similar toxicity profile to the nonpegylated drug in CML patients,⁵¹ PEG-IFN- α_{2b} can be administered weekly as compared with daily administration for the nonpegylated formulation.⁵²

④ The past enthusiasm for the use of IFN- α in the treatment of chronic-phase CML was based on reports that 20% to 50% of patients achieve a major cytogenetic response, which led to prolonged survival.⁷ In the 10% to 15% of patients achieving a complete cytogenetic response, the median survival was more than 10 years.^{22,32} The unimpressive results of IFN- α in the IRIS trial in comparison to imatinib has limited the agent's use in CML. Only 14% of patients treated with IFN- α achieved a complete cytogenetic response, as compared to 76% of patients treated with imatinib.²¹ Although imatinib has generally replaced IFN- α as initial treatment of chronic-phase CML, some patients continue to receive IFN- α . These patients include those who had achieved a cytogenetic response to IFN- α and continue to receive the drug as maintenance therapy. With the introduction of new *bcr-abl* tyrosine kinase inhibitors to treat patients who fail imatinib, the usage of IFN- α will probably continue to decline.

IFN- α use is also limited by its toxicity profile.⁵³ IFN- α use is associated with both short-term constitutional toxicities and potentially dose-limiting long-term toxicities. In the IRIS trial, 26% of patients discontinued IFN- α as a result of intolerable side effects.²¹ The most predictable early toxicity is a flu-like syndrome characterized by fever, chills, myalgia, headache, and anorexia. These dose-dependent effects may be a result of IFN- α -induced leukocytosis and release of inflammatory cytokines. This acute flu-like syndrome can be ameliorated by starting IFN- α dosing at 50% of the final dose during the first week, giving the drug at bedtime, and coadministering acetaminophen or indomethacin with each IFN- α dose.⁵³ Reduction of initial WBC counts to about 10,000 cells/mm³ with hydroxyurea may also reduce these symptoms. Despite these methods of ameliorating toxicity, the flu-like syndrome is an important source of morbidity, occasionally requiring termination of therapy. Cardiovascular toxicities (tachycardia, hypotension) are seen in approximately 15% of patients in the first few weeks. Long-term adverse effects include weight loss, alopecia, neurologic effects (paresthesia, cognitive impairment, depression), and immune-mediated complications (hemolysis, thrombocytopenia, nephrotic syndrome, systemic lupus erythematosus, hypothyroidism), which can be dose limiting in approximately 5% to 20% of patients.^{1,53}

The role of IFN- α in the treatment of CML is quite limited with the introduction of tyrosine kinase inhibitors. According to the 2008 NCCN guidelines and European Leukemia Network, patients who are unable to tolerate other therapies may consider IFN- α .^{22,32} However, despite its limited use, IFN- α is a disease-modifying agent and ongoing clinical trials are investigating the use of imatinib and IFN- α in combination for the treatment of CML.^{32,54}

■ HEMATOPOIETIC STEM CELL TRANSPLANTATION

⑤ Allogeneic HSCT remains the only therapy proven to cure patients with CML, with many patients alive and disease-free decades after transplant. Patients undergoing allogeneic HSCT from a human leukocyte antigen (HLA)-matched sibling donor have 5-year survival rates ranging from 60% to 80% and long-term survival of approximately 50%.^{1,32,55,56} In most long-term survivors, the *bcr-abl* translocation is absent in all diagnostic tests including RT-PCR.

Prognostic risk factors associated with survival outcomes include age, phase of disease and disease duration. Increasing age is associated with poorer prognosis, with higher transplant-related mortality in patients older than age 50 years. Patients with early disease who receive transplantations have better outcomes than those in accelerated phase or blast crisis. The time from diagnosis to transplantation also affects outcomes. Patients who undergo matched-sibling allogeneic HSCT within the first year of diagnosis have a better 5-year survival rate than those who undergo transplantation more than 1 year after their diagnosis (70% to 80% vs. 50% to 60%).^{1,32,55,56}

Unfortunately, fewer than 30% of patients eligible for allogeneic HSCT will have an HLA-matched sibling donor, and alternative donors must be considered. The most common alternative donor is an HLA-matched unrelated individual. Results from several studies show that using matched unrelated donors, 40% to 70% of patients are alive at 5 years posttransplant, which is only slightly lower than the results reported for matched-sibling transplantations.^{7,55,56}

The remarkable activity of imatinib has resulted in fewer transplant for CML and has stimulated debate as to which, if any, subgroup should be treated with allogeneic HSCT as primary therapy. The difficulty is identifying those patients who will have suboptimal responses and might benefit from early transplantation. A recent study by the German CML Study Group reported that survival with drug therapy (IFN- α or imatinib) is superior to early allogeneic HSCT for low-risk patients, but no difference in survival was observed in high-risk patients.⁵⁷ The results from this study suggest allogeneic HSCT should be reserved for high-risk patients. The use of imatinib prior to transplantation is also controversial. Although imatinib is probably not curative for most patients, nearly all patients with newly diagnosed chronic-phase CML are started on imatinib therapy at the time of their diagnosis. Recent studies show that imatinib use prior to transplantation does not negatively affect survival.^{58,59} These studies suggest that patients must be monitored carefully for early signs of imatinib nonresponse or relapse.

The European Leukemia Network expert recommendations lists allogeneic HSCT as one of two strategies (the other being imatinib) used in high-risk patients with low transplant-related mortality. It is also considered an option when patients fail imatinib or other therapies.³² The 2008 NCCN guidelines no longer list allogeneic HSCT as a potential front-line option for patients.²² All patients should be informed that imatinib probably is not curative and disease progression can occur at any time, sometimes without warning. Patients who should consider allogeneic HSCT are newly diagnosed CML patients who are young enough to tolerate the procedure and who have a HLA-matched related or unrelated donor; patients who do not achieve a hematologic remission within 3 months of therapy; patients who do not achieve a cytogenetic response after 6 to 12 months; and patients who are in accelerated phase or blast crisis CML. With the median age of onset for CML being in the sixth decade of life and the high risk of mortality in patients older than 50 years of age, more than half of CML patients will be excluded from allogeneic HSCT based on age alone. Even when all the criteria are met (matched donor and younger age), 100-day mortality after allogeneic HSCT is between 10% and 20% in established transplant centers. This risk of early mortality associated with allogeneic HSCT may be too high in the imatinib era where most patients have complete cytogenetic responses without significant toxicity. The clinical decision is further complicated by the observation that there is a recognized window when transplantation is optimally performed. Better outcomes are observed when a patient undergoes transplantation within the first 2 years of diagnosis.^{22,32} Consequently, delaying transplantation might negatively impact survival outcomes. Ongoing studies need to investigate whether this concern is valid in the imatinib era.

CLINICAL CONTROVERSY

Although the controversy of whether to use imatinib or allogeneic HSCT as initial therapy is relevant to fewer than 30% of newly diagnosed CML patients, it continues to be controversial. Because early versus late transplantation is associated with better outcomes, one reasonable approach is to evaluate hematologic remission at 3 months in patients receiving imatinib. If patients do not have a complete hematologic remission and are eligible for transplantation, it should be considered. Cytogenetic responses should be evaluated every 3 months and those who obtain a complete cytogenetic remission on imatinib within 9 to 12 months of diagnosis should remain on imatinib. Delaying the transplantation might compromise the success of the allogeneic HSCT or lead to disease progression, in which transplantation outcomes are poorer.

Treatment options in patients who relapse after transplantation include inducing a graft-versus-leukemia (GVL) effect, imatinib, or IFN- α . The infusion of donor lymphocytes as a form of adoptive immunotherapy can induce a GVL effect. In relapsed CML, donor lymphocytes induce durable responses and these responses strongly correlate with the development of graft-versus-host disease (GVHD).^{60,61} Tumor burden also predicts the likelihood of response to donor lymphocyte infusion in relapsed CML. A study by Raiola stratified the response rate of donor lymphocyte infusion according to relapse type. The response rate to donor lymphocytes was 100% in patients with molecular relapse, 90% in patients with cytogenetic relapse, 75% with relapsed chronic phase, and 35% in patients with relapsed accelerated phase or blast crisis.⁶² The dose, timing, and method of administration of donor lymphocytes may also impact effectiveness. In one study, there was a significantly lower incidence of GVHD with escalating doses of donor lymphocyte infusion (fractionated dosing) rather than single-dose donor lymphocytes while maintaining a similar 70% to 90% complete cytogenetic remission rate.⁶³ This study suggests that the administration of donor lymphocytes in fractionated doses rather than a single large dose after the patient recovers from tissue damage may induce a GVL effect while minimizing GVHD. The optimal method of administering donor lymphocytes remains unclear, but these data suggest it may be possible to partially separate the GVL effect from GVHD.

Imatinib has been used in patients who have residual disease after allogeneic HSCT. Most patients respond to imatinib with complete molecular response of 70% without development of acute GVHD, which is often associated with donor lymphocyte infusions.⁶⁴ Although more work needs to be done on imatinib salvage after allogeneic HSCT, this high response rate is promising.

It is too early to define the role of nonmyeloablative transplants in CML but early results suggest equivalent efficacy to myeloablative transplants. Although early mortality is low following nonmyeloablative transplantation, transplant-related mortality is approximately 25% at 2 years.^{65,66}

EVALUATION OF THERAPEUTIC OUTCOMES

Because nearly all patients with newly diagnosed chronic-phase CML will receive imatinib therapy, the goal of disease monitoring in CML is to identify patients who have optimally responded to an initial course of imatinib. A suboptimal response to imatinib is defined as no complete hematologic response at 3 months or lack of a complete cytogenetic response at 9 to 12 months. Recently published guidelines suggest that monitoring of *bcr-abl* transcripts is currently the best available test to monitor disease response.^{23,24} These guidelines suggest that *bcr-abl* levels should be measured at baseline and then every 3 months to assess response.^{22,32} The increase in *bcr-abl* levels

may allow practitioners to identify patients who have progressive disease and may need a change in therapy. Imatinib dose escalation, dasatinib, nilotinib, or allogeneic HSCT should be considered in patients who do not respond or fail to maintain a molecular response.^{22,32}

CHRONIC LYMPHOCYTIC LEUKEMIA

CLL is a lymphoproliferative disorder characterized by accumulation of functionally incompetent clonal B lymphocytes.⁶⁷ CLL is the most common form of leukemia in the United States, but is rare in other countries, such as Japan and China. It is estimated that about 15,340 new cases of CLL will be diagnosed in the United States in 2007.² Occasional family clusters have been recognized, and first-degree relatives of patients with CLL are at three times the risk of developing a lymphoid malignancy as compared to the general population. CLL is a disease of the elderly, with a median age of onset between 65 and 75 years, although 20% to 30% of CLL occurs in patients who are younger than 55 years of age.³ Etiologic factors have not been identified in CLL, and there is no data supporting either radiation or viral oncogenesis.¹

CLINICAL PRESENTATION OF CHRONIC LYMPHOCYTIC LEUKEMIA

Constitutional Symptoms

- Fever, fatigue, weight loss

Physical Examination

- Lymphadenopathy (87%)
- Splenomegaly (54%)
- Hepatomegaly (14%)

Laboratory Tests

- Peripheral blood
 - Lymphocytosis
 - Coombs-positive autoimmune hemolytic anemia
 - Hyper- or hypogammaglobulinemia
 - Monoclonal gammopathy
 - Anemia
 - Thrombocytopenia
- Bone marrow
 - Hypercellular
 - Increased mature lymphocytes
 - Increased megakaryocytes
- Molecular markers
 - Cytogenetics (17p-)
 - ZAP-70 mutations

STAGING AND PROGNOSIS

Survival times for patients with CLL are widely variable, with some patients dying within 2 years and others living two decades from the time of diagnosis. Two systems are used to estimate prognosis: the Rai and the Binet staging systems. Prognosis depends on stage and tumor burden at diagnosis. The Rai staging system has been combined into a risk classification scheme: low risk (stage 0), intermediate risk (stages I and II), and high risk (stages III and IV) with median survivals of greater than 10 years, 7 years, and 2 to 4 years, respectively.^{1,68} The other common staging system is the Binet system, which is more commonly used in Europe.

Despite the prognostic importance of staging, the disease course varies within each stage so that one patient may have an indolent course with long survival time, while another patient may have more aggressive disease and a relatively short survival time. Because staging systems, such as the Rai system, incompletely predict for individual patients who progress rapidly within each stage, additional parameters are being developed to accurately identify patients who have poorer prognosis. Some of the more promising biologic markers include CD38 expression, ZAP-70 expression, and cytogenetic changes such as deletion of the short arm of chromosome 17 (17p-) corresponding to p53 silencing. CD38 is a cell-surface marker that is associated with early progression, significantly shorter overall survival and a poor response to fludarabine.^{67–70} ZAP-70 is an intracellular protein with tyrosine kinase activity. Once considered as simply a surrogate marker for the unmutated variable region of the immunoglobulin heavy chain gene (IgVH), ZAP-70 appears to predict for rapid CLL disease progression and independently correlates with prognosis. Patients who have elevated ZAP-70 expression by flow cytometry have poorer prognosis.^{68,71,72} These newer biomarkers, like ZAP-70 and CD38 expression, may help identify high-risk patients. The cytogenetic abnormality, 17p-, may be the most consistent of the prognostic markers identifying poor-risk patients who respond poorly to fludarabine-based therapy.

CLINICAL CONTROVERSY

Certain molecular and cellular markers have been identified that may predict CLL disease progression. ZAP-70 expression, CD38 expression, IgVH mutations, and 17p- are associated with a more aggressive form of CLL, although current treatment guidelines do not indicate when and how to initiate treatment based on these biologic markers. Controversy surrounds whether or not treatment should be based on these biologic markers alone. 17p- is the most consistent poor prognostic marker and results in a loss of the tumor suppressor gene, p53. One approach may be to treat young patients with these adverse prognostic markers with more aggressive combination therapy or consider allogeneic transplantation. For older patients, it may be reasonable to consider initiating less-intensive therapy, or if the patient is asymptomatic, waiting until symptoms arise. Although there is limited data supporting this approach, the hope is that early treatment may achieve complete remission and improve overall survival in those with aggressive disease.

TREATMENT

Chronic Lymphocytic Leukemia

Because CLL is considered to be an incurable disease, the primary goals of treatment are to improve quality and duration of life. ⁶ The management of patients with CLL is highly variable, with some patients receiving therapy immediately and delaying therapy in others. The decision to begin treatment is based on several factors, including age of the patient, symptoms, aggressiveness of the tumor, and high-risk molecular features. Treatment is often instituted after signs and symptoms of progressive disease, autoimmune complications, symptomatic splenomegaly, bulky lymph nodes, severe lymphocytosis (greater than 100,000 to 200,000 cells/mm³), and increased infectious complications.^{67,73,74}

Most stage 0 patients do not require treatment and can be managed with observation. In patients with stage I or II disease, treatment is controversial. A consistent survival benefit from early therapy has not been reported in asymptomatic patients.^{74,75} Cytotoxic chemotherapy in early stage CLL is usually reserved for

TABLE 138-4 Treatment for Newly Diagnosed and Previously Treated Chronic Lymphocytic Leukemia

Treatment	Overall Response	Complete Response
Chlorambucil		
Untreated	37%	4%
Fludarabine alone		
Untreated	60–80%	20–30%
Previously treated	13–59%	3–37%
Fludarabine + cyclophosphamide		
Untreated	80–90%	25–40%
Previously treated	60–70%	10–15%
Rituximab alone		
Untreated	50–60%	10–20%
Previously treated	80–90%	20–40%
Fludarabine + rituximab		
Untreated	80–100%	30–50%
Previously treated	80–90%	20–40%
Fludarabine + cyclophosphamide + rituximab		
Untreated	95%	70%
Previously treated	73%	25%
Alemtuzumab alone		
Untreated	80–90%	20–30%
Previously treated	30–50%	0–20%
Alemtuzumab + fludarabine		
Previously treated	83%	17–30%

patients who have disease characteristics consistent with a more aggressive course, such as short lymphocyte doubling times and presence of biologic markers such as ZAP-70 or high-risk cytogenetics. In stages III and IV disease, treatment is required, with the goal of achieving a partial or complete remission. Survival is improved in those patients who achieve a complete remission and is longest in those who become minimal residual disease negative. Table 138–4 reviews the current drug therapies used in newly diagnosed and previously treated CLL.^{73,74,76,77}

■ CYTOTOXIC CHEMOTHERAPY

Orally administered alkylating agents such as chlorambucil and cyclophosphamide can be used as primary treatment for CLL. The timing of therapy is controversial. Results from a meta-analysis involving 2,048 patients from six randomized controlled studies evaluated low-dose alkylating agents in CLL. The analysis showed that delayed treatment in asymptomatic patients did not adversely effect 10-year survival. More importantly, if only deaths caused by CLL were considered, significantly longer survival was observed when treatment was deferred.⁷⁵ Chlorambucil continues to be widely used in elderly, symptomatic patients as initial treatment for CLL, but its use is based on a small number of studies with no demonstrable survival advantage.^{1,67} Commonly used dosing schedules for chlorambucil are intermittent pulse dosing of 15 to 40 mg/m² orally every 28 days or daily doses of 4 to 8 mg/m² per day.⁷⁶ The dose of chlorambucil is often titrated to minimize myelosuppression. The addition of prednisone to chlorambucil is likely to increase infectious risk with no advantage in the treatment of CLL, but prednisone may have value in patients with autoimmune blood dyscrasias.¹

Cyclophosphamide produces a similar response rate as chlorambucil (overall response rate: 40% to 60%; complete response: 4%) and can be used in patients who cannot tolerate chlorambucil or in whom response is not optimal.¹ Some patients who don't respond to chlorambucil do respond to single-agent cyclophosphamide. Cyclophosphamide is typically given orally at a daily dose of 1 to 3 mg/kg. Oral cyclophosphamide is less-commonly used compared to

chlorambucil because of the risk of hemorrhagic cystitis and bladder cancer with prolonged treatment.

Fludarabine-based therapy is a common initial treatment in CLL. It is particularly useful in younger patients and in those patients who can tolerate immunosuppressive chemotherapy. Fludarabine, along with the other purine analogs, 2-chlorodeoxyadenosine (cladribine) and 2-deoxycoformycin (pentostatin), is highly active in CLL, with fludarabine being the most widely studied purine analog in the treatment of CLL.^{73,74,77,78} Most patients receive fludarabine 20 mg/m² intravenously daily for 5 days when used as single-agent chemotherapy. Cladribine and pentostatin have similar activity, although head-to-head trials comparing these three nucleosides have not been conducted.^{67,73,76,77,79}

Fludarabine was initially studied in CLL patients who were refractory to chlorambucil. Several trials reported overall response rates to fludarabine in previously treated patients ranging from 13% to 59% and complete response rates of 3% to 37%.^{80,81} The most durable responses occurred in patients with lower-stage disease.⁸¹ Based on these encouraging results in patients with refractory disease, fludarabine was studied in chemotherapy-naïve patients. Three large phase II trials conducted in symptomatic, untreated CLL patients confirmed the efficacy of fludarabine. In these trials, fludarabine produced higher overall response rates and complete remissions than did alkylating-based therapies. In one of the randomized studies that compared fludarabine to chlorambucil in chemotherapy-naïve patients, fludarabine-treated patients had a higher complete remission rate as compared with chlorambucil (20% vs. 5%).⁸² However, the higher complete remission rate did not translate into a significant difference in overall survival, and patients treated with fludarabine had a higher rate of severe neutropenia and infection. The study allowed chlorambucil failures to cross over to the fludarabine arm, which may have reduced the ability to show a survival advantage in patients treated with fludarabine. Based off the following studies, there have been concerns about the higher incidence of opportunistic infections seen with fludarabine. A recent review of younger patients enrolled in a large phase III trial showed 33% of patients receiving fludarabine or fludarabine-based therapy had infectious complications.⁸³ An increase in *Pneumocystis* infections was not observed, but a 6% increase in herpes and varicella zoster infection was documented. Dose reductions occurred frequently during the infectious episode.⁸³ Based on the increased risk of infectious complications, some practitioners recommend antiviral and antibacterial prophylaxis to prevent these infections.^{84,85}

■ BIOLOGIC THERAPY

Monoclonal antibodies, such as rituximab and alemtuzumab, are increasingly being used in the treatment of CLL. Rituximab is a chimeric monoclonal antibody that targets the CD20 antigen expressed on B lymphocytes. Rituximab was originally studied in patients with non-Hodgkin's lymphoma. The results from early trials of rituximab in CLL showed limited efficacy, with a 10% to 15% partial response rate.⁸⁶ This finding was attributed to the lower CD20 expression on the surface of the CLL cells as compared to non-Hodgkin's lymphoma and a more rapid clearance of rituximab in CLL, possibly through shedding of CD20.^{73,87} When rituximab was used as the sole therapy in CLL, higher doses than those used in indolent non-Hodgkin's lymphoma had to be given to overcome these biologic features. Subsequent studies with higher rituximab doses (up to 2,250 mg/m²) have reported increased overall response rates to 40% to 75% in previously treated patients.^{73,87,88}

7 Alemtuzumab is a monoclonal antibody that targets the CD52 antigen found on B and T lymphocytes. It was FDA approved in 2001 for the treatment of patients with CLL who had been treated with alkylating agents and had failed fludarabine therapy. Alemtuzumab

has generally been used in CLL patients who are refractory to other available therapies, although data as first-line therapy are accumulating.^{73,89,90} Alemtuzumab is often titrated to a maintenance dose of 30 mg intravenously given three times a week for 12 weeks. As a single agent, alemtuzumab has produced response rates from 33% to 53% in patients with refractory disease, but the complete response rates have been low.^{73,78,90} Results from a randomized phase III trial comparing alemtuzumab to chlorambucil in chemotherapy-naïve patients with symptomatic CLL showed higher complete response rates with alemtuzumab than with chlorambucil, 24% vs. 2%, respectively.⁹¹ These differences in response rate translated into a significant difference in progression-free survival (hazard ratio 0.58, 95% confidence interval 0.43-0.77). Based on these results, alemtuzumab received FDA approval in 2007 as first-line treatment for CLL. Alemtuzumab may also have a role in clearing minimal residual disease after patients have been treated with chemotherapy. O'Brien et al. reported that 38% of patients with residual disease after fludarabine could achieve a molecular remission following alemtuzumab therapy and some of these remissions appeared to be durable.⁹² Currently it is not known whether eliminating residual disease improves overall survival outcomes in CLL. Investigations are ongoing with the expectation that undetectable residual disease will correlate with improved remission duration and survival.⁷³ The activity of alemtuzumab in CLL is encouraging, but the drug is also associated with serious, potentially life-threatening toxicities, including pancytopenia, infusion reactions, and opportunistic infections. Because of alemtuzumab's profound immunosuppression, the 2008 NCCN guidelines recommend antibacterial and antiviral prophylaxis to prevent *Cytomegalovirus* reactivation and *Pneumocystis* infections.⁸⁵ Prophylaxis with trimethoprim-sulfamethoxazole and foscarnet or valganciclovir is recommended with the use of alemtuzumab.^{1,86}

Infusion-related reactions are one of the most frequently reported toxicities with alemtuzumab. The reactions experienced with intravenous administration include fever, rigors, and hypotension. Although alemtuzumab is FDA approved for intravenous administration, the use of subcutaneous alemtuzumab has been explored to reduce the frequency of these reactions.^{73,90,93} In a study by Lundin et al., 41 patients received 30 mg of subcutaneous alemtuzumab three times a week for 12 weeks. The response rate was 87%. The responses occurred after 18 weeks of therapy, which is longer than intravenous therapy. The major adverse event was grades 1 and 2 skin reactions, which was seen in 90% of patients, but fever, rigors, and hypotension were rare.⁹⁴ Approximately 10% of patients had reactivation of *Cytomegalovirus* and required ganciclovir treatment. It appears that antiviral and antibacterial prophylaxis is warranted with subcutaneous alemtuzumab.^{90,94}

The exact role of rituximab or alemtuzumab in CLL is still being investigated. The 2008 NCCN guidelines recommend that rituximab be used in combination with other agents for first-line treatment of CLL in those patients who can tolerate aggressive chemotherapy. The guidelines do not recommend single-agent rituximab.⁸⁵ Alemtuzumab is primarily used as second-line therapy for CLL after failing combination-based therapy. The 2008 NCCN guidelines recommend that alemtuzumab be used as first-line therapy in high-risk patients with the 17 p- mutation. Clinicians must assess the risk-to-benefit ratio with alemtuzumab for reactivation of *Cytomegalovirus* can be deleterious.⁸⁵ Appropriate infection prophylaxis must be given.

■ COMBINATION THERAPY

The high single-agent activity of fludarabine has led to fludarabine-based combination regimens in patients with CLL. The most widely studied combination is fludarabine with cyclophosphamide, which produces complete response rates between 25% and 40% in treatment-naïve patients as compared to 20% to 30% for single-agent

fludarabine.^{73,78,86} Although improved response rates and progression-free survival have been reported with fludarabine and cyclophosphamide combinations compared with fludarabine alone, no benefit in overall survival has yet been observed.^{73,78}

Combination fludarabine and rituximab has promising activity. In vitro studies suggest that rituximab is synergistic with fludarabine and cyclophosphamide and has led investigators to evaluate this combination in clinical trials.^{73,86} 8 Results from an uncontrolled trial of fludarabine, cyclophosphamide, and rituximab reported a complete remission rate of 70% in previously untreated CLL patients. This is the highest complete remission rate reported for any treatment of CLL.⁸⁶ This same combination was impressive in previously treated patients, with a complete remission rate of 25%.⁹⁵

Combinations with alemtuzumab have also been studied. The combination of fludarabine and alemtuzumab achieved an overall response rate of 83% in heavily pretreated patients.⁹⁶ Combinations of alemtuzumab and rituximab produced a response rate of 53% in a group of CLL patients. The response rates were higher (63%) in patients who had not received prior antibody therapy.⁹⁷ The investigators did note that more than half the patients experienced an infection suggesting severe treatment-related immunosuppression. The treatment of CLL increasingly involves fludarabine combined with monoclonal antibody therapy. Patient selection is critical given the high risk of serious infection. Most younger patients will be candidates for fludarabine-monoclonal antibody based combination therapy. Symptomatic elderly patients with aggressive disease who can tolerate immunosuppressive therapy may also be candidates for this regimen.⁷⁴

■ HEMATOPOIETIC STEM CELL TRANSPLANTATION

There is limited experience with the use of HSCT in CLL. Early mortality with autologous and allogeneic HSCT is approximately 10% and 40%, respectively.^{67,80,98} 9 Patients treated with allogeneic HSCT achieve higher rates of molecular remission and appear to have a longer duration of disease-free survival, but at the expense of high treatment-related mortality.⁹⁸ Contrary to the high mortality reported in most studies, a randomized phase II study of high-risk CLL patients comparing allogeneic and autologous HSCT reported 100-day mortality of 4% in both arms. After 6 years of followup, no difference in overall survival (58% autologous and 55% allogeneic) was observed.⁹⁹ This low early mortality must be interpreted carefully, given that only 25 carefully selected patients received allogeneic HSCT as compared to 137 who received autologous transplantation. Also, T-cell depletion was performed on the allogeneic grafts, which may reduce early mortality at the cost of increased relapse as a consequence of reduced GVL effect.⁹⁹

Although this modality of treatment may hold some promise of cure, the advanced age of most CLL patients and the associated high treatment-related mortality limits the use of allogeneic HSCT in CLL. HSCT is an option for younger patients with aggressive disease. Older patients who are not candidates for full-intensity allogeneic HSCT may be candidates for nonmyeloablative allogeneic HSCT.⁸⁰

EVALUATION OF THERAPEUTIC OUTCOMES

CLL is considered an incurable indolent disease and the goal of therapy is to increase the duration and quality of life. Careful risk-to-benefit analysis should be applied in older patients with indolent disease. A reasonable strategy in asymptomatic patients is observation (i.e., no therapy). Therapy should be considered in patients with symptomatic disease. Younger patients with aggressive disease should receive a fludarabine-based therapy, possibly in combination with rituximab and cyclophosphamide.⁸⁵

TREATMENT SUMMARY OF CHRONIC LEUKEMIA

The treatments used for CML and CLL are vastly different with tyrosine kinase inhibitors used in CML and biologics playing an increasingly important role in CLL. For the vast majority of patients with chronic-phase CML, imatinib is used as initial therapy. In patients who do not achieve an adequate response, dose escalation of imatinib, allogeneic HSCT, other tyrosine kinase inhibitors, or clinical studies should be considered. Allogeneic HSCT still remains the only curative therapy for CML. IFN- α is no longer a first-line option for CML based on its inferior activity as compared with imatinib and is reserved to those who can not tolerate tyrosine kinase inhibitors.

The goal in the treatment of CLL is to optimize quality of life rather than to use aggressive, toxic therapy. Observation is appropriate in asymptomatic patients with low-risk disease characteristics. Treatment should be reserved for patients with symptomatic or high-risk disease. In the older patient, the use of chlorambucil may still be preferred over fludarabine because of the lower infectious risk and ease of administration. In the younger patient, fludarabine-based combination therapy is often given with the goal of obtaining complete remissions. The combination of fludarabine, cyclophosphamide, and rituximab has reported the highest response rates in CLL. Alemtuzumab is most frequently used in previously treated patients, but is being studied as part of initial therapy in patients with high risk disease. The use of alemtuzumab is limited by its severe immunosuppressive profile.

TIMOTHY R. MCGUIRE

KEY CONCEPTS

- 1 Multiple myeloma (MM) is a cancer that develops in plasma cells leading to excessive production of a monoclonal immunoglobulin (M protein).
- 2 Most patients have skeletal involvement at the time of diagnosis with associated bone pain and fractures. Anemia, hypercalcemia, and renal failure may also be present. A bone marrow biopsy with 10% or more plasma cells and a M-protein spike on plasma or urine electrophoresis confirm the diagnosis.
- 3 Most patients will require treatment after diagnosis but treatment can be deferred in patients with smoldering (asymptomatic) or stage I MM. Treatment of patients with symptomatic or stage II or III disease produces benefits in various measures of survival and quality of life.
- 4 Thalidomide plus dexamethasone is a commonly used induction regimen. It produces higher complete remission rates as compared to melphalan plus prednisone but at the cost of greater grade III and IV toxicity which can include venous thromboembolism (VTE) and neuropathy.
- 5 Bortezomib is an FDA-approved treatment for relapsed MM and is being studied as initial therapy combined with dexamethasone or chemotherapy. Bortezomib may have superior activity in chromosome 13 deletion patients.
- 6 Lenalidomide is a more potent, and perhaps less toxic, thalidomide analog that is being studied as initial therapy combined with dexamethasone or chemotherapy.
- 7 Autologous hematopoietic stem cell transplantation (autoHSCT) is used after induction in patients with reasonably good performance status to maximize complete remissions and prolong survival.
- 8 The use of myeloablative allogeneic hematopoietic stem cell transplantation (alloHSCT) produces high early mortality but the use of nonmyeloablative alloHSCT may offer a chance for long-term disease-free survival.
- 9 Bisphosphonates are used to treat bone disease associated with MM, which results in decreased pain and skeletal-related events and improvement in quality of life.

- 10 Salvage therapy for patients with relapsed or refractory MM can include any of the prior listed therapies, depending on performance status of the patient and prior treatments used for induction.

Multiple myeloma (MM) is a relatively common hematologic malignancy that develops in plasma cells or immunoglobulin-producing B lymphocytes.^{1,2} The plasma cells produce excessive monoclonal immunoglobulins that can be measured in the plasma or urine. Because of the various bone-mobilizing cytokines secreted from the MM clone and bone marrow stromal cells, patients often have skeletal involvement at diagnosis. The lytic bone lesions result from the double insult of pathologic activation of osteoclasts (bone mobilizing cells) and inhibition of osteoblasts (bone-forming cells). MM is initially sensitive to chemotherapy but drug resistance often develops rapidly, primarily because of upregulation of multidrug resistant proteins such as P-glycoprotein and regulators of apoptosis such as *bcl-2*. Although therapy is not curative, several new agents have been developed that have improved the duration and quality of life of MM patients.

Disease progression is influenced by cytokines that are able to stimulate plasma cell growth and angiogenesis. Several of these cytokines, including interleukin-6 (IL-6), basic fibroblast growth factor (bFGF), tumor necrosis factor- α (TNF- α), and vascular endothelial growth factor (VEGF), have become targets for new therapies such as thalidomide, its congener lenalidomide, and bortezomib.

EPIDEMIOLOGY AND ETIOLOGY

In the United States, it is estimated that 19,900 cases of MM will be diagnosed in 2007, with 10,790 deaths. It is a disease that affects older adults with a median age at diagnosis of 70 years. MM occurs more frequently in males and African Americans.¹⁻³

No cause can be identified in most patients. Exposure to high doses of radiation increases the risk of developing MM.^{1,2} Although not proven, there may be a hereditary component to MM, given the reports of familial associations. The relationship between viral infection and risk of MM is controversial. Human herpes virus-8 is often reported to be a likely candidate virus for development of MM.¹ However, a recent study was unable to isolate human herpes virus-8 from patients with MM and it is unlikely that human herpes virus-8 is an etiologic agent in this disease.⁴ Patients with human immunodeficiency virus-1 infections have 4.5 times the risk of developing MM, which suggests a role for human immunodeficiency virus-1 as a viral cofactor. Human immunodeficiency virus-1-positive patients develop MM at an earlier age and with disease that has aggressive characteristics leading to poorer outcomes.⁵

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

PATHOPHYSIOLOGY

MM presents a very complex picture of multistep malignant transformation. A precursor condition called monoclonal gammopathy of undetermined significance (MGUS) is associated with monoclonal immunoglobulin in the blood (≤ 3 g/dL) without clinical manifestations of the complications of MM.^{6,7} The conversion rate of MGUS to MM is approximately 1% per year. The molecular changes associated with the conversion of MGUS to MM are not clear, but genome-wide studies have identified several candidate genes for disease progression.⁸ Smoldering MM is asymptomatic disease with low tumor burden and an indolent course.^{1,9} In patients with smoldering MM, the risk of progression is approximately 10% per year for the first 5 years after diagnosis, approximately 3% per year for the next 5 years, and approximately 1% per year for the next 10 years.⁹

In early MM, the balance between apoptotic and antiapoptotic genes is disrupted with overexpression of antiapoptotic genes.¹⁰ As the disease progresses, a greater number of gene products that confer resistance, such as mutated p53, are overexpressed.¹¹ Molecules such as IL-6 and the transcriptional regulator nuclear factor kappa B (NF- κ B) also stimulate clonal growth and promote resistance to therapy.¹² Given their imprecise but important role in initiation and progression of MM, IL-6 and NF- κ B are targets for both old and new therapies.

1 MM is characterized by the accumulation of malignant plasma cells in the bone marrow and the production of a monoclonal immunoglobulin (M protein). These proteins, secreted by the malignant clone, are frequently referred to as paraproteins.¹ Both MM and normal plasma cells are produced from differentiated B cells after antigen stimulation. Normal plasma cells will die within days to weeks after differentiation whereas MM plasma cells are immortalized.^{1,2} MM cells are seldom seen in large quantities in the

peripheral blood because of their interaction with bone marrow stromal cells. This interaction between MM cells and bone marrow stroma is mediated by adhesion molecules within an abnormal bone marrow microenvironment and is required for growth and disease progression.¹³ Figure 139–1 describes several of the factors involved in disease pathogenesis and progression and potential molecular drug targets.

The major target for the newer therapies is NF- κ B. The effects of NF- κ B are pleiotropic and integral to MM progression. NF- κ B activation is high in MM and results in an abnormally high production of MM growth factors such as IL-6 and adhesion molecules in the bone marrow. Thalidomide is a potent inhibitor of TNF- α , which is a cytokine with important NF- κ B-inducing activity. Thalidomide also has direct NF- κ B-inhibiting activity by conserving inhibitor of NF- κ B (I κ B), the cytosolic inhibitor of NF- κ B. Lenalidomide has similar mechanisms of action as thalidomide but is significantly more potent. Thalidomide and lenalidomide also activate important antimyeloma immune responses. Bortezomib is the most specific of the NF- κ B inhibitors. Through its inhibition of the protease complex, the proteasome, bortezomib prevents I κ B degradation and termination of NF- κ B signal. Understanding the targets of these newer agents has led to a better understanding of the pathophysiology of MM.

CLINICAL PRESENTATION

2 Most MM patients present with complaints of bone pain and fatigue at diagnosis. Approximately 10% to 20% of patients are asymptomatic at the time of diagnosis, most of whom will have either smoldering or stage I disease.¹⁴ Most patients show evidence of end-organ damage at the time of diagnosis. Initial laboratory evaluation often reveals hypercalcemia, renal insufficiency, anemia, and abnormalities in various disease markers, such as albumin and

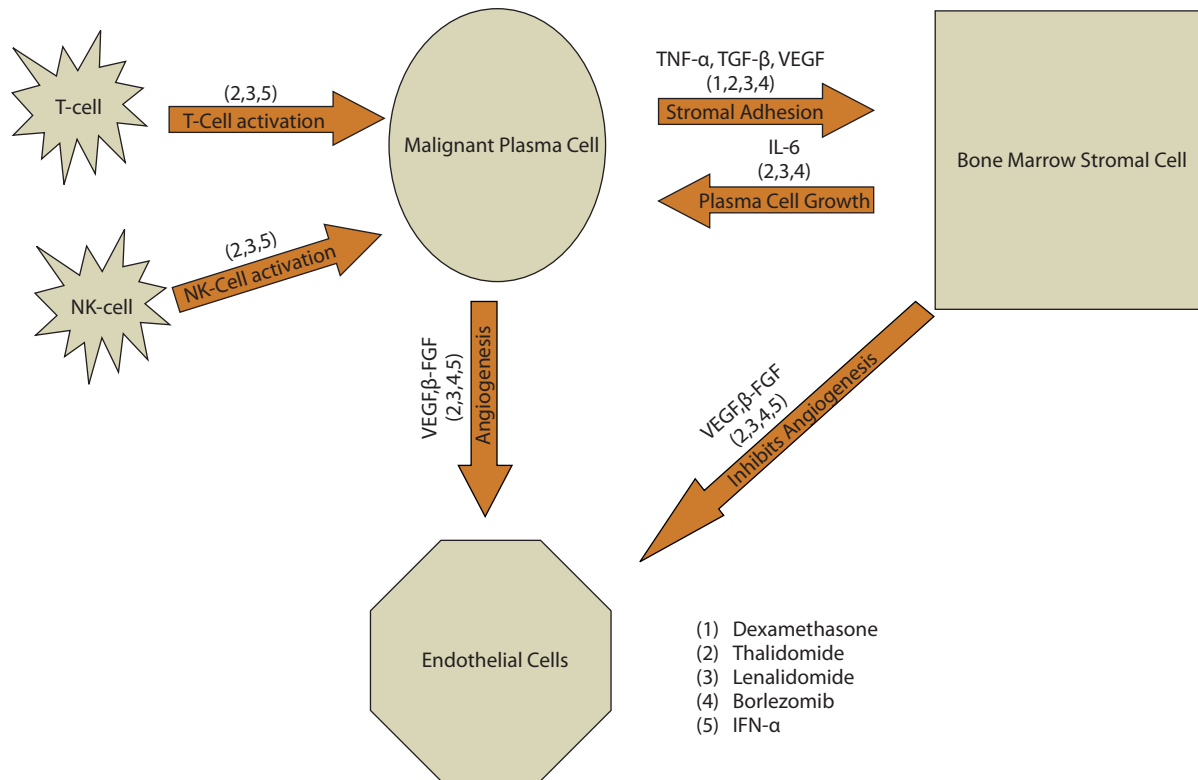

FIGURE 139-1. Sites of action of selected drugs used in the treatment of multiple myeloma. (bFGF, basic fibroblast growth factor; IFN- α , interferon alpha; IL, interleukin; NK, natural killer; TNF- α , tumor necrosis factor; TGF- β , transforming growth factor; VEGF, vascular endothelial growth factor.)

β_2 -microglobulin. Skeletal evaluation shows gross abnormalities in most patients. Bone scans show abnormalities that often include lytic lesions, osteoporosis, and fractures. This group of findings (hypercalcemia, renal insufficiency, anemia, and bone lesions) is often referred to as CRAB.⁶ A bone marrow biopsy with 10% or more plasma cells and an M-protein spike on plasma or urine electrophoresis confirms the diagnosis.¹⁵ Immunofixation after electrophoresis identifies the M-protein isotype being secreted. In approximately 20% of patients, no M protein can be detected in the plasma but is found in the urine, requiring that urine be examined as part of a complete diagnostic workup. Approximately 60% of patients will have intact monoclonal immunoglobulin G, 20% will have monoclonal immunoglobulin A, and the remaining 20% will secrete only monoclonal light chains. Antibodies are composed of two light chains where antigen binds and two heavy chains. Light-chain immunoglobulin alone can be secreted by the MM clone. Free monoclonal light chains in the urine are called Bence Jones proteins because they were first described by Dr. Henry Bence Jones and are primarily responsible for MM-associated renal failure.^{1,15}

CLINICAL PRESENTATION OF MULTIPLE MYELOMA

General Criteria

- 80% of patients present with symptomatic disease

Signs and Symptoms

- Bone pain (fractures, lytic lesions)
- Fatigue (anemia)
- Infection (reduced polyclonal response)
- Neurologic symptoms (nerve compression)
- Polyuria (hypercalcemia)
- Nausea and vomiting (hypercalcemia)

Laboratory Parameters

- Elevated paraproteins
 - Plasma electrophoresis
 - Urine electrophoresis
 - Immunofixation
- Elevated serum creatinine
- Hypercalcemia
- Low hemoglobin
- Low albumin
- Elevated β_2 -microglobulin
- Elevated C-reactive protein

Bone Marrow

- $\geq 10\%$ plasma cells

Cytogenetics

- Chromosome 13 deletion
- Translocation (4;14)
- Del (17p)

The skeleton is involved at the time of diagnosis in most patients with MM.¹⁶ Bone scans show abnormalities that often include lytic lesions, osteoporosis, or fractures. The effects of MM on the skeleton result from abnormal production of cytokines including IL-1, IL-6, TNF- α , and the receptor for activation of NF- κ B ligand (RANK-L). Bone disease is the net effect of the activation of osteoclasts and inhibition of osteoblastogenesis.¹⁷

In addition to bone disease, patients are frequently anemic from infiltration of the bone marrow with the MM clone and poor

TABLE 139-1 The International Staging System (ISS) for Multiple Myeloma

Stage	Characteristics	Median Survival (Months)
I	Serum β_2 -microglobulin <3.5 mcg/mL Serum albumin ≥ 3.5 g/dL	62
II	Not stage I or stage III	44
III	Serum β_2 -microglobulin ≥ 5.5 mcg/mL	29

erythropoietin response. Those patients with low erythropoietin levels benefit most from erythropoietic therapy. Patients can have clinically important hypercalcemia, which results from calcium mobilization from the bone. Renal failure can occur as a result of high protein load from the monoclonal protein secretion as well as dehydration.

STAGING AND PROGNOSTIC FACTORS

Some patients with MM are asymptomatic and have no evidence of end-organ damage at the time of diagnosis. These patients are categorized as having smoldering (or asymptomatic) MM.¹⁹ Most patients will have evidence of end-organ damage (hypercalcemia [>10.5 g/dL], renal impairment [>2.0 mg/dL], anemia [<10 g/dL or >2 g/dL below normal], or bone disease) at the time of diagnosis and are categorized as having active (symptomatic) disease. Patients with asymptomatic disease have an indolent course, with a median survival of about 5 years.⁹

A new International Staging System (ISS) uses serum β_2 -microglobulin and albumin concentrations to stage patients.¹⁸ These two routine laboratory tests are powerful prognostic discriminators. Using the ISS, researchers have shown that older age negatively affects survival. ISS predicts survival in patients treated with either conventional treatment or autologous hematopoietic stem cell transplantation (autoHSCT). An older staging system, Durie-Salmon, uses hemoglobin, serum calcium, bone involvement, and M protein to categorize patients in one of three stages. Table 139-1 describes the ISS and median survival for each of the three ISS stages.

Several negative prognostic factors have been proposed for MM, including chromosome 13 deletion and other cytogenetic abnormalities, elevated β_2 -microglobulin, elevated C-reactive protein, high plasma cell labeling index, low albumin, and high bone marrow microvessel density.¹ Some of these prognostic factors are incorporated into the ISS. These prognostic factors generally represent the underlying pathologic changes associated with MM including genetic damage (chromosome 13 deletion), proinflammatory changes (C-reactive protein), tumor load (β_2 -microglobulin) and dysregulated cellular growth (labeling index and marrow microvessel density).

TREATMENT

Multiple Myeloma

OVERVIEW OF INITIAL THERAPY

③ MM is not a curable disease. The role of therapy is to prolong progression-free and overall survival and improve quality of life. Patients with more active (symptomatic) or advanced disease (stages II and III) require therapy.^{1,14,19} In patients with smoldering (asymptomatic) or stage I disease, watchful waiting is the general practice despite a systematic review that suggests early treatment with chemotherapy slows disease progression and may decrease vertebral compression.²⁰ These benefits are offset by the absence of convincing

evidence that early treatment improves overall survival and important toxicities associated with therapy. The National Comprehensive Cancer Network (NCCN) Guidelines support watchful waiting for smoldering or stage I MM.¹⁴

Initial management of symptomatic MM depends on high-risk features of the disease (cytogenetics), patient age, performance status, and whether autoHSCT is planned. Although current treatments are not curative, median survival has increased significantly from about 7 months to 24 to 36 months primarily as a result of improved treatment of symptomatic MM and supportive care.¹ There is no standard initial or induction therapy for the treatment of symptomatic MM. Table 139-2 lists commonly used regimens, which are categorized based on whether or not the patient is an autoHSCT candidate. The age restriction for autoHSCT has changed because of low transplant-related mortality, but autoHSCT is generally reserved for patients ≤65 years of age.

The choice of induction therapy in autoHSCT candidates include VAD (vincristine, doxorubicin, and dexamethasone) or VAD-like chemotherapy, dexamethasone combined with thalidomide, lenalidomide, or bortezomib, and high-dose dexamethasone alone. Melphalan is usually avoided in patients who are eligible for autoHSCT because of its adverse effect on stem cell mobilization. When autoHSCT is not an option, melphalan plus prednisone is an acceptable choice for induction therapy but many clinicians add thalidomide to melphalan and prednisone (MPT) based on the results of randomized controlled trials that show significantly higher response rates and longer progression-free survival with MPT. MPT is listed as a preferred first-line therapy in the NCCN Guidelines and a recently published Mayo Clinic Consensus Statement (Table 139-3).^{14,19} Maintenance therapy is not recommended outside of the context of a clinical trial.

CLINICAL CONTROVERSY

For patients who are autoHSCT candidates, induction therapy has usually involved the administration of 4 months of VAD. High-dose dexamethasone alone is also an option, given that most of the activity of VAD resides with dexamethasone. Newer agents, such as thalidomide, bortezomib, or lenalidomide, combined with dexamethasone show promising activity and are increasingly being used as induction therapy. However, thalidomide or lenalidomide combined with high-dose dexamethasone have increased toxicity as compared to high-dose dexamethasone alone. The elevated risk of venous thromboembolism requires prophylaxis, which makes these regimens less conve-

TABLE 139-3 Evidence-Based Treatment Recommendations for Newly Diagnosed Multiple Myeloma

Recommendation	Strength of Recommendation and Level of Evidence ^a
Melphalan, prednisone, and thalidomide (MPT) should be used as initial therapy for standard-risk patients ineligible for autoHSCT	A I-II
MPT (as an alternative, consider a bortezomib-containing regimen to maximal response) should be used as initial therapy for high-risk patients ineligible for autoHSCT	D III (for MPT) D III-IV (for considering bortezomib-based regimen)
Lenalidomide and low-dose dexamethasone should be used as induction therapy for standard- and high-risk patients eligible for autoHSCT	B II-III
Early autoHSCT, followed by a second HSCT (if the patient does not achieve a very good partial response or better with the first HSCT) should be used as consolidation therapy for standard-risk patients eligible for HSCT	B I

autoHSCT, autologous hematopoietic stem cell transplantation.
^aStrength of recommendations: A, evidence of type I or consistent findings from multiple studies of types II, III, or IV; B, evidence of types II, III, or IV, and findings are generally consistent; C, evidence of types II, III, or IV, but findings are inconsistent; D, little or no systematic empirical evidence. Quality of evidence: I, evidence from meta-analysis of multiple, well-designed, controlled studies, randomized trials with low false-positive and low false-negative errors (high power); II, evidence from at least one well-designed experimental study, randomized trials with high false-positive and/or negative errors (low power); III, evidence from well-designed, quasiexperimental studies, such as nonrandomized, controlled single-group, prepost, cohort, time, or matched case-control studies; IV, evidence from case reports and clinical examples.
Data from Dispenzieri A, Rajkumar SV, Gertz MA, et al. Treatment of newly diagnosed multiple myeloma based on Mayo Stratification of Myeloma and Risk-adapted Therapy (mSMART): Consensus statement. *Mayo Clin Proc* 2007;82:323-341.

nient. The Mayo Clinic Consensus Statement lists the combination of lenalidomide plus low-dose dexamethasone as a preferred induction regimen in autoHSCT candidates because of its high activity and lower incidence of venous thromboembolism.¹⁹ Bortezomib is generally well tolerated but is associated with significant rates of neuropathy and requires intravenous administration. There are no convincing data to show that the higher response rates associated with these newer regimens lead to improved outcomes in patients undergoing autoHSCT. Therefore, none of the available induction regimens can be considered standard of care, and VAD and high-dose dexamethasone induction remain acceptable options.

Clinical response to therapy is generally defined by a reduction in paraprotein in blood and urine.¹ Clinical complete response is defined as elimination of plasma paraprotein, as measured by electrophoresis and immunofixation, and plasma cells (≤5%) in the bone marrow. Complete responses are uncommon in MM and lesser responses, including minor response, partial response, and very good partial response, are more commonly attained. These lesser responses can be important because they may correlate with improved survival. Table 139-4 describes the most common types of responses that are used clinically.¹⁴

DRUGS USED IN THE MANAGEMENT OF MULTIPLE MYELOMA

Conventional Chemotherapy

Two of the common conventional chemotherapy regimens used to treat MM are melphalan plus prednisone (MP) and VAD (Table 139-5).²¹ The use of conventional-dose melphalan has an adverse effect on stem cell mobilization and subsequent autoHSCT. Mel-

TABLE 139-4 Definition of Clinical Response in Multiple Myeloma

Type of Response	Definition ^a
Minor response (MR)	<ul style="list-style-type: none"> • 25%–49% decrease in serum M protein • Reduction in 24-hour urine light chain by 50–89%
Partial response (PR)	<ul style="list-style-type: none"> • ≥50% decrease in serum M protein • Reduction in 24-hour urine light chain by ≥90%
Very good partial remission (vgPR)	<ul style="list-style-type: none"> • Serum and urine M protein detected on immunofixation but not electrophoresis
Complete remission (CR)	<ul style="list-style-type: none"> • Negative immunofixation on serum and urine • No soft-tissue plasmacytomas • <5% plasma cells in the bone marrow

^aMaintained for a minimum of 6 weeks.

phalan may also lead to the development of myelodysplastic syndrome.²² Despite these adverse effects, MP remains an acceptable initial therapy for older patients who are not eligible for autoHSCT.¹⁴

The use of VAD (or VAD-like) chemotherapy as initial treatment became more common because of these concerns with melphalan. However, the slightly higher response rates with VAD and similar combination chemotherapy did not translate into improved survival as compared to melphalan.²³

Dexamethasone accounts for most of the antimyeloma activity of VAD (see Table 139–5), which led to the use of dexamethasone alone as upfront therapy. However, a recent study reported that melphalan plus prednisone produced similar response rates and survival as compared to dexamethasone. The higher rate of infection and CNS toxicity in patients treated with dexamethasone led these investigators to conclude that high-dose dexamethasone be used with caution as upfront therapy, particularly in older patients who are not eligible for autoHSCT and who would usually receive MP.²⁴ Increasingly, patients who are autoHSCT candidates receive dexamethasone and thalidomide to maximize initial response rates. In addition, newer therapies, such as bortezomib and lenalidomide, continue to be investigated as upfront therapy.^{14,19,25}

Thalidomide (Thalomid)

Thalidomide was first used clinically in Europe in the late 1950s as a sedative and antiemetic but its use was largely abandoned when

teratogenicity was reported. Its immunomodulatory effects became evident with its use in Hansen's disease (or leprosy), and it continues to be used for this rare indication. These clinical benefits are thought to be related to the anti-TNF activity of thalidomide. Because of the role of inflammatory cytokines in the pathophysiology of MM, thalidomide was first studied in refractory MM in 1999. The realization that thalidomide had activity against myeloma rejuvenated it as an important therapeutic agent.²⁶

Thalidomide has multiple immune effects including inhibition of inflammatory mediators, antiangiogenic activity, and T-cell modulating activity.²⁷ Thalidomide destabilizes TNF- α messenger RNA leading to increased destruction of the transcripts and reduction in TNF- α production. One potential explanation for thalidomide's anti-myeloma activity is inhibition of TNF-mediated NF- κ B activation, which results in increased apoptosis of the MM clone. Thalidomide also has TNF-independent effects; it protects the cytosolic I κ B and prevents signal transduction to the nucleus, resulting in a decline in MM growth factors.^{26,27}

Myeloma bone marrow has a high rate of neovascularization, which makes it susceptible to antiangiogenic therapy. Bone marrow microvessel density has been identified as an independent prognostic factor in MM.²⁸ One explanation for the angiogenesis that occurs in MM is the paracrine release of TNF- α by the myeloma clone and bone marrow stromal cells, which leads to the release of angiogenic factors, including VEGF, IL-8, bFGF, and IL-1, through NF- κ B induction. Thalidomide treatment can reduce bone marrow microvessel density, which may contribute to its antimyeloma activity.

The role of TNF- α inhibition is supported by a small study that showed that TNF- α polymorphisms predicted for thalidomide response in patients with MM.²⁹ High producers of TNF- α had significantly higher response rates and improved survival with thalidomide therapy as compared to patients without the hypersecretory phenotype. These results may be explained by inhibition of TNF- α as a required growth factor in patients with the TNF- α hypersecretory phenotype. The authors commented that larger studies are required to confirm and explain these results. Figure 139–1 shows that thalidomide inhibits proliferation and angiogenesis, stimulates T lymphocytes, and modifies the cytokine-secreting ability of bone marrow stromal cells.

Single-agent thalidomide has been extensively evaluated in refractory MM where it produces overall response rates (includes minor responses) in the 30% to 40% range with rare complete remissions.³⁰ Although minor and partial responses are the most common types of responses, these end points result in improvement in survival.³¹

4 With the activity of thalidomide in refractory MM established, subsequent studies evaluated its activity in newly diagnosed patients and in combination with other therapies, including dexamethasone and chemotherapy. Partial response rates with single-agent thalidomide in untreated patients are approximately 30% to 40%, and response rates increase to 60% to 70% when minor responses are included.³² When dexamethasone is added to thalidomide in untreated patients, response rates increase to approximately 90% if minor responses are included.³³ The higher response rate with thalidomide plus dexamethasone makes this an attractive combination for initial therapy. However, the higher rate of thromboembolism with this combination (15% to 20%) is a concern.³⁴ In addition, the complete remission rate remains low (<5%).

The addition of thalidomide to chemotherapy also increases response rates (see Table 139–5). Two randomized controlled trials in newly diagnosed MM showed that the addition of thalidomide to MP results in an increased response rate.^{35,36} In the first randomized trial, the overall response rate with MPT was 76% with a complete and near-complete response rate of greater than 15%.³⁵ The higher response rates with MPT translated into superior 2-year event-free (54% vs. 27%; $P = 0.0006$) and a trend in improved 3-year survival

TABLE 139-5 Initial Therapies for Multiple Myeloma

Regimen	Type of Response		
	OR (%)	CR (%)	CR + near CR (%)

alloHSCT, allogeneic hematopoietic stem cell transplantation; autoHSCT, autologous hematopoietic stem cell transplantation; CR, complete response; OR, overall response (at least PR); RI, reduced intensity; VAD, vincristine, doxorubicin, and dexamethasone.

(80% vs. 64%; $P = 0.19$).³⁵ The second randomized trial was stopped early because MPT showed clear improvements over the other treatment arms. Results of that trial also showed significantly improved median progression-free (27.5 vs. 17.8 months) and overall survival (51.6 vs. 33.2 months) with MPT.³⁶ Based on these impressive results, some have recommended that MPT be the new standard induction therapy in older patients ineligible for autoHSCT (see Table 139–3).^{19,25} The increased response rate of MPT is at the expense of higher rates of grades III and IV toxicity (48% vs. 25%), particularly venous thromboembolism (VTE), peripheral neuropathy, and infection.³⁵

The combination of thalidomide, dexamethasone, and pegylated liposomal doxorubicin produces a high overall response rate of 98% and a complete remission rate of 34%. The major grades III and IV toxicities were VTE (14%) and infection (22%). Toxicity was acceptable, even in patients older than 65 years of age.³⁷ Although the activity of doxorubicin plus thalidomide compares favorably with other combinations (see Table 139–5), one disadvantage of this regimen is that pegylated liposomal doxorubicin requires intravenous administration. The high response rate of thalidomide plus pegylated liposomal doxorubicin combinations needs to be confirmed in a randomized trial that compares it with an accepted standard.

Thalidomide dose correlates with response and toxicity. In one large trial of single-agent thalidomide, a higher response rate was observed when more than 42 g of thalidomide was administered over a 3-month period, which is equivalent to a daily dose of about 450 mg.³¹ As expected, the higher dose was associated with higher rates of thalidomide-related toxicity. When thalidomide is combined with chemotherapy, thalidomide doses of 100 mg/day are associated with high complete remission rates.^{35,37} Neuropathy, one of the important dose limiting toxicities, may correlate with cumulative thalidomide doses. Thalidomide-induced neuropathy is usually, but not always, reversible and is associated with demyelinating changes in peripheral neurons. Approximately 10% to 20% of patients are unable to tolerate thalidomide and neuropathy is often the toxicity associated with discontinuation of therapy.^{31,38} Unfortunately, no effective methods have been identified to prevent or treat thalidomide-induced neuropathy.

Other common toxicities associated with thalidomide include constipation, sedation, and rash. While these toxicities can be problematic, they rarely require discontinuation of thalidomide treatment. Stimulant laxatives can be used to prevent severe constipation. Constipation and rash appear to be dose-related while sedation occurs at all dose levels. The severity of constipation and sedation declines over time in many patients.^{30,38}

The rate of VTE with single-agent thalidomide is relatively low (1% to 3%) and may not exceed the baseline incidence for MM patients. VTE prophylaxis is not recommended in patients receiving single-agent thalidomide.¹⁹ When thalidomide is combined with dexamethasone, MP, or doxorubicin, the risk of thrombosis is elevated. The underlying mechanism for thrombosis in these patients is unknown but rates in several studies of combination therapy were as high as 10% to 30%.^{36,39,40} VTE prophylaxis is recommended and preventive strategies include therapeutic doses of warfarin or low-molecular-weight heparin.¹⁹ Warfarin is associated with bleeding complications and should be reserved for patients with a history of VTE. Aspirin (81 mg or 325 mg) may be beneficial in preventing thrombosis, but large, well-controlled studies are required. Aspirin should be reserved for those patients at high risk of bleeding on warfarin or low-molecular-weight heparin.^{34,41}

Bortezomib (Velcade)

5 Bortezomib is a proteasome inhibitor approved for use in refractory MM. The proteasome is a protease complex responsible

for degrading cytosolic proteins that are conjugated to ubiquitin. Ubiquitin is a 8.5-kilodalton polypeptide that tags various proteins for destruction.⁴² By reversibly binding to the chymotrypsin site in the catalytic core of the 26S proteasome, bortezomib inhibits the degradation of these targeted proteins.

In MM, NF- κ B activity is increased, resulting in increased transcription of inflammatory cytokines such as IL-6 and TNF- α , which are involved in the pathogenesis and progression of MM. In the cytosol, NF- κ B is bound to and inhibited by I κ B. The proteasome degrades I κ B. When the proteasome is inhibited with bortezomib, cytosolic concentrations of I κ B remain high and NF- κ B is retained in the cytosol as an inactive complex. The resulting inhibition of NF- κ B signal leads to a reduction in cytokine production and growth inhibition of the MM clone. Other proteins involved in cell-cycle regulation and apoptotic signaling that may be affected by bortezomib include p53, JNK proteins, and caspase-3.⁴²

In phase I studies in patients with refractory hematologic malignancies, bortezomib was administered twice weekly for 2 consecutive weeks followed by a week of rest. The responses observed in those studies included a complete response in 1 of 8 patients who completed the first course of therapy and minor responses in two patients. These responses were impressive for a phase I trial and confirmed the promising activity in preclinical studies.⁴³

Patients with refractory MM were enrolled into a phase II trial and received 1.3 mg/m² of bortezomib twice weekly for 2 weeks followed by a week of rest. Patients received up to eight cycles. The overall response rate was 35% (includes minor responses) with 7 (3.6%) patients achieving a complete response.⁴⁴ In a second phase II study, the overall response rate increased to 50% (includes minor responses) when bortezomib was combined with dexamethasone. Based on the phase I and II studies, bortezomib was approved in May 2003 under the FDA's accelerated approval process for relapsed or refractory MM in patients who had failed at least two prior therapies.⁴⁵

Subsequently, a large phase III study (Assessment of Proteasome Inhibition for Extending Remissions [APEX] trial) demonstrated that bortezomib had superior activity as compared to high-dose dexamethasone in relapsed MM.⁴⁶ Bortezomib-treated patients had higher complete and partial response rates (38% vs. 18%), longer median time to progression (6.2 vs. 3.5 months), and improved 1-year overall survival (80% vs. 66%) as compared to patients receiving dexamethasone. The differences in each of these end points were statistically significant. The results from this study led to expanded FDA approval in 2005 to include patients who had relapsed after one therapy.

Combination therapy with bortezomib has shown promising results in relapsed MM in a number of small phases I and II studies. It had been observed that patients who had suboptimal response to bortezomib responded after the addition of dexamethasone. Subsequent studies reported improved results with the combination of bortezomib and corticosteroids with the complete and near complete response rate ranging between 5% and 15%.⁴⁷ The combination of bortezomib with either doxorubicin or melphalan is being evaluated, with early results suggesting similar or higher overall response rates than when it is combined with dexamethasone.⁴⁷

There are limited data on bortezomib in newly diagnosed patients (see Table 139–5). Bortezomib alone produces about a 40% response rate (complete remission plus partial response) with approximately 3% of patients obtaining a complete remission. When combined with dexamethasone, the overall response rate increases to approximately 90% (complete remission plus partial response) with complete remissions of 5% to 20%.^{48,49} In a phase II study of bortezomib combined with MP in newly diagnosed elderly MM patients, the overall response rates of 89% and complete remission rates of 32% are among the highest reported with induction therapies.⁵⁰ Based on these results, the Mayo Clinic Consensus Statement recommends that a bortezomib-containing regimen be considered as initial ther-

apy for high-risk patients who are not eligible for hematopoietic stem cell transplantation (see Table 139–3).¹⁹

Bortezomib is a relatively well-tolerated drug. The most common toxicities include mild-to-moderate fatigue and gastrointestinal toxicities. Neuropathy occurs less frequently but is the most common cause for discontinuation of therapy. In the APEX trial, the rate of neuropathy was 36% in the bortezomib group versus 9% in the dexamethasone group.⁴⁶ Eight percent of patients with refractory or relapsed MM required discontinuation of therapy because of severe neuropathy. Newly diagnosed patients tolerate bortezomib better than patients with relapsed or refractory MM, with only 1% to 2% discontinuing therapy. Other important toxicities included thrombocytopenia, fever, neutropenia, and infection. An increased incidence of shingles was reported in bortezomib-treated patients, and the NCCN Guidelines recommend that herpes zoster prophylaxis be considered.¹⁴ VTE prophylaxis is not required with bortezomib-containing regimens.

Lenalidomide (Revlimid)

6 Lenalidomide is a thalidomide analog that shares a similar mechanism of action with thalidomide, but is significantly more potent than thalidomide. Because of differences in the toxicity profile, the use of lenalidomide is likely to increase. In a phase II study, patients with relapsed, refractory MM were randomized to two doses of lenalidomide (15 vs. 30 mg). Overall response rates were 24% in this group of heavily pretreated patients who were generally resistant to thalidomide.⁵¹ The 30-mg dose was well tolerated and had better complete response rates as compared to the 15 mg dose (0 vs 6%).

The addition of lenalidomide to high-dose dexamethasone has been shown to increase response rate and prolong survival in patients with relapsed MM. In 2006, lenalidomide received FDA approval based on the results of two recently published randomized controlled trials.^{52,53} One trial was conducted in North America while the other trial was conducted outside of North America. In both trials, patients were randomized to receive a combination of either lenalidomide (25 mg per day on days 1 to 21 of a 28-day cycle) or an identical placebo and high-dose dexamethasone. In the North American trial, patients in the lenalidomide and dexamethasone group had overall (complete, near-complete, or partial) and complete response rates of 61% and 14%, as compared to 20% and 0.6% in the dexamethasone alone group ($p < 0.001$).⁵³ These improved response rates translated into longer median overall survival in the lenalidomide and dexamethasone group (29.6 vs. 20.5 months). Similar results were reported in the trial conducted outside of the United States.⁵²

Lenalidomide has been studied as upfront therapy in newly diagnosed MM (see Table 139–5). Preliminary results of phase I and phase II studies of lenalidomide plus dexamethasone report an overall response rate of 90% and a complete response rate of 18%.³⁰ These rates are higher than those reported with thalidomide plus dexamethasone. Lenalidomide causes less neurotoxicity and constipation but more myelosuppression than thalidomide.^{51–53} When used as part of combination therapy, the risk of VTE with lenalidomide is similar to that observed with thalidomide and VTE prophylaxis is recommended. Preliminary results from a phase III trial in newly diagnosed MM reported that patients randomized to lenalidomide plus high-dose dexamethasone had an 25% incidence of VTE as compared to a 9% rate in those randomized to the lenalidomide plus low-dose dexamethasone arm.⁵⁴ That trial also reported superior 18 month survival in the lenalidomide plus low-dose dexamethasone group (91% vs. 80%) and this regimen could become the new standard induction regimen for patients undergoing autoHSCT. Based on these results, the Mayo Clinic Consensus Statement lists lenalidomide plus low-dose dexamethasone as the preferred induction regimen in patients undergoing autoHSCT

because of its low toxicity profile and its activity in relapsed patients (see Table 139–3).¹⁹ The low risk of VTE in the lenalidomide plus low-dose dexamethasone arm may allow for VTE prophylaxis with aspirin alone.¹⁹

Summary of Newer Therapy Combinations as Initial Therapy

Increasingly, chemotherapy is being added to thalidomide, lenalidomide, or bortezomib as upfront therapy. Melphalan and prednisone can be the backbone to which these newer drugs are added if the patient is not a candidate for autoHSCT. As previously discussed, MPT produces high response rates and bortezomib added to melphalan plus prednisone produces similar results.^{25,35,36} Based on the results of phase III trials demonstrating superiority of MPT over MP, many experts believe that MPT is the preferred induction regimen in patients who are ineligible for autoHSCT, at least until results of randomized controlled trials with lenalidomide or bortezomib are available (see Table 139–3).^{14,19} The addition of bortezomib to melphalan and prednisone may be particularly useful in MM patients with high-risk cytogenetics (chromosome 13 deletion, t(4;14), and 17p-).

If autoHSCT is planned after induction therapy, melphalan plus prednisone should be avoided, and thalidomide, bortezomib, or lenalidomide can be added to dexamethasone or VAD-like chemotherapy. The NCCN Guidelines lists several induction therapies (see Table 139–2). Because there is no standard induction regimen, clinicians can select from a wide range of possible induction regimens (see Table 139–5). Although some experts recommend lenalidomide and low-dose dexamethasone in patients who are autoHSCT candidates (see Table 139–3), thalidomide plus dexamethasone remains a reasonable choice until more data are available. Patients with chromosome 13 or 17p deletion may benefit most from bortezomib-containing induction regimens because of its activity in these high-risk patients.¹⁹ Because patients with high-risk cytogenetics may have poorer outcomes after autoHSCT, bortezomib-containing regimens should be considered in this group of patients, regardless of their eligibility for autoHSCT (see Table 139–3).¹⁹

Several ongoing phase III trials should determine the comparative efficacy of the various induction regimens. Thalidomide plus MP is being compared to lenalidomide plus MP in a United States Intergroup trial, while bortezomib plus MP is being compared to MP in the VISTA (Velcade as Initial Standard Therapy in multiple myeloma: Assessment with melphalan and prednisone) trial. The results of these trials are eagerly awaited for treatment of elderly MM patients.

AUTOLOGOUS HEMATOPOIETIC STEM CELL TRANSPLANTATION

Although MM is a chemosensitive tumor with significant response rates after treatment with conventional chemotherapy, complete remission rates are low and the duration of response is short. In an attempt to improve outcomes with chemotherapy, high-dose chemotherapy regimens that require stem cell support have been used after initial induction therapy. The intent of the induction therapy prior to transplant is to reduce tumor load but it remains controversial whether or not the quality of response (partial vs. complete) associated with induction is predictive of outcomes when followed by transplantation.

Several well-designed, randomized, controlled trials have evaluated the role of high-dose chemotherapy followed by autoHSCT. Previously untreated patients were usually randomized to induction therapy alone versus the same induction therapy followed by high-dose chemotherapy and autoHSCT. The results generally showed that autoHSCT improved progression-free survival with a more

variable effect on overall survival.^{55–57} No survival plateau has been observed in the group treated with autoHSCT, which suggests that few, if any, patients are cured of their disease. Despite these variable effects on overall survival, MM has become the leading indication for autoHSCT worldwide.

7 A systematic review of autoHSCT in newly diagnosed MM was published in 2007.⁵⁷ The review pooled results from 9 studies comprising 2,411 patients randomized to either autoHSCT or standard therapy. The combined hazard ratio for overall survival with autoHSCT was 0.92 (95% confidence interval 0.74 to 1.13) and for progression-free survival was 0.75 (95% confidence interval 0.59 to 0.96). These results indicate that high-dose therapy with autoHSCT significantly improves progression-free survival but does not significantly improve overall survival. This benefit in progression-free survival was at the expense of greater transplant-related mortality. Patients who received autoHSCT had a threefold higher risk of treatment-related death as compared to conventional dose chemotherapy. The authors concluded that for every 26 patients who received a transplant, there would be one excess death from autoHSCT as compared to conventional chemotherapy.

Two of the randomized trials comparing autoHSCT to standard therapy in newly diagnosed MM included in the systematic review were recently updated. Barlogie et al. reported that progression-free and overall survival were equivalent between high-dose and conventional-dose groups.⁵⁸ This is different than the conclusions of the systematic review, which reported a significant improvement in progression-free survival. That study has been criticized for using total-body irradiation plus melphalan rather than the more commonly used high-dose melphalan alone. However, several other studies that used total-body irradiation in addition to melphalan have reported variable results, which suggest that the differences in the preparative regimen do not explain these negative results. In the second study, Fermand et al. showed a benefit in event-free survival but no benefit in overall survival. These results were consistent with the systematic review. This study used standard high-dose melphalan and compared it to conventional therapy in previously untreated patients.⁵⁹

Although the use of autoHSCT as upfront therapy has become standard of care in patients younger than age 65 years, it is associated with higher treatment-related mortality and there is no convincing evidence that it prolongs overall survival. The widespread adoption of autoHSCT as standard therapy is related to the significant improvement in progression-free survival. But as conventional therapy continues to improve, response rates and progression-free survival are likely to approach those seen with autoHSCT without the elevated risk of transplant-related mortality.

Most patients are treated with autoHSCT as initial therapy after a short course of induction chemotherapy. However, a smaller number of patients receive autoHSCT as salvage therapy after patients have failed conventional treatments. A study in the early 1990s compared autoHSCT with chemotherapy in previously treated MM patients.⁶⁰ The results of that study showed that high-dose therapy was no better than VAD alone. However, more recent studies report benefit from autoHSCT in both primary treatment failures and relapsed MM.^{61,62} The NCCN Guidelines list autoHSCT as one of the acceptable options in the salvage setting. Responses to autoHSCT in the salvage setting can occur even in patients who have relapsed after prior successful autoHSCT.¹⁴

The optimal timing of autoHSCT (early vs. late) in MM was investigated in a randomized controlled trial. Patients were randomized to early (N = 91) or late transplantation (N = 94) and no significant difference in 5-year overall survival was observed between the groups.⁶³ Event-free survival, however, was significantly longer in the early transplantation group (39 months vs. 13 months). In an analysis that factors in the time without symptoms,

treatment, or treatment toxicity (TWisTT), patients receiving early transplantation had a longer time in a state associated with good quality of life (27.8 vs. 22.3 months). The results of this study support early autoHSCT because of its effects on event-free survival and quality of life.

A specialized form of autoHSCT is tandem transplantation, which involves the use of two separate autoHSCT procedures separated by a rest period of several months. In a heterogeneous group of 1,000 newly diagnosed and previously treated patients receiving autoHSCT for MM, 70% were able to receive a second autoHSCT. The complete remission rate was 44% with a 5-year event-free survival of 25% and 5-year overall survival of 40%.⁶⁴ Transplant-related mortality was low but was higher in patients receiving both transplants (2.7% vs. 4.8%). Approximately 10% to 15% of patients who did not achieve a complete remission with the first transplantation, attained it with the second transplantation.^{64,65} Because of this increased risk of mortality with tandem transplantation, it would be helpful to identify those patients who would benefit most. The French group reported that patients who did not achieve at least a very good partial response after the first transplantation benefited most from the second transplant.⁶⁶ That study reported an estimated 7-year overall survival of 21% in the single-transplantation arm and a 42% survival in the double-transplantation arm.

Because nearly all patients treated with either single or tandem transplantations will eventually relapse, maintenance therapy after autoHSCT has been studied. Maintenance therapy after autoHSCT may be the ideal situation as maintenance is likely to be most effective in patients with minimal residual disease. Variable results and high toxicities have been reported with IFN- α and dexamethasone and neither drug can be recommended outside of a clinical trial.⁶⁷ Thalidomide has also been studied as maintenance after autoHSCT. In the largest study to date, 593 patients were randomized to receive either no maintenance, pamidronate alone, or the combination of thalidomide plus pamidronate. Patients randomized to the thalidomide group had significantly longer event-free and overall survival as compared with those who received no thalidomide.⁶⁸ The median duration of thalidomide maintenance was 15 months and the average dose was 200 mg per day. Nearly 40% of patients had to discontinue thalidomide as a consequence of toxicity. In a subgroup analysis, patients with deletion of chromosome 13 did not benefit and other maintenance therapies need to be found for this high-risk group. Maintenance trials are ongoing with bortezomib and lenalidomide, which may be more effective in these high-risk MM patients. Bortezomib and lenalidomide may also be better tolerated than thalidomide. The NCCN Guidelines indicate that there is no consensus on the use of dexamethasone and IFN- α maintenance. Thalidomide, lenalidomide, or bortezomib should be used as maintenance therapy in the context of a clinical trial.^{14,19}

The primary conclusion that can be drawn from the current data on autoHSCT in MM is that it should be used in younger patients with good performance status as part of initial therapy.^{14,19} Prior to transplant, all patients should receive induction therapy to reduce tumor burden. Because of higher transplant-related mortality, a second autoHSCT or allogeneic hematopoietic stem cell transplantation (alloHSCT) should only be considered in patients who do not achieve a very good partial response or better with the first autoHSCT (see Table 139–3).

■ ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

AlloHSCT uses a stem cell source other than the patient themselves and is therefore a transplant across immunologic barriers. The major posttransplant complications associated with transplanting across these barriers, are graft failure and acute and chronic graft-

versus-host disease. Acute or chronic graft-versus-host disease may be associated with a graft-versus-myeloma effect. The graft-versus-myeloma effect, which is mediated by antitumor effector cells from the graft-versus-host disease reaction, reduces relapse risk and may offer the patient the best chance for long-term disease-free survival.⁶⁹ Unlike autoHSCT, which is simply a method of increasing the dose-intensity of chemotherapy, alloHSCT is an immune therapy. This is supported by the success of nonmyeloablative alloHSCT in some leukemias, where reduced-intensity preparation provides sufficient immunosuppression for the graft to survive and mediate a graft-versus-tumor effect.⁷⁰

8 Despite data reporting lower relapse rates in MM patients, myeloablative alloHSCT produces high transplant-related mortality (20% to 50%), leading to overall survival rates similar to autoHSCT.⁶² The reasons for the high transplant-related mortality in alloHSCT are not entirely clear. One possible explanation is that MM patients come to transplantation heavily pretreated, at an older age, and with greater existing organ damage as compared to other cancers. However, a study was closed prematurely in MM patients younger than 55 years of age with minimal pretreatment because of unacceptably high transplant-related mortality (approximately 50%).⁶⁵

With the high transplant-related mortality associated with myeloablative alloHSCT, the use of nonmyeloablative alloHSCT is an attractive option to reduce early posttransplant mortality. Several conclusions can be made based on the available data on the use of nonmyeloablative alloHSCT in MM patients. First, the transplant-related mortality associated with nonmyeloablative alloHSCT is lower than that reported with myeloablative alloHSCT.^{65,71} Second, the cytoreductive activity of the reduced-intensity preparation may be insufficient for the graft-versus-myeloma effect to have its full impact.⁶⁵ Most immune therapies, including the graft-versus-myeloma reaction, are most effective when patients have minimal residual disease and nonmyeloablative alloHSCT may have insufficient antitumor activity to achieve important tumor reduction. The need for cytoreduction may be accomplished by autoHSCT preceding the reduced-intensity alloHSCT procedure. Two recent trials of this novel approach produced conflicting results when comparing tandem autoHSCT to single autoHSCT followed by reduced-intensity alloHSCT. In a trial by Garban et al., neither event-free nor overall survival differed between tandem autoHSCT and single autoHSCT followed by reduced-intensity alloHSCT.⁷² However, a more recent trial reported significantly improved event-free and overall survival when autoHSCT was combined with reduced-intensity alloHSCT.⁷³ These conflicting results may relate to the inclusion of particularly high-risk patients and the use of more aggressive immunosuppression in the negative trial. In both trials, transplant-related mortality was not higher in the combined autoHSCT and reduced-intensity alloHSCT arm.^{72,73} Until more data is available, combining autoHSCT with reduced intensity alloHSCT cannot be recommended outside of a clinical trial.⁶⁵

■ SUPPORTIVE CARE

Bisphosphonates

Along with the anti-MM therapy described thus far in this chapter, supportive care measures are aggressively used to stabilize skeletal abnormalities. Bisphosphonates have been used for more than a decade in the management of MM. Once a well-accepted standard of care, the optimal use of bisphosphonates has become more controversial as a result of osteonecrosis of the jaw (ONJ), a rare, but serious adverse effect of bisphosphonate use in MM.

9 Bisphosphonates have a major role in the treatment of bone-related complications associated with MM. Bone resorption is a manifestation of the disease process and is mediated in part by inflammatory molecules including IL-6, IL-1, and TNF- α .¹ Bone

disease is not seen in MGUS but occurs in approximately 80% of MM patients at diagnosis.⁷⁴ Although the classic cytokine mediators of bone loss are important, a newer view involves excessive production of RANK-L, which activates NF- κ B through its receptor (RANK).⁷⁵ As previously stated, NF- κ B is a transcriptional regulator that increases the production of various inflammatory molecules. Normally, RANK-L mediated activation is in equilibrium with osteoprotegerin, which inhibits NF- κ B by serving as a decoy receptor for RANK-L.^{75,76} In the bone marrow of MM patients, excess RANK-L is produced particularly from stromal cells, which, when coupled with a decline in osteoprotegerin from both stromal cells and osteoblasts, leads to osteoclast activation and bone destruction. Macrophage inflammatory protein α_1 , macrophage colony-stimulating factor, and VEGF may also play important roles in MM bone disease by stimulating the production and activation of osteoclasts.⁷⁷ Macrophage inflammatory protein α_1 is also an important chemotactic factor released by MM cells; it attracts osteoclast precursors, enabling myeloma cells to influence the maturation and activation of osteoclasts, which suggests that antimyeloma drugs can have a beneficial effect on MM bone disease.^{77,78} Although MM bone disease may involve many cell types and many soluble and cell-bound molecules, it is useful to simplify its pathophysiology and consider it to be an imbalance between RANK-L and osteoprotegerin.

Activation of osteoclasts leads to a net loss of bone mass and to many of the common clinical features of MM, including fractures, hypercalcemia, and bone pain. The bone resorption is influenced by the MM cells in proximity to the osteolytic lesions and is associated with recruitment of osteoclasts.^{78,79} The disruptive effect on skeletal integrity can lead to direct mortality, but more commonly has a major impact on morbidity and quality of life.¹

Bisphosphonates are analogs of endogenous pyrophosphate but are more resistant to hydrolysis than pyrophosphate. Like endogenous pyrophosphate, the bisphosphonates bind to crystalline calcium in the bone and is then phagocytized by osteoclasts.⁸⁰ The best described effect of the bisphosphonates is the inhibition of osteoclast activity, which likely occurs by direct osteoclast cytotoxicity.⁸¹ In addition to osteoclast inhibition, bisphosphonates may also promote apoptosis in MM cells. This effect may result from the inhibition of the mevalonic acid pathway, which produces several molecules required for growth of the MM clone.⁸² The inhibition of mevalonic acid pathway is similar to the activity of the statins which have been shown to induce apoptosis in osteoclasts and MM cells. In addition, other potential antimyeloma effects of bisphosphonates may include modifying the cytokine microenvironment, inhibiting the adhesion of MM cells to bone marrow matrix cells, and inhibiting angiogenesis.⁸⁰ Although it is possible that bisphosphonates have an antimyeloma effect, there is little direct clinical evidence to support this activity.

The use of bisphosphonates in MM is based on the results from two large, randomized, controlled trials. In a pamidronate study, the drug was compared to placebo in a group of MM patients undergoing their first or second course of chemotherapy.⁸³ Several clinical end points were found to be positively impacted by pamidronate therapy. The investigators reported that patients in the pamidronate group had a lower risk of skeletal-related events, lower pain scores, and improved quality of life. Importantly, a survival advantage was observed in the pamidronate-treated patients who had already received one or more courses of antimyeloma chemotherapy. This finding of improved survival in subgroup analysis is part of the circumstantial evidence to propose an antimyeloma effect for the bisphosphonates.

Guidelines for the use of zoledronic acid in MM are based largely on a randomized study in MM and breast cancer. In patients with bone metastases, zoledronic acid was compared to pamidronate with the intent of demonstrating clinical equipoise.⁸⁴ The study did

show equivalence between pamidronate and zoledronic acid. The lack of a placebo arm because of ethical concerns of restricting an effective therapy complicates interpretation of this study. Despite this limitation, pamidronate and zoledronic acid appear to have equivalent clinical benefit in stabilizing the skeleton.

Other randomized, controlled trials have been conducted, and the results of these trials were pooled in a systematic review.⁸⁵ Eleven randomized trials were included, which accounted for 1,113 MM patients receiving bisphosphonate therapy along with 1,070 MM patients in a control arm who received no bisphosphonate therapy. The risk of vertebral fractures was significantly lower in the bisphosphonate-treated patients as compared to controls (odds ratio = 0.59; 95% CI 0.45 to 0.78). Pain scores were also reduced (odds ratio = 0.59; 95% CI 0.46 to 0.76). Given that the aggregate data in the systematic review agreed with the large controlled studies described above, the effect on vertebral fractures and pain are well-supported benefits of bisphosphonate therapy.

Clinical practice guidelines for the use of bisphosphonates in MM were recently updated by an expert panel under the auspices of the American Society of Clinical Oncology Health Services Research Committee.¹⁶ The evidence-based guidelines recommend that symptomatic MM patients be placed on bisphosphonate therapy at the time of diagnosis to reduce pain and skeletal-related events, and to improve quality of life. No firm recommendation was made on the duration of bisphosphonate therapy and which of the two agents should be used. However, the expert panel recommended a duration of bisphosphonate use of 2 years in those patients with responsive or stable disease. Reinstating bisphosphonate therapy at relapse or progression is at the discretion of the clinician.¹⁶

CLINICAL CONTROVERSY

Although bisphosphonates are indicated in MM patients with bone disease, controversies surrounding the selection of agent and duration of therapy remain. Because of recent reports of ONJ in MM patients, a more cautious approach on bisphosphonate use is being considered. ONJ is associated with patients undergoing dental procedures, those receiving the more potent bisphosphonates, and those receiving longer than 2 years of bisphosphonate therapy. Clinical practice guidelines developed by Mayo Clinic recommend that all dental procedures be performed prior to the administration of bisphosphonates, that therapy be given for no more than 2 years, and that pamidronate rather than zoledronic acid be used in newly diagnosed patients.⁸⁶ Given the benefit of bisphosphonates on skeletal-related events, limiting therapy to 2 years remains controversial. The preference of pamidronate over zoledronic acid is also controversial given that ONJ also has been reported with pamidronate and the higher risk of ONJ with zoledronic acid is based on observational studies and not head-to-head randomized comparisons.

Although a good case can be made for the use of bisphosphonates early after the diagnosis of MM, many controversies remain, including whether an antimyeloma effect exists, how long patients should remain on this expensive therapy, and, most importantly, the risk of ONJ. The recent association between bisphosphonates and ONJ suggests a more cautious approach with bisphosphonate therapy.

ONJ is characterized by an area of exposed necrotic bone and often affects the mandible and the maxilla, but can also affect the soft palate. The development of ONJ may be related to dental disease and tooth extraction, and appears to be more common with zoledronic acid than with pamidronate. The relationship with zoledronic acid is sufficiently strong to lead the Mayo Clinic to recommend that pamidronate be used in newly diagnosed MM patients.⁸⁶ The incidence of ONJ is unknown but may be as high as 10% in MM patients receiving zoledronic acid for extended periods of time. Because the risk of ONJ during the first 2 years of pamidronate appears to be very

low, the Mayo Clinic Guidelines recommend monthly infusions of pamidronate for 2 years after diagnosis.

Pamidronate and zoledronic acid are usually well tolerated. Flu-like symptoms can occur following the administration of bisphosphonates. Acute renal dysfunction can occur with both agents and is related to both infusion time and dose. For zoledronic acid, the risk of acute renal dysfunction is higher with the 8-mg dose (vs. 4 mg) and when the duration of infusion is 5 minutes (vs. 15 minutes). Similarly pamidronate should be dosed at 90 mg and infused over at least 2 hours. Patients with moderate renal dysfunction (creatinine clearance: 30 to 60 mL/min) should have the dose of zoledronic acid adjusted downward by 25% (3 mg). This recommendation was included in the zoledronic acid package insert and is based on a greater renal toxicity in patients with preexisting renal dysfunction.¹⁶ Randomized studies suggest that renal effects are similar between pamidronate and zoledronic acid, and for this reason patients on bisphosphonate therapy should have serum creatinine measured at baseline and then periodically thereafter.^{16,87}

SALVAGE THERAPY

10 The same drugs used to treat MM initially can also be used as salvage therapy in MM patients who have relapsed. Salvage therapy is used at relapse, regardless of whether the patient had received a previous transplant. Patients who relapse 6 months after initial induction therapy can have that induction therapy repeated. Bortezomib is an effective salvage therapy. When bortezomib was compared to high-dose dexamethasone, response rates were 38% versus 18%, respectively.⁴⁶ The activity of bortezomib in patients with high-risk cytogenetics is particularly useful because these high-risk patients are more likely to relapse and require salvage therapy. Lenalidomide plus dexamethasone is also approved for treating patients in the salvage setting, based on the results of two phase III trials.^{52,53} Thalidomide can also be used at relapse with overall response rates that are somewhat lower than bortezomib and lenalidomide.³¹ Thalidomide, bortezomib, and lenalidomide can be combined with chemotherapy in the salvage setting to improve responses.

The combination of bortezomib and pegylated liposomal doxorubicin is another active regimen in relapsed or refractory MM. In a recently published phase III trial, patients randomized to the bortezomib and pegylated liposomal doxorubicin arm had significantly longer median time-to-progression (9.3 vs. 6.5 months, hazard ratio = 0.55; 95% CI 0.43 to 0.71) and 15-month survival (76% vs. 65%) as compared with patients randomized to receive bortezomib alone.⁸⁸ It is interesting to note that the overall (complete and partial) response rate was only slightly higher in the bortezomib and pegylated liposomal doxorubicin group (44% vs. 41%). Based on the results of this study, the combination of bortezomib and pegylated liposomal doxorubicin received FDA approval in 2007 for patients with previously treated MM and is listed as a category I recommendation in the NCCN Guidelines.¹⁴ As expected, patients who received the combination experienced more adverse effects.

Cycling therapies may be important in maximizing response rates. Patients who relapse after a specific induction therapy probably should not receive that same regimen as salvage therapy. The NCCN Guidelines offer many options for salvage, including thalidomide, lenalidomide, or bortezomib with or without dexamethasone or chemotherapy. In addition, autoHSCT or nonmyeloablative alloHSCT may have a role as salvage therapy in some patients.¹⁴

EVALUATION OF THERAPEUTIC OUTCOMES

Because MM is currently not a curable disease, the goals of therapy are to prolong survival and to improve quality of life. Patients with asymptomatic MM are usually followed and not treated. Asymptomatic patients

are assessed every 3 to 6 months for disease progression, which would then require therapy. Assessment involves measurement of M protein in blood and urine and laboratory tests that include complete blood count, serum creatinine, and calcium. Patients are treated as the disease produces symptoms. Disease response is defined by a decline in M protein. After completion of the initial course of therapy and response is obtained, patients should be monitored every 3 months. Bone surveys are performed yearly or as required because of changes in symptoms. Various other tests are performed on an as-needed basis to evaluate disease status, including bone marrow biopsy, magnetic resonance imaging, and positron emission tomography, or computed tomography scan.

CONCLUSIONS

MM remains an incurable disease despite significant therapeutic advances. Thalidomide plus dexamethasone or lenalidomide plus dexamethasone are reasonable upfront regimens for those that require treatment and are candidates for autoHSCT. Chemotherapy is a reasonable alternative to these regimens in autoHSCT-ineligible patients, with melphalan and prednisone with or without thalidomide the most likely regimen. Younger patients with good performance status should receive autoHSCT after a short course of induction. The use of maintenance therapy after autoHSCT should be considered as part of a clinical trial. Nonmyeloablative alloHSCT may produce long-term disease-free survival but may require that the patient achieve a minimal residual disease state prior to the transplant procedure. When patients progress after initial therapy, salvage therapy may include regimens that contain thalidomide, lenalidomide, or bortezomib; autoHSCT and alloHSCT may be used in patients who are able to tolerate transplantation. Although there now are multiple therapies that can be used and there has been improvement in survival times and quality of life, MM remains a fatal disease that requires continued treatment advances.

ABBREVIATIONS

AlloHSCT: allogeneic hematopoietic stem cell transplantation
 AutoHSCT: autologous hematopoietic stem cell transplantation
 bFGF: basic fibroblast growth factor
 IL: interleukin
 I κ B: inhibitor of NF- κ B
 ISS: International Staging System
 MGUS: monoclonal gammopathy of undetermined significance
 MM: multiple myeloma
 MP: melphalan plus prednisone
 MPT: melphalan, prednisone, plus thalidomide
 NF- κ B: nuclear factor kappa-B
 ONJ: osteonecrosis of the jaw
 RANK-L: receptor for activation of NF- κ B ligand
 TNF- α : tumor necrosis factor- α
 VAD: vincristine, doxorubicin, dexamethasone
 VEGF: vascular endothelial growth factor

JULIANNA A. BURZYNSKI AND TREVOR MCKIBBIN

KEY CONCEPTS

- 1 Myelodysplastic syndromes (MDSs) are primarily a disease of the elderly, with a median age at diagnosis between 60 and 75 years.
- 2 MDS are associated with environmental, occupational, and therapeutic exposures to chemicals or radiation.
- 3 The manifestations of MDS are due to a combination of immune dysregulation and genomic instability, which creates a dysplastic, clonal population of cells in a milieu unable to support normal hematopoiesis.
- 4 Most patients with MDS present with fatigue and lethargy or symptoms related to tissue hypoxia due to anemia.
- 5 The prognosis of patients with MDS is variable. Overall survival ranges from a few months to several years and can be estimated with the International Prognostic Scoring System (IPSS) or World Health Organization Classification-based Scoring System (WPSS).
- 6 Palliation of symptoms and improvement in quality of life are the goals of therapy for most patients.
- 7 Patients with MDS with low or intermediate-1 IPSS risk, serum erythropoietin level less than 500 IU/L, and low requirement for red blood cell (RBC) transfusions are most likely to respond to erythropoietin.
- 8 Allogeneic hematopoietic stem cell transplantation (HSCT) offers potentially curative therapy to patients with MDS who have a donor and are healthy enough for the procedure.
- 9 Hypomethylating agents are appropriate for patients with transfusion-dependent or symptomatic MDS who are not candidates for allogeneic HSCT.
- 10 Antithymocyte globulin is an appropriate treatment option for patients with low or intermediate-1 IPSS risk MDS who express human leukocyte antigen DR15 with symptomatic anemia that is unlikely to respond to erythropoietic agents.
- 11 Lenalidomide is recommended as a treatment option for patients with symptomatic anemia and low-risk MDS expressing a 5q deletion.

Myelodysplastic syndromes (MDS) encompass a spectrum of clonal myeloid disorders characterized by ineffective hematopoiesis that results in anemia, thrombocytopenia, leukopenia, or a combination of peripheral cytopenias.^{1,2} MDS are frequently associated with clonal chromosomal abnormalities, qualitative disorders of blood cells, and a variable propensity for progression to acute myeloid leukemia (AML). The clinical course of patients with MDS varies along a continuum from a rapid progression to AML to years of slowly progressive bone marrow failure.^{3,4}

Our understanding of MDS and the available treatment options have advanced in recent years. In 1999, the World Health Organization (WHO) developed a classification system in an attempt to make the categories of MDS more homogenous with respect to natural history of the disease.² The International Prognostic Scoring System (IPSS) for MDS was developed to better enable clinicians to categorize patients according to risk for progression to AML and predict median survival from the time of diagnosis.³ Until 2004, supportive care was the most common therapy for most patients because no medications for treatment of MDS were approved by the Food and Drug Administration (FDA). Three medications (azacitidine, decitabine, and lenalidomide) currently are approved by the FDA for treatment of MDS, and several more are being investigated. The change in classification of MDS, improvement in risk stratification, and development of new treatment options represent steps forward in our understanding and management of MDS.

EPIDEMIOLOGY

1 MDS are primarily a disease of the elderly, with a median age at diagnosis between 60 and 75 years.⁵ Males predominate, with an estimated male-to-female ratio of approximately 1.7:1.⁶ Overall, an estimated 3 to 12 cases of MDS are diagnosed per 100,000 persons per year. The incidence of MDS increases with age; in patients older than 70 years, an estimated 15 to 50 new cases per 100,000 persons occur per year.⁵ Approximately 10,300 new cases are diagnosed in the United States each year, making MDS roughly as common as chronic lymphocytic leukemia.⁶ Many experts predict that the prevalence of MDS is likely to increase as the population of the United States ages and clinicians become more aware of MDS.

ROWENA N. SCHWARTZ AND LINDSAY J. CORPORON

KEY CONCEPTS

- 1 Cutaneous melanoma is an increasingly common malignancy, but it is a cancer that can be cured if detected early. Public education about screening and early detection is one strategy for controlling the increase in incidence and the mortality associated with cutaneous melanoma.
- 2 Surgical resection can cure patients with early-stage melanoma.
- 3 The toxicities associated with interferon- α_{2b} therapy are significant and require patient education, close patient monitoring, and appropriate dose modification based on toxicity.
- 4 Patients with locally advanced disease should be evaluated for adjuvant therapy; recommended options include interferon- α_{2b} or participation in a clinical trial.
- 5 High-dose aldesleukin (interleukin-2) is an option for some individuals with metastatic melanoma. The toxicities associated with this regimen are significant and warrant close patient selection. Individuals receiving high-dose aldesleukin require close monitoring and management by an experienced health-care team. A small subset of patients experiences a durable response with this therapy, although the question of risk versus benefit should be assessed on an individualized basis.
- 6 Metastatic melanoma remains a clinical challenge. At this time, there is not a single standard treatment approach for individuals with metastatic disease. Dacarbazine and temozolomide are considered the most active chemotherapy and can be used as single agents. Combination chemotherapy has not been shown to be superior to single-agent therapy with dacarbazine.
- 7 As the biology of melanoma has been further delineated, a growing number of potential targets for drug therapy have been identified. Recent work has focused on drugs that target specific pathways of melanoma development and progression.
- 8 Nonmelanoma skin cancers, including basal cell carcinoma and squamous cell carcinoma, are the most common forms of skin cancer. The most effective treatment is surgery.

The incidence of skin cancer has steadily increased in recent years. Although nonmelanoma skin cancers (NMSCs) are the most com-

mon malignancies of the skin, cutaneous melanoma accounts for most skin cancer-related deaths. As the incidence of skin cancer increases and the mortality rates associated with melanoma rise, it is essential to consider issues of care beyond that of disease treatment. Skin cancer prevention and screening have a major impact on public health and on the success of treatment for those individuals diagnosed with both NMSC and melanoma. Skin cancers tend to occur more frequently in older individuals (e.g., median age at diagnosis for melanoma is 45–55 years). As the population continues to age, there is need to find effective strategies to prevent, detect, and treat individuals with these cancers.

MELANOMA

The incidence and mortality rates of cutaneous melanoma have increased during the past several decades and continue to increase dramatically.¹ In men, the incidence of melanoma is increasing more rapidly than any other malignancy. In women, lung cancer is the only malignancy that has a higher increase in its incidence rate. In the year 2007, it is estimated that approximately 59,940 new cases of melanoma will be diagnosed in the United States. Unfortunately, this estimate is not accurate because many superficial and in situ melanomas are managed in facilities that do not routinely report their cases to cancer registries.² In the last decade of the 20th century, the rate of increase of melanoma in select subgroups of the United States population (e.g., women) has declined although the incidence overall has continued to increase. It has been suggested that the increase in cutaneous melanoma over time is due to a cohort effect. It appears that individuals born before 1950 show increased risk, whereas those born after 1950 show a stable or declining rate.³ More simply stated, the rate of increase in the incidence of melanoma may be declining in younger patients, but the incidence and mortality in older individuals have increased, particularly in men over age 65 years.⁴ Childhood and adolescent melanoma is rare, but in young adults between the ages of 15 and 19 years melanoma accounts for approximately 7% of all cancers.⁵

Of all the skin cancers, melanoma has the highest mortality. It is estimated that in 2007 approximately 8,110 individuals will die of melanoma.² Melanoma is second only to adult leukemia in terms of the loss of years of potential life for cancers. The incidence and mortality of melanoma vary worldwide. The overall mortality rate from melanoma appears to have stabilized and possibly declined in recent years in Australia, the United States, and Europe.¹ The stabilization of mortality rates appears to be related to efforts at both primary and secondary prevention of melanoma in addition to advances in the management of melanoma patients, such as adjuvant treatment. Importantly, this change in mortality rate overall has not been seen throughout the population. Mortality rates have increased 157% in older men (7.5 to 19.3 per 100,000) in the United States.⁴

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

TABLE 141-1 Risk Factors for Melanoma

Host risk factors

- Adulthood (age >15 years)
- History of cutaneous melanoma
- Dysplastic nevi
- Cutaneous melanoma in first-degree relative
- Immunodeficiency/immunosuppression
- High density of common nevi and atypical nevi
- High degree of freckling
- Sunburns easily/tans rarely
- Blonde or red hair
- Blue, green, or gray eyes
- Socioeconomic status (higher > lower)
- White (vs. black) race

External risk factors

- Intense intermittent sun exposures
- History of sunburn
- More than four painful sunburns before age 15 years
- Outdoor leisure

ETIOLOGY AND EPIDEMIOLOGY

The etiology of melanoma, like most other malignancies, is not fully understood. A number of host factors and environmental factors have been identified (Table 141-1), and it is likely that these factors alone or in combination increase the occurrence of cutaneous melanomas.

A number of genes have been implicated in melanoma development and progression, and molecular profiling studies have identified several distinct molecular subclasses of melanoma.⁶ Familial atypical multiple mole syndrome or hereditary dysplastic nevus syndrome is a hereditary disease characterized by a predisposition to develop dysplastic nevi and cutaneous melanoma. Only approximately 8% to 10% of cases of melanoma are thought to be associated with a family history or hereditary dysplastic nevus syndrome. Older case-control studies of patients with familial atypical multiple mole syndrome suggest a risk for melanoma of 400- to 1,000-fold higher than that seen in the general population. The mode of inheritance is somewhat controversial and is believed to be polygenic.

Genetic studies of this heritable trait in families led to the identification of CDKN2A as the familial melanoma gene, located at chromosome 9p21. CDKN2A encodes two distinct proteins: inhibitor of cyclin-dependent kinase 4 (INK4A; also known as p16^{INK4a}) and ARF. INK4A inhibits the G₁ cyclin-dependent kinases that phosphorylate and inactivate the retinoblastoma protein, allowing the cell to go into the S phase. ARF (also known as p14^{ARF} in humans) inhibits p53 degradation; therefore, loss of ARF inactivates p53.

The genomic complexity of the 9p21 locus has raised questions of the importance of neighboring genes, such as CDKN2B.⁷ Growing evidence implicates hyperactive receptor tyrosine kinase signaling in the development and progression of melanoma. One of the major signaling mediators of receptor tyrosine kinase is the mitogen-activated protein kinase pathway resulting in activation of RAS and BRAF. Activating BRAF mutations are the most common somatic genetic event in human melanoma, occurring in 25% to 70% of melanoma patients. BRAF does not appear to be an inherited disposition gene, but the high prevalence of BRAF mutations in cutaneous melanoma appear to be an epidemiologic link between ultraviolet (UV) radiation and melanoma. BRAF mutations are common in melanomas arising from skin with intermittent sun exposure but is not as commonly seen in melanomas in chronically sun-exposed areas.⁸

Individuals with germ-line inactivation of the retinoblastoma gene are predisposed to melanoma.⁶ Individuals with a history of bilateral retinoblastoma have a 4- to 80-fold higher lifetime risk of

melanoma. Of interest, these melanomas do not occur at the site of radiation for treatment of retinoblastoma.

Sunlight is one of the most important environmental factors in the pathogenesis of melanoma, and the incidence of melanoma has been associated with latitude and the intensity of solar exposure among susceptible populations. Radiation in the ultraviolet B (UVB) range (280–320 nm) is historically considered to be the critical factor linking sunlight and melanoma, although prolonged exposure to ultraviolet A (UVA) radiation (320–400 nm) also may be important. Use of older UVB-blocking sunscreens may not be as protective as once thought because they allow more sustained sun exposure without any clinical symptoms of burn (e.g., erythema or pain), ultimately resulting in intense irradiation of the skin by UVA light.⁹

Individual physical characteristics can determine responses to UV radiation. White persons with fair-colored hair (red and blond), light-colored eyes (blue and green), and high degrees of freckling and those who have a tendency to burn and rarely tan with exposure to sunlight appear especially at risk.^{1,10} Epidemiologic research has not been able to show a relationship between cumulative exposure to sunlight and occurrence of cutaneous melanoma, although cumulative exposure does appear to play a role in NMSC. Studies have demonstrated a lower risk for development of melanoma in outdoor workers compared to indoor workers.⁹ Intermittent over-exposure to sunlight, blistering sunburns, and the time of life of exposure to the sun now are believed to be the more critical factors for development of cutaneous melanoma. Individuals who have a history of severe sunburns appear to have a higher risk for development of melanoma than do individuals who have had chronic sun exposure without a history of burning. The risk with sunlight and UV radiation seems to be greatest during childhood and adolescence. Intensive exposure to sunlight during infancy and early adolescence is more hazardous than exposure during adult life.

One of the most important risk factors for melanoma is the number of melanocytic nevi (pigmented lesions) on the body. A second risk factor is the presence of atypical melanocytic nevi.¹ Small congenital melanocytic nevi are present in up to 1% of newborns.⁵ Acquired melanocytic nevi often appear after infancy and often are located in sun-exposed areas. The risk of melanoma may be related to the number of melanocyte nevi acquired during childhood.⁵

Immunocompromised patients are at an increased risk for development of cutaneous melanoma.^{5,10} Immunodeficiency includes individuals with ataxia telangiectasia, chronic lymphocytic leukemia, Hodgkin's lymphoma, and immunosuppression following organ transplant. Acquired immunodeficiency syndrome has been shown to increase the risk of developing cutaneous melanoma, and the disease often is more aggressive.¹¹ Personal history of nonmelanoma or melanoma skin cancers is a risk factor for subsequent melanoma.

A rare but important risk for melanoma is maternal–fetal transfer of melanoma. Although melanoma is not the most common cancer in pregnancy, it is the cancer most likely to metastasize to the placenta and the fetus.¹² Maternal–fetal transmission of melanoma results in approximately 25% mortality risk to babies born to mothers with placental involvement. Neonates delivered with concomitant placental involvement but without clinical evidence of disease still are considered to be at increased risk for development of disease.

PATHOGENESIS

Melanomas most often arise within epidermal melanocytes of the skin, although they also can arise from noncutaneous melanocytes. Human melanocytes are dendritic pigmented cells that arise from the neural crest tissue during early fetal development and migrate over a predictable route to a variety of sites within the body, including the skin, uveal tract, meninges, and ectodermal mucosa. In adults, most melanocytes are located at the epidermal–dermal junc-

tion of the skin and the choroid of the eye, but they can be found in other tissues such as the meninges and the alimentary and respiratory tract. Primary melanoma can arise in any area of the body with melanocytes. The skin is the most frequent site of melanoma; cutaneous melanoma constitutes 90% of all melanoma. Primary melanoma can arise in the eye (ocular melanoma)¹³ and less frequently in the meninges, respiratory tract, colon, and gallbladder.¹⁴

Normal melanocytes arise from melanoblasts and undergo a series of differentiation events before reaching a final end-cell differentiation state. Normal melanocytes can be arrested in their differentiation process at any given state of maturation without loss of their proliferation capacity. Melanocytes adhere to the basement membrane of the epidermis and, despite a resting state, maintain a lifelong proliferation potential. The existence of melanoma stem cells has been suggested from work with cells from melanoma lines.⁶

Melanocytes synthesize melanin to protect various tissues, such as the skin, from UV radiation (UVR)-induced damage and reach the keratinocytes in the upper layers of the epidermis via dendrites. Tyrosinase is an essential enzyme within melanosomes that synthesizes melanin.

Skin melanocytes transform from preexisting nevocellular nevi in the development of melanoma. A series of distinct steps are involved in the development and progression of melanoma from melanocytes. The pathologic components of the progression in human melanoma involve a series of morphologic stages: (a) acquired or congenital melanocytic nevus, (b) melanocytic nevus with architectural atypia, (c) histologically dysplastic nevus with cytologic atypia and architectural atypia, (d) primary melanoma in the radial growth phase in which limited growth and radial expansion of the nevi may occur without metastatic competence (nontumorigenic melanoma), (e) primary melanoma in the vertical growth phase with or without in-transit metastases in which there appears to be uncontrolled proliferation and increased angiogenesis, (f) regional lymph node metastatic melanoma (lymphatic), and (g) distant metastatic melanoma (hematogenous).¹⁵ Primary melanoma is characterized by radial growth and limited vertical thickness (<0.75 mm). Primary melanoma demonstrates little tendency to metastasize. Melanoma has a potential for metastasis formation with the onset of a vertical growth phase. Therefore, the thickness of a primary melanoma is an important prognostic factor and is used in the staging classification of cutaneous melanoma. Of note, melanomas can skip steps in this development pathway.

Normal melanocytes require growth factors for proliferation, but melanoma cells can proliferate without growth factors.¹⁶ Melanoma cells secrete a variety of growth autocrine and paracrine factors that may facilitate proliferation. Additionally, with disease progression, melanoma cells increase production of certain growth factors and cytokines. The phosphatidylinositol 3-kinase (PI3K)-AKT pathway often is overactive in melanoma. Integrins and growth factors promote growth and survival of melanoma through these pathways.

Basic fibroblast growth factors (bFGFs) are thought to be important mediators of growth stimulation and cell survival and act as motility factors for melanoma cells. In addition, bFGFs upregulate serine proteinases and metalloproteinases. Melanoma cells are strong producers of chemoattractive proteins such as interleukin-8. Vascular endothelial growth factor can be triggered in the vertical growth phase.¹⁷ Most of these changes occur between the radial growth phase and vertical growth phase of primary melanoma, and metastatic cells often show the highest cytokine production.

Understanding the biology of melanoma has provided potential targets for drug therapy.^{18,19} For example, the role of bFGF in the pathogenesis of melanoma has led to investigation of antisense oligonucleotides to block bFGF. Other pathways, such as mitogen-activated protein kinase pathway has been targeted by RAF and MEK inhibitors and the PI3K/AKT pathway by TOR inhibitors. As pathways are

identified and as agents that inhibit these pathways enter clinical trials and practice, there is growing excitement about the opportunities to impact treatment of melanoma in new and effective ways.

Immune factors appear to be involved in the progression of melanoma more often than in most other solid tumors.^{10,16} Spontaneous cancer regressions are rare but are a well-documented phenomenon seen in melanoma. Focal regression in primary melanoma has been reported. Tumor regression appears to be associated with host immunity.

A number of different tumor antigens have been identified in the cellular membrane and cytoplasm of melanoma cells and are referred to as melanoma-associated antigens. Ganglioside antigens have been of particular interest in the development of immunotherapy for melanoma. A large number of monoclonal antibodies to melanoma-associated antigens have been developed and are being evaluated in clinical trials for diagnosis of and therapy for melanoma.

The humoral and cellular responses of individuals with melanoma who express melanoma-associated antigen have been described and provide the rationale for immunotherapy in the management of metastatic melanoma.¹⁰ Melanoma-directed antibodies have been isolated in the sera of patients with melanoma. The presence of antimelanoma antibodies in the sera of patients correlates with the clinical status of the patients, and the antibodies gradually disappear from the serum as the disease progresses. This phenomenon may be explained by the possible formation of anti-idiotypic antibodies directed against the antimelanoma antibodies, an increase in the circulation of soluble tumor antigens that saturate all antibody combining sites, increased levels of immunosuppression, or absorption of antibodies on the tumor mass.

Interest has focused on the role of cell-mediated immune response in melanoma. Specific cell-mediated responses may play a role in tumor regression, but the role of specific cells, such as cytotoxic T lymphocytes (CTLs), is not fully understood. Tumor-infiltrating lymphocytes (TILs) have been shown in vivo and in vitro to possess antitumor reactivity. TILs contain a large number of mature tumor-specific lymphocytes and have been a target for manipulation in immunotherapeutic approaches for melanoma.¹⁰ Two recently identified targets are cytotoxic T lymphocyte antigen 4 (CTLA-4) and toll-like receptor 9 (TLR9). CTLA-4 is a glycoprotein expressed on the surface of activated T cells that appears to have an inhibitory effect on T cells. Blocking the effect of CTLA-4 could be an effective strategy for increasing the T-cell antitumor response.²⁰

HISTOLOGIC SUBTYPES OF MELANOMA

Dysplastic nevi are believed to be a link between benign nevi and melanoma. Dysplastic nevi are defined by a number of architectural and cytologic criteria.²¹ Dysplastic nevi may appear as flat macules with asymmetry, border irregularity, color variation, and usually a diameter greater than 5 mm. Compared to melanoma lesions, dysplastic nevi appear less evolved.

Cutaneous melanomas are categorized by growth patterns. Four major histologic subtypes or growth patterns of primary cutaneous melanoma have been identified: superficial spreading melanoma, nodular melanoma, lentigo maligna melanoma, and acral lentiginous melanoma. Desmoplastic melanoma is a less common subtype but is more commonly seen in older individuals. Desmoplastic melanoma is of concern because the clinical presentation is similar to that seen in NMSC. If a biopsy of the lesion is not obtained, the disease may be mismanaged. Clinical outcomes of the four major melanoma subtypes are similar, if the comparison controls for depth of penetration or tumor thickness. Any of the four subtypes can present as an amelanotic variant. Amelanotic melanomas appear to be devoid of clinically apparent pigmentation. Uveal melanoma is considered a separate disease from cutaneous melanoma.

The ability to predict the metastatic potential of melanomas would be a valuable prognostic tool. An attempt to predict the likelihood for metastasis is based on radial and vertical growth phases. Radial growth phase describes the early stage of melanoma when the tumor is thin and primarily intraepidermal in location.²² By definition, malignant melanoma *in situ* is a form of radial growth phase melanoma. Vertical growth phase is the stage of melanoma with clear metastatic potential.

Superficial spreading melanoma is the most common morphologic type of cutaneous melanoma, accounting for approximately 70% of all melanomas.^{10,22} The lesions usually arise from a preexisting nevus, known as a *precursor lesion*, and evolve slowly over 1 to 5 years. At some point, superficial spreading melanoma may progress to a more rapid growth phase. Early in lesion development, the superficial spreading melanoma is flat, but the surface becomes irregular and asymmetrical as the lesion progresses. The lesion enlarges when it enters into a rapid growth phase, and the edges appear notched or lacy. The lesions can be blue, black, or pink. Areas within the lesion may be hypopigmented. These patches of color variation, specifically the hypopigmented areas, are thought to be associated with tumor regression within the lesion or pigment inconsistency. The clinical differential diagnosis of superficial spreading melanoma includes both benign and malignant skin disease. This subtype is sometimes confused with seborrheic keratoses or pigmented basal cell carcinoma (BCC). Superficial spreading melanoma may occur at any anatomic site on the body, but they are more commonly seen on the back in men and on the legs in women. This subtype of melanoma is more common in women. The mean age of diagnosis of superficial spreading melanoma is 50 years, which is earlier than that seen for other subtypes. Superficial spreading melanoma usually occurs after puberty.

Lentigo maligna melanoma represents a small percentage of melanomas. It is unique from other histologic subtypes because it does not have the same propensity to metastasize.^{10,22} Lentigo maligna melanoma arises on chronically sun-exposed sites in older individuals and presents as a freckle-like lesion. Lentigo maligna melanomas are generally large (>3 cm), flat, and tan-colored lesions with shades of brown and black. The lesions gradually grow and develop darker, with asymmetric flecks in areas. Lentigo maligna melanoma is uncommon before age 50 years and may have been present for more than 5 years. Like some forms of NMSC, lentigo maligna melanoma is linked to cumulative sun exposure. Only approximately 5% to 8% of lentigo maligna melanoma evolve into invasive melanoma, which is characterized by nodular development within the flat precursor lesion. Lentigo maligna melanoma can be difficult to distinguish from solar lentigo, which typically is a smaller and evenly pigmented flat-appearing lesion.

Nodular melanoma is the second most common growth pattern of melanoma, occurring in 15% to 30% of patients. Nodular melanoma is a pure vertical growth phase disease. In nodular melanoma, a small expansive nodule in the papillary dermis invades the reticular dermis and subcutis. The radial growth phase is absent at all times. Nodular melanomas are more aggressive and develop more rapidly than superficial spreading melanoma. Nodular melanomas are dark blue-black and often uniform in color with a shiny surface, although a small percentage of nodular melanomas are amelanotic and have a fleshy appearance. Nodular melanomas are raised and often symmetric. Nodular subtype of melanoma accounts for most thick lesions at the time of diagnosis.²³ They can occur at any age (median age 53 years) and are most common on the trunk, head, and neck. Nodular melanomas are more common in men. Of note, nodular melanomas can resemble a traumatized nevus.

Acral lentiginous melanoma presents as three distinct clinical subtypes: melanoma on the palms of the hands or soles of the feet, subungual melanoma, and mucosal melanoma.^{10,22} Most acral lentigi-

nous melanomas are located on the soles of the feet and look like a large tan or brown stain. The lesions often have irregular convoluted borders. The initial macular component of palmar/plantar melanomas can be masked by the thickened stratum corneum at these sites. Many of these lesions look verrucous in appearance, making them difficult to distinguish from warts by the untrained eye. Suspicious lesions on the palms or soles of the feet should be evaluated. Acral lentiginous melanoma includes subungual melanoma, which arises in the nail matrix or nail bed. The most common presentation is a brown or black line in the great toe or the thumbnail. Mucosal melanoma is rare but can occur on any mucosal surface. Mucosal melanoma occurs most commonly in the oropharyngeal mucosa, followed by the anal/rectal mucosa, genital mucosa, and urinary mucosa. Unfortunately, mucosal melanoma often does not become clinically apparent until the mass is large or the lesion bleeds. Acral lentiginous melanoma occurs in less than 10% of white people with melanoma but is the most common type of melanoma reported in individuals with a dark complexion (e.g., African Americans, Asians, and Hispanics).

Unusual subtypes of primary melanoma include desmoplastic/neurotropic melanoma, mucosal melanoma, malignant blue nevus, melanoma arising in giant congenital nevus, and clear cell sarcoma. These subtypes account for less than 5% of primary melanomas.¹⁰

Uveal melanoma is the most common primary intraocular malignancy seen in adults but is an uncommon tumor.²⁴ Unlike cutaneous melanoma, the frequency and mortality of uveal melanoma have remained steady. This melanoma arises from the pigmented epithelium of the choroid. Iris melanoma is a subset of uveal melanoma and tends to have a more benign course. The risk of metastasis varies with the histologic type and size of the tumor as well as the location in the eye. Metastases occur most frequently in the liver but have been documented in a variety of tissues.

CLINICAL PRESENTATION

The initial clinical presentation of melanoma often is a cutaneous lesion (see Chap. 99). The lesion can be located anywhere on the body but is most commonly discovered on the lower extremities in women and on the back and trunk in men. The cardinal clinical feature of a cutaneous melanoma is a pigmented skin lesion that changes over a period of time. The clinical features used to describe or evaluate a questionable lesion are highlighted by the mnemonic “ABCDE.” Unlike benign pigmented lesions, the shape of a melanoma lesion is often (A) *asymmetric*. Benign lesions tend to have regular margins, whereas melanoma lesions often have irregular (B) *borders*. The (C) *color* of melanoma lesions is often variegated, ranging in color from tan to blue-black, and at times the lesion is intermingled with colors of red, purple, and white. The size or (D) *diameter* of a melanoma lesion is frequently 6 mm or greater when identified, whereas benign lesions usually are smaller. Early melanoma lesions may be diagnosed at a smaller size, and size of a lesion should not be used as “the trigger” to have a suspicious lesion evaluated. Another warning sign of a potential melanoma is the *evolution* (E) in preexisting nevi. Changes such as a sudden or continuous enlargement of a lesion, an elevation of a lesion, or any change in the skin surrounding a nevus, including redness or swelling, are important clinical signs. Uncommonly, the sensation of the lesion may become itchy or tender and painful. Friability of the lesion resulting in bleeding or oozing is a danger sign. Perhaps the most important warning sign of danger is the evolution in any characteristic of a lesion.

The clinical appearance of a melanoma depends on the histologic subtype and the stage of development of the lesion. It usually is possible to distinguish three variants of cutaneous melanoma: flat melanoma, nodular melanoma, and flat melanoma with a nodular area. Flat melanoma usually corresponds to the histologic classification of superficial spreading melanoma.

The diagnosis of melanoma is complicated by a number of pigmented moles (melanocytic nevi) and nonmelanocytic lesions that resemble melanoma. An average of 10 to 40 ordinary nevi can be found on the skin of white adults. These lesions usually are absent at birth, increase in number through adult life,⁵ and then gradually decline in number. They appear as tiny pinpoint macules and usually are uniform in color but increase in size to a maximum of 4 to 6 mm. Nonmelanocytic pigmented lesions, such as seborrheic keratoses, pigmented BCC, and vascular lesions, also can appear similar to a melanoma lesion.

1 Improved survival rates for melanoma have been attributed to the identification and treatment of disease at an early stage, when the disease is limited and has not yet metastasized. It follows that one strategy to improve survival rates would be to increase efforts to identify early-stage melanoma. The cost effectiveness of massive screening for all adults by a physician has never been demonstrated. A number of agencies, such as the American Academy of Dermatology and the American Cancer Society, have sponsored free annual screenings. Routine examination of the skin by physicians is recommended for individuals at high risk. The entire cutaneous surface, including the scalp, should be examined.

It has been estimated that approximately 50% of the initial melanoma lesions found are discovered by self-examination. Therefore, one of the most direct strategies to improve early detection would be a method to increase effective skin self-examination (SSE) by the individual, the individual's partner, and/or a caregiver. Identification of early melanoma allows the opportunity to treat the lesions when they are thin and curable. Persons who perform SSE present for care at an earlier stage in the disease process and have 50% less advanced melanoma and lower mortality from the disease.²⁵ Healthcare individuals who routinely work with the public, such as community pharmacists, have an opportunity to increase public awareness concerning the benefits and appropriate methods for SSE. Educational pamphlets describing SSE (Table 141-2) for the public are widely available through the American Cancer Society, American Academy of Dermatology, and Skin Cancer Foundation. If a newly discovered pigmented lesion is identified or if a preexisting pigmented lesion changes, the individual should be evaluated by a physician immediately. As with adults, a change in the appearance of a pigmented lesion in a child is the most common clinical presentation in pediatric and adolescent populations. In children, any change in a mole, such as bleeding or change in color or size, should be evaluated.⁵

SSE is of special interest in the elderly. As the population of older adults (65 years and older) increases, it is expected that the mortality from melanoma also will increase. Barriers to successful SSE in the elderly, such as failing eyesight, lack of partners, and poor memory, impact the older adult in detecting new or changing lesions. These barriers, coupled with the higher incidence of melanoma in males, present a challenge and an opportunity for the healthcare professional to target education on this growing segment of our population.

A biopsy of the lesion is critical to establish diagnosis of melanoma. Subsequent pathologic interpretation of the biopsy will help provide information on prognosis and treatment options. An exci-

sional biopsy with a margin of normal-appearing skin is recommended for a suspicious lesion and should include a portion of underlying subcutaneous fat for microstaging. Although a biopsy is recommended for large lesions where an excisional biopsy is impractical, an incisional biopsy can be performed but should include a core of full-thickness skin and subcutaneous tissue. When excisional biopsies are not appropriate, as with the face or palmar surface of the hands, a full-thickness incisional or punch biopsy is preferred over a shave biopsy.

Evaluation of any individual with a suspected melanoma includes a complete history and total body skin examination. The focus of the patient history is identifying potential risk factors. Risk-related questions include an assessment of family history of melanoma, personal history of skin cancer and/or nevus excisions, sun exposure, and phototype. Total dermatologic examination is necessary to determine melanoma risk factors (e.g., mole pattern, mole type, or freckling) and for staging. For patients with melanomas 1 mm or more in thickness, a baseline chest x-ray film and liver chemistries are generally recommended even though these tests are relatively insensitive at detecting clinically occult distant disease. The appropriate workup of individuals with early-stage disease is controversial.¹⁰ Lactate dehydrogenase should be measured because elevated serum lactate dehydrogenase level is an independent predictor of decreased survival in published studies, even after accounting for site and number of metastases.²⁶ Any clinical indication of regional lymph node involvement should be confirmed with fine-needle aspiration or on biopsy of the enlarged lymph node. Additionally, any other signs or symptoms suggestive of metastatic disease should be completely evaluated.

STAGING AND PROGNOSTIC FACTORS

The size of a primary melanoma lesion is associated with the likelihood of metastases. The prognostic factor originally used to determine survival was based on the cross-sectional profile of the primary tumor. The cross-sectional profile could be evaluated if the deepest invasive tumor cells lay above or below the sweat glands. This assessment was further clarified by Clark,²⁷ who described the relationship of depth of invasion of the cancer cells to the standard anatomic landmarks of the skin (Table 141-3). Clark's classification is a practical approach for patients with more superficial tumors, because tumors classified as Clark levels I through III seldom metastasize. The classification system has been criticized because of problems associated with practical measurements. Melanoma lesions that occur in the presence of lymphoid infiltration, fibrosis, or even the cells of preexisting nevi are difficult to assess with classic reference landmarks.

Breslow²⁸ replaced Clark's classification of reference landmarks with the use of thickness of the primary melanoma lesion. Tumor thickness is quantified to the nearest tenth of a millimeter using an ocular micrometer, measuring from the top of the granular layer of the overlying epidermis to the deepest contiguous invasive melanoma cell. The correlation between tumor thickness and probability of tumor metastases is strong but does not include aspects such as tumor satellites, defined rather arbitrarily as skin involvement within 2 cm of the primary lesion, and vascular invasion. It was once thought that

TABLE 141-2 Self-Examination of Suspicious Moles

1. Examine your body front and back in the mirror, and then right and left sides with arms raised.
2. Bend the elbows and look carefully at the forearms and upper arms and palms.
3. Look at the backs of the legs and feet. Look specifically in the spaces between toes and at the soles of the feet.
4. Examine the back of the neck and scalp with the help of a hand-held mirror; part hair (or use a blow dryer) to lift hair and give yourself a closer look.
5. Check the back and buttocks with a hand-held mirror.

the presence of satellite nodule(s) had the same impact on prognosis as a high-risk primary lesion (tumor thickness >4 mm). It is now thought that patients with satellitosis have a worse prognosis than patients with thick primary lesions, and prognosis is more similar to that of patients with nodal metastases. A number of prognostic factors, in addition to tumor thickness and level of invasion, are associated with the risk for developing metastatic disease.²⁹

The American Joint Committee on Cancer (AJCC) developed a staging system for melanoma that divides patients with localized melanoma into four stages according to microstaging criteria of Breslow and Clark.³⁰ In addition to consideration of the primary lesion, the AJCC staging system includes aspects of the tumor satellite, extent of lymph node involvement, and presence of metastatic disease.³⁰ Analysis of several large databases worldwide identified areas in which the AJCC staging system, which was published in 1997, did not reflect the natural history of melanoma. Issues such as the appropriate cutoff values for primary tumor thickness, ulceration of the melanoma, and satellite lesions of the primary tumor should be considered when making decisions about therapy.²⁹ The cutoff values initially proposed by Breslow for primary tumor thickness were initially used in the AJCC staging system, but it appears that cutoff depths of 1, 2, and 4 mm of thickness may better predict overall survival. Melanoma ulceration is associated with increased mitotic rate within a primary melanoma. The presence of ulceration of the primary lesion has been correlated with poorer survival for patients with very thin or thick lesions, but ulceration of the melanoma was not included in the 1997 AJCC staging system.

A revised staging system for cutaneous melanoma was developed by the AJCC and has been used for several years.³¹ It is important to carefully examine older clinical trials to determine which staging system was used to determine patient inclusion and exclusion criteria, as results may differ based on these patient criteria. Revisions of the new melanoma staging system include (a) melanoma thickness and ulceration for all tumors (except T1 tumors); (b) number of metastatic lymph nodes versus gross dimensions and delineation of clinically occult versus clinically apparent nodal metastases; (c) site of distant metastases and presence of elevated serum lactate dehydrogenase for metastatic disease; (d) upstaging of all patients with stage I, II, and III disease when a primary melanoma is ulcerated; and (e) new convention for separating clinical and pathologic staging to include information obtained from intraoperative lymphatic mapping and sentinel node biopsy. Clinical staging includes microstaging of the primary melanoma and clinical and radiologic evaluation. It is used after complete excision of the primary melanoma with clinical assessment for regional and distant metastasis. Pathologic staging includes microstaging of the primary melanoma and pathologic information about the regional nodes after partial or complete lymphadenectomy. At this time, it appears that patients with very limited disease (stage 0) do not require pathologic evaluation of lymph nodes (Tables 141–4 and 141–5). As with other solid tumors, the presence of regional lymph node involvement is a powerful predictor of tumor burden and patient outcome. In the past, the primary method for determining nodal status was surgical resection and analysis of the lymph nodes via a regional lymph node dissection. The extent of lymph node dissection was determined by the anatomy of the area of the lesion. In recent years, preoperative lymphoscintigraphy and intraoperative sentinel node mapping have become more widely used methods for identifying the first or sentinel lymph node in the direct pathway of lymph drainage from the primary cutaneous melanoma. Sentinel lymph node biopsy (SLNB) is a minimally invasive procedure that is used to determine if a patient is a candidate for a complete lymph node dissection. The rationale for lymphatic mapping and subsequent sentinel node biopsy is based on the observation that regions of the skin have patterns of lymphatic drainage to specific lymph nodes in the

TABLE 141-4 Melanoma TNM Classification		
T Classification	Thickness	Ulcerative Status
TX	Primary tumor cannot be addressed (e.g., shave biopsy)	
T0	No evidence of primary tumor	
Tis	Melanoma in situ	
T1	≤1 mm	A: No ulceration and level II/III B: With ulceration or level IV/V
T2	1.01–2 mm	A: No ulceration B: With ulceration
T3	2.01–4 mm	A: No ulceration B: With ulceration
T4	>4 mm	A: No ulceration B: With ulceration
N Classification	No. of Metastatic Nodes	Nodal Metastatic Mass
NX	Regional lymph nodes cannot be assessed	
N0	No regional lymph nodes	
N1	1 node	A: Micrometastasis B: Macrometastasis
N2	2–3 nodes	A: Micrometastasis B: Macrometastasis C: In-transit metastases/satellite(s) without metastatic nodes
N3	≥4 metastatic lymph nodes, matted nodes, ulcerated melanoma, metastatic lymph nodes, or in-transit metastatic or satellite lesions	
M Classification	Site	Serum Lactate Dehydrogenase
MX	Distant metastases cannot be assessed	
M0	No distant metastasis	
M1a	Distant skin, subcutaneous tissue, or nodal metastatic disease	Normal
M1b	Lung metastases	Normal
M1c	All other visceral metastases or distant metastasis at any site associated with elevated serum lactic dehydrogenase	Normal
	Any distant metastasis	Elevated

Micrometastases are diagnosed after sentinel or elective lymphadenectomy. Macrometastases are defined as clinically detectable lymph node metastases confirmed by therapeutic lymphadenectomy or when any lymph node metastasis exhibits extracapsular extension. Data from Barch CM, Buzaid AC, Soong SJ, et al. Final version of the American Joint Committee on cancer staging system for cutaneous melanoma. *J Clin Oncol* 2001;19:3635–3648.

regional lymphatic basin. The sentinel lymph node is believed to be the first node in the lymphatic basin into which the primary melanoma drains. Unlike other solid tumors, melanoma appears to progress in an orderly nodal distribution. Evaluation of sentinel nodes has been used for detection of micrometastases in breast cancer and in melanoma. SLNB allows for more thorough examination of a single sentinel node than is possible when examining multiple lymph nodes with a lymph node dissection and may be most useful for melanomas located in ambiguous drainage sites such as the head and neck areas. SLNB is associated with low false-negative rates and low complication rates.³² Detection of clinically undetectable disease in a lymph node basin that is not directly adjacent to the primary lesion may allow for upstaging of patients who initially are believed to have node-negative disease.

There is great interest in further developing methods to improve the detection of occult micrometastases in biopsied lymph nodes

with more sensitive reverse-transcription polymerase chain reaction assays to detect the presence of tyrosinase messenger RNA. Early results of this technique for detection of occult melanoma cells in the blood of patients with small clinical lesions have not been as successful as hoped, but strategies that combine several methods are being evaluated.^{1,33} Polymerase chain reaction–based detection of melanoma cells in sentinel lymph nodes of patients with melanoma also is being evaluated as a prognostic tool.³⁴

The stage of melanoma at the time of diagnosis is one of the primary indicators of natural history of the disease. Other factors such as tumor growth phase, mitotic rate, density of TILs infiltrating the tumor tissue, anatomic site of the primary tumor, gender, and age, also have been reported to have an impact on survival (Table 141–6). In addition, a number of additional prognostic factors have been identified in patients with advanced disease. The number of metastatic sites, disease involvement of the gastrointestinal tract, liver, pleura, or lung, Eastern Cooperative Oncology Group (ECOG) performance status ≥ 1 , male gender, and patients with prior immunotherapy have been associated with poor prognosis.

TREATMENT

Melanoma

Treatment of cutaneous melanoma depends on the stage of disease. Local disease is managed, and often cured, with surgical ablation. Regional disease is treated with surgical resection of the primary lesion and, depending on the risk of recurrence, possibly adjuvant therapy. Use of adjuvant therapy after surgical resection and the role of interferon- α as adjuvant therapy remain controversial. Treat-

ment of disseminated melanoma remains a challenge. Although numerous clinical trials have evaluated single-agent and combination chemotherapy, immunotherapy, targeted therapy, and biochemotherapy regimens, there is not a single standard approach for management of the individual with metastatic melanoma.^{1,10,35,36}

■ SURGERY

2 Patients who present with a suspicious pigmented lesion should undergo a full-thickness excisional biopsy, if possible. Sites at which excisional biopsy is inappropriate include the face, palm of the hand, sole of the foot, distal digit, and subungual lesions. A full-thickness incisional or punch biopsy is preferred in these cases to provide microstaging and ultimately to determine therapy.

Localized cutaneous melanoma often can be cured with surgical excision. The extent of the excision margin is important in preventing local recurrence and ultimate survival. For melanoma in situ, excision of the visible lesion or biopsy site with a 0.5- to 1-cm border of clinically normal skin and a layer of subcutaneous tissue with confirmation of histologically negative peripheral margins is recommended. The recommended clinical margin for invasive melanoma depends on the tumor thickness. Excision with a 1-cm margin of clinically normal skin and underlying subcutaneous tissue is recommended for invasive melanomas ≤ 1 mm thick.^{35,37} This recommendation is a significant reduction from the previous practice of a large 5-cm margin. The appropriate margin of excision for melanomas between 1 and 2 mm in thickness is controversial. A study suggests the risk of locoregional recurrence is higher when melanomas that are at least 2 mm thick are excised with a 1-cm margin rather than a 2-cm margin.³⁸ Current National Comprehensive Cancer Network (NCCN) guidelines recommend a 1- to 2-cm margin for melanoma with tumor thickness of 1.01 to 2 mm.³⁵ Lesions that are 2 to 4 mm thick should be excised with a 2-cm margin. Primary tumors more than 4 mm thick require at least a 2-cm margin, but whether a larger margin is beneficial is not clear.³⁹ Surgical management of lentigo maligna melanoma is problematic, as subclinical extension of atypical junctional melanocytic hyperplasia may extend beyond the visible margins. Complete excision of these lesions is important.

When isolated regional lymph nodes are detected via physical examination in the absence of distant disease, therapeutic lymphadenectomy is recommended. The extent of therapeutic lymph node dissection often is modified according to the anatomic area of the lymphadenopathy. The role of lymphadenectomy is not as established when the regional lymph nodes do not appear to be involved under clinical examination. Although a subgroup of patients with early-stage melanoma will have microscopic metastatic disease in nonpalpable lymph nodes, prophylactic regional lymph node dissec-

TABLE 141-6 Prognostic Factors for Cutaneous Melanoma

tion does not prolong survival or decrease time to relapse in randomized clinical trials.^{10,36} Selective regional lymphadenectomy performed after scintigraphic and dye lymphographic identification of the affected sentinel draining lymph node(s) is becoming increasingly available and common. If the sentinel node is found to have micrometastatic melanoma, regional dissection of the involved nodal basin is performed. Lymphatic mapping with sentinel node biopsy, if available, should be considered in patients with melanomas that are more than 1 mm thick. If the lesion is 0.75 to 1 mm in thickness with ulceration or is Clark level IV or V, lymphatic mapping with sentinel node biopsy may be considered based on patient characteristics such as ulceration of the tumor.³⁶ Of note, the likelihood of detecting metastatic disease in the sentinel lymph node depends on tumor thickness. The likelihood of detecting metastatic disease is approximately 1% in tumors that are less than 0.8 mm but increases to more than 30% in tumors 4 mm thick.³⁵

One of the most important aspects of surgical management of cutaneous melanoma is the role of patient follow-up.^{1,35} Postsurgical follow-up of patients who have had a melanoma excised is essential to monitor for undetected metastatic disease and the development of a second primary cutaneous melanoma or nonmelanoma primary malignancy. Scheduled screening in addition to routine surgical follow-up are required for any patient with a melanoma; the recommended frequency and duration depend on the stage of melanoma. The optimal duration of follow-up remains controversial. Most patients who are going to have recurrent disease will do so in the first 5 years after treatment, but late recurrences more than 10 years after surgery have been observed. The increased lifetime risk of developing a second primary melanoma supports lifetime dermatologic surveillance for all patients.

Curative surgery usually is limited to patients with early-stage disease. A patient with stage III melanoma usually has lymph node involvement, but in-transit metastases also may occur. In-transit metastasis is the clinical manifestation of tumor that develops in lymphatics between the primary melanoma and the regional lymph node basin.¹⁰ In-transit metastases are more than 2 cm from the original lesion. In-transit metastases are more common in individuals with thick ulcerated lesion. Surgery is used for management of in-transit lesions, and the goal is complete resection. Unfortunately, subsequent recurrence in the same extremity often occurs after initial resection of in-transit metastases. When in-transit metastases occur in extremities, local therapy with isolated limb perfusion or isolated limb infusion has been used.¹⁰

The role of surgery beyond that of cure is less clear, although surgery may offer palliation for patients with isolated metastases.⁴⁰ Resection of isolated lesions in the brain and lungs may be appropriate in certain cases and should be evaluated based on individual patient criteria. Surgery can be an option in situations where the lesion is accessible and where the lesion may cause problems if not removed. Surgery can extend survival in select patients with metastatic disease. Patients whose metastases can be completely resected may experience improved quality of life, improved overall survival, and occasionally long-term disease control.⁴⁰

Brain metastases is a frequent complication of advanced melanoma. Approximately 20% to 50% of patients with stage IV disease will develop clinically apparent central nervous system involvement. Surgical resection, with or without radiation, has been used in select individuals. More recently, high control rates of brain metastases have been achieved with focal radiation therapy such as linear accelerator-based stereotactic radiosurgery or gamma-knife technologies.^{41,42} Melanoma in the gastrointestinal tract can lead to bowel obstruction, and appropriate resection or bypass may allow the patient significant relief of symptoms. Despite the lack of controlled clinical trials, the impact on palliative surgery should be evaluated in the context of a patient's comfort and quality of life.

Surgery may be an appropriate option if the perceived outcome is to provide patient comfort. On the other hand, surgery may constitute a significant physical challenge or financial burden to a patient with a limited life expectancy. The clinical scenarios involving surgical resection should be fully evaluated in terms of overall quality of life.

The risk of relapse and death after resection of a local or regional cutaneous melanoma is the primary determinant for use of adjuvant therapy after primary resection. Adjuvant trials have focused on patients at intermediate or high risk for recurrence.

■ IMMUNOTHERAPY

Melanoma is considered one of the most immunogenic solid tumors, and it appears to interact with and respond to the immune system of the host in which it arises. Spontaneous regressions of melanoma suggest the importance of the immune system in disease modulation. Lymphoid infiltration into the primary melanoma also suggests that immunomodulation may impact the biology of melanoma. Early work showed that nonspecific immunomodulators, such as levamisole and bacillus Calmette-Guérin, for treatment of melanoma were associated with some regression of the tumor, although many of these responses were limited and short-lived. Because melanoma is one of the cancers most resistant to traditional treatment modalities such as radiation and chemotherapy, immunotherapy offers an avenue of treatment. Although the complete response rate seen in patients with melanoma treated with biotherapy is relatively low, the durability of responses in individuals who respond can be significant. Remaining unanswered questions are what is the best approach to biotherapy in a patient with melanoma and can biotherapy be combined with other available and emerging antineoplastic therapy.

Interferon

One of the oldest, and most controversial, immunotherapy approaches to treatment of melanoma is the use of interferons.¹ The *interferons* are a group of proteins with diverse immunomodulatory and antiangiogenic properties. A number of studies have evaluated various doses and schedules of recombinant interferon for treatment of metastatic melanoma. Response rates in metastatic melanoma range from 10% to 30%, and overall response rates are approximately 15% for interferon- α . Unfortunately, the optimal dose, treatment schedule, and treatment combination/regimens have not been established for management of metastatic melanoma.¹⁰

In clinical trials of interferon therapy for patients with metastatic melanoma, response rates were highest in patients with minimal disease. Responses were seen at all sites of disease but were most frequent in subcutaneous, lymph node, and pulmonary metastases. The success of interferon in patients with minimal disease encouraged investigators to evaluate the role of adjuvant interferon after curative surgical resection in patients who were at high risk for recurrent disease (bulky disease or regional lymph node involvement). Early trials of short-term or low-dose regimens of interferon- α did not demonstrate a survival benefit in the adjuvant setting. In an attempt to optimize response in the adjuvant setting, maximum tolerated doses of interferon- α were administered for 1 month, followed by prolonged therapy of interferon- α at more tolerable doses for 48 weeks. The rationale for the intensive induction phase was to provide peak interferon levels sufficient to inhibit tumor growth and avoid the development of anti-interferon antibodies. A large, multicenter cooperative group trial (E1684) of adjuvant interferon- α_{2b} versus observation was designed for 287 patients with high-risk (stage IIB and III disease based on the 1997 AJCC staging criteria) melanoma following curative surgical resection.⁴³ Interferon- α_{2b} was given intravenously as an induction therapy at maximum tolerated doses of 20 million international units/m² per dose 5 days per week for 4 weeks in an

TABLE 141-7 Results of Eastern Cooperative Oncology Group Trials of Adjuvant High-Dose Interferon- α_{2b} Therapy in Melanoma Patients at High Risk for Recurrence

Trial	Regimen	5-Year Relapse-Free Survival	5-Year Overall Survival	Reference
E1684	High-dose IFN ^a	37%	46%	Kirkwood et al. ⁴³
	Observation	26%	37%	
E1690	High-dose IFN ^b	44%	52%	Kirkwood et al. ⁴⁵
	Low-dose IFN	40%	53%	
	Observation	35%	55%	

^aHigh-dose interferon (IFN) 20 million international units/m²/day IV for 1 month and 10 million international units/m² three times per week subcutaneously (SC) for 48 weeks.

^bHigh-dose IFN 20 million international units/m²/day 5 days per week IV for 4 weeks and 10 million international units/m² three times per week subcutaneously (SC) for 48 weeks.

outpatient setting; treatment was continued for 48 weeks with subcutaneous interferon- α_{2b} 10 million international units/m² per dose three times per week at home. This therapy now is often referred to as *high-dose interferon* (HDI). With a median follow-up of 6.9 years, patients treated with HDI had significantly longer relapse-free and overall survival compared to patients who were observed following surgical resection (1.72 vs 0.98 years and 3.8 vs 2.8 years, respectively).⁴³ Table 141-7 shows 5-year relapse-free and overall survival results. With longer follow-up (median 12.6 years), however, the difference in overall survival was no longer significant.⁴⁴ Further analysis of the hazard function showed that the greatest reduction in melanoma recurrence occurred during the first few months of treatment. Subgroup analysis of this study indicated that patients with large primary tumors and node-negative disease (T4N0M0) did not receive the same benefit from therapy, but the small number of patients in this group made it difficult to draw definite conclusions about the role of interferon for adjuvant therapy in this subgroup.

HDI treatment is associated with multiple toxicities, including flu-like syndrome. Other toxicities include depression, nausea, weight loss, fatigue, myelosuppression, elevations in liver function tests, and renal insufficiency. Toxicities of interferon therapy in the adjuvant HDI trials were common and severe, and most patients required dose reductions and/or delays at some point during treatment. Dose modifications were required for dose-limiting constitutional symptoms, myelosuppression, and hepatic toxicities, but 74% of patients were able to complete the year of therapy in an outpatient setting.

One of the strategies for reducing the toxicities associated with interferon was to modify the dose and duration. A subsequent ECOG trial (E1690) of low-dose interferon (LDI; three million units per dose given subcutaneously three times weekly) for 24 months compared to the HDI regimen described above versus observation did not demonstrate an overall survival advantage of HDI versus observation.⁴⁵ At median followup of 52 months, the 5-year estimated relapse-free survival rates for HDI, LDI, and observation were 44%, 40%, and 35%, respectively. Relapse-free survival was significantly longer in the HDI group, prolonging the median time to relapse by 10 months compared to observation and LDI. With longer follow-up, however, the difference in relapse-free survival was no longer significant.⁴⁴ A significant overall survival benefit was not seen for HDI or LDI compared to observation, although the investigators speculated that this analysis of survival was affected by the number of patients in the observation arm who received interferon therapy after disease progression.⁴⁵

Use of interferon in the adjuvant setting remains controversial. Although the HDI regimen is used in the United States, the LDI strategy remains standard in many European countries.¹ In a pooled analysis of 713 patients who participated in two randomized controlled trials (E1684 and E1690), HDI was associated with a signifi-

cant reduction in relapse-free survival compared with observation ($P < 0.006$).⁴⁴ No benefit in overall survival was observed in the pooled analysis. The results of nine randomized clinical trials of adjuvant HDI or LDI versus observation in melanoma were included in a systematic review. The systematic review observed a trend toward reduction of risk of recurrence of melanoma and of death among the interferon-treated patients in nearly all studies.⁴⁶ Adjuvant interferon- α has been evaluated in a number of clinical trials in patients with intermediate- to very-high-risk melanoma after surgical resection. A systematic review evaluated nine randomized controlled trials of high- and low-dose regimens.⁴⁶ Due to differences in dose, frequency, and duration of interferon- α treatments in the various trials, the review was not able to compare LDI versus HDI. Furthermore, the wide variability in number of patients enrolled, end points, patient selection, quality, type of therapy, duration of treatment, and follow-up precluded statistical analysis of the pooled results. Although the differences in overall survival were not always statistically significant, HDI remains the only adjuvant treatment shown to prolong survival in prospective randomized trials. Interferon- α_{2b} is approved by the Food and Drug Administration (FDA) for treatment of patients with primary melanomas larger than 4 mm (stage IIB and IIC) and in patients with melanoma involving regional lymph nodes who are disease-free following lymph node dissection (stage III).

Although interferon is widely used in the adjuvant setting, there are concerns over the considerable treatment toxicities and the lack of consistent overall survival advantage of a toxic and expensive regimen. In addition, whether the results from the HDI trials should be extrapolated to patients with local recurrences, satellite lesions, or in-transit metastases is not clear. Remaining questions include the following: (a) Are the toxicities associated with HDI treatment worth the potential benefits for patients? (b) What are the mechanism(s) and best approaches to managing interferon toxicity? (c) Is the regimen/schedule of interferon used in the initial positive trial (HDI) necessary to achieve the benefits seen in this study? Aggressive toxicity evaluation and individualized management are essential to help preserve quality of life in individuals receiving interferon therapy.

③ A mechanism for optimizing the care of patients receiving interferon is to effectively prevent and manage treatment-related toxicities. A common syndrome seen with interferon- α therapy is a diverse group of side effects referred to as *constitutional symptoms*, which can include acute symptoms such as fever, chills, myalgia, and fatigue, and can encompass some of the more chronic toxicities such as fatigue, anorexia, and depression.⁴⁷ Acetaminophen can be used to prevent or minimize acute dose-related symptoms such as fever, myalgia, and chills. Opiates such as meperidine are often required when patients experience severe chills or rigors, most commonly during the initial month of the HDI induction phase. Nonsteroidal antiinflammatory drugs (NSAIDs) have been used to manage interferon-related myalgia but may have overlapping side effects with interferon, such as a decrease in renal blood flow and nausea. NSAIDs, like acetaminophen, may mask fevers that occur in patients who experience neutropenia while undergoing therapy. Fatigue is one of the most frequently observed dose-limiting toxicities seen with interferon therapy.⁴⁷ The mechanisms of interferon-induced fatigue are not fully understood and may be multifactorial in individual patients. Interferon-induced fatigue appears to be dose related and may worsen with continued therapy. Pharmacologic (e.g., amantadine) and nonpharmacologic interventions (e.g., exercise, psychosocial techniques, distraction, energy management, and dietary modifications) for treatment cancer-related fatigue and now interferon-related fatigue are being evaluated.^{47,48} Anorexia was reported in approximately 70% of patients receiving adjuvant interferon therapy for melanoma and is thought to be mediated through direct effects on hypothalamic neurons, modification of normal hypothalamic neurotransmitters/neuropeptides, or effects from stimulation

of other cytokines.^{47,49} Depression is common and should be fully evaluated and treated based on patient-related symptoms.⁴⁷ Contributing factors such as interferon-induced hypothyroidism and/or concomitant interferon symptoms (e.g., nausea and fatigue) should be evaluated concurrently with depression symptoms to optimize treatment decisions. Taste alterations may contribute to anorexia. Investigational strategies for ameliorating interferon-induced anorexia include nutritional intervention, use of appetite stimulants such as megestrol acetate, and patient education. Glucocorticoids should not be used for appetite stimulation or as part of an antiemetic therapy because they may adversely impact the immunomodulatory effects of interferon. Other toxicities such as hematologic or hepatic toxicities require monitoring and appropriate dose modification.

Because of the associated toxicity and adverse effects seen with interferon- α therapy, there has been worldwide concern about the usefulness of this intensive adjuvant therapy for melanoma despite the possible benefits in relapse-free and overall survival.⁵⁰ A subsequent report from the cooperative group study demonstrated a quality-of-life benefit with interferon therapy based on the quality-of-life-adjusted survival analysis.⁵¹ This analysis calculates the quality-of-life-adjusted years gained as a result of interferon- α treatment or the clinical benefit of time without toxicities and without disease.

4 The role of interferon as adjuvant therapy is not clear at this time. If adjuvant interferon is given, what product (e.g. pegylated interferon), dose, and duration of therapy should be used are not clear. The issues of patient side effects and cost must be carefully weighed against the potential disease-free survival benefit. Because HDI is the only therapy to demonstrate benefit in large comparative trials, it should be considered for patients with high-risk disease. The 2008 NCCN Guidelines for melanoma list interferon- α as one of several options for select patients with high-risk disease.³⁵ Other options include observation and probably, most importantly, clinical trials. Individuals should be prescreened for potential problems associated with therapy; relative contraindications to HDI therapy include autoimmune diseases, immunosuppression, decompensated liver disease, severe neuropsychiatric diseases, and life-threatening infection.⁴⁷ Efforts continue to better define the optimal treatment regimen for HDI versus other strategies in well-designed clinical trials.

CLINICAL CONTROVERSY

The role of interferon- α as adjuvant therapy for high-risk patients after surgical resection of melanoma is controversial. Assessment of patient risk factors, availability of clinical trials, and cost of therapy should be evaluated prior to initiation of therapy.

The role of interferon in advanced disease is even less clear, especially for patients who have recurred after treatment with adjuvant interferon therapy. Interferon- α has been used as a single agent in patients with metastatic disease who have not received adjuvant therapy and in combination with chemotherapy and/or other biotherapy for metastatic melanoma. The challenges of combination therapy are that many of the toxicities seen with interferon can be exacerbated by concomitant chemotherapy (e.g., nausea, vomiting, and neutropenia).

Interleukin-2

Interleukin-2 (IL-2) is a glycoprotein produced by activated lymphocytes.⁵² IL-2 was first identified as a T-cell growth factor, but now IL-2 clearly is a growth factor for a variety of cells including lymphocytes, T cells, and natural killer (NK) cells. IL-2 also may be immunosuppressive. The role of each of these effects of IL-2 on disease control in melanoma is not clear.

The precise mechanism of cytotoxicity of IL-2 is unknown. High concentrations of IL-2 have not been shown to have a direct antitumor effect on cancer cells in vitro. In vitro and in vivo, IL-2 stimulates the production and release of many secondary monocyte-derived and T-cell-derived cytokines, including IL-4, IL-5, IL-6, IL-8, tumor necrosis factor- α , granulocyte-macrophage colony-stimulating factor, and interferon- γ , which may have direct or indirect antitumor activity. In addition, IL-2 stimulates the cytotoxic activities of NK cells, monocytes, lymphokine-activated killer (LAK) cells, and CTLs. IL-2 also appears to activate endothelial cells, which results in increased expression of adhesion molecules.⁵²

5 Based on preclinical studies that demonstrated a dose-response relationship between recombinant IL-2 (aldesleukin) and tumor response, initial clinical trials of aldesleukin in patients with melanoma used relatively high doses of the drug as a single agent or in combination with LAK cells. The response rates seen in these trials ranged from 15% to 25%, and 2% to 5% of patients achieved complete responses, some of which were durable. Responses were seen at a number of metastatic sites, such as lung, liver, bone, lymph nodes, and subcutaneous tissue. Based on reevaluation of early clinical trials,⁵³ aldesleukin received FDA approval for treatment of metastatic melanoma. Overall, objective response rates were approximately 16%, but in some cases responses were durable and were observed in patients with large tumor burdens. The high doses of aldesleukin used in the initial clinical trials and recommended in the labeling of the drug are associated with serious toxicities and may limit the practicality of therapy for individual patients and broad application in certain healthcare systems. The high-dose aldesleukin regimen used for treatment of metastatic melanoma is 600,000 international units/kg per dose every 8 hours for 14 doses maximum in a 5-day period given for two cycles, with a 10- to 14-day rest period between cycles. At these doses, cytokine-induced capillary leak syndrome is a common problem and often is accompanied by significant hypotension, visceral edema, dyspnea, tachycardia, and arrhythmias. Increased permeability of capillary walls allows for a fluid shift from the intravascular space into tissue. As the patient becomes intravascularly dehydrated, hypotension may occur, resulting in reflex tachycardia and arrhythmias. In addition, the decrease in blood volume may result in decreased renal blood flow and urine output, manifesting as an increase in blood urea nitrogen, serum creatinine, edema, weight gain, and a decrease in urine output (input greater than output). Visceral edema can result in pulmonary congestion, pleural effusions, and edema. The management of patients receiving high-dose aldesleukin requires careful monitoring and a staff trained in aspects of critical care such as hypotension management. Although patients initially receiving high-dose aldesleukin are treated in an intensive care unit, most patients can be managed on a designated oncology unit if the staff is familiar with the toxicities and management strategies of the toxicities. Additional side effects seen with aldesleukin include constitutional symptoms, pruritus, eosinophilia, bone marrow suppression including thrombocytopenia, increased liver function tests, and nausea.⁵⁴

CLINICAL CONTROVERSY

Although aldesleukin has been associated with long-term durable responses in a small subset of patients with metastatic melanoma, the toxicity profile, intensity of therapy, and cost have limited its acceptance in the United States. Patients should be evaluated for treatment prior to initiation of therapy.

In an attempt to reduce treatment-related toxicities, a number of studies have evaluated continuous-infusion aldesleukin and lower doses of aldesleukin, given either alone or combined with chemotherapy and interferon therapy. Although initial reports were

encouraging, survival has not been significantly affected. At this time, direct head-to-head comparisons of various dosing schedules and regimens are needed to determine the optimum approach to aldesleukin therapy in metastatic melanoma. Coadministration of LAK cells with aldesleukin does not appear to significantly improve clinical response.⁵⁵ Although some studies have suggested improved response with coadministration of TILs with recombinant IL-2, the therapy is technically difficult and costly, and the overall clinical benefit has not been clearly demonstrated.⁵⁶

One of the greatest treatment challenges in treatment of metastatic melanoma is determining the role of aldesleukin therapy for each patient. Based on reports of long-term responses (>10 years) experienced by some patients, the risk certainly is worth the benefit for those individuals. Unfortunately, at this time it is difficult to determine which individuals will respond to aldesleukin therapy, as no biologic or immunologic parameters have been found to correlate with response. The decision to treat an individual with high-dose aldesleukin should be based on an analysis of an individual patient's risk versus potential benefit. Patients with inadequate pulmonary function, cardiac function, renal insufficiency, active infection, or poor performance status are poor candidates for this therapy. Aldesleukin can be safely administered with a properly trained healthcare team and is one of only two approved therapies for treatment of metastatic melanoma.

Vaccines

The rationale for vaccination as a therapeutic modality is based on the observation that antigens expressed on the surface of tumor cells differ from normal cells and the hope that vaccines might induce effective tumor-specific immune responses with fewer toxicities than conventional chemotherapy or other immunotherapies. Greater knowledge about tumor antigens and the mechanism of antigen presentation and immune response to antigens has led to the development of several vaccination strategies for treatment of early and advanced melanoma.

A variety of melanoma vaccines based on whole tumor cells, peptides, proteins, and tumor lysates have been evaluated for treatment of patients with metastatic disease and for intermediate- and high-risk patients after surgical resection of disease.^{57–60} Although tumor responses with some of these approaches have been observed in phase I and II trials, none of the vaccine responses have been confirmed in phase III trials.⁵⁹ These early trials have focused on safety, feasibility, and immunogenicity of the vaccine. Vaccines are a promising but still experimental approach in the treatment of melanoma.

Vaccination is a form of active specific immunotherapy directed against a particular cellular target or specific membrane antigen. The ideal tumor vaccine would generate an active, systemic, long-lived immune response in the cancer-bearing host against tumors; protect against primary development or subsequent relapse of cancer; or induce regression of established cancer. Obstacles in the development of a vaccine include identifying appropriate antigens to target and generating immune responses against tumor antigens to which the immune system has been already exposed.

Whole-cell tumor vaccines can be derived from cell lines that are already established (allogeneic vaccines) or from the patient's own tumor cells (autologous). Whole-cell vaccines are challenging to produce for several reasons: a new vaccine must be prepared for each patient, patients must have sufficient tumor available to provide adequate material, and considerable delay may exist between time of tumor removal and vaccine administration.⁵⁷ In addition there are technical challenges to producing the vaccine in the laboratory.⁵⁸ Currently no autologous tumor cell vaccine has been successfully studied in a phase III randomized clinical trial. An example of a whole-cell tumor vaccine that is being studied is Canvaxin. Canvaxin

(CancerVax, Carlsbad, CA) is an allogeneic whole-cell vaccine that uses bacillus Calmette-Guérin as an immune adjuvant. Small trials have shown improvements in survival compared with historical controls, and some objective clinical responses have been seen in patients with metastatic melanoma. Two large randomized trials have compared Canvaxin to observation, one in patients with metastatic melanoma and one in stage III melanoma. The results of these trials have not yet been published, but have been reported to show no significant differences between the vaccine and observation.⁵⁹

Antigen vaccines use individual antigens to stimulate immune responses, as compared with whole-cell vaccines, which contain many thousands of antigens.⁶⁰ These antigens usually are proteins or pieces of proteins called *peptides*. Antigen vaccines may be specific for a certain type of cancer, but they are not made for a specific patient. Vaccines against GM2 ganglioside, a glycolipid expressed on most melanomas, are examples of vaccines targeted against an antigen. Two randomized controlled trials with anti-GM2 vaccines have failed to show any benefit with the vaccine.⁵⁹

Peptide antigen vaccines match the patient's haplotype with the spectrum of immunity that he or she expresses. T cells recognize antigens as peptide epitopes on the surface of major histocompatibility complex (MHC) molecules. Antigenic peptides can be mixed with an immunologic adjuvant and administered with the goal of loading empty MHC molecules in vivo. To date the most commonly used peptides have shown activity only in patients who express human leukocyte antigen (HLA)-A2. However, because not all patients express this HLA antigen, many patients would not be eligible for this vaccine.⁵⁷ Additional peptide antigens that are compatible in other haplotypes have been identified, and eventually this disadvantage may be overcome. Peptide vaccination can generate quantifiable and functional tumor-reactive T cells, but clinical responses are rare and do not consistently correlate with CTL response.

Because protein antigen vaccines have a slightly broader spectrum of antigen diversity, all patients with melanoma potentially could be eligible for vaccination with this particular type of vaccine. Proteins intrinsically produced by the cell are presented only to CD8⁺ T cells, whereas proteins taken up by antigen-presenting cells are presented only to CD4⁺ T cells. Under certain conditions, antigen-presenting cells can present protein-derived antigens to both CD4⁺ and CD8⁺ in a process known as *cross-presentation*.⁵⁷

Tumor lysates can be generated from tumor cells by mechanical disruption or enzymatic digestion.⁵⁷ Tumor cells that shed antigens in culture can be purified and used as an antigen source for vaccines. Production of a vaccine from these sources raises concern because standardization of production and verification of purity and biological activity are more difficult.

Vaccines in combination with other biologic therapies are being evaluated. In a randomized trial of 604 patients with resected stage III cutaneous melanoma, LDI combined with an allogeneic melanoma lysate vaccine (2 years) was compared with HDI alone (1 year).⁶³ Median overall survival was not significantly different between the two treatment arms ($P = 0.56$). Five-year relapse-free and overall survival were similar in the two treatment arms. The incidence of serious treatment-related adverse events was similar in the two arms, but more severe neuropsychiatric toxicity was observed in patients receiving HDI. Although the results of this trial suggest that the vaccine has some activity in melanoma, the study was not powered sufficiently to show either equivalency or small differences in efficacy. HLA typing was optional based on whether the centers were able to perform the typing. With ongoing research, hopefully standards can be made and additional trials performed with this vaccine specifically in patients with certain HLA types.

Occasional clinical responses have been observed in clinical trials of melanoma vaccines, which demonstrate the potential of this form of treatment. Many clinical trials with vaccine therapy in melanoma

patients are ongoing. The results of completed clinical trials have not yet shown definitive evidence of improved survival. Further research is needed to improve vaccine responses and to determine how to apply treatment to melanoma patients.

Other Approaches

Dendritic cells are potent antigen-presenting cells that initiate antigen-specific immune responses. Dendritic cells express high levels of MHC class I and class II molecules, which are essential in antigen presentation. Activation of T cells and recruitment of non-antigen-specific effectors, such as NK cells and macrophages, result in a broad immune response. One strategy that uses dendritic cells for inducing antitumor immune responses is peptide-pulsed dendritic cells. Antimelanoma CTLs can be generated from healthy donors and patients with melanoma with dendritic cells pulsed with melanoma-derived peptides. A number of clinical trials are evaluating dendritic cell-based immunotherapy.^{58,59}

Monoclonal antibodies have been used for diagnosis and treatment of melanoma. Monoclonal antibodies can be used to target biologic pathways (e.g., bevacizumab to target angiogenesis) that are associated with tumor progression and as a delivery system for antineoplastic drugs. Monoclonal antibodies have been conjugated to cytotoxic agents, radioisotopes, and toxins such as ricin A.^{10,20} More recently, monoclonal antibodies have been developed to target processes that are involved in the host immune response to melanoma. Cytotoxic T-lymphocyte antigen-4 (CTLA4) is a transmembrane protein that suppresses the induction of immune responses against tumor antigens.^{61,62} CTLA4 blockade may represent a novel approach to enhance the immune response against melanoma antigens. Ipilimumab (MDX-010) and tremelimumab (CP-675206; formerly known as ticilimumab) are two monoclonal antibodies against CTLA4 that are in clinical development. Preliminary results of clinical trials show promising activity in malignant melanoma. MDX-010 is a fully human immunoglobulin G₁ monoclonal antibody in clinical trials that targets CTLA-4, which results in increased antitumor activity mediated by T cells.²⁰

Gene therapy of human melanoma is in its infancy but suggests several exciting approaches to management of metastatic melanoma. Several strategies for gene therapy are under investigation for treatment of melanoma. One approach to gene therapy for melanoma is modification of melanoma cells with insertion of one or more cytokine genes and then administration of these altered allogeneic or autologous cells as a vaccine. Cytokine gene transduction has been accomplished with a number of cytokines, including aldesleukin (IL-2), tumor necrosis factor- α , IL-4, and interferon. It is hoped that insertion of cytokine genes into melanoma cells will significantly increase the cells' immunogenicity.

Genes can be transferred *in vitro* into TILs associated with melanoma in an attempt to potentiate the cytotoxicity of these cells. Rosenberg et al. were the first to attempt to transduce the gene coding for resistance to neomycin into human TILs.⁵⁶ This approach has since been used to transfer the tumor necrosis factor gene into TILs.

Thalidomide and thalidomide analogs are being evaluated for management of melanoma. Thalidomide, given either as a single agent or in combination with chemotherapy or cytokines, is being evaluated in a variety of studies. Thalidomide analogs also are being evaluated in an attempt to avoid toxicities associated with the parent compound. The thalidomide analogs are grouped into two classes: selective cytokine inhibitory drugs and immunomodulatory derivatives. Both classes appear to have antiangiogenic and antiinflammatory properties, but the selective cytokine inhibitory drugs are phosphodiesterase inhibitors. Immunomodulatory derivatives also have effects on T-cell stimulation and inhibition of tumor necrosis factor- α . Several of these agents are being evaluated in clinical trials of metastatic melanoma.⁶⁴

CHEMOTHERAPY

A number of antineoplastic agents have demonstrated *in vitro* activity against melanoma, but only a few drugs have consistently shown a response rate greater than 10% in individuals with metastatic melanoma. Most clinical trials that evaluate new agents in melanoma measure activity in terms of response rates, which often include partial response rates in addition to complete response. It is important to understand that these response rates do not always correlate with survival and do not evaluate benefit to the patient. Response rates also do not represent the toxicities and the complications of therapy. Complete responses can be durable in a small number of patients.

6 *Dacarbazine*, a cytotoxic drug thought to exert its antitumor effect through alkylation, currently is the most effective single agent for treatment of melanoma. Dacarbazine remains the only FDA-approved chemotherapeutic agent for treatment of metastatic melanoma in the United States.^{64,65} Prospective controlled clinical trials have observed response rates of 10% to 25%, with an average duration of response of 5 to 7 months. Complete responses are uncommon, with less than 5% of patients treated with single-agent dacarbazine sustaining long-term complete responses. There does not appear to be a survival benefit for dacarbazine relative to other treatments or supportive care. Patients with skin, subcutaneous tissue, and lymph node involvement respond most frequently, whereas patients with metastatic disease to the liver, bone, and central nervous system often are unresponsive. The optimum dose schedule of dacarbazine has never been determined; therefore, single-dose regimens are often preferred for patient convenience. Common side effects of dacarbazine therapy include moderate myelosuppression, severe nausea and vomiting, and a flu-like syndrome after large doses. Nausea and vomiting can be prevented and managed with available antiemetics and is not a major complication. At this time, dacarbazine has no defined role in the adjuvant setting.

Temozolomide is one of a series of imidazole tetrazine derivatives that was developed as a potential alternative to dacarbazine.⁶⁴ Temozolomide is an oral prodrug of the active metabolite of dacarbazine. Dacarbazine requires hepatic transformation to its active intermediate, whereas at physiologic pH, temozolomide chemically degrades to the cytotoxic monomethyltriazenoimidazole carboxamide (MTIC). Temozolomide is administered orally and appears to be less emetogenic than dacarbazine, although nausea can be a challenging chronic toxicity. Temozolomide appears to cross into the central nervous system and so initially was thought to have benefit for patients with central nervous system metastases. In chemotherapy-naïve individuals with metastatic melanoma, temozolomide showed efficacy at least equivalent to that of dacarbazine in terms of objective response rates, time to progression, and overall and disease-free survival. There was suggestion that temozolomide may have been associated with improvement in some aspects of quality of life in this phase III trial, although overall disease control was similar to dacarbazine.⁶⁶

A potential advantage of temozolomide is the convenience of the oral dosing form, which allows a potentially more effective dosing schedule (e.g., multiple doses per day or a multiple-day administration). It is believed that prolonged administration may help to overcome some of the chemotherapy drug-resistance mechanisms of intermittent dosing temozolomide or dacarbazine. The active metabolite of dacarbazine and temozolomide, MTIC, methylates guanine residues in DNA at the O⁶ position. Resistance to agents that produce O⁶ methylation is partly due to increased levels of O⁶-allylguanine-DNA alkyltransferase. Temozolomide administration results in decreased activity of alkyltransferase for at least 24 hours. Daily administration of temozolomide may be a strategy to increase the cytotoxicity of the drug.⁶⁷ Clinical evaluations of prolonged administration of temozolomide are ongoing, often in combination with other agents such as interferon.^{68,69}

The *nitrosoureas* are active against melanoma. Nitrosoureas, such as carmustine and lomustine, have antitumor activity similar to that of dacarbazine, with reported response rates between 10% and 20%. Sites of responses are similar to those seen with dacarbazine. It was initially hoped that use of the lipophilic nitrosoureas would provide added benefit against a malignancy that can metastasize to the brain. Unfortunately, despite the ability of these agents to cross the blood–brain barrier, the commercially available nitrosoureas have not been shown to have increased activity against melanoma in the central nervous system. Fotemustine, a nitrosourea available in Australia and some European countries, appears to cross the blood–brain barrier more rapidly than do other nitrosoureas. Response rates of 30% have been reported in previously untreated patients, with response rates of 25% of patients who had cerebral metastases. Fotemustine is considered standard therapy in some countries.⁷⁰ The most common toxicity of the nitrosoureas is delayed myelosuppression, particularly thrombocytopenia. Leukopenia and thrombocytopenia may be seen as long as 3 to 5 weeks after drug administration and may limit the inclusion of these agents to multidrug regimens.

Cisplatin and related compounds have been evaluated in the management of metastatic melanoma. The effectiveness of platinum compounds as single agents is limited, with reported response rates of 10% to 15% with a short median duration. The activity of cisplatin in melanoma may be dose dependent, and higher response rates have been seen with higher doses of cisplatin in single-institution studies.⁷¹ The toxicities of cisplatin can be problematic, especially in higher doses, and include acute and delayed nausea and vomiting, renal toxicity, and neurotoxicity. Other platinum analogs, such as carboplatin and oxaliplatin, are being evaluated for treatment of melanoma.

Taxanes have demonstrated encouraging results in initial trials of metastatic melanoma. Response rates of 15% to 17% have been seen in initial phase II trials with paclitaxel and docetaxel. Abraxane, the albumin-bound nanoparticle formulation of paclitaxel, has shown encouraging results in a very small phase II trials and is being evaluated in a randomized phase III trial.⁷² At this time, these agents are not routinely used as single-agent therapy for melanoma but are being incorporated into multidrug strategies undergoing evaluation for use against metastatic melanoma.

In an attempt to improve the limited responses seen with single-agent chemotherapy, a variety of combination chemotherapy regimens (Table 141–8) have been evaluated in both small and large clinical trials. Response rates as high as 30% to 50% were reported in single-institution phase II trials of patients with metastatic melanoma. The combination of dacarbazine with other chemotherapy, most commonly cisplatin, increased the response rates reported with dacarbazine alone, but the survival benefit has been minimal. Responses often were limited to metastases in soft tissue, lymph nodes, and the lung, the sites most likely to respond to single-agent dacarbazine therapy. The concern with combination chemotherapy is increased toxicity, and any reports of increased response rates should be weighed against the effect of toxicities on overall quality of

life. The initial reports with the cisplatin, vinblastine, and dacarbazine (CVD) regimen were exciting, with reported response rates greater than 50%, 4% complete response rate, median response duration 9 months, and acceptable toxicities.⁷³ Comparisons of this regimen to dacarbazine alone have been conflicting. Subsequent reports showed no difference in response rates or survival.

The Dartmouth regimen is a combination that includes carmustine, dacarbazine, cisplatin, and tamoxifen. Initial reports from uncontrolled phase II trials of this combination have demonstrated high response rates of 20% to 50%, but few patients achieve long-term survival. The benefit of tamoxifen to this regimen has been controversial, but a controlled clinical trial from the National Cancer Institute of Canada demonstrated no benefit in response or survival from tamoxifen in this combination.⁷⁴ Careful analysis of the initial studies demonstrates that the criteria used to measure response were not consistent with standards used in large multicenter studies. Phase III trials have shown no benefit of the Dartmouth regimen compared to single-agent dacarbazine.^{75,76} Response rates were 15%, and median survival was approximately 7 months in both studies. Of concern, toxicities were higher with the combination study and included bone marrow suppression, nausea, vomiting, and fatigue.

TARGETED THERAPY

7 The role of protein kinases in the regulation and proliferation signals in cancer cells is becoming a key focus for anticancer agents. The role of protein kinase inhibitors has emerged as standard therapy for malignancies such as renal cell carcinoma, chronic myelogenous leukemia, and gastrointestinal stromal tumors. As the biology of melanoma continues to unfold, there has been an increasing excitement about the development of targeted therapies against targets important for the development and progression of melanoma.^{20,77} There now is greater interest in identifying potential targets in melanoma and determining the applicability in specific patients and/or patient subsets.

Mutations of BRAF have been described in melanoma cell lines, and it appears that approximately 50% to 70% of melanomas exhibit BRAF alteration.^{18,78} Sorafenib, a biaryl urea originally synthesized as a BRAF and CRAF inhibitor, is being evaluated in melanoma. Sorafenib inhibits both wild-type and mutant BRAF, in addition to other tyrosine kinases involved in angiogenesis and tumor progression. Preclinical studies demonstrated activity against human melanoma tumor xenografts in preclinical trials, modest activity as a single agent in phase II clinical trials in refractory metastatic melanoma, and promising results in combination trials with chemotherapy.^{64,78,79} Early results from phase II studies look promising for the combination of sorafenib and other anticancer agents. Based on these early promising results from phase II trials, a number of phase II trials are evaluating the efficacy of sorafenib with carboplatin and paclitaxel. It will be important to evaluate the efficacy of the addition of sorafenib to the “untested” combination of carboplatin and paclitaxel for treatment of metastatic melanoma.

Another agent of interest is imatinib mesylate, an oral agent that inhibits c-Kit and PDGFR. Expression of c-Kit has been observed in nearly 50% of early stage melanomas, but it appears that *c-Kit* expression is progressively reduced as the cells transform to a more highly metastatic phenotype.⁸⁰ PDGFR is also highly expressed on melanoma cells. Imatinib has been shown to suppress melanoma cell growth in preclinical studies. In a phase II study, high-dose imatinib was shown to be inactive in metastatic melanoma.⁸¹

ENDOCRINE THERAPY

The role of endocrine therapy in the management of melanoma has been debated over the last decade.¹⁰ Initial reports that described

TABLE 141–8 Combination Chemotherapy Regimens for Metastatic Melanoma

Dartmouth regimen (CDBT): Repeated every 3–4 weeks
Cisplatin 25 mg/m² IV daily × 3 (days 1, 2, and 3)
Dacarbazine 220 mg/m² IV daily × 3 (days 1, 2, and 3)
Carmustine 150 mg/m² IV daily × 1 (day 1)
Tamoxifen 10 mg orally twice a day

CVD

Cisplatin 20 mg/m² IV daily × 4 (days 2, 3, 4, 5)
Vinblastine 1.6 mg/m² IV daily × 5 (days 1, 2, 3, 4, 5)
Dacarbazine 800 mg/m² IV daily × 1 (day 1)

high-affinity cytoplasmic estrogen receptors in patients with metastatic melanoma caused some experts to speculate about the possibility that antiestrogens or other hormonal manipulation may be beneficial in modulating the biology of melanoma. Additionally, estrogens have been shown to suppress T-lymphocyte activity and to suppress or stimulate the activities of B lymphocytes, macrophages, and NK cells, supporting a hypothesis that estrogens influence the immunologic mechanisms that appear to be important in melanoma.

In a randomized trial, tamoxifen was shown to have a response and survival benefit when combined with dacarbazine in patients with metastatic melanoma; this benefit was most pronounced in women.⁸² Well-designed prospective randomized studies demonstrate that tamoxifen does not significantly enhance the antitumor effect of dacarbazine alone or the combination of dacarbazine with cisplatin and carmustine.^{10,83} As discussed previously, subsequent trials have not been able to confirm the initial reported benefit of the antiestrogen when combined with chemotherapy, and tamoxifen is no longer routinely included in chemotherapy regimens.⁶⁴

■ BIOCHEMOTHERAPY

Low overall response rates and toxicity have limited the routine use of chemotherapy alone or immunotherapy alone in the management of metastatic disease. Over the past decade, the strategy of a combination of chemotherapy and cytokines, aldesleukin, and/or interferon, often termed *biochemotherapy*, has been a major focus of investigation in the management of metastatic melanoma and more recently in the adjuvant setting. The primary rationale is to combine two therapies with some biologic activity to increase overall activity and perhaps response rates. Additionally, some preclinical trials suggest potential synergistic interactions between cytokines and some chemotherapy agents. As with other treatment strategies in melanoma, the results from initial trials suggested a higher response rate with biochemotherapy than the rates seen with either chemotherapy or biotherapy alone. Although several studies have suggested an increase in response rate with the addition of interferon- α to chemotherapy, results of most studies have shown that the addition of interferon- α does not increase the antitumor effect of dacarbazine but does increase toxicity and cost. Similarly, the combination of aldesleukin to chemotherapy has not been consistently shown to increase response or survival. The most encouraging results have been seen with combination chemotherapy and combination biotherapy, but the results of phase III studies have not demonstrated a clear advantage of biochemotherapy compared to chemotherapy alone. A recently published meta-analysis of 18 randomized trials of chemotherapy versus biochemotherapy showed that biochemotherapy was associated with a significantly higher response rate in treatment of metastatic melanoma.⁸⁴ However, these differences in response rates did not translate into a significant difference in overall survival. Toxicities can be severe and are consistent with the individual agents in the regimen.

One of the problems with most studies of biochemotherapy is the relatively short duration of response. Recurrence rates among patients who respond to therapy are as high as 50% within 18 to 24 months. Strategies such as subcutaneous low-dose aldesleukin are being investigated in an effort to prolong overall survival and time to progression in patients who do respond to treatment. Initial response rates, durable complete remission, and activity in patients in whom HDI therapy was not successful has stimulated interest in evaluating biochemotherapy in the adjuvant setting for high-risk patients with node-positive disease as compared to HDI.

A more recent strategy for biochemotherapy is substitution of newer agents into the combination. For example, a small phase II trial of patients with metastatic melanoma evaluated the substitution of temozolomide for dacarbazine.^{86,87}

■ LIMB PERFUSION AND LIMB INFUSION

Isolated limb perfusion is a surgical procedure of regional intravascular delivery of chemotherapy and/or biotherapy into an extremity with cutaneous melanoma.^{88,89} Isolated limb perfusion is a method for escalating the dose of chemotherapeutic drugs to a specific region of the body while limiting the systemic toxicities of the agent. Most perfusions can be performed with drug exposures of less than 2%. The most significant side effect of isolated limb perfusion is regional toxicity; all of the skin, subcutaneous tissue, and tissue of the extremity receives the same dose and is subjected to the same perfusion conditions as the tumor located within the extremity. After regional perfusions, objective response rates greater than 50% in treated limbs have been reported, with overall response rates possibly as high as 80%. The role of hyperthermia (39°C–40°C [102°F–104°F]) with regional isolated perfusion is not clearly defined. Although most clinical trials have used melphalan, whether the combination of melphalan with other agents may improve results is not known.⁹⁰ Agents that have been combined with melphalan include actinomycin D, nitrogen mustard, thiopeta, and cisplatin. Work with biologic response modifiers, such as tumor necrosis factor- α , have been encouraging.⁹¹ A simplified form of isolated limb perfusion, called isolated limb infusion, is a low-flow isolated limb perfusion performed under hypoxic conditions via small-caliber arterial and venous catheters. It has been proposed that the hypoxia that develops during isolated limb infusion may be beneficial with certain cytotoxic agents such as melphalan.

■ TREATMENT BY STAGE

Treatment of cutaneous melanoma is determined by many factors, including disease-related and patient-related issues. Most available reviews^{36,64} and guidelines³⁵ provide treatment recommendations based on stage of disease. Most patients present with localized disease.³⁵ Treatment of localized disease is surgical excision, with the extent of excision based on the tumor size. Wide excision is recommended for in situ melanoma and wide excision with SLNB for stage IA, IB, and II disease. Long-term survival of individuals with early-stage disease and thin tumors (<1 mm) is good, but survival is negatively impacted as tumor thickness increases.

The role of adjuvant therapy in the management of individuals with high risk for recurrence remains controversial. One controversy is determination of which patients are appropriate candidates for treatment after resection of the primary tumor. Although adjuvant therapy has been considered historically in patients with locally advanced disease (stages II and III), it is increasingly being considered after surgical resection of an isolated distant metastases.

Another controversy with adjuvant therapy is the choice of therapy. HDI has the most evidence supporting its use and is FDA approved for this indication. The challenges with this therapy have been discussed, and the therapy has limited worldwide acceptance. The most appropriate option is a clinical trial, if available. New therapies and combinations must be evaluated to help answer the questions that remain about adjuvant therapy in melanoma. Clinical trials of chemotherapy, immunotherapy, vaccines, and emerging therapies are ongoing and often are available through academic health centers and within the community through oncologist office-based practices.

Another treatment challenge is the management of patients with advanced disease. The 2008 NCCN guidelines list a variety of systemic therapies for advanced or metastatic melanoma, including dacarbazine, temozolomide, high-dose aldesleukin, and combination therapies of biochemotherapy that include dacarbazine or temozolomide.³⁵ Of note, the preferred treatment is participation in a clinical trial. Best supportive care is also an option in some individuals. Data suggest that surgical treatment of metastatic mela-

noma should be considered in select individuals based on the extent and location of disease.

An important consideration for treatment of melanoma is the presentation of the disease. As discussed, treatment of melanoma isolated to the limb may be most appropriately treated with regional therapy. Treatment options for metastatic uveal melanoma include strategies for managing hepatic metastasis, such as chemoembolization to the liver and intrahepatic chemotherapy.⁹²

Prevention and Detection

The results of early treatment emphasize the role of early detection and prevention. The American Academy of Dermatology recommends monthly self-examination of skin to serve as a mechanism for recognizing moles or marks on the skin that may be melanoma. Patients with a strong family history should have a clinical examination and, in some cases, screening photography to document the size, shape, and location of moles.

There are three different strategies for chemoprevention for melanoma. Primary chemoprevention is used to prevent occurrences of melanoma in healthy individuals. Secondary chemoprevention is used to prevent premalignant melanoma precursors from becoming melanoma. Tertiary chemoprevention is used to prevent melanoma recurrence in individuals who were treated for melanoma and have no evidence of disease. A variety of agents have been studied in human and in vitro models, with varying results and no clear choice for any of these agents (Table 141-9).⁹³ The mainstay of melanoma prevention remains strategies to protect individuals from harmful effects of the sun.

UV light exposure plays a complex role in melanoma development. Childhood sunburns and intermittent sun exposure correlate positively with melanoma risk. Education and reeducation about the importance of sun protection have the potential to help decrease the rising incidence of this disease. More recently, the method of sun protection has become an area of controversy.

Historically, patients have been counseled that the risk of skin cancer can be limited by the use of sunscreens with a sun protection factor (SPF) of 15 or greater. Although some studies have found a decreased risk of melanoma in sunscreens users, others have demonstrated no association and even increased melanoma risk with sunscreen use. Methodologic difficulties may explain the discrepancy in study results. Factors that include variables in sun exposure, sunscreen use, and sun sensitivity are very difficult to control in these trials. In addition, all sunscreens are not the same. Sunscreens traditionally have been designed to prevent erythema by blocking UVB, leaving users relatively unprotected from wavelengths such as UVA. Use of sunscreens, especially those with higher SPFs, may lead to the ability of individuals to increase their time in the sun without clinical indication of sunburn. Another concern is that irregular use of sunscreens increases the risk of intermittent UV exposure.

It is important to counsel patients about the appropriate use of sunscreens to optimize benefits from these products. One study noted that most consumers typically apply less sunscreen than is needed to establish the SPF number on the bottle; the actual SPF received is 20%

to 50% that of number.^{94,95} Sunscreens should be applied 15 to 30 minutes before going into the sun and should be reapplied every 2 hours, after swimming, and after perspiring heavily. Sun protection must be used regularly and not limited to times of recreation or anticipated “prolonged” exposure. Times of season changes, when the potential for sun exposure can be perceived as erratic, are possible times for the “first-of-the-season sunburn.”

The other question concerning sunscreen lotions is product selections. Older sunscreen lotions are more efficient in protecting against shorter UV wavelengths that lead to sunburns than in protecting against the longer wavelengths in the UVA range that may lead to skin damage and skin cancers such as melanoma. UVA radiation, unlike UVB, is consistent. Newer forms of sunscreens combine protection for UVA and UVB. Unfortunately, no currently approved system rates products for UVA protective capabilities. SPF is a measure of protection from UVB radiation only. The impact of the use of high-potency sunscreens on the incidence of melanoma is not clear at this time, because the lag time for melanoma is approximately two decades and high-potency sunscreens have only been popular for approximately 10 years.

One strategy for sun protection is use of protective clothing to minimize damage to the skin for individuals who spend time in the sun. The slogan “Slip! Slop! Slap!” (slip on a shirt, slop on the sunscreen, and slap on a hat), initially developed for public health campaigns in Australia, provides a more comprehensive approach to sun protection. Clothing designed to protect an individual from sun exposure but allows physical activities such as water sports and hiking are widely available. The clothes are designed for skin protection, but it is important to realize that not all clothing provides sufficient protection from UV radiation. Clothes with tight weaves provide greater protection. Hats are important (slap on a hat!), especially hats with a brim to protect ears, neck, and nose. Other strategies, such as sun avoidance, especially during peak hours of sun intensity (10 AM to 4 PM), and staying in the shade when outdoors, are important education concepts for individuals who are in the sun for prolonged periods and/or who are at high risk for burning.⁹⁶ Skiers and winter sports enthusiasts should be cautioned about exposure to UV radiation, as the reflection off snow and high altitude contribute to increased UV exposure.

EVALUATION OF THERAPEUTIC OUTCOMES

The outcome of patients treated with melanoma depends on the stage of disease at presentation. The prognosis of patients with thin tumors (<1 mm in thickness) and localized disease is good, with long-term survival in more than 90% of patients. The risk of regional nodal involvement increases with increasing tumor thickness, so survival rates decrease in patients with nodal involvement. Long-term survival in patients with distant metastases is even lower. Therefore, early diagnosis and appropriate treatment of early disease are essential. Patients with suspicious pigmented lesions should be evaluated and the lesion excised whenever possible. Treatment is determined by patient factors and stage of disease.

There is no clear recommendation regarding appropriate follow-up of patients with melanoma. Clinical practice guidelines published by the NCCN provide some guidance for follow-up of patients with melanoma.³⁵ Intensive surveillance has the benefit of early detection of recurrent disease, which may lead to better options of surgical resection. Emphasis on evaluation of locoregional areas is important. For patients with in situ melanoma, periodic skin examinations for life are recommended, although frequency is determined based on patient risk factors. Local recurrence is associated with aggressive tumor biology and frequently is a manifestation of an aggressive primary tumor. If a local recurrence occurs after inadequate primary disease, the patient should undergo a workup based on the lesion thickness of the original melanoma. Patients with nodal recurrence

TABLE 141-9 Sunscreens

Physical Blockers (Reflectants)	Chemical Absorbers

Talc	Salicylates
Titanium dioxide	Cinnamates
Red petrolatum	Camphor derivatives
	Aminobenzoates
	Ultraviolet A absorbers
	Benzophenone-6
	Dibenzoylmethanes

should be evaluated for lymph node metastases. Patients with systemic recurrence should be evaluated and treated in a fashion similar to patients presenting with systemic disease.

NONMELANOMA SKIN CANCER

8 Nonmelanoma skin cancers (NMSCs), which are malignant growths of the external surface or epithelia layer of the skin, are the most common form of cancer in the United States and the most common form of skin cancer. The incidence of NMSC is increasing each year, although the absolute incidence is not known because NMSCs often are excluded from cancer registry statistics. More than one million cases of basal cell and squamous cell skin cancers are expected to be diagnosed in 2007. The incidence rate has been increasing worldwide at a rate of 3% to 8% per year since 1964, with greater increases near the equator.^{2,97} There is a wide geographic variation in the incidence of NMSC, believed to be due to the differences in climate and the skin type of local populations. As with melanoma, the incidence is increasing in older persons, but of concern is the increase of NMSC in younger individuals.⁹⁸ BCC accounts for approximately 80% of NMSCs. Squamous cell carcinoma (SCC) is the second most common form of skin cancer, with more than 200,000 new cases estimated to occur each year in the United States.

NMSCs have a good prognosis when detected and treated early. Although these skin cancers have low mortality, they may produce significant morbidity and healthcare cost.⁹⁹

BCC, like SCC, develops within the epidermis. BCC derives from the basal layer of keratinocytes, which is the deepest cell layer of the epidermis. SCC arises from the more superficial layers of keratinocytes. Keratinocyte damage secondary to exposure to UV radiation is thought to be a primary cause of NMSC, and the risk for skin cancer is highest in susceptible individuals. Damage to keratinocytes results in actinic keratosis (AK), solar lentigo, and dermatoheliosis (photoaging). AKs are sun-induced premalignant skin lesions and can develop into SCC. Some argue that AK should be considered a very-early-stage SCC. Approximately 5% to 20% of AK will transform into SCC within 10 to 25 years, with no means available for determining which AK lesions will transform.

BASAL CELL CANCER

BCC is the most common form of skin cancer. The true incidence is unknown because a diagnosis may not be possible in individuals with multiple primaries or in those with no determined histology. Age-standardized yearly rates in the United States have been estimated at 407 cases of BCC per 100,000 white men and 212 cases per 100,000 white women.¹⁰⁰ As with melanoma, rates are highest in elderly men.

The genetics of BCC are not fully understood. Certain genetic syndromes predispose individuals to NMSC, specifically those that affect the impact of sunlight on the individual (e.g., albinism). In the majority of BCCs, there is a mutation in the tumor suppressor PTCH gene system found on chromosome 9q.

A major risk factor for BCC is exposure to UV radiation; pattern and amount of exposure to UV radiation appears to be important. Intense intermittent exposure to the sun is associated with a higher risk for BCC versus continuous exposure. As with melanoma, physical characteristics such as light skin color, light eyes (green or blue), and blond or red hair have been identified as independent risk factors. Additionally, immunosuppression increases the risk for BCC. For example, renal transplant recipients have a 10 times higher risk for BCC than do individuals who did not undergo renal transplantation.¹⁰¹ The incidence of subsequent cases of BCC is increased by a factor of 10 for individuals after an initial BCC compared to the general population.

The hallmark of BCC is a waxy, translucent, or pearly appearance (see Chap. 99). Often the lesions have central ulcerations and a raised pale border. Telangiectasias are common and lead to lesion friability, poor healing, and bleeding. Pigmented BCCs are not common and may be confused with melanoma. BCCs most often arise in areas of the body exposed to sun; the most common presentation is a lesion on the head or neck area, followed by the trunk, arms, and legs. These cancers can be found in other areas of the body. There are a variety of histologic subtypes of BCC, and lesions can often be a mixed histology.¹⁰² The most common form of BCC is nodular BCC, which presents as a pearly papule or nodule with overlying telangiectasia. Superficial BCC may present as a scaly erythematous patch. Melanin may be present in either form of BCC lesions, so the lesion may present with a dark blue or black coloring. Amelanotic or minimally pigmented melanomas can appear similar to BCC.

BCCs do not tend to metastasize but can be very locally destructive. Although BCCs often are considered a skin cancer that remains localized, left untreated these cancers can spread. Risk factors for extensive spread include diameter greater than 2 cm, location on the central part of the face or ears, long-standing duration, incomplete excision, aggressive histologic pattern of growth, and perivascular involvement.¹⁰³ Some histologic subtypes of BCC are associated with aggressive behavior; micronodular, infiltrative, sclerosing, and morpheaform patterns are more likely to recur than nodular and superficial BCCs.

Treatment

The goal of primary treatment of BCC is cure. Because BCCs do not tend to metastasize, the goals of treatment are local control and preservation of the function and cosmetic appearance of the area. Treatment of BCC often is surgical. Individuals who have low-risk disease in whom surgery or radiation is not an option may benefit from local topical therapies, such as topical 5-fluorouracil. Few randomized trials have compared different treatments. When evaluating new treatments, the clinician should critically evaluate issues such as duration of followup and impact of treatment on the primary lesion versus recurrent disease.

BCCs are most commonly treated with surgery. Surgical approaches include curettage and electrodesiccation, cryosurgery, excision, and Mohs micrographic surgery. Factors that determine the most appropriate surgical approach include the individual's age and overall health, histologic subtype, lesion location and size, and whether the lesion is a primary or recurrent tumor.

Curettage and electrodesiccation are methods commonly used for management of BCCs that are small in diameter. The tumor is scraped with a curette and the area is treated with electrosurgery to control bleeding and eradicate cancer cells that may remain. Often multiple treatments are used to completely remove the tumor. Scarring is a risk with this procedure. Curettage and electrodesiccation are used for low-risk tumors but should not be used in hair-bearing regions or if fat is reached during the procedures. Five-year cure rates are greater than 90% with curettage and electrodesiccation and cryosurgery when used for individuals with low-risk lesions.

Excisional treatments include Mohs surgery and excision with postoperative margin assessment. Postoperative margin assessment is an option if the lesion can be excised with 4-mm clinical margins and repair to the area. If the margins are positive, then resection is expanded or radiation is recommended. Primary lesions of any size on the neck, trunk, arms, or leg have a very high 5-year cure rate with surgical excision (>99%), whereas excision of lesions on the head is less effective with increasing tumor size.¹⁰¹ Mohs micrographic surgery with intraoperative frozen section assessment is a specialized surgical procedure recommended for all high-risk tumors or tumors with positive margins during excision. If any part of the specimen shows infiltration of the margin, serial excisions can

be done to the area affected. Mohs micrographic surgery is used for individuals with large (>2 cm) tumors, high-risk histologic subtypes, recurrent BCC, and at locations that are cosmetically sensitive (e.g., face). The availability of surgical margin assessment during the procedure allows for margin control of affected margins and tissue conservation of unaffected margins. The disadvantage of Mohs micrographic surgery is that specialization and/or training are required to perform the procedure. Complications of Mohs micrographic surgery are mainly postoperative and associated with the procedures, especially bleeding. Scarring and cosmetic effects depend on the extent and location of surgery and postsurgical management. Mohs micrographic surgery has the lowest 5-year recurrence rate compared to other surgical procedures. Recurrent BCC is often treated with Mohs micrographic surgery. Cryosurgery is a cytotoxic technique that involves the use of liquid nitrogen spray or probe to induce cell necrosis by exposing tissue to low temperatures.

Nonsurgical approaches of BCC include radiotherapy, local (e.g., topical or local drug injection) therapy, and photodynamic therapy. Radiation therapy is used for management of BCC, often for individuals who are not good surgical candidates (i.e., because of lesion location). Radiation is not recommended for younger individuals, based on the potential for carcinogenesis and long-term cosmetic effect. Radiation is contraindicated for patients with genetic conditions that predispose to skin cancer.

Topical 5-fluorouracil, an antimetabolite antineoplastic agent used intravenously for a variety of cancers, has been used topically in solutions and cream formulations for treatment of BCC when conventional methods are not practical. 5-Fluorouracil monotherapy is often associated with low clearance rates; the actual rate depends on many patient and drug therapy (e.g., concentration) factors. Topical 5-fluorouracil has been used in combination with surgical strategies such as curettage and electrodesiccation, but the benefit of this strategy is not clear. Some challenges with topical 5-fluorouracil are the side effects of local reactions, including pain and burning, pruritus, inflammation, tenderness, and scarring at the site of application. Special instructions for safe handling of the product should be provided for the patient and any caregivers.

Imiquimod is a topical immune response modifier used for treatment of small (<2 cm in diameter) superficial lesions on the trunk, neck, legs, and arms of some patients with a normal immune system. Imiquimod activity is mediated through activation of macrophages and other cells by binding of cell surface receptors (TLR7), which induces proinflammatory cytokines such as interferon- γ and tumor necrosis factor- α . Imiquimod 5% cream may induce Fas receptor-mediated apoptosis in BCC.¹⁰⁴ Imiquimod currently is approved for treatment of external genital and perianal warts and AK on the face and scalp. The optimal regimen for treatment of superficial BCC is imiquimod administered daily for 5 days per week for 6 weeks.¹⁰⁵ Higher dosing regimens have been used but are limited by cutaneous reactions. Longer treatment regimens have not yet shown benefit. The treatment regimens used for nodular BCC often include daily treatment (i.e., 7 days per week) for a longer duration. Side effects usually are mild to moderate skin reactions, including erythema, crusting, flaking, and erosion.

Topical photodynamic therapy involves the use of light to activate a photosensitizer, resulting in the formation of a cytotoxic reactive oxygen species that is selectively destructive to tumor.¹⁰⁶ Photodynamic therapy with methyl 5-aminolevulinate as a photosensitizer has been shown to be effective for superficial BCC but has been shown to be associated with high rates of recurrence.

As with melanoma, the issues with NMSC, such as BCC, extend beyond treatment. Cancer prevention and early detection are important concerns. Early detection efforts extend beyond identification of initial BCCs, with additional focus on identification of any

recurrence or secondary primary. Identification and aggressive followup of groups at high risk for recurrence, individuals with truncal BCC, or those presenting with tumor clusters may impact on the overall success of any treatment program.¹⁰⁷

SQUAMOUS CELL CANCER

SCC is a type of nonmelanoma skin cancer that shows malignant characteristics, including anaplasia, rapid growth, local invasion, and metastatic potential. This type of NMSC is a tumor of the epidermis that grows by expansion and infiltration of the surrounding skin and structures. SCCs, unlike most BCCs, may metastasize via lymphatic or hematogenous spread.

SCC is the second most common form of skin cancer, with more than 200,000 new cases estimated to occur each year in the United States. Risk factors for developing SCC include fair complexion, poor tanning ability, and predisposition to sunburn. UV light is an important risk factor for SCC. A study found that UV exposure correlates with the risk of SCC and the aggressiveness of the SCC.¹⁰⁸ SCC appears to be the skin cancer most associated with chronic exposure to sun. In dark-skinned ethnic groups, SCC is the most common cutaneous malignancy and arises most often on sites of preexisting inflammatory sites, burn injuries, scars, prior sites of radiation therapy, or trauma.¹⁰⁹ Similar to other skin cancers, the risk of SCC is higher in individuals on immunosuppressive medications after organ transplantation.¹¹⁰ Another high-risk group includes patients treated with psoralens and UVA light for psoriasis.¹¹¹

SCC appears as a slightly raised, red, hyperkeratotic macule or papule on sun-exposed sites but may occur anywhere (see Chap. 99). SCCs arising from AK are scaly but tend to be thicker. The lesions may appear like a patch, plaque, nodule, or scaling. Unlike BCC, the edges tend to be fleshy in appearance. SCC most commonly occurs on the face, ear, neck, lip, and back of the hands.

Appropriate biopsy should be performed on any lesion suspected of being SCC, considering the potential for invasive disease. A shave biopsy is sufficient and will not lead to spread of the cancer. A grading system has been devised to classify SCC with respect to percentage of differentiated cells: grade 1 tumors have greater than 75% well-differentiated cells, grade 2 tumors have 50% to 75% well-differentiated cells, grade 3 tumors have 25% to 50% well-differentiated cells, and grade 4 tumors have less than 25% well-differentiated cells. The prognosis of patients with SCC worsens as the percentage of well-differentiated cells decreases.¹¹²

The type of treatment should be selected based on lesion size, anatomic location, depth of invasion, degree of cellular differentiation, and history of treatment. The three general approaches to treatment of SCC are destruction by curettage and electrodesiccation or cryosurgery; removal by traditional excisional surgery or Mohs surgery, and radiation. Invasive SCC can be a potentially lethal neoplasm that warrants close followup. Most cases of SCC are treated by successful complete excision, although patients have a lifelong risk of developing second primary skin cancers, which require repeated surgical resections and reconstructive procedures.¹¹³

Although rarely fatal, SCC has tremendous social and economic burden due to high medical costs. Advanced cases have been shown to result in diminished quality of life, functional impairment, and other serious consequences.¹¹⁴ SCCs are more likely than BCCs to metastasize and lead to mortality. Risk factors that can predict aggressive disease behavior and poor clinical outcome are lesion size at least 4 cm, histologic evidence of perineural and deep invasions into underlying tissues, and inadequate initial treatment of patients with nodal involvement.¹¹⁵ Long-term prognosis for metastatic disease is extremely poor. Ten-year survival rates are less than 20% for patients with regional lymph node involvement and less than 10% for patients with distant metastases.¹¹⁶

Basosquamous carcinomas, which are lesions with microscopic features of both BCC and SCC, should be excised completely because of the aggressive nature of this cancer.

CHEMOPREVENTION OF NONMELANOMA SKIN CANCER

Chemoprevention is the oral or topical use of a dietary or pharmacologic agent to inhibit or reverse the development of cancer. The first step in the development of many skin cancers is exposure to UV radiation. One step in chemoprevention is the protection of individuals against exposure, or “unsafe” exposure to UV radiation. Other strategies target the many steps between exposure to the UV radiation and development of cancer. The retinoids have been shown to be chemopreventive in patients with xeroderma pigmentosum, renal transplant recipients, and individuals with risk associated with premalignant lesions (>10 AKs). In addition, oral retinoids (acitretin and isotretinoin) has been shown to reduce the development of precancers and skin cancers in high-risk patients, specifically individuals with a history of SCC and BCC.¹¹⁷ Side effects of retinoids depend on dose and range from mucocutaneous reactions to elevations in cholesterol, triglycerides, and liver function tests. Chronic use of retinoids causes skeletal changes associated with demineralization and calcification of ligaments and vertebral disks. These agents are associated with toxicities, and their therapeutic effects are limited to the time the individual is taking the drug. When the medication is stopped, the benefit is diminished. Approaches to optimizing safety and effectiveness of these agents have been published.¹¹⁸

Potential agents for chemoprevention of NMSC include a variety of substances, including many over-the-counter topical or oral preparations. Vitamin E, β -carotene, and selenium once were thought to prevent skin cancer but now are not considered effective.¹¹⁷

Hematopoietic Stem Cell Transplantation

JANELLE B. PERKINS AND GARY C. YEE

KEY CONCEPTS

- 1 Hematopoietic stem cell transplantation (HSCT) is a process that involves intravenous infusion of hematopoietic stem cells from a donor into a recipient, after the administration of chemotherapy with or without radiation. The rationale is to increase tumor cell kill by increasing the dose of chemotherapy. Immune-mediated effects contribute to the tumor cell kill observed after allogeneic HSCT.
- 2 Hematopoietic stem cells used for transplantation can come from the recipient (autologous) or from a related or unrelated donor (allogeneic). If the related donor is a twin, the transplant is referred to as a syngeneic transplant.
- 3 Human leukocyte antigen (HLA) mismatching of allogeneic donor/recipient pairs at either a class I or class II locus correlates with the risk of graft failure, graft-versus-host disease (GVHD), and survival. The ideal donor is matched at HLA-A, HLA-B, HLA-C, HLA-DRB1, and HLA-DQB1.
- 4 Hematopoietic stem cells are found in the bone marrow, peripheral blood, and umbilical cord blood. Because of their rarity and their similarity to other cells, hematopoietic stem cells are difficult to isolate and measure. These stem cells express the CD34 antigen, and quantification of the number of CD34⁺ cells has become a clinically useful measure of the number of hematopoietic stem cells.
- 5 Because of clinical and economic advantages, peripheral blood has replaced bone marrow as the source of hematopoietic stem cells in the autologous and adult allogeneic HSCT setting. Bone marrow continues to be the primary graft source in children undergoing allogeneic HSCT.
- 6 The purpose of the preparative (or conditioning) regimen in traditional myeloablative transplants is two-fold: (a) maximal tumor cell kill and (b) immunosuppression of the recipient to reduce the risk of graft rejection (allogeneic HSCT only).
- 7 Reduced-intensity conditioning regimens (including those that are nonmyeloablative) have been developed in order to reduce early posttransplant morbidity and mortality while maximizing the graft-versus-tumor (GVT) effect of the allogeneic graft. The advantage of this approach is that patients who otherwise would not be eligible for allogeneic HSCT now can be offered a potentially curative therapy.
- 8 Posttransplant immunotherapy is based on the GVT effect caused by certain subsets of T cells responsible for eradication of malignant cells. Posttransplant immunotherapy includes the use of donor lymphocyte infusions, immunomodulatory cytokines, monoclonal antibodies, or antitumor vaccines.
- 9 Transplant-related mortality associated with allogeneic HSCT ranges from 10% to 80%, depending mostly on age, donor, and disease status. Major causes of death include infection, organ toxicity, and GVHD. The most common cause of death after autologous HSCT is disease relapse. Transplant-related mortality usually is less than 5%, depending on the conditioning regimen, age, and disease status.
- 10 Treatment of acute GVHD often is unsuccessful, and the resulting complications can be fatal. Patients undergoing allogeneic HSCT are given prophylactic immunosuppressive therapy, which inhibits T-cell activation and/or proliferation. The most commonly used GVHD prophylaxis regimen is cyclosporine or tacrolimus and methotrexate.
- 11 Initial treatment of both acute and chronic GVHD consists of prednisone, either alone or combined with cyclosporine or tacrolimus. Treatment of patients with steroid-refractory GVHD is problematic.

1 Hematopoietic stem cell transplantation (HSCT) is a process that involves intravenous infusion of hematopoietic stem cells from a compatible donor into a recipient, usually after administration of high-dose chemotherapy. Hematopoietic stem cells can be derived from the bone marrow, peripheral blood, or umbilical cord blood. The rationale for HSCT for treatment of malignant disease is based on studies showing that most anticancer drugs have a steep dose-response relationship and that bone marrow suppression limits the chemotherapy dosage that can be safely administered. Although standard-dose chemotherapy can prolong survival in many cancer patients, most patients are not cured of their disease (Fig. 142-1). Infusion of hematopoietic stem cells allows administration of very high doses of chemotherapy (as much as 10-fold higher). If tumor cells that are resistant to standard doses are sensitive to higher doses of chemotherapy, then tumor cell kill will be greatly increased, and the likelihood of cure would be higher with HSCT. However, the chemotherapy dose cannot be escalated indefinitely because of the risk for death caused by nonhematopoietic toxicity. The success and increasing use of reduced-intensity regimens (including those used in nonmyeloablative transplants [NMT]) show that immune-mediated effects contribute to the tumor cell kill observed after allogeneic HSCT.

High-dose chemotherapy followed by HSCT has become an important modality for treatment of a variety of malignant and nonmalignant

Learning objectives, review questions,
and other resources can be found at
www.pharmacotherapyonline.com.

FIGURE 142-1. Patients represented by the middle column are the best candidates for hematopoietic stem cell transplantation because the technique allows for administration of chemotherapy or radiation in doses that otherwise would be intolerable because of severe myelosuppression.

nant diseases. It is estimated that 50–60,000 transplants are performed worldwide each year, primarily for malignant diseases.¹ Approximately 40% of these transplants are performed in North America. The number of transplants has declined in the last decade because of declining use of autologous transplants for breast cancer and increasing use of tyrosine kinase inhibitors for treatment of chronic myelogenous leukemia. However, this decline is being offset in part by an increase in the number of patients receiving umbilical cord blood (UCB) transplants and patients older than 55 years being transplanted after reduced-intensity conditioning regimens.

Historically, the most common type of donor was a genetically nonidentical individual, such as a histocompatible sibling (referred to as allogeneic HSCT [alloHSCT]). However, the number of autologous transplants in which the patient serves as his or her own donor has increased dramatically, and the number of autologous transplants (autoHSCT) performed (approximately 35,000) currently exceeds the number of alloHSCTs (approximately 20,000) performed each year.¹ This chapter focuses on the application of HSCT for treatment of malignant disease, but it is important to note that many nonmalignant diseases—including aplastic anemia, thalassemia, sickle cell anemia, immunodeficiency disorders, and other genetic disorders—are potentially curable with alloHSCT. Transplantation is also being investigated as a treatment modality for patients with life-threatening autoimmune diseases, such as rheumatoid arthritis, systemic and multiple sclerosis, and systemic lupus erythematosus.

This chapter summarizes the procedures involved in HSCT, current issues in the field of HSCT, and application of HSCT in the treatment of malignant diseases. More detailed information on HSCT can be found in published reviews and books.^{2–5} Information on HSCT also can be found on several websites (Center for International Blood and Marrow Transplant Research [CIBMTR; www.cibmtr.org] and National Marrow Donor Program [www.marrow.org]).

DONORS AND HISTOCOMPATIBILITY TESTING

2 Different types of donors are used in HSCT. In *autologous* transplants, patients receive their own hematopoietic stem cells, which were collected and stored before intensive cytotoxic therapy. In *syngeneic* transplants, an identical twin serves as the donor. In *allogeneic* transplants, the donor is genetically not identical to the recipient but shares some common tissue antigens. Immunologic compatibility is evaluated by studies of cell surface antigens (human leukocyte antigens [HLAs]) encoded by genes of the major histo-

compatibility complex (MHC), which is located on the sixth chromosome.⁶ The genes of the HLA system are clustered in three distinct regions designated as class I, class II, and class III. Class I and class II antigens function as major transplantation antigens; products of class III genes have other important roles in the immune system. The major class I loci in humans are referred to as HLA-A, HLA-B, and HLA-C. The one major class II locus is HLA-D. Class II genes encode for the α and β polypeptide chains of the class II molecules. The designation of class II genes consists of three letters: the first (D) indicates the class, the second (M, O, P, Q, or R) the family, and the third (A or B) the chain (α and β , respectively). Class I and class II antigens differ in their tissue distribution, structure, and function. Class I antigens are expressed on virtually all nucleated cells and serve as the primary targets for cytotoxic T lymphocytes. Class II antigens normally are expressed only on macrophages, B lymphocytes, and activated T lymphocytes, and they serve as the primary targets for helper T lymphocytes.

HLA genes are closely linked to one another within the MHC and generally are inherited together. The series of HLA alleles occurring on a single chromosome is termed a *haplotype*. The combination of two parental haplotypes inherited by an individual determines an individual's *genotype*. For a given HLA locus, an individual generally has two different corresponding antigens expressed in their genotype (e.g., HLA-A2 and HLA-A3; HLA-B44 and HLA-B7; HLA-DR4 and HLA-DR2).

Historically, the most important HLA loci in allogeneic HSCT were HLA-A, HLA-B, and HLA-D (or HLA-DR [D-Related]). Typing for HLA-A and HLA-B traditionally was performed by serologic typing with standard microcytotoxicity assays having panels of antisera containing HLA molecules.⁷ HLA types determined by this method were reported as the locus (A or B), followed by a number that designated the cell surface HLA antigen (e.g., HLA-A2). Typing for the HLA-D was performed with cellular typing methods, such as the mixed lymphocyte reaction (MLR) or mixed lymphocyte culture (MLC). A “positive” MLR or MLC indicated incompatibility somewhere in the HLA-D region. Individuals who had a low degree of reactivity in the MLR or MLC (expressed as a low percent relative response), and who met other selection criteria, could serve as donors.

Serologic methods of HLA typing have been replaced by DNA-based techniques that use polymerase chain reaction (PCR) amplification of specific HLA genes from genomic DNA. DNA typing methods are categorized by the level of discrimination they provide in defining the sequence of an HLA gene. *Low-resolution* methods provide limited sequence information about a particular HLA gene and allow identification only to the antigen level, much like older serologic methods. Results of low-resolution typing are given in the form HLA-A*02, where the asterisk denotes DNA-based typing and the corresponding serologic equivalent of the antigen is labeled as a two-digit number. Low-resolution typing typically is used to identify sibling donors. However, neither serologic nor low-resolution techniques can distinguish the extremely polymorphic nature of many of the HLA antigens. For example, more than 2,800 alleles have been defined, approximately 1,900 HLA class I alleles and approximately 900 HLA class II alleles (www.ebi.ac.uk/imgt/hla/stats.html). Each of these alleles may correspond to a unique HLA molecule. Different alleles can be distinguished only by *high-resolution* typing techniques. Results of high-resolution techniques are reported as the corresponding HLA antigen, followed by an asterisk and a four-digit number identifying the allele. For example, the HLA-A*02 antigen may be encoded by alleles HLA-A*0201, A*0202, A*0203, etc. (up to A*0249). In some cases, the four-digit allele name includes several alleles. For example, HLA-B*4006 includes B*40060101 and B*40060102. Methods that define the HLA type A beyond the serologic level but short of the allele level are termed *intermediate-*

resolution. For example, this method might identify the presence of either HLA-A*0201 or A*0205 but may not be able to discriminate one allele from the other.

③ HLA mismatching at either the class I and II locus correlates with the risk of graft failure, graft-versus-host disease (GVHD), and survival.⁷ HLA *antigen* mismatches, particularly when they involve both class I and II antigens, are generally more important risk factors than *allele* mismatches. In an analysis of 1,874 patients who received matched unrelated donor transplants under the auspices of the National Marrow Donor Program (NMDP), low-resolution mismatches at HLA-A, HLA-B, HLA-C, and HLA-DRB1 each were similarly associated with increased risk of GVHD and mortality.⁸ High-resolution mismatches, particularly at HLA-A and HLA-DRB1, also were associated with increased mortality. In addition, among patients who received transplants from “6 antigen-matched” (HLA-A, HLA-B, and HLA-DRB1 matched) donors, the number of allele mismatches correlated with the risk of grades III to IV acute GVHD and survival. The observation concerning the prognostic value of HLA-C was particularly important, since until that time the locus was omitted from most matching algorithms. HLA-C typing now is included in standard typing protocols.

The most common donor for alloHSCT is an HLA-identical sibling. The odds that any one full sibling will match a patient are 1:4. Only approximately 30% of Americans have an HLA-identical sibling. In an effort to offer alloHSCT to patients who lack an HLA-identical sibling donor, alternative donors are being used. Rarely, a parent is HLA identical with his or her child. A relative can be a zero- (rare), one-, two-, or three-loci antigen mismatch (assuming testing for HLA-A, HLA-B, and HLA-DR antigens). Although some patients who receive transplants from mismatched related donors experience long-term survival, their risks of graft failure and acute GVHD are higher than for recipients of matched-sibling transplants.⁹ It is estimated that only another 10% of patients will have a closely HLA-matched related donor.

The most common type of alternative donor is an individual unrelated to the recipient who is fully or closely HLA-matched. To facilitate identification of these donors, the NMDP (www.marrows.org) was started in 1986 with initial funding from a U.S. Navy contract. To date, the NMDP has registered more than seven million donors in the United States, and the NMDP has facilitated more than 30,000 matched unrelated donor transplants. Patients searching the NMDP Registry have access to an additional four million donors through agreements with international cooperative registries. Approximately one third of the alloHSCTs performed worldwide are from unrelated donors.¹ The NMDP currently requires that the recipient be typed by high-resolution methodology at HLA-A, HLA-B, HLA-C, and HLA-DRB1. The NMDP also suggests typing other DR and DQ alleles when developing a search strategy. Although it is the transplant center's responsibility to select the donor, the NMDP *recommends* that selected donor and recipient be matched at HLA-A, HLA-B, HLA-C, and HLA-DRB1 by high-resolution typing, when possible. To permit an NMDP donor as a source for transplant, the NMDP *requires* a low-resolution match for at least five of six HLA antigens at HLA-A, HLA-B, and HLA-DR for marrow or peripheral blood transplants and four of six for UCB transplants. The following guidelines should be used for unrelated donor selection: (a) assume that HLA-A, HLA-B, HLA-C, and HLA-DRB1 are equally important; (b) avoid antigen mismatches, if possible; (c) accept one allele mismatch over one antigen mismatch; and (d) minimize the number of allele mismatches.¹⁰

The likelihood of any one unrelated individual being an antigen-level match ranges from 1:100 to 1:1,000,000, depending on the prevalence of the patient's HLA type and ethnic background. With the current size of the NMDP registry, the matching likelihood is higher than 80% for white people. Because most minorities are not as well represented as whites in the program, the likelihood of

finding a donor for patients from certain ethnic groups is lower. Agreements between NMDP and international registries may improve the likelihood of finding donors for patients who are not white. Another limitation is the time needed to search for a potential donor. Some donor searches take up to 3 to 4 months, and many patients with acute leukemia may relapse while waiting for completion of the search. Cost is a concern, with the cost for donor search and marrow procurement ranging from \$25,000 to \$50,000. The clinical results of alloHSCT with unrelated donors are encouraging. With improved HLA typing techniques and better supportive care, most reported outcomes are no longer significantly different than with related sibling donors.^{7,11,12}

COLLECTION OF HEMATOPOIETIC STEM CELLS

Hematopoietic stem cells serve as “mother” cells for all blood cells, including erythrocytes, leukocytes, and platelets (see Chap. 103).¹³ Stem cells have varying degrees of “stemness.” True *pluripotent* stem cells are capable of replicating indefinitely and can give rise to stem and progenitor cells of *all* tissues. *Multipotent* stem cells, such as hematopoietic stem cells, have the capacity for self-renewal and can differentiate into more than one cell type in a particular tissue lineage. Because of their capacity for self-renewal, hematopoietic stem cells are capable of repopulating the recipient's marrow.

④ Hematopoietic stem cells are rare cells, composing less than 0.01% of all bone marrow cells. Isolation and quantitative measurement of stem cells is extremely difficult because of their rarity and their similar appearance to other cells. For these reasons, surrogate markers are used to measure the number of stem cells. Determination of the number of cells expressing the CD34 antigen (CD34⁺ cells), as determined by flow cytometry, has become the standard method of measuring hematopoietic stem cell content.¹⁴ CD34 is an antigen expressed on hematopoietic stem cells and other early progenitor cells.

Hematopoietic stem cells are found in the bone marrow, peripheral blood, and UCB. Hematopoietic stem cells from the bone marrow are obtained by multiple aspirations from the anterior and posterior iliac crests while the donor is under general anesthesia. The procedure takes approximately 1 hour and yields 200 to 1,500 mL, depending on the size of the donor. The marrow is transferred into tissue culture medium containing preservative-free heparin. The pooled marrow is passed through a series of stainless steel screens to break up aggregated particles, resulting in an essentially single-cell suspension. In alloHSCT, the marrow stem cells are given to the recipient 12 to 24 hours after harvest. In autoHSCT, the marrow is frozen and stored until needed. After intravenous infusion, the marrow stem cells enter the systemic circulation and find their way to the bone marrow cavity, where they reseed and grow in the bone marrow microenvironment. Although the donor experiences local soreness for a few days, the procedure usually is well tolerated, with no delayed complications resulting from the marrow aspiration. The major risk of serving as a marrow donor is the risk of undergoing general anesthesia.

Hematopoietic stem cells in peripheral blood (peripheral blood progenitor cells or peripheral blood stem cells [PBSCs]) are found in the mononuclear fraction of white blood cells (lymphocytes and monocytes) and are collected by a procedure called *leukapheresis* (or *apheresis*). In this outpatient procedure, approximately 9 to 14 L of blood is processed over several hours during each daily leukapheresis session. Most of the blood cells are returned to the donor, and each leukapheresis yields approximately 200 mL of cells.

The number of hematopoietic stem cells that circulate in peripheral blood normally is too low for this approach to be technically

FIGURE 142-2. Schema for collection of peripheral blood progenitor cells after hematopoietic growth factor administration (top) or after chemotherapy and hematopoietic growth factor administration (bottom). Symbols with gray shading represent procedures performed only if adequate numbers of CD34⁺ cells have not been collected. (G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor.)

feasible. Without mobilization techniques, at least six leukaphereses usually are required to collect a sufficient number of PBSCs. Several methods have been used clinically to “mobilize” hematopoietic stem cells from the bone marrow into peripheral blood.^{14–17} The first method is administration of chemotherapy, which can briefly increase the number of PBSCs as much as 100-fold. The second and most common method is administration of a recombinant hematopoietic growth factor such as granulocyte colony-stimulating factor (G-CSF; filgrastim) or granulocyte-macrophage colony-stimulating factor (GM-CSF; sargramostim). Each agent has its own potential advantages and disadvantages.¹⁸ Both agents are approved by the Food and Drug Administration for this indication, but G-CSF is the most commonly used growth factor. Commonly used dosages are 5 to 16 mcg/kg/day for G-CSF and 250 mcg/m²/day for GM-CSF. The combination of chemotherapy followed by a hematopoietic growth factor increases the number of PBSCs to a greater extent than either method alone. This approach is more expensive and is associated with more adverse effects than a growth factor alone, but the number of leukaphereses is reduced, and the additional chemotherapy may further reduce the tumor burden before transplant. With current mobilization techniques, most HSCT centers collect sufficient PBSCs with three or fewer leukaphereses. Figure 142–2 shows representative schemas for mobilization and collection of PBSCs.

Several studies show that the number of CD34⁺ cells infused correlates significantly with the rate of neutrophil and platelet recovery after high-dose chemotherapy.^{14–16} Rapid neutrophil recovery usually is observed in patients who receive at least 2×10^6 CD34⁺ cells/kg (body weight of recipient). More rapid platelet recovery is observed when at least 5×10^6 CD34⁺ cells/kg are transplanted compared to lower cell doses. As a result, most transplant centers use 2×10^6 CD34⁺ cells/kg as a minimum number to collect for autologous transplant, with an optimal target of 5×10^6 CD34⁺ cells/kg. Some studies suggest clinical and economic benefits are associated with infusion of higher CD34⁺ cell doses.^{19,20} Although the difference in the median number of days to neutrophil or platelet recovery usually is no more than 1 to 2 days in patients who receive more than 5×10^6 CD34⁺ cells/kg compared to those who receive less than 5×10^6 CD34⁺ cells/kg, fewer patients who receive more than 5×10^6 CD34⁺ cells/kg have delayed engraftment. This small effect may be important, because patients with delayed engraftment consume a disproportionate share of healthcare resources, such as additional transfusions, hospital days, and drugs (e.g., antibiotics and growth factors).

The optimal regimen for mobilizing PBSCs is not clear.^{15–17} Results of some randomized studies show that G-CSF alone provides higher yields of CD34⁺ cells than GM-CSF alone.^{17,18} Higher doses of G-CSF or twice-daily administration of G-CSF also may mobilize more CD34⁺ cells. Many cytokines and other novel agents,

given either alone or in combination with G-CSF, are being evaluated for use in mobilization regimens.^{16–18,21}

In some otherwise-eligible transplant candidates, an optimal number of CD34⁺ cells will not be obtained with standard mobilization methods. Risk factors associated with poor mobilization include the amount (greater than six cycles) and type of prior chemotherapy (alkylating agents) and prior radiation therapy.^{15–17} Older age and some diagnoses also are associated with poor mobilization. Several strategies for overcoming the obstacle of poor mobilization have been evaluated, including remobilization with the same or higher doses of the same hematopoietic growth factor, a combination of hematopoietic growth factors, or a combination of chemotherapy and a hematopoietic growth factor. Bone marrow harvest is an option but often is of limited value.

5 Use of peripheral blood instead of bone marrow as a source of hematopoietic stem cells offers several clinical and economic advantages. The most clinically important advantage is that patients who receive mobilized PBSCs experience more rapid hematopoietic engraftment. Although engraftment of all lineages is more rapid when PBSCs are used, the most significant effect is observed with platelet recovery. Patients who receive mobilized PBSCs experience platelet recovery as much as 2 to 3 weeks earlier and require fewer platelet transfusions than those who receive bone marrow stem cells. As a result, patients usually are discharged earlier from the hospital, so the overall cost of autoHSCT is reduced with the use of PBSCs. Another advantage is that the donor does not experience the discomfort associated with marrow aspirations and is not exposed to the risk associated with general anesthesia. PBSCs may be less likely to be contaminated with malignant cells compared with marrow stem cells. Finally, because PBSCs are collected from the mononuclear cell fraction, a fraction that also contains immunocompetent cells (e.g., natural killer [NK] cells and T lymphocytes), some investigators believe that infusion of PBSCs represents a form of “adoptive immunotherapy.” In this model, NK cells and lymphocytes targeted against tumor cells help to kill residual tumor cells. As a result of these clinical and economic advantages, peripheral blood has replaced bone marrow as the source of stem cells in the autologous setting.

Peripheral blood is increasingly being used as a source of hematopoietic stem cells in alloHSCT.^{22,23} Approximately 75% of alloHSCTs performed in adults currently come from PBSCs harvested from normal donors, despite early concerns that the increased numbers of T lymphocytes found in peripheral blood could increase the risk of GVHD.¹ Concerns also were raised over the safety and ethics of administering G-CSF to normal individuals volunteering as donors. G-CSF is generally well tolerated. Short-term effects are similar to those seen in cancer patients (e.g., bone pain, headache, fever, arthralgias, malaise). Although there are concerns about increased risk of acute leukemia in healthy subjects given G-CSF, no higher risk has been observed.²⁴

Randomized controlled trials and large registry studies show that patients who received allogeneic PBSC transplants from HLA-identical siblings experienced more rapid hematopoietic recovery and required fewer transfusions compared to patients receiving bone marrow.^{22,23,25} The difference in the rate of engraftment may be related to the three-fold higher numbers of CD34⁺ cells infused in recipients of PBSC transplants. Although most of these studies did not report an increased risk of acute GVHD or transplant-related mortality in patients receiving allogeneic PBSC transplants, a higher incidence of chronic GVHD has been observed. In a meta-analysis of nine randomized trials, the risk of chronic GVHD was nearly two-fold higher for patients who received allogeneic PBSC transplants compared to those who received bone marrow transplantation (BMT).²⁶ Some studies have reported a correlation between CD34⁺ cell dose and the risk of chronic GVHD, which suggests that the higher CD34⁺ cell dose explains, in part, the

increased risk of chronic GVHD.²⁷ Use of PBSCs from unrelated donors is being investigated.²³ Approximately 25% of the matched unrelated transplants coordinated by the NMDP use PBSCs.

In addition to bone marrow and peripheral blood, hematopoietic stem cells are found in UCB. UCB is an attractive source for several reasons.^{28,29} Because the stem cells are collected from placental blood, there is no risk to the mother or the baby and a very low risk of transmissible infectious diseases, such as cytomegalovirus and Epstein-Barr virus. The cells are available immediately because the donor does not have to be located and the material harvested. UCB initially was obtained from siblings, but now recipients of transplants from unrelated donors account for almost all patients who receive UCB transplants. More than 8,000 unrelated UCB transplants have been performed worldwide.

Results of uncontrolled studies show that recipients of UCB transplantation have a lower risk of GVHD but a higher risk of graft failure compared with recipients of BMT.²⁸ Recipients of UCB transplantation usually receive a CD34⁺ cell dose more than 1 log lower than that given to recipients of BMT, and this difference in CD34⁺ cell dose may explain the delayed engraftment in recipients of UCB transplantation. The number of infused total nucleated and CD34⁺ cells correlates with outcomes following UCB transplantation. Although no randomized comparisons have been performed, a recently published analysis of data from the CIBMTR and the New York Blood Center showed similar survival in children with acute leukemia who underwent either unrelated UCB transplantation or BMT.³⁰

A major limitation of UCB transplants is the small volume of blood collected, usually 60 to 150 mL. Although the relatively low numbers of hematopoietic cells may be adequate for hematopoietic engraftment in children and small adults, it may not be adequate for larger recipients. Efforts to expand the number of hematopoietic stem cells include culturing them *ex vivo* with combinations of hematopoietic growth factors or “pooling” several units of UCB for one recipient. Preliminary results with unrelated UCB transplants in adult recipients are encouraging,^{28,29} but more experience is needed with adult recipients before this procedure can be recommended for that population.

APPROACHES TO ERADICATE MALIGNANT CELLS

MYELOABLATIVE CONDITIONING REGIMENS

6 Nearly all patients who receive HSCT must be prepared (or “conditioned”) before infusion of hematopoietic stem cells.³¹ In patients with malignant disease, the goal of the preparative or conditioning regimen is to kill as many malignant cells as possible. Myeloablative conditioning regimens usually include commonly used anticancer drugs given at very high doses, doses that would be associated with severe and life-threatening bone marrow suppression if hematopoietic stem cells were not infused. In patients undergoing alloHSCT, another purpose of the conditioning regimen is to suppress the immune system of the recipient so that the graft is not rejected.

In some conditioning regimens, the only drug given is cyclophosphamide, a drug with both immunosuppressive and cytotoxic effects. Because of the inadequate antitumor activity of cyclophosphamide in some types of cancers, other drugs are often added. Examples of drugs that are included in preparative regimens are cytarabine (ara-C), busulfan, thiopeta, etoposide (VP-16), carboplatin, cisplatin, carmustine (BCNU), melphalan, and ifosfamide.³¹

Total-body irradiation (TBI) is sometimes used in pretransplant conditioning regimens, particularly in patients with leukemia.³² In patients with malignant disease, the rationale is to eradicate malignant cells located in areas inaccessible to the systemic circulation and thus to the cytotoxic agents. TBI also has significant immunosuppres-

sive activity. Historically, the standard TBI regimen involved administration of a midline tissue dose of approximately 1,000 cGy (1 cGy = 1 rad), which is more than twice the lethal dose of radiation for a normal person. Many centers currently give fractionated (split over several days, once or twice a day) rather than single-dose TBI to patients with malignant disease. The rationale for this approach is an improved therapeutic ratio, that is, destruction of more leukemic cells and marrow stem cells while sparing other normal tissues. The acute toxicities of TBI consist of fever, nausea, vomiting, diarrhea, mucositis, and tender swelling of the parotid gland. Long-term complications of TBI-containing regimens include cataract formation, growth retardation, carcinogenesis, permanent reproductive sterility, and secondary malignancies.

Leukemia

Most patients with leukemia undergoing alloHSCT receive either cyclophosphamide and TBI (CyTBI) or busulfan and cyclophosphamide (BuCy). When given with TBI, cyclophosphamide usually is given first as two doses of 60 mg/kg/day, followed by TBI. TBI can be given as a single dose or fractionated over several days. One variation of the regimen is administration of hyperfractionated TBI first, followed by cyclophosphamide. In that regimen, which is used primarily in patients with acute lymphoblastic leukemia (ALL), 11 TBI doses of 120 cGy are given; doses are given three times per day on days –7 to –5 (*Note:* Day 0 is designated as the day of transplant) and twice per day on the last day (day –4). After TBI, two doses of cyclophosphamide are given intravenously once per day at a dosage of 60 mg/kg on days –3 and –2.

Because of the many acute and chronic toxicities of TBI, the need for specialized equipment, and the lack of convincing evidence showing superiority over non-TBI-containing regimens, most protocols no longer include TBI in the conditioning regimen. One widely used conditioning regimen that does not include TBI is busulfan and cyclophosphamide (BuCy). In the original regimen (BuCy4), busulfan was given orally at a dosage of 1 mg/kg every 6 hours (4 mg/kg/day) for 16 doses on days –9 to –6, followed by four doses of cyclophosphamide given intravenously once daily at a dosage of 50 mg/kg on days –5 to –2. In one widely used modification of the regimen (BuCy2), the total cyclophosphamide dosage is reduced from 200 (50 × 4) to 120 (60 × 2) mg/kg. Plasma busulfan concentrations are monitored at some centers because some studies suggest that systemic exposure correlates with outcome,³³ and use of a targeted busulfan and cyclophosphamide preparative regimen may improve patient outcome.³⁴ A commercially available intravenous form of busulfan (Busulfex) reduces some of the interpatient variability in systemic exposure.³⁵ Use of intravenous busulfan may reduce the risk of sinusoidal obstruction syndrome. The dose of intravenous busulfan approved for pretransplant conditioning regimens is 0.8 mg/kg every 6 hours for 4 days. Once-a-day dosing regimens that may facilitate outpatient administration of intravenous busulfan have been developed.

CLINICAL CONTROVERSY

Based on studies showing that busulfan concentrations correlate with outcomes, some centers routinely monitor busulfan concentrations in patients undergoing alloHSCT. However, the busulfan assay is not available at most centers because it is technically difficult and the number of patients receiving BuCy is small. Therefore, therapeutic drug monitoring of busulfan usually is inconvenient and expensive because samples must be sent to another center. Some centers have switched to intravenous busulfan to reduce the interpatient variability in pharmacokinetics and avoid the need for monitoring busulfan concentration.

Several prospective randomized studies have compared CyTBI to BuCy in patients with acute or chronic myelogenous leukemia undergoing alloHSCT.^{36–38} The results of these studies show that BuCy has similar or greater antileukemic activity than CyTBI in patients with chronic myelogenous leukemia (CML). However, some studies suggest that the CyTBI regimen in patients with acute myelogenous leukemia (AML) was associated with slightly better disease-free survival rates than BuCy. However, none of the patients in these studies who were randomized to BuCy received busulfan doses adjusted on the basis of plasma concentrations. In children with ALL, a retrospective study showed higher survival among children who received CyTBI as a preparative regimen.³⁹ Long-term toxicities between the two regimens appear to be comparable.

Other drugs have been evaluated in addition to or instead of cyclophosphamide in the preparative regimen.^{31,38} Examples include cytarabine or etoposide in combination with TBI. No convincing data indicate that any of these regimens is superior to CyTBI or BuCy. The same preparative regimens usually are given to patients undergoing autoHSCT for leukemia.

Lymphoma

Based on experience in patients with leukemia, CyTBI was the initial regimen used for many patients with Hodgkin's and non-Hodgkin's lymphoma, particularly in alloHSCT. Most preparative regimens used in autoHSCT for lymphoma include an alkylating agent (either cyclophosphamide or melphalan), carmustine, and etoposide.^{31,40} TBI usually is not included in the conditioning regimen because many patients with lymphoma have received prior radiotherapy. One widely used regimen in autoHSCT is the CBV regimen, which consists of cyclophosphamide, carmustine (BCNU), and etoposide (VP-16). In that original regimen, cyclophosphamide was given at a dosage of 1.5 g/m² on days –6 to –3, carmustine at a dosage of 300 mg/m² on day –6, and etoposide at a dosage of 100 mg/m² every 12 hours for six doses on days –6 to –4. Some centers have modified the original CBV regimen by changing the dosage of some of the drugs or adding or substituting other drugs, including cytosine arabinoside, etoposide, melphalan, lomustine, and thioguanine. Other widely used nitrosourea-based regimens are BEAC (BCNU, etoposide, ara-C, and cyclophosphamide) and BEAM (BCNU, etoposide, ara-C, and melphalan). No single preparative regimen is clearly superior to other regimens for treatment of lymphoma.

Although TBI usually is not included in the conditioning regimen, some form of radiation therapy is often given, depending on the type, location, and extent of disease. Instead of TBI, some patients receive localized radiation in high doses to areas of residual or bulky disease. Many patients with Hodgkin's lymphoma have received thoracic radiation as primary therapy for their disease, so TBI usually is avoided in these patients. Conversely, most patients with indolent non-Hodgkin's lymphoma receive TBI as part of their preparative regimen because of the known sensitivity of these tumors to low doses of radiation.⁴¹

One disadvantage of TBI is that it delivers as much radiation to normal organs as it does to tumor cells. The availability of anti-CD20–radiolabeled monoclonal antibodies offers the potential to deliver more radiation to tumor cells and less to normal organs. In these trials, ¹³¹I-tositumomab was given, either alone or combined with high-dose cyclophosphamide and etoposide, with autoHSCT in patients with non-Hodgkin's lymphoma.^{42,43} With this approach, very high radiation doses could be delivered to sites of disease. Preliminary results with this approach are encouraging.⁴⁴

Solid Tumors

Most conditioning regimens in autoHSCT include at least one alkylating agent because of their steep dose–response curve. Many regi-

mens include more than one alkylating agent, based on preclinical studies showing that resistance to a specific alkylating agent does not impart cross-resistance to other alkylating agents. Other anticancer drugs that modulate the activity of alkylating agents in a synergistic manner, such as etoposide, are attractive drugs for inclusion in high-dose preparative regimens. The dose of nonalkylating agents with antitumor activity has been increased in patients with solid tumors based on tumor-specific activity. Examples include mitoxantrone, paclitaxel, and topotecan. Whether these regimens offer any clinical advantages to those that include only alkylating agents is not clear.

REDUCED-INTENSITY CONDITIONING REGIMENS

7 The primary goal of myeloablative conditioning regimens is to eradicate malignant cells by administering very high doses of anticancer drugs. It was later discovered that donor T cells contributed to the tumor cell kill observed after alloHSCT, an effect referred to as the *graft-versus-tumor* (GVT) effect. Evidence for the GVT effect is based on retrospective studies showing that patients who developed GVHD had a lower risk of leukemic relapse than those who did not develop GVHD.⁴⁵ However, the overall survival rate was not different because of the increased nonrelapse mortality associated with GVHD. Other anecdotal evidence supporting a T-cell-mediated GVT effect was the increased risk of relapse found with T-cell-depleted transplants compared to unmodified transplants and the difference in relapse rates between recipients of syngeneic and HLA-identical sibling transplants.

Attempts to deliver higher doses of chemotherapy or TBI generally did not improve survival but increased regimen-related toxicities. In the early 1990s, researchers began to evaluate reduced-intensity conditioning (RIC) regimens as a method to take advantage of the GVT effect. The rationale for RIC is based on the assumption that most of the tumor cell kill associated with alloHSCT is the result of the GVT effect and not the result of the myeloablative doses of chemotherapy or radiation (Fig. 142–3).^{46–49} If this assumption is correct, the major role of the conditioning regimen is to suppress the host immune system, thus allowing engraftment of donor hematopoietic stem cells and donor T-cell cytotoxicity. Approximately 30% of allogeneic transplants are performed with RIC regimens.¹

RIC often is used synonymously with “nonmyeloablative,” and NMTs refer to transplants performed with these conditioning regimens. A *nonmyeloablative regimen* is defined based on the following characteristics: (a) no eradication of host hematopoiesis and reversible myelosuppression (usually less than 28 days) without stem cell support, (b) presence of mixed chimerism upon engraftment, and (c) low rates of nonhematologic toxicity.⁴⁸ Based on these criteria, not all RIC regimens should be considered nonmyeloablative. A major advantage of this approach is that potentially curative transplants are being offered to patients who typically would not be considered for alloHSCT because of their unacceptably high risk of transplant-related complications (e.g., increased age or moderately compromised organ function). More than 60% of patients receiving RIC regimens are older than 50 years compared to less than 20% of those receiving myeloablative regimens.¹ In addition, because of the lower rate of toxicity, alloHSCT with RIC can be offered to patients who have relapsed after traditional myeloablative autologous or allogeneic transplants.

A number of RIC regimens that vary in their cytotoxic (and thus myelosuppressive) and immunosuppressive activity have been developed.^{46–49} Most regimens include fludarabine (125–240 mg/m²) because of its potent immunosuppressive activity, combined with either low-dose TBI (at doses up to 8 Gy) or an alkylating agent, such as cyclophosphamide (2–3.6 g/m² or 120–200 mg/kg), busulfan (up to 10 mg/kg), or melphalan (up to 180 mg/m²). Antithymocyte globulin or alemtuzumab is sometimes given for additional immuno-

FIGURE 142-3. Schema for nonmyeloablative transplantation for hematologic malignancy. Recipients (R) receive a nonmyeloablative conditioning regimen and an allogeneic hematopoietic stem cell transplant (HSCT). Initially, mixed chimerism is present with the coexistence of donor (D) cells and recipient-derived normal and leukemia/lymphoma (R_L) cells. Donor-derived T cells mediate a graft-versus-host hematopoietic effect that eradicates residual recipient-derived normal and malignant hematopoietic cells. Donor lymphocyte infusions (DLI) can be administered to enhance graft-versus-tumor effects. (Adapted from Champlin R, Khouri I, Anderlini P, et al. Nonmyeloablative preparative regimens for allogeneic hematopoietic transplantation: Biology and current indications. *Oncology* 2003;17:94–100.)

suppression, and other purine analogs (e.g., pentostatin or cladribine) are sometimes used instead of fludarabine.

Because some RIC regimens are not completely myeloablative, host hematopoiesis can persist and lead to mixed chimerism (blood cells from both donor and recipient are present; see Fig. 142–3).⁵⁰ Several studies have reported significant correlations between donor T-cell chimerism levels and the risk of graft rejection, GVHD, and relapse. For example, a low percentage of donor T and NK cells present on day 14 has been associated with graft rejection, whereas high T-cell donor chimerism on day 28 has been associated with acute GVHD.⁴⁶ Achievement of full donor chimerism was associated with better progression-free survival. These data suggest that monitoring donor chimerism posttransplant may allow early interventions to prevent graft rejection or relapse.

Several clinical studies have reported the results of RIC regimens from HLA-matched related or unrelated donors.^{46–49} In the largest series, 253 patients received HLA-matched-related NMT at one of several transplant centers that are part of an international consortium of transplant centers led by the Fred Hutchinson Cancer Research Center.^{51,52} All patients had a hematologic malignancy. The source of hematopoietic stem cells was G-CSF-mobilized PBSCs. Median age was 54 years; the oldest patient was 73 years. Median followup was 13 months. The first 58 patients were conditioned with TBI alone (2 Gy); 17% of these patients experienced nonfatal graft rejection. Fludarabine was added to the conditioning regimen in the remaining patients, and the incidence of graft rejection decreased to less than 5%. A combination of cyclosporine and mycophenolate mofetil was given as GVHD prophylaxis. Most patients did not require platelet transfusions, and only approximately two thirds of patients required RBC transfusions. Most of the transplants were performed entirely in the ambulatory care setting. Typical side effects, such as mucositis, diarrhea, and organ toxicities, were absent. Although the risk of infection in the first 100 days appeared to be lower than that seen with myeloablative alloHSCT, the risk of late viral and fungal infections persisted.^{53,54} GVHD, although delayed compared to historical controls, still was a significant problem.⁵⁵ Transplant-related mortality was only 5% at day 100. Compared with matched controls, patients who received NMT had significantly lower transplant-related mortality at day 100 and at 1 year.⁵⁶

Under a similar protocol, the same consortium of transplant centers treated 89 patients with HLA-matched unrelated NMT.⁵⁷ Durable engraftment was observed in 85% of patients who received G-CSF-mobilized PBSCs but only in 56% of marrow recipients. Transplant-related mortality was 11% at day 100. Patients who received PBSCs had improved progression-free and overall survival compared with marrow recipients.

Progression-free survival varies depending on the specific RIC regimen, disease type and status at the time of transplant, donor type, and patient age and comorbidities. Patients with indolent lymphoid malignancies had the lowest relapse rate after NMT, whereas those with advanced myeloid and lymphoid malignancies had the highest relapse rate.⁵⁸ Patients transplanted while in remission had lower relapse rates than those who were not in remission at the time of transplant. Direct comparison of the results of NMT versus myeloablative transplants is difficult because patients undergoing NMT tend to be older and have more comorbidities. In two retrospective comparisons of RIC regimens versus standard myeloablative transplants in patients with AML who were older than 50 years, nonrelapse mortality was lower in the RIC-treated patients, but leukemia-free survival was equivalent due to the higher relapse rate seen in the RIC groups.^{59,60} Studies evaluating “disease-targeted” therapy (radiolabeled monoclonal antibody, imatinib, or rituximab) combined with NMT to improve outcomes in specific malignancies are ongoing.⁴⁶

CLINICAL CONTROVERSY

Although RIC regimens reduce transplant-related mortality, whether this approach results in improved survival compared with myeloablative regimens is not clear. Also unclear is whether this approach improves survival compared with conventional chemotherapy. Direct comparison of the results of NMT versus myeloablative transplants is difficult because patients undergoing NMT tend to be older and have more comorbidities. Randomized controlled trials addressing these questions are ongoing, and the results of these studies should better define the role of RIC regimens and NMT.

Antitumor responses have been observed with RIC regimens in patients with renal cell carcinoma, melanoma, breast cancer, and other solid tumors.^{46,61} In order to improve on the efficacy seen in this setting, some investigators are evaluating novel approaches that enhance allogeneic immune responses against tumor-associated antigens (if available), such as posttransplant vaccination.

In summary, transplants with RIC regimens from HLA-matched related or unrelated donors are a promising treatment modality for patients who are not candidates for myeloablative alloHSCT because of their age, comorbidities, or poor organ function. Myelosuppression is mild, and most patients do not develop severe neutropenia or thrombocytopenia. Because of the reduced intensity of the conditioning regimen, early transplant-related mortality is

FIGURE 142-4. Use of ex vivo marrow purging to remove or destroy T cells (allogeneic only) or residual malignant cells (autologous only).

less than that seen with myeloablative alloHSCT. GVHD and infections, although occurring later after transplant, continue to be a significant cause of morbidity and mortality. Antitumor responses have been observed in hematologic malignancies and solid tumors.

PURGING THE STEM CELL PRODUCT

One disadvantage of autoHSCT is that the stem cell product (graft) may be contaminated with malignant cells. Infusion of these malignant cells may contribute to tumor relapse. Many approaches have been developed to eliminate (“purge”) the marrow of these tumor cells.⁶² The most common approach is addition of substances, such as chemicals or monoclonal antibodies, to the stem cell product while it is outside of the body (ex vivo; Fig. 142–4). Because the substances are removed before the stem cells are infused, nonhematopoietic tissues are not exposed to the substances and therefore are not damaged. However, these substances can remove or damage hematopoietic stem cells, which are essential for complete and rapid engraftment, and purging has been associated with delayed marrow recovery. Ex vivo marrow purging also is performed in alloHSCT in an attempt to eliminate T lymphocytes believed to be responsible for acute GVHD (Fig. 142–4). Results with this approach are discussed in the section on Graft-versus-Host Disease.

One approach is the addition of one or more monoclonal antibodies that are directed against specific antigens present on the tumor cells but are absent on nearly all other cells.^{43,63} Although this approach is theoretically attractive, it is limited because not all cells from patients with the same type of cancer express a specific antigen. Furthermore, for some types of cancers, identifying antigens distinct from those present on normal hematopoietic stem cells is difficult. To date, this strategy has been used most commonly in patients with lymphoid malignancies, either ALL or non-Hodgkin’s lymphoma.

Another method of ex vivo purging involves adding chemicals or drugs to kill the tumor cells.⁶⁴ The advantage of this technique is that it can be used for a broader range of tumor types. However, chemical purging is not completely selective for tumor cells, so the precise amount of chemical or drug that kills sufficient numbers of tumor cells while sparing the largest number of hematopoietic stem cells must be added. The chemical most commonly used for purging is 4-hydroperoxycyclophosphamide (4-HC, or perfosfamide), a congener of cyclophosphamide. 4-HC is a stable compound that enters cells and is rapidly reduced to 4-hydroxycyclophosphamide, which serves as the precursor to the reactive phosphoramidate mustard. The level of aldehyde dehydrogenase, the enzyme that inactivates 4-

hydroxycyclophosphamide, appears to be highest in early hematopoietic progenitors and decreases as these cells differentiate. This observation may explain why 4-HC appears to have an acceptable therapeutic index. Other analogs of cyclophosphamide (e.g., mafosfamide) also are being investigated as chemical purging agents.

Although ex vivo purging has been extensively studied, convincing evidence that it improves transplant outcomes is lacking. The techniques can be cumbersome and add cost to the transplant procedure, so their use should be restricted to clinical trials.

Rituximab has been used pretransplant for in vivo purging of the stem cell graft prior to autoHSCT in patients with non-Hodgkin’s lymphoma.^{41,43} When used for in vivo purging, rituximab usually is given before each leukapheresis. Although use of rituximab was effective in reducing the number of tumor cells in the stem cell graft, whether this approach improves disease-free survival after autoHSCT is not clear.

POSTTRANSPLANT IMMUNOTHERAPY

8 The rationale for posttransplant immunotherapy is based on observations that certain subsets of T cells are responsible for eradication of malignant cells. This is referred to as the *graft-versus-leukemia* or *graft-versus-tumor* (GVT) effect.

Donor Lymphocyte Infusions

Perhaps the most commonly used form of posttransplant immunotherapy is donor lymphocyte infusions (DLI) for treatment of disease relapse after alloHSCT.^{65,66} Lymphocytes are collected from the same donor who provided hematopoietic stem cells. Most experiences with DLI have been cases of patients with CML. More than 80% of patients who are in cytogenetic or molecular relapse respond to DLI. The response rate of patients in more advanced phases is approximately 15% to 30%. Although the time to response is delayed (median 3–4 months), patients often have a durable molecular remission to DLI.

Response rates to DLI of patients with other myeloid malignancies, such as AML and myelodysplasia, are generally lower (25%–30%) than the rates of patients with CML.^{65–67} This may be related to the rapid proliferation of acute leukemia within the often prolonged time to response after DLI or to the lack of suitable target antigens on non-CML cells for recognition by donor cytotoxic T cells. Patients with relapsed AML post-HSCT are more likely to achieve a complete response to DLI if they had a longer remission period after transplant and had some GVHD after the DLI.^{65,68}

Administration of induction chemotherapy prior to DLI administration may improve the antitumor activity of DLI in patients with AML, but this method has not been tested in a randomized study. DLI has been shown to have limited benefit in patients with relapsed ALL after transplant.

DLI appears to be effective in patients with multiple myeloma who relapse after alloHSCT, with reported response rates of 40% to 50%.^{65–67} Unfortunately, these responses tend to be transient and associated with the occurrence of GVHD. Anecdotal evidence suggests a graft-versus-lymphoma effect in patients with indolent non-Hodgkin's lymphoma and chronic lymphocytic leukemia (a disease entity closely related to indolent non-Hodgkin's lymphoma).

DLI is sometimes given posttransplant for treatment of residual or progressive disease in patients with mixed chimerism after NMT. Preliminary results show that DLI in this setting is effective and is associated with acceptable toxicity (mostly GVHD) in patients with early signs of disease persistence or progression.^{66,69} Prophylactic DLI to eradicate residual disease and reduce the risk of relapse is being investigated.

The most serious complications of DLI are pancytopenia and GVHD. The cytopenias generally are transient and can be treated with hematopoietic growth factors. A small percentage of patients may have a more prolonged course of aplasia with associated risk of infection, bleeding, and anemia. These patients may benefit from another infusion of donor stem cells. Acute GVHD (grade II or greater) occurs in 40% to 60% patients receiving DLI. Although the severity of GVHD has been correlated with the GVT effect, complete responses have been seen in the absence of GVHD, suggesting that the effects can be separated. DLI is associated with 10% to 15% nonrelapse mortality at 1 year.

Because of the potential of DLI to cure some patients with certain hematologic malignancies, investigators are evaluating strategies to separate the GVT effect from the GVH effect, which would make DLI more tolerable. Other investigators are developing methods that would expand the efficacy of DLI to other malignancies. Some of these strategies include T-cell depletion from the stem cells, followed by delayed T-cell add-back transplant for patients with evidence of residual disease approximately 3 months posttransplant; selective depletion of CD8⁺ cells from the DLI; in vivo or in vitro T-cell activation with interleukin (IL)-2; and infusion of T cells that are selected to recognize tumor-specific antigens.^{65,67}

Immunomodulatory Cytokines

Another approach to inducing a GVT effect in patients who relapse after HSCT is posttransplant administration of a cytokine with immunomodulatory activity, such as IL-2.^{45,70,71} Some benefit in terms of effects on NK cells and other important antitumor immune responses has been observed with the use of IL-2. Toxicities have been tolerable in most patients but can be serious and life-threatening. Studies that will define the role of these cytokines in prolonging relapse-free survival after HSCT are necessary.

Monoclonal Antibodies

Rituximab is being evaluated as adjuvant therapy in patients with non-Hodgkin's lymphoma treated with autoHSCT.^{43,72} The timing and number of doses of rituximab therapy vary. The Stanford program reported promising results with two 4-week courses starting at day 42 and 6 months posttransplant.⁷² Neutropenia was observed in approximately 50% of the patients treated.

TRANSPLANT-RELATED COMPLICATIONS

9 Although many patients with cancer who are treated with high-dose chemotherapy and autoHSCT or alloHSCT experience long-

term survival and cure of their disease, this modality is associated with many serious and potentially life-threatening complications. In the early 1970s, early posttransplant mortality was extremely high, and most HSCT patients did not survive beyond 100 days. During those early years of alloHSCT, death usually was related to infection, GVHD, interstitial pneumonia, and leukemic relapse. Today, largely because of the availability of improved broad-spectrum antibiotics, immunosuppressive drugs, antiviral drugs, and hematopoietic growth factors, transplant-related mortality after alloHSCT with HLA-matched sibling donors has been reduced to less than 30% at most centers. Mortality is even lower with the use of RIC regimens. Causes of death usually are related to transplant-related organ toxicity, GVHD, or immunosuppression. Until recently, alloHSCT usually was restricted to patients younger than 50 years with an HLA-identical sibling donor. With advances in the prevention and treatment of transplant-related complications and the availability of RIC regimens, alloHSCT now is being offered to many patients older than 50 years. The risk of transplant-related mortality after high-dose chemotherapy with autoHSCT is less than 5% at many centers, depending on patient population and conditioning regimen. Mortality is lower with autologous transplants because of the lack of GVHD and associated complications of immunosuppression. Transplant-related mortality in autoHSCT usually is caused by conditioning regimen organ toxicity or infection.

Table 142-1 lists the dose-limiting nonhematologic toxicities for several drugs that are commonly included in conditioning regimens. These toxicities may be uncommon or rare with administration of conventional doses of specific drugs. When these agents are given in high doses, the toxicities seen with conventional doses (e.g., mucositis, enteritis, nausea, vomiting, hematuria) can be more frequent and/or severe. Several unusual and severe manifestations of regimen-related toxicities are discussed in this section.

SINUSOIDAL OBSTRUCTION SYNDROME

Sinusoidal obstruction syndrome (SOS), formerly known as hepatic venoocclusive disease, occurs as a result of chemotherapy-induced dilation of hepatic sinusoids, necrosis of perivenular hepatocytes, and collagenization of the hepatic sinusoids and venules. These histologic changes can lead to portal hypertension and hepatic failure.⁷³ Clinical signs of SOS include fluid retention (resulting in sudden weight gain

TABLE 142-1 Dose-Limiting Nonhematologic Toxicities for Selected Chemotherapeutic Agents Included in Myeloablative Conditioning Regimens in Hematopoietic Stem Cell Transplantation

Drug	Conventional Dose ^a (mg/m ²)	HSCT Dose (mg/m ²)	Dose-Limiting Toxicity
Busulfan (oral)	2	450	Hepatic
Carboplatin	400	2,000	Hepatic, renal
Carmustine	200	1,200	Pulmonary, hepatic
Cisplatin	100	200	Renal, peripheral neuropathy
Cyclophosphamide	1,000	7,500	Cardiomyopathy
Etoposide	300–600	2,400	Mucositis
Ifosfamide	5,000	18,000	Renal
Melphalan	40	225	Mucositis
Thiotepa	20–50	1125	Mucositis, central nervous system

HSCT, hematopoietic stem cell transplantation.

Modified from Eder JP, Elias A, Shea TC, et al. A phase I-II study of cyclophosphamide, thiotepa, and carboplatin with autologous bone marrow transplantation in solid tumor patients. *J Clin Oncol* 1990;8:1242.

and ascites), hepatomegaly (sometimes painful), and hyperbilirubinemia/jaundice. SOS usually occurs within the first 3 weeks after transplant. The incidence of SOS ranges from 5% to 20% in most published series. Severe SOS is fatal in 50% to 75% of patients who develop the condition. Factors that reportedly increase the risk of SOS include use of TBI-containing conditioning regimens (dose-dependent), individual variability in cyclophosphamide metabolism, and elevated liver function tests pretransplant. Pretransplant exposure to gemtuzumab ozogamicin (Mylotarg) has been implicated in the development of SOS in patients undergoing alloHSCT.⁷⁴ Use of some drugs in the conditioning regimen, such as busulfan, cyclophosphamide, or carmustine, may increase the risk of SOS.

The pharmacokinetics of busulfan or cyclophosphamide may correlate with the risk of SOS. Because busulfan concentrations have been correlated with the risk of SOS, many HSCT centers adjust busulfan doses based on plasma concentrations.³³ Use of IV busulfan reduces the interpatient variation in systemic exposure associated with the oral formulation and has been associated with a reduced risk of SOS.³⁵ Exposure to the O-carboxyethyl-phosphoramide mustard metabolite of cyclophosphamide has been reported to correlate with the risk of SOS and nonrelapse mortality.⁷⁵ In addition, when busulfan and cyclophosphamide are given in combination, the order in which they are given may contribute to the risk of SOS. Presumably because of the effect of busulfan on cyclophosphamide pharmacokinetics (increased exposure to active and/or toxic metabolites), liver toxicity appears to be worse when busulfan is given first, as traditionally given in the BuCy regimen.⁷⁶

Some studies suggest that prostaglandin E₁, unfractionated and low-molecular-weight heparin, or ursodiol may be partially effective in preventing SOS.⁷⁷ In a systematic review of three randomized trials comparing prophylactic ursodiol versus no treatment, Tay et al.⁷⁸ found a reduced risk of SOS (relative risk 0.34, 95% confidence interval 0.17–0.66) with prophylactic ursodiol. These studies were conducted in patients undergoing myeloablative transplants. Transplant-related mortality was reduced (relative risk 0.58, 95% confidence interval 0.35–0.95). Other outcomes, such as relapse and overall survival, were not affected. Prophylactic defibrotide may also be effective.⁷⁹

Treatment is generally supportive. Recombinant tissue plasminogen activator has been given to patients with severe SOS because of the possible role of the coagulation cascade in the pathogenesis of SOS. Responses have been reported, but patients also experienced a higher risk of bleeding.⁷⁷ Defibrotide may also be beneficial.⁸⁰

PULMONARY COMPLICATIONS

Pulmonary complications following HSCT can be categorized as infectious and noninfectious (infectious complications are discussed in Chap. 126). Noninfectious complications are categorized as early (first 100 days posttransplant) and late (>100 days posttransplant). Patients who receive high-dose BCNU are also at risk for pulmonary fibrosis as a result of direct pulmonary tissue damage caused by this agent. Early complications include diffuse alveolar hemorrhage, engraftment syndrome, and idiopathic interstitial pneumonitis.⁸¹ Diffuse alveolar hemorrhage is characterized by dyspnea, hypoxia, dry cough, and fever. Chest x-ray film usually shows diffuse infiltrates in an alveolar pattern. Diffuse alveolar hemorrhage is diagnosed by examination of bronchoalveolar lavage fluid, which reveals progressively bloodier fluid with each instilled aliquot, and negative findings on microbiologic analysis. Although the condition can be life-threatening or fatal, prompt treatment with high doses of corticosteroids is sometimes beneficial.

Fever, erythrodermatous skin rash, and noncardiogenic pulmonary edema can occur during neutrophil recovery after HSCT. Because these clinical manifestations usually occur immediately

before or at the time of neutrophil engraftment, this clinical entity has been referred to as *engraftment syndrome*.⁸² The incidence of engraftment syndrome is not known because of the lack of uniform diagnostic criteria, although some series report that approximately 10% of patients who receive autoHSCT develop the syndrome. Engraftment syndrome can progress to life-threatening respiratory failure with or without multiple organ failure. Corticosteroids are effective in some patients.

Idiopathic interstitial pneumonitis (also called idiopathic pneumonia syndrome) is defined as widespread alveolar injury in the absence of active lower respiratory tract infection following HSCT. Patients with idiopathic interstitial pneumonitis are clinically indistinguishable from patients with interstitial pneumonitis related to infection. Idiopathic interstitial pneumonitis is postulated to have a multifactorial etiology, including toxic effects of myeloablative conditioning, immunologic cell-mediated injury, inflammatory cytokine-induced lung damage, and occult pulmonary infections. The risk is similar in recipients of autoHSCT or alloHSCT but appears to be higher in patients who are conditioned with a TBI-containing regimen or who have acute GVHD. Mortality as high as 70% has been reported, and treatment consists of supportive care only. The incidence of idiopathic interstitial pneumonitis may be lower after RIC compared to conventional regimens.⁸³

Late pulmonary complications cover a wide spectrum of disorders and include both obstructive and restrictive lung diseases. Included in these disorders are bronchiolitis obliterans with or without organizing pneumonia, diffuse alveolar damage, and lymphocytic interstitial pneumonia.^{81,84,85} Therapy consists of steroids, which are approximately 50% effective. Patients with mild-to-moderate airflow impairment appear to have the best response. Mortality from these disorders is approximately 40%.

GRAFT FAILURE

Initial engraftment after high-dose chemotherapy conditioning regimens usually occurs in the first 2 to 4 weeks posttransplant. Engraftment is evidenced by rising peripheral blood counts and the presence of hematopoietic precursor cells in the marrow. In alloHSCT, the presence of donor cells (i.e., chimerism) is confirmed by fluorescent in situ hybridization of sex chromosomes and PCR-based analysis of polymorphic DNA sequences.⁵⁰ Full chimerism is defined as greater than 95% of T cells of donor origin. In most patients, engraftment is sustained with complete recovery of hematopoiesis.

Graft failure can occur after autologous, syngeneic, and allogeneic HSCT. It can be the result of an immunologic reaction between donor and host, heavy pretreatment with chemotherapy and/or radiation therapy, infusion of insufficient numbers of hematopoietic stem cells, viral infection, recurrence of primary hematologic malignancy, drug reaction (e.g., to ganciclovir), or development of a secondary myelodysplasia. Two syndromes have been observed. Early graft failure occurs when the rate of hematopoietic recovery is delayed (primary graft failure or delayed engraftment), whereas late graft failure is characterized by a decline in peripheral blood counts after initial engraftment (secondary graft failure). With widespread use of PBSCs and posttransplant growth factors, primary graft failure is rare after autologous and HLA-matched related alloHSCT. Graft failure that occurs after alloHSCT, characterized by regrowth of immunocompetent host cells and a simultaneous loss of donor cells, is referred to as *graft rejection*. Graft rejection occurs rarely after HLA-matched related alloHSCT. An increased risk of graft rejection has been observed in recipients of hematopoietic stem cells from HLA-mismatched related or unrelated donors, recipients of T-cell-depleted marrow, and patients with severe aplastic anemia.^{7,9,86}

The long-term prognosis of patients with graft failure is poor. Despite supportive care, death may result from infection or bleed-

ing. In some patients with an allogeneic donor, a second infusion of stem cells can be attempted. The most effective therapy for graft failure is G-CSF or GM-CSF.

Hematopoietic growth factors usually are given posttransplant to patients who receive autoHSCT, although some clinicians believe that posttransplant G-CSF or GM-CSF is unnecessary because of the already rapid engraftment seen after mobilized PBSC transplants.^{87,88} The usual dosage of GM-CSF is 250 mcg/m²/day. Many different dosages and schedules of G-CSF have been used after autoHSCT. Originally, G-CSF was given at a dose of 5 to 10 mcg/kg/day beginning on the day of or the day after infusion of stem cells and continued until neutrophil recovery to greater than an arbitrary number of neutrophils (500–1,000 cells/mm³). In one study of three different G-CSF dosages (5, 10, and 16 mcg/kg/day), no significant difference in the rate of hematopoietic recovery between the different dosages was observed.⁸⁹ In another study, delayed initiation of G-CSF at a dosage of 5 mcg/kg/day until day 5 posttransplant did not impair hematopoietic recovery after autoHSCT.⁹⁰ Pegfilgrastim in the transplant setting is being studied.

Hematopoietic growth factors accelerate the rate of hematopoietic recovery in patients undergoing alloHSCT. However, laboratory studies show that growth factors can modify T-cell and dendritic cell function, and one retrospective study of patients with acute leukemia reported that G-CSF use after allogeneic BMT was associated with significantly increased risk of acute GVHD and death.⁹¹ No detrimental effects of G-CSF were noted in patients receiving allogeneic PBSC transplants. In a meta-analysis of 34 randomized controlled trials, no increased risk of acute GVHD or treatment-related mortality was observed when G-CSF or GM-CSF was used after alloHSCT.⁹² In another retrospective analysis of 2,719 patients from the CIBMTR, no association between G-CSF use and acute or chronic GVHD, transplant-related mortality, or survival was observed in recipients of HLA-identical sibling bone marrow, recipients of HLA-identical sibling peripheral blood, and recipients of HLA-matched unrelated donor bone marrow.⁹³ As a result of these concerns, use of growth factors after alloHSCT is not considered standard of care.⁸⁸

None of the commercially available hematopoietic growth factors has a significant effect on platelet recovery. Results of studies with investigational platelet growth factors, such as thrombopoietin and IL-11, given posttransplant have been disappointing.⁸⁷ Platelet transfusions remain the standard of care in patients with thrombocytopenia below a given threshold (e.g., 10,000 cells/mm³) or in patients with significant bleeding.

Anemia may be problematic in the posttransplant setting, especially in patients receiving alloHSCT. The etiology is unclear and most likely is multifactorial. Erythropoietin administration may be useful in reducing the need for red blood cell transfusions and may be given in regimens similar to those given for malignancy-associated anemia.⁸⁷

GRAFT-VERSUS-HOST DISEASE

GVHD is caused by immunocompetent donor T cells reacting against recipient/host antigens presented by antigen-presenting cells. In that setting, donor T cells recognize histocompatibility antigens of the host as genetically foreign, become activated, proliferate, and attack recipient tissue, thereby producing the clinical syndrome of GVHD.⁹⁴

Two different clinical GVHD syndromes (acute and chronic) are recognized, depending on the time of onset and clinical presentation.^{95–97} Acute GVHD usually presents prior to day 100 posttransplant (*classic* acute GVHD), but it can be *persistent*, *recurrent*, or *late-onset* with clinical manifestations occurring after day 100. Acute GVHD observed after day 100 usually is the result of immunosuppression withdrawal for relapsed or persistent malignancy or administration of DLI, or occurs in the setting of NMT. *Chronic* GVHD usually occurs

after day 100, either with or without characteristics of acute GVHD. Chronic GVHD without characteristics of acute GVHD (*classic* chronic GVHD) occurs after resolution of acute GVHD (quiescent or interrupted) or *de novo* (no prior acute GVHD). An “overlap syndrome” may occur in which features of both acute and chronic GVHD are present simultaneously, usually when chronic GVHD develops prior to resolution of acute GVHD (progressive onset). Acute GVHD usually is limited to the gastrointestinal tract, skin, and liver, whereas signs and symptoms of chronic GVHD resemble an autoimmune disorder and can affect many organ systems.

A “hyperacute” form of GVHD may occur in patients with multiple HLA mismatches and in patients who receive T-cell-replete transplants without adequate GVHD prophylaxis, especially in myeloablative regimens.^{98,99} Descriptions of hyperacute GVHD vary but usually include fever, generalized erythroderma, desquamation, and edema. More severe forms with accompanying organ failure have been seen in haploidentical donors. Hyperacute GVHD typically occurs approximately 1 week after transplant before engraftment of neutrophils. The response rate to first-line therapy appears to be lower in patients with hyperacute GVHD compared to patients who develop GVHD later posttransplant, but no difference in survival has been observed.⁹⁹

Acute Graft-Versus-Host Disease

The pathophysiology of acute GVHD has been described as a three-step process.⁹⁴ In step 1, the high-dose conditioning regimen damages host tissues. Damage to the intestinal mucosa leads to release of lipopolysaccharides into the systemic circulation, which stimulates secretion of inflammatory cytokines such as IL-1 and tumor necrosis factor- α (TNF- α). These cytokines upregulate MHC gene products and host antigen-presenting cells such as dendritic cells, which play a critical role in this immune response. In step 2, donor T cells are activated, and secretion of other cytokines (IL-2 and interferon- γ) by activated T cells results in recruitment of macrophages and alteration of target cells in the gastrointestinal tract and skin so that they are more susceptible to damage. In step 3, multiple cytotoxic effector cells (T cells and macrophages) are generated and contribute to target tissue injury by secreting more inflammatory cytokines that cause target cell apoptosis. The term *cytokine storm* is sometimes used to describe the critical role of inflammatory cytokines in this process.

Based on this three-step model, three general approaches can be used to prevent GVHD in humans.⁹⁴ The first is to reduce host tissue damage with the use of RIC regimens. The second and most widely used approach is to modulate donor T cells by reducing T-cell numbers (T-cell depletion), activation (most immunosuppressive agents), or proliferation (antiproliferative agents). The third approach is to block inflammatory stimulation and effectors (e.g. TNF- α inhibitors, IL-1 receptor antagonist).

The principal target organs in acute GVHD are the skin, liver, and gastrointestinal tract.^{95,98} Acute GVHD is classified into four grades, depending on the number of organs involved and the degree of involvement of each organ (Table 142–2). Grade I disease involves only the skin. Grades II through IV involve the skin and either the liver, gastrointestinal tract, or both. The initial sign of acute skin GVHD usually is a generalized maculopapular rash that initially involves the face, ears, palms, soles, and upper trunk. The skin rash can spread to the rest of the body and, if untreated or refractory to treatment, will progress to bullae formation and desquamation, much like a burn injury. Gastrointestinal GVHD is manifested as diarrhea but may progress to abdominal pain/cramping and ileus. GVHD of the upper intestinal tract has been described presenting as nausea, vomiting, anorexia, and dyspepsia. The diagnosis of gastrointestinal GVHD should be made by biopsy of the intestinal tract (stomach, duodenum, or rectum). Hepatic GVHD usually is asymptomatic, consisting of hyperbilirubinemia and elevated alkaline phosphatase

TABLE 142-2 Consensus Grading of Acute Graft-Versus-Host Disease

Stage	Organ/Extent of Involvement		
	Skin	Liver	Intestinal Tract
1	Rash on <25% of skin ^a	Bilirubin 2–3 mg/dL ^b	Diarrhea >500 mL/day ^c or persistent nausea ^d
2	Rash on 25–50% of skin	Bilirubin 3–6 mg/dL	Diarrhea >1,000 mL/day
3	Rash on >50% of skin	Bilirubin 6–15 mg/dL	Diarrhea >1,500 mL/day
4	Generalized erythroderma with bulla formation	Bilirubin >15 mg/dL	Severe abdominal pain with or without ileus
Grade			
0	None	None	None
I	Stage 1–2	None	None
II	Stage 3	or Stage 1	or Stage 1
III	—	Stage 2–3	or Stage 2–4
IV ^e	Stage 4	or Stage 4	—

^aUse the “rule of nines” to determine body surface area involvement.
^bRange given as total bilirubin. Downgrade one stage if an additional cause of elevated bilirubin has been documented.
^cVolume of diarrhea applies to adults. For pediatric patients, the volume of diarrhea should be based on body surface area.
^dPersistent nausea with histologic evidence of graft-versus-host disease in the stomach or duodenum.
^eGrade IV may include lesser organ involvement but with extreme decrease in performance status.
This article was published in Semin Hematol, Vol. 43, Deeg HJ, Arin JH. The clinical spectrum of acute graft-versus-host disease, pages 24–31. Copyright Elsevier 2006.

levels; increases in serum aminotransferases occur less consistently. The diagnosis can be made by biopsy, although many patients cannot provide biopsy samples because of the inherent risk of hemorrhage.

The overall incidence of moderate to severe (grades II–IV) acute GVHD ranges from 10% to more than 80%.⁹⁵ Mortality directly attributable to acute GVHD or its treatment occurs in 10% to 20% of patients. The incidence of GVHD is related to the degree of histocompatibility, number of T cells in the graft, donor and recipient age, intensity of the conditioning regimen, source of hematopoietic cells (bone marrow vs peripheral blood), and prophylactic regimen. Acute GVHD can occur in patients receiving DLI for treatment of relapsed disease following HSCT.^{66,69} The risk of acute GVHD is lower in recipients of UCB transplants.²⁸ The most severe acute GVHD is observed in alloHSCT with non-HLA-identical donors. In these settings, the incidence of grades II to IV acute GVHD exceeds 50% despite aggressive GVHD prophylaxis.

Multiorgan acute GVHD and the drugs given to prevent or treat the disease are associated with delayed immunologic recovery and increased susceptibility to infections. Infection is often the primary cause of death in patients with GVHD. Patients with GVHD treated with an immunosuppressive regimen should receive prophylactic antiviral, antibacterial, and antifungal therapy and be monitored routinely for the occurrence of these infections.

10 Because treatment of established acute GVHD often is unsatisfactory, aggressive preventive measures usually are taken. The most common strategy used to prevent acute GVHD is blocking the activation of T cells by administration of immunosuppressive agents.^{94,95,100} Several immunosuppressive agents have been used, including methotrexate, cyclosporine, tacrolimus, mycophenolate mofetil, antithymocyte globulin, corticosteroids, and monoclonal antibodies directed at T cells. The pharmacology of these drugs is reviewed elsewhere.¹⁰¹ Most GVHD prophylaxis regimens combine two or more immunosuppressive agents that affect different stages of T-cell activation. Another strategy is removing or depleting most T cells from donor bone marrow ex vivo prior to transplant by

physical separation (i.e., lectin agglutination) or by treatment with monoclonal antibodies directed at T cells (see Fig. 142–4).⁸⁶

In alloHSCT with HLA-matched donors, the combination of cyclosporine or tacrolimus and either methotrexate or corticosteroids reduces the incidence of grades II to IV acute GVHD to 25% to 40%. Intravenous cyclosporine or tacrolimus usually is started a few days before or on day 0. Cyclosporine is given at an initial dosage of 3–5 mg/kg/day and tacrolimus at 0.02–0.03 mg/kg/day. Dosages are adjusted based on trough concentrations. Patients are converted to oral formulations when they can be tolerated. Cyclosporine and tacrolimus typically are given at full doses until days 50 to 100, gradually tapered in the absence of GVHD, and discontinued by day 180. Methotrexate is given intravenously on days 1, 3, 6, and 11 posttransplant. The methotrexate dosage is 10 mg/m², except for the first dose given on day 1 (15 mg/m²). Alternatively, some centers use 5 mg/m² (same schedule). The day 11 dose is sometimes omitted because of the drug’s myelosuppressive effects, severe mucositis, or development of conditions that may prolong methotrexate systemic exposure (e.g., renal failure or third spacing). When corticosteroids are used, methylprednisolone or prednisone usually is started during the first 2 weeks posttransplant, given at full dosages for several weeks, and gradually tapered in the absence of GVHD. Although the efficacy of methotrexate-based regimens and corticosteroid-based regimens appears to be similar, use of methotrexate may increase the risk of delayed engraftment and is associated with significant mucositis, and corticosteroid administration is associated with a higher incidence of infections. Three-drug regimens composed of cyclosporine, methotrexate, and corticosteroids have been studied but have not been shown to be more efficacious in HLA-matched transplants.^{95,100}

Two large multicenter randomized trials compared cyclosporine and methotrexate with tacrolimus and methotrexate. One study was performed in patients undergoing HLA-identical sibling alloHSCT,¹⁰² whereas the other study was performed in patients undergoing matched unrelated alloHSCT.¹⁰³ Both studies found the tacrolimus combination to be significantly superior to the cyclosporine combination in preventing grades II to IV acute GVHD. The incidence of renal impairment was higher in patients receiving tacrolimus, and more tacrolimus-treated patients in the HLA-identical sibling alloHSCT trial required hemodialysis. The incidence of hypertension was significantly higher in cyclosporine-treated patients in the HLA-matched sibling alloHSCT trial. No difference in the overall or relapse-free survival rate was reported in the two trials. However, in the subgroup of patients with advanced disease in the HLA-identical sibling alloHSCT trial, cyclosporine-treated patients had significantly better overall and disease-free survival rates at 2 years compared to patients who received tacrolimus. The authors explained that lowering the target blood levels to less than 20 ng/mL might reduce the renal toxicity of tacrolimus. Based on the results of these two studies, many transplant centers use tacrolimus and methotrexate as first-line acute GVHD prophylaxis.

Because of the gastrointestinal and hematologic toxicities of methotrexate, a GVHD prophylaxis regimen that uses sirolimus in place of methotrexate in combination with tacrolimus has been developed by investigators at the Dana-Farber Cancer Institute. In an uncontrolled study of 53 patients receiving myeloablative alloHSCT, the combination of sirolimus and tacrolimus was associated with rapid engraftment and low incidences of grades II to IV acute GVHD and treatment-related mortality.¹⁰⁴ Randomized trials comparing this regimen to standard methotrexate-containing regimens are needed.

Acute GVHD prophylaxis regimens used in NMT usually are similar to those used in myeloablative alloHSCT. However, some centers have developed novel prophylactic regimens specifically for patients undergoing NMT. An example of such a regimen is cyclosporine and mycophenolate mofetil,^{51,52} which was developed based on preclinical studies.¹⁰⁵

The role of ex vivo T-cell depletion from donor grafts is controversial (see Fig. 142–4).⁸⁶ Although use of T-cell–depleted marrow can reduce the incidence and severity of acute GVHD, it is associated with an increased risk of graft failure, delayed immune reconstitution, leukemic relapse, cytomegalovirus reactivation, and Epstein-Barr virus–related lymphoproliferative disorders. As a result, this approach does not improve the survival rate in recipients of HLA-identical sibling donor marrow. These observations suggest that important cell populations are being eliminated in the depletion process. Various approaches that selectively remove the T cells responsible for GVHD while leaving those cells that mediate engraftment, antileukemic effect, and suppression of Epstein-Barr virus–transformed lymphocytes are being investigated.¹⁰⁰ Another approach is infusion of the T cells originally depleted from the graft later in the posttransplant period to prevent leukemic relapse.¹⁰⁶ Because of the higher risk of GVHD in alloHSCT with HLA-mismatched donors, T-cell depletion is sometimes included as part of the GVHD prophylaxis regimen in that setting.

With alternative donors, the risk of moderate-to-severe (grades II–IV) acute GVHD is 50% or higher with conventional two-drug prophylaxis. Several approaches are used to reduce the risk of acute GVHD in this high-risk group of patients: three-drug GVHD prophylaxis, pretransplant administration of antithymocyte globulin, or ex vivo T-cell depletion of donor bone marrow (see Fig. 142–4). Encouraging results have been reported with the addition of novel immunosuppressive agents, such as sirolimus, to two-drug prophylaxis regimens.¹⁰⁷ The addition of antilymphocyte/antithymocyte globulin to the pretransplant conditioning regimen reduced the risk of acute and chronic GVHD but increased the risk of serious infections.¹⁰⁸ Uncontrolled studies suggest that ex vivo T-cell depletion significantly reduces the risk of early graft failure and acute GVHD, with apparent preservation of the graft-versus-leukemia effect.⁸⁶

If a patient develops grades II to IV GVHD, prophylactic agents are continued and high-dose corticosteroids in the form of intravenous methylprednisolone are given.¹⁰⁹ The usual dosage is 1 to 2 mg/kg/day, given in two divided doses. The initial dosage is as high as 10 mg/kg/day in some protocols, although there is no convincing evidence that higher dosages are more effective. Approximately 25% to 40% of patients with established acute GVHD respond to high-dose corticosteroids. If the patient responds, the corticosteroid dose is tapered gradually over several weeks, depending on response. In patients who experience a flare in GVHD during the taper phase, therapy consists of increasing the steroid dose and then tapering more slowly. Oral beclomethasone dipropionate, a topically active corticosteroid, has been shown to reduce the frequency of gastrointestinal GVHD relapses when continued after prednisone taper.¹¹⁰ Administration of beclomethasone has been associated with a better survival at 200 days and 1 year after transplant. GVHD-associated mortality is strongly correlated to response to initial treatment and ranges from approximately 25% in patients who had a complete response to approximately 80% in patients who had no response or progressive disease.

Several randomized trials have evaluated other agents combined with methylprednisolone as initial therapy for acute GVHD.^{95,109} In particular, the addition of anti-T-cell antibodies, such as antithymocyte globulin or monoclonal antibodies (e.g., daclizumab), has not been shown to improve patient outcome.^{109,111} Similarly, the combination of methylprednisolone and the anti-TNF- α monoclonal antibody infliximab has not been shown to increase response rate compared to methylprednisolone alone.

If the manifestations of acute GVHD in any organ worsen over 3 days of treatment or if the skin does not improve by 5 days, the patient likely will not respond and secondary therapy should be considered.¹⁰⁹ Most clinicians continue administration of steroids and add another agent, such as antithymocyte globulin, denileukin diftitox, a monoclonal antibody, or another immunosuppressive

agent (e.g., mycophenolate mofetil, sirolimus, or pentostatin).^{95,109} One approach that has shown benefit as steroid-sparing therapy is extracorporeal photopheresis. During this procedure, the patient's blood is exposed extracorporeally to 8-methoxypsoralen followed by ultraviolet A radiation, and then returned to the patient. This process is thought to result in suppression of T-cell reactivity and induction of regulatory T cells. Clinical results have been positive, especially in patients with skin GVHD.¹⁰⁹ In addition, a variety of humanized monoclonal antibodies or fusion proteins, such as denileukin diftitox (Ontak), daclizumab (Zenapax), infliximab (Remicade), and etanercept (Enbrel), are being evaluated for treatment of steroid-refractory acute GVHD.¹⁰⁹

CLINICAL CONTROVERSY

Optimal treatment of steroid-refractory GVHD is unclear. Comparative trials are needed to determine a standard approach to this difficult condition.

Chronic Graft-Versus-Host Disease

Chronic GVHD is the major determinant of late transplant-related morbidity and mortality.^{95,112,113} The pathophysiology of chronic GVHD is poorly understood but is generally thought to be a result of pathogenic donor T cells that proliferate unchecked by normal mechanisms. These T cells are responsible for tissue damage through direct cytolytic attack, stimulation of inflammatory cytokines, or B-cell activation and antibody production. Chronic GVHD is often considered an autoimmune disease because of its similarity to other autoimmune disorders.

The incidence of chronic GVHD in patients who survive more than 150 days ranges from 20% to 70%.⁹⁵ The risk of chronic GVHD increases with increasing donor and recipient age and is higher in patients who receive transplants from HLA-nonidentical donors and in patients who receive PBSC transplants (especially with higher CD34 cell doses). Chronic GVHD can occur in patients receiving DLI posttransplant.⁶⁶ A meta-analysis reported that the risk of chronic GVHD is increased by nearly two-fold in patients who receive allogeneic PBSC transplants compared with BMT.²⁶ The risk of chronic GVHD is lower after UCB transplantation.^{28,114} The incidence of chronic GVHD is rising because of increasing use of alternative donors, use of PBSCs as the graft source, use of DLI for treatment of recurrence, and older recipient age. Previous acute GVHD increases the risk of chronic GVHD, but approximately 20% to 30% of patients who develop chronic GVHD after HLA-matched alloHSCT have no history of acute GVHD (“de novo”). Unlike acute GVHD, prophylactic immunosuppression does not appear to reduce the incidence or severity of chronic GVHD.

Chronic GVHD resembles autoimmune diseases and can affect any organ or tissue of the body.^{95–97,115} The most common sites involved are the skin, mouth, liver, and eye. The National Institutes of Health Consensus Development Project developed standardized criteria for the diagnosis of chronic GVHD and proposed a new clinical scoring system for the evaluation of patients with chronic GVHD.⁹⁶ The Working Group recommends that the diagnosis of chronic GVHD be made with the presence of at least one *diagnostic* clinical sign of chronic GVHD (e.g., poikiloderma or esophageal web) or a *distinctive* manifestation (e.g., keratoconjunctivitis sicca) confirmed by biopsy or other test (e.g., Schirmer test). In addition, a consensus scoring system was developed to measure the severity of involvement of individual organs.

The most widely used staging system for chronic GVHD prior to the National Institutes of Health Consensus Development Project was the limited/extensive classification proposed by the Seattle HSCT program.^{95,112} In that system, chronic GVHD is classified as

limited or extensive, depending on pathologic findings and the extent of systemic involvement. *Limited* chronic GVHD indicates localized skin involvement, mild hepatic dysfunction, or both. Most patients have *extensive* disease, with involvement of the skin, liver, eyes, mouth, esophagus, or other organs. Many patients with extensive chronic GVHD will die of infections or become disabled.

Several investigators have proposed improved staging systems based on large numbers of patients.^{96,116} The National Institutes of Health Consensus Working Group recommends a global staging system that categorizes chronic GVHD into mild, moderate, and severe.⁹⁶ *Mild* chronic GVHD involves only one or two organs or sites (except the lung) with no clinically significant functional impairment (maximum score of 1 in all affected organs or sites). *Moderate* chronic GVHD involves at least one organ or site with clinically significant but no major disability (maximum score of 2 in any affected organ or site), or three or more organs or sites with no clinically significant functional impairment (maximum score of 1 in all affected organs or sites), or lung score of 1. *Severe* chronic GVHD indicates major disability caused by chronic GVHD (score of 3 in any organ or site) or lung score of 2 or greater.

The long-term survival rate is worse in certain subgroups of patients, such as patients with extensive skin involvement, thrombocytopenia, progressive onset of chronic GVHD (development of chronic GVHD prior to the resolution of acute GVHD), and those who do not respond to immunosuppressive therapy.⁹⁵

⑪ If no functional impairment is present, patients with mild skin-only disease can be treated with a variety of topical preparations, such as clobetasol, tacrolimus, and pimecrolimus.¹¹⁷ Initial treatment of patients with more severe or systemic involvement of chronic GVHD consists of prednisone 1 mg/kg/day.^{95,97,112} To reduce the amount of corticosteroid exposure, many clinicians use either alternate-day prednisone or add cyclosporine. However, a randomized trial showed no differences in response or survival between prednisone alone or in combination with cyclosporine in standard-risk patients (platelet counts >100,000 cells/mm³).⁶⁸ Treatment is continued until signs and symptoms of the disease have resolved and then are tapered gradually, usually over a period of several months to years. Approximately 50% of patients will require long-term immunosuppression to control chronic GVHD.

In addition to topical therapy for skin manifestations, other treatments can be applied to lessen the symptoms of chronic GVHD.¹¹⁷ Patients should be educated on the use of sunscreens (and/or avoidance of sun exposure) to reduce skin injury and exacerbation of GVHD skin lesions. Nonsclerotic skin lesions without erosions or ulcerations may respond well to topical steroids and emollients. Patients should be advised to maintain good oral hygiene with routine dental care. Saliva substitutes can be given for dry mouth symptoms, and topical corticosteroid gels can be used for localized and symptomatic oral lesions. Artificial tears or, if necessary for more severe symptoms, cyclosporine or steroid eye drops are useful for patients with chronic GVHD manifesting as dry eyes or conjunctivitis. Physical therapy is recommended to reduce functional loss as a result of steroid myopathy, joint contractures, and deconditioning.

Patients who do not respond to initial therapy have a very poor prognosis. Noncomparative trials have investigated several therapies with varying degrees of success, including thalidomide, ultraviolet A irradiation after oral treatment with β -methoxypsoralen, extracorporeal photophoresis, tacrolimus, sirolimus, pentostatin, mycophenolate mofetil, hydroxychloroquine, rituximab, and others.^{95,97,112,113} In a trial of 21 patients with steroid-refractory chronic GVHD, the clinical response rate to rituximab was 70%.¹¹⁸ Some of these agents are being tested in phase III randomized trials of patients with newly diagnosed chronic GVHD.

Infection is the primary cause of death in patients with chronic GVHD, and antimicrobial prophylaxis is an important component

of the care of patients being treated for chronic GVHD. Patients should receive oral trimethoprim-sulfamethoxazole, penicillin, an antifungal azole agent, and acyclovir to prevent infections commonly seen in immunocompromised patients.^{95,97,115,117,119} Routine monitoring for cytomegalovirus reactivation should be performed. Some HSCT centers also administer intravenous immunoglobulin to patients with low serum immunoglobulin G levels.

INFECTION

Patients undergoing high-dose chemotherapy with autoHSCT or alloHSCT are severely immunocompromised and therefore are at high risk for bacterial, fungal, and viral infection. Management of these infections is discussed in detail in Chapter 126. Comprehensive guidelines for monitoring, prophylaxis, and treatment of infections in HSCT recipients are available at www.cdc.gov/mmwr/preview/mmwrhtml/rr4910a1.htm and www.nccn.org.

LATE COMPLICATIONS

With the success of HSCT, the number of long-term survivors has grown. Many survivors experience delayed complications of transplantation, especially those receiving alloHSCT, and primary care physicians will care for these patients.¹²⁰ Major late complications include restrictive and obstructive pulmonary disease; bone and joint disease (including avascular necrosis); cataract formation; endocrine dysfunction, including sterility and thyroid dysfunction; impaired growth and development; infections; cardiovascular disease; cirrhosis as a result of chronic hepatitis C infection; and secondary malignancies.^{121,122} Physical recovery tends to occur earlier than psychological or work recovery.¹²³ Full recovery usually takes several years, and approximately two-thirds of patients do not have major limitations by 5 years.

SECTION 18

NUTRITION DISORDERS

CHAPTER

143

Assessment of Nutrition Status and Nutrition Requirements

KATHERINE HAMMOND CHESSMAN AND VANESSA J. KUMPF

KEY CONCEPTS

- 1 Classification of nutrition status is often desired as a means to identify those who are nutritionally at risk or malnourished.
- 2 Nutrition screening programs should identify those at risk for poor nutrition-related outcomes as a consequence of either over- or undernutrition.
- 3 Nutrition assessment is the first step in formulating a patient-specific nutrition care plan for a patient who is found to be nutritionally at risk or malnourished.
- 4 A nutrition-focused medical, surgical, and dietary history and a nutrition-focused physical examination are key components of nutrition assessment and will reveal risk factors for and the likelihood of malnutrition and nutrient deficiencies.
- 5 Appropriate anthropometric measurements are essential in a complete nutrition assessment and should be evaluated based on published standards.
- 6 Biochemical (laboratory) tests are also essential for nutrition assessment but must be interpreted in the context of the physical findings, medical and surgical history, and clinical status of the patient, as well as specific test limitations.
- 7 Nutrient deficiencies involving micronutrients (e.g., vitamins or trace elements) or macronutrients (e.g., fat, protein, or carbohydrate) are possible, and a comprehensive nutrition assessment will identify the presence of these.
- 8 When determining patient-specific nutrition requirements, goals should be established based on the patient's clinical condition and the need for maintenance or repletion in adults, as well as for continued growth and development in children.
- 9 Drug-nutrient interactions can affect a patient's nutrition status as well as the response to and adverse effects seen with drug

therapy, and must be considered when evaluating a patient's nutrition care plan.

- 10 An initial nutrition assessment and determination of nutrition requirements only defines an empirical starting point for a nutrition care plan. Close monitoring is required so that timely adjustments to the nutrition care plan can be made based on patient-specific responses to ensure appropriate nutrition-related outcomes.

Nutrition care is a vital component of quality patient care. This chapter reviews the tools most commonly used for nutrition screening and accurate, relevant, and cost-effective nutrition assessment. Determination of patient-specific macro- and micronutrient requirements and potential drug-nutrient interactions are also discussed.

CLASSIFICATION OF NUTRITION DISEASE

- 1 Undernutrition usually results from starvation (inadequate nutrient intake), impaired absorption of nutrients or altered metabolism (inappropriate use of ingested nutrients).¹ An alteration in nutrient metabolism exists when the cell has altered substrate demands or use, such as cachexia associated with inflammatory or neoplastic conditions. In such situations, enhancing nutritional intake may not be sufficient to meet the increased demand.¹ Regardless of the cause, undernutrition results in changes in subcellular, cellular, and/or organ function that expose the individual to increased risks of morbidity and mortality (see Chap. 144). In general, deficiency states can be categorized as those involving protein and calories or single nutrients such as individual vitamins or trace elements. Protein-calorie malnutrition can be classified as marasmus, kwashiorkor, or mixed marasmus/kwashiorkor.

Marasmus is a chronic condition resulting from prolonged inadequate intake or use of protein and calories. Somatic protein (skeletal muscle) and adipose tissue (subcutaneous fat) wasting occurs, but visceral protein production (e.g., albumin and transferrin) is usually preserved. Weight loss typically exceeds 10% of usual body weight (UBW; typical weight). When severe, cell-mediated immunity, measured by delayed cutaneous hypersensitivity (DCH), and muscle function are impaired. Patients with wasting diseases such as cancer commonly have marasmus and a prototypical starved, wasted appearance.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

Kwashiorkor develops when there is adequate calorie but inadequate protein intake. These patients generally appear well nourished but are extremely catabolic, usually secondary to trauma, infection, or burns. There is depletion of visceral (and to some degree somatic) protein stores with relative adipose tissue preservation, and hypoalbuminemia and edema are commonly seen. In the setting of severe metabolic stress and protein deprivation, kwashiorkor may develop rapidly and may result in impaired immune function.

Mixed marasmus/kwashiorkor is a form of severe protein-calorie malnutrition that develops in chronically ill, starved patients during periods of hypermetabolic stress. There is reduced visceral protein synthesis superimposed on wasting of somatic protein and energy (adipose tissue) stores. Immunocompetence is lowered, increasing the incidence of infection, and wound healing is compromised.

Obesity (overnutrition) is a major healthcare concern in the United States. Recently, 66% of American adults were estimated to be overweight (defined as a body mass index [BMI] of 25 kg/m² or greater), while 32% of American adults were noted to be obese (BMI of 30 kg/m² or greater).² Additionally, approximately 15% of children and adolescents (ages 6 to 19 years) are obese (BMI at or above the 95th percentile for age³ on the gender-appropriate BMI-for-age growth chart published by the Centers for Disease Control National Center for Health Statistics [NCHS]).⁴ Many more children are considered to be at-risk for obesity (BMI at or above the 85th percentile for age). Nutrition assessment allows identification of obese individuals or those at risk of becoming obese. The consequences of obesity are numerous and include type 2 diabetes mellitus, cardiovascular disease, and stroke (see Chap. 148).

NUTRITION SCREENING

² Because it is neither practical nor warranted to conduct a comprehensive nutrition assessment on every patient, nutrition screening provides a systematic way to identify individuals who are overweight, obese, malnourished, or at risk for malnutrition,⁵ and to predict the probability of their outcome as a result of nutrition factors.⁶ Risk factors for undernutrition include any disease state, complicating condition, treatment, or socioeconomic condition that may result in a decreased nutrient intake, altered metabolism, and/or malabsorption. Risk factors for obesity include family history of obesity, certain medical diagnoses, poor dietary habits, lack of exercise, and some drug therapies. Nutrition screening is typically a rapid and simple process that can be done in the home by the patient or home healthcare professional, in long-term care facilities, in ambulatory care clinics, or in a hospital. Various rating and classification systems have been proposed to assess nutrition risk and guide subsequent interventions.^{5–8} Checklists are used in many clinical settings to quantify a person's food and alcohol consumption habits; ability to buy, prepare, and eat food; weight history; diagnoses; or medical/surgical procedures. Depending on the specific criteria evaluated, the presence of three to four risk factors may increase a person's risk for malnutrition. Pediatric screening programs most often evaluate growth parameters against the NCHS growth charts and medical conditions known to increase nutrition risk. Hospital screening programs must also identify patients receiving specialized nutrition support (enteral or parenteral nutrition) prior to admission.

Nutrition screening using simple tools in the community or outpatient setting, especially in young children and the elderly, can identify potential nutrition issues early before they become significant problems.^{4–8} The Joint Commission, formerly called the Joint Commission on Accreditation of Healthcare Organizations, includes nutrition screening and assessment in their performance standards for institutions.⁹ For inpatients, a nutrition screening process that uses institution-specified criteria should be conducted within 24 to 72 hours of admission. Patients initially determined to be “not at

risk” should be reevaluated every 7 to 14 days to detect deterioration in nutrition status secondary to changes in food intake or clinical condition. By identifying at-risk individuals, nutrition screening can be a cost-effective way to help decrease complications and length of hospital stay. In any setting, patients determined to be “at nutrition risk” should receive a subsequent comprehensive assessment that includes formulation of a nutrition care plan.

ASSESSMENT OF NUTRITION STATUS

³ A comprehensive nutrition assessment is the first step in formulating a patient-specific nutrition care plan. Nutrition assessment has four major goals: (a) identification of the presence of factors associated with an increased risk of developing malnutrition, including disorders resulting from macro- or micronutrient deficiencies (undernutrition), obesity (overnutrition), or impaired metabolism; (b) determination of risk of malnutrition-associated complications; (c) establishment of estimated nutrition needs; and (d) establishment of baseline parameters against which to measure nutrition therapy outcomes.

A comprehensive nutrition assessment should include a nutrition-focused medical, surgical and dietary history, a nutrition-focused physical examination including anthropometrics and laboratory measurements. Nutrition assessment provides a basis for determining the patient's nutrition requirements and the optimal type and timing of nutrition intervention.

CLINICAL EVALUATION

⁴ Clinical evaluation of nutrition status correlates well with objective evaluations (e.g., laboratory and anthropometric measurements). The medical, surgical, and dietary history components of the clinical evaluation provide information regarding those factors that predispose to malnutrition (e.g., prematurity, chronic diseases, gastrointestinal [GI] malfunction, and alcohol abuse) and overnutrition (e.g., poor dietary habits, limited exercise, chronic diseases, and family history). The clinician should direct the interview to elicit any history of weight gain or loss, anorexia, vomiting, diarrhea, and decreased or unusual food intake (Table 143–1).

The nutrition-focused health history and physical examination takes a systems approach to assess lean body mass (LBM) and findings of vitamin, trace element, or essential fatty acid deficiencies or excesses. The assessment should include documentation of the presence and degree of muscle wasting, edema, loss of subcutaneous fat, dermatitis, glossitis, cheilosis, and/or jaundice (Table 143–2).^{5,8}

Since the 1980s, the subjective global assessment, a simple, reproducible, cost-effective approach to nutrition assessment, has been used by many practitioners. Five aspects of the medical and dietary history make up the subjective global assessment: weight changes in the previous 6 months, dietary intake changes, GI symptoms, functional capacity of the GI tract, and the presence of disease states. Weight loss of less than 5% of UBW is considered a “small” loss, 5% to 10% loss is a “potentially significant loss,” and more than a 10% loss is a “definitely significant loss.” Dietary intake should be characterized as either normal or abnormal, and the length of time and degree of abnormal intake should be noted. The presence of GI symptoms (e.g., anorexia, nausea, vomiting, or diarrhea) on a daily basis for longer than 2 weeks is significant. Functional capacity assesses the patient's energy level and whether the patient is active or bedridden. Finally, disease states present are assessed as to their impact on metabolic demands (i.e., no stress, low, moderate, or high stress). Four physical examination findings are rated as normal, mild, moderate, or severe: loss of subcutaneous fat (triceps and chest), muscle wasting (quadriceps and deltoids), edema (ankle and sacral), and ascites. The clinician then ranks the patient's nutrition

TABLE 143-1 Pertinent Data from Nutrition-Focused Medical, Surgical, and Dietary History

Nutrition intake and dietary habits
Anorexia
Unusual or absent taste
Dietary intake and special diets, including enteral or parenteral nutrition
Supplemental vitamin, mineral, or herbal intake
Food allergies or intolerance
Underlying pathology with nutritional effects
Chronic infections or inflammatory states
Neoplastic diseases
Endocrine disorders
Chronic illness including pulmonary disease, cirrhosis, and kidney failure
Hypermetabolic states such as trauma, burns, and sepsis
Digestive or absorptive disease, nausea, vomiting, diarrhea, constipation
Hyperlipidemia
End-organ effects
Weight changes
Skin or hair changes
Exercise intolerance, fatigue
Gastrointestinal tract symptoms: diarrhea, vomiting, constipation
Gastrointestinal surgery
Bariatric surgery
Small bowel and/or colon resection
Gastrectomy
Miscellaneous
Catabolic medications or therapies: corticosteroids, immunosuppressive agents, radiation, or chemotherapy
Other medications: diuretics, laxatives, or anabolic steroids
Genetic background: body habitus of parents, siblings, and family
Alcohol or drug abuse

status as adequately nourished, moderately malnourished, or severely malnourished.^{8,10} Other nutrition assessment tools have been developed and evaluated in various populations.^{8,11}

ANTHROPOMETRIC MEASUREMENTS

5 Anthropometric measurements, gross measurements of body cell mass, are used to evaluate LBM and fat stores. The most common measurements are weight, stature (height or length, depending on age), head circumference (for children younger than 3 years of age), and measurements of limb size, such as skinfold thickness, midarm muscle circumference, wrist circumference, and waist circumference. Bioelectrical impedance analysis (BIA) is also an anthropometric assessment tool. These parameters are used to compare an individual with normative standards for a population and as repeated measurements in an individual to monitor response to a nutrition care plan. In adults, nutrition-related changes in anthropometric measurements occur slowly; several weeks or more are usually required before detectable changes are noted. In infants and young children, however, changes may occur more quickly. Acute changes in anthropometric measurements, specifically weight and skinfold thickness, usually reflect changes in hydration status, which must be considered when interpreting these parameters, particularly in hospitalized patients.

WEIGHT, STATURE, AND HEAD CIRCUMFERENCE

Body weight is a nonspecific measure of body cell mass, representing skeletal mass, body fat, and the energy-using component referred to as LBM. Change in weight over time, particularly in the absence of edema, ascites, and voluntary losses, is an important indicator of altered LBM. Interpretation of actual body weight (ABW) should take into consideration ideal weight-for-height, also referred to as ideal body weight (IBW), UBW, fluid status, and age

TABLE 143-2 Physical Findings Suggestive of Malnutrition

General appearance
Edema (especially ankle and sacral)
Cachexia or obesity
Ascites
Signs and symptoms of dehydration: poor skin turgor, sunken eyes, orthostasis, or dry mucous membranes
Muscle wasting or loss of subcutaneous fat
Skin and mucous membranes
Thin, shiny, dry or scaly skin
Decubitus ulcers
Ecchymoses or perifollicular petechiae
Poor healing of surgical or traumatic wounds
Pallor or redness of gums or fissures at mouth edge
Glossitis, stomatitis, or cheilosis
Musculoskeletal
Retarded growth
Bone pain or tenderness or epiphyseal swelling
Muscle mass less than expected for habitus, genetic history, and level of exercise
Neurologic
Ataxia, positive Romberg test, or decreased vibratory or position sense
Nystagmus
Convulsions or paralysis
Encephalopathy
Failure to meet age-appropriate developmental milestones
Hepatic
Jaundice
Hepatomegaly

(Table 143-3).⁸ The UBW is intended to describe an individual's typical weight and is generally more useful when assessing weight loss or gain than comparing the current weight to an IBW or desirable weight. Dehydration will result in decreased ABW but not a loss in LBM. Once the patient is rehydrated, rechecking the weight is important to establish the baseline weight to use for nutrition evaluation. The presence of edema or ascites increases total body

TABLE 143-3 Evaluation of Body Weight

Actual body weight (ABW) compared to ideal body weight (IBW)	
ABW <69% IBW	Severe malnutrition
ABW 70–79% IBW	Moderate malnutrition
ABW 80–89% IBW	Mild malnutrition
ABW 90–120% IBW	Normal
ABW >120% IBW	Overweight
ABW ≥150% IBW	Obese
ABW ≥200% IBW	Morbidly obese
Actual body weight (ABW) compared to usual body weight (UBW)	
ABW 85–95% UBW	Mild malnutrition
ABW 75–84% UBW	Moderate malnutrition
ABW <75% UBW	Severe malnutrition
Body mass index (BMI) (kg/m²) or (lb/in²)	Interpretation
Adults	
<16	Severe malnutrition
16–16.9	Moderate malnutrition
17–18.5	Mild malnutrition
19–25	Healthy (19–34 years of age)
21–27	Healthy (older than 35 years of age)
25–30	Overweight (19–34 years of age)
27.5–29.9	Overweight (older than 35 years of age)
30–40	Moderate obesity
>40	Severe or morbid obesity
Children	
BMI-for-age <5th percentile	Underweight
BMI-for-age 5th–85th percentile	Healthy
BMI-for-age >85th percentile	At risk for overweight
BMI-for-age ≥95th percentile	Overweight

water (TBW), thus increasing ABW. Weights of patients with severe edema and ascites should not be used for nutrition assessment without taking the extra water weight into consideration. Subtle changes in fluid status that may affect ABW can be detected by monitoring the patient’s daily fluid intake and output.

The IBW provides one population reference standard against which the ABW can be compared to detect both over- and undernutrition states. The IBW for a given height is the weight that correlates with maximum longevity. Numerous reference tables have been generated based on various population statistics. In clinical practice, mathematical equations based on gender and height are used commonly to estimate IBW. IBW is calculated as 50 kg + [2.3 × (inches over 5 feet)] for adult men, and for adult women as 45.5 kg + [2.3 × (inches over 5 feet)]. For obese adults, an adjusted IBW may be used for nutrition-related calculations: adjusted IBW = [(ABW–IBW) × 0.25] + IBW. The IBW of children can be calculated as [(height in cm)² × 1.65]/1,000. Alternatively, IBW-for-height in children can be determined by identifying the weight corresponding to the same growth percentile as the child’s measured stature (length or height) on the appropriate NCHS growth chart.⁴

Change in weight over time can be calculated as the percentage of UBW, where percent change = (ABW/UBW) × 100 (see Table 143–3).⁸ Use of the UBW as a reference point provides a more accurate reflection of clinically and nutritionally significant weight changes. Determining a patient’s UBW, however, depends on patient or family recall, which may be inaccurate. The use of UBW avoids the problems of normative tables, and it documents comparative changes in body weight. The change in weight also should be interpreted relative to time. In adults, unintentional weight loss of more than 10% in less than 6 months correlates with a poor clinical outcome.

Stature is determined by genetics and nutrition intake. If it is not possible to obtain a standing height, other methods to estimate height may be used. The measurement of demispan, the distance from the sternal notch to the web between the middle and ring fingers measured along a horizontally outstretched arm with the wrist in neutral rotation and zero extension or flexion, can be obtained in the seated position. Demispan may more accurately assess height in the elderly, especially those with kyphosis and/or vertebral collapse. Once the demispan is measured, height can be estimated using the following equations: women: height (cm) = 1.35 × demispan (cm) + 60.1; men, height (cm) = 1.4 × demispan (cm) + 57.8. Knee height may also be used to estimate height and is especially helpful in patients with limb contractures, such as patients with cerebral palsy.^{12,13} The knee height is measured from just under the heel to the anterior surface of the thigh just proximal to the patella. Using the average of two measurements rounded to the nearest 0.1 cm, height is estimated using the following equations: women: height (cm) = 84.88 (0.24 × age [years]) + (1.83 × knee height [cm]); men, height (cm) = 64.19 (0.04 × age [years]) + (2.02 × knee height [cm]).¹³

The best indicator of adequate nutrition in a child is appropriate rate of growth. At each medical encounter, weight, stature, and head circumference should be plotted on the appropriate NCHS gender- and age-based growth curve. These charts were developed in 1977 from a large population of healthy, primarily white children and recently revised to better reflect the ethnic mix of the United States’ population. Special growth charts are available for assessment of short- and long-term growth of premature infants^{14,15} and children with Down’s syndrome.¹⁶ For premature infants with corrected postnatal age of 40 weeks or more, the NCHS growth charts can be used; however, weight-for-age and length-for-age should be plotted according to corrected postnatal age until 2 years and 3.5 years of age, respectively.

Recommended intervals between measurements are weight, 7 days; length, 4 weeks; height, 8 weeks; and head circumference, 7

TABLE 143-4 Expected Growth Velocities in Term Infants and Children		
Age	Weight (g/day)	Height (cm/month)
0–3 months	24–35	2.8–3.4
4–6 months	15–21	1.7–2.4
7–12 months	10–13	1.3–1.6
1–3 years	5–9	0.6–1
4–6 years	5–6	0.5–0.6
7–10 years	7–11	0.4–0.5
Example of growth assessment:		
Age: 2 months; weight: 3.9 kg; weight at 1 month of age, 3.1 kg; days since last wt: 30		
Growth velocity = [(3.9 kg–3.1 kg) × 1,000 g/kg]/30 days = 26.7 g/day		
Interpretation: normal growth		

days in infants and 4 weeks in children up to 3 years of age. Growth velocity can be used to assess growth at intervals too close to plot accurately on a growth chart (Table 143–4).⁴ In newborns, average weight gain is 10 to 20 g/kg per day (24 to 35 g/day in term infants and 10 to 25 g/day in preterm infants). Weight gain declines considerably after 2 to 3 months of age.⁴ Head growth (measured by head circumference), which is usually 0.5 cm/week during the first year of life, can be compromised during periods of critical illness or malnutrition. Sustained head growth during these periods, especially at a rate above expected, suggests hydrocephalus.

Growth failure or failure-to-thrive is defined as weight-for-age or weight-for-height (or length) below the 5th percentile or a falloff of two or more major percentiles (major percentiles are defined as 95th, 90th, 75th, 50th, 25th, 10th, and 5th). Weight-for-height evaluation is age-independent and helps differentiate the stunted child (chronic malnutrition) from the wasted child (acute malnutrition). Short stature, which is associated with many chronic diseases, is a manifestation of chronic undernutrition. Short stature in the absence of malnutrition suggests an endocrinopathy such as growth hormone deficiency but may also be a normal variant.

BODY MASS INDEX

BMI, which is most commonly defined as body weight in kilograms divided by the square of the height in meters (kg/m²), is another index of weight-for-height. Using pounds and inches, BMI (lbs/in²) can also be estimated as (weight [pounds]/height [inches²]) × 703. BMI is more highly correlated with body fat than any other indicator using height and weight. It can be used to categorize both obesity and undernutrition in adults and children. Various tables listing BMI stratified by height and weight are available for quick reference. According to the World Health Organization and others, a person with a BMI greater than 25 kg/m² is overweight and one with a BMI of 30 kg/m² or higher is obese. BMI has also been used to assess undernutrition with a BMI less than 18.5 kg/m² indicating undernutrition (see Table 143–3).^{8,17–19}

In general, a healthy weight is one associated with a reduction in disease risk. A BMI greater than 25 kg/m² is considered a risk factor for premature death and disability as consequences of being overweight and of obesity (see Chap. 148). These health risks increase as the BMI increases. Although BMI correlates strongly with total body fat, individual variation, especially in very muscular persons, may lead to erroneous classification of either obesity or malnutrition when BMI alone is used to assess nutrition status. BMI should be interpreted based on individual characteristics including gender, frame size, and age.¹⁸ A major advantage of the revised NCHS growth charts for children 2 years of age and older is the addition of age- and gender-specific BMI charts. Use of these charts helps to heighten parental and healthcare provider awareness of children whose BMI and family history put them at risk for adult obesity and its associated risks.⁴

CLINICAL CONTROVERSY

Clinicians disagree whether an individual's nutrition status is best evaluated using IBW, ABW, adjusted IBW, or BMI. Frame size and muscle mass, as well as gender and height, can influence both IBW and BMI, leading to misclassification of nutrition status. Use of adjusted IBW in obese individuals may lead to under- or overestimation of needs.

SKINFOLD THICKNESS AND MIDARM MUSCLE CIRCUMFERENCE

Skinfold thickness measurement provides an estimate of subcutaneous fat, whereas midarm muscle circumference estimates skeletal muscle mass. Although simple and noninvasive, these anthropometric measurements are not used commonly in clinical practice but can be used for both population analysis and individual long-term monitoring. Triceps skinfold thickness is the most commonly used skinfold measurement, although reference standards also exist for subscapular and iliac sites. More than 50% of the body's fat is subcutaneous, and changes in subcutaneous fat usually reflect changes in total body fat. Careful technique in the use of pressure-regulated calipers is essential for reproducibility and reliability in measuring triceps skinfold thickness. Midarm muscle circumference is a calculated value based on the measurement of the midarm circumference and triceps skinfold thickness.

Individual anthropometric measurements should be interpreted cautiously because standards do not account for individual variations in bone size, muscle mass, hydration status, or skin compressibility; reference standards do not account for obesity, ethnicity, illness, and increased age; and technique is critical (interobserver error can be as high as 30%). Furthermore, these parameters are slow to change in adults, often requiring weeks before significant alterations from baseline can be detected.

WAIST CIRCUMFERENCE

Waist circumference is used to assess abdominal fat content. Excess abdominal fat that is disproportionate to total body fat is an independent predictor of risk for obesity-related complications. Waist circumference is determined by measuring the distance around the smallest area below the rib cage and the top of the iliac crest. Interpretation varies with age. Men are considered at risk if the waist circumference is greater than 40 inches; women are at risk if the waist circumference is greater than 35 inches. These standards do not apply if the patient is less than 5 feet tall or has a BMI of 35 kg/m² or greater.¹⁹

WAIST-TO-HIP RATIO

The waist-to-hip ratio is also associated with undesirable health consequences. For most people, extra weight around the waist confers more of a health risk than extra weight around the hips and thighs. The waist-to-hip ratio is determined by dividing the waist circumference by the hip circumference (maximal posterior extension of the buttocks). For both men and women, a waist-to-hip ratio of 1 or greater is considered a risk factor for adverse health consequences. A ratio of less than 1 in men or 0.8 or less in women is considered "not-at-risk."¹⁹

BIOELECTRICAL IMPEDANCE

BIA is a simple, noninvasive, and relatively inexpensive technique used to measure LBM.^{20,21} The technology is based on the fact that lean tissue has a higher electrical conductivity (less resistance) than

fat, which is a poor current conductor because of its greater fluid and electrolyte content. By applying a very small electric current to appendages (wrist and ankle or both feet), impedance (resistance) to flow can be measured. Assessment of LBM, TBW, and water's distribution into compartments can be determined with BIA. Increased TBW decreases impedance; therefore, it is important to evaluate fluid status along with BIA measurements. Other potential limitations of BIA include variability with electrolyte imbalance, interference by large fat masses (obesity), and the lack of reference standards that reflect variations in individual body size and clinical condition. Although BIA equations have high validity when used in the population in which they were developed (mostly young, healthy adults), BIA calculations are subject to considerable errors if applied to other populations. BIA is not superior to BMI as a predictor of overall adiposity in the general population and is therefore currently used primarily as a research tool.²¹

BIOCHEMICAL ASSESSMENT OF LEAN BODY MASS

6 LBM includes skeletal muscle, somatic protein, and functional proteins such as the circulating and visceral proteins. Biochemically, LBM can be assessed by measuring the serum visceral proteins, albumin (ALB), transferrin (TFN), and prealbumin (thyroxine-binding prealbumin or transthyretin). Retinol-binding protein, fibronectin (an opsonic protein), and somatomedin-C (insulin-like growth factor-1), proteins with a very short half-life (less than 12 to 24 hours), have also been evaluated as indicators of nutrition status. However, the clinical availability of these alternative tests is limited, and their relevance to nutrition status and patient outcome is debatable. Creatinine-height index has historically been used to assess LBM but is seldom used today because of the lack of evidence to support its usefulness in assessing muscle mass.^{8,22}

Visceral Proteins

Measurement of serum concentrations of the transport proteins synthesized by hepatocytes can be used to assess the visceral protein compartment. It is assumed that a low serum protein concentration in states of undernutrition reflects the hepatic protein synthetic mass, and therefore indirectly reflects the functional protein mass of other organs such as heart, lung, kidney, and intestines. The visceral proteins with the greatest relevance for nutrition assessment are serum ALB, TFN, and prealbumin. Many factors other than nutrition may affect the serum concentration of these proteins, including age, abnormal kidney (nephrotic syndrome) or GI tract (protein-losing enteropathy) losses, hydration status (dehydration results in hemoconcentration, overhydration in hemodilution), hepatic function (because this is the primary synthesis site), and metabolic stress (sepsis, trauma, surgery, and/or infection). Visceral protein concentrations must be interpreted relative to the individual's overall clinical condition (Table 143–5).^{5,8,22,23}

Albumin remains one of the most widely used biochemical markers of malnutrition and has long been used in population studies. It is, however, a relatively insensitive index of early protein malnutrition because there is a large amount normally found in the body (4 to 5 g/kg of body weight), it is highly distributed in the extravascular compartment (60%), and it has a long half-life (18 to 20 days). However, chronic protein deficiency in the setting of adequate nonprotein calorie intake leads to marked hypoalbuminemia because of a net ALB loss from the intravascular and extravascular compartments. Serum ALB concentrations also are affected by moderate-to-severe calorie deficiency; hepatic, kidney, and GI disease; and infection, trauma, stress, and burns. In many cases, interpretation of serum ALB concentrations relative to nutrition status is difficult; however, a positive correlation between decreased

TABLE 143-5 Visceral Proteins Used for Assessment of Lean Body Mass

Serum Protein	Half-Life (Days)	Function	Factors Resulting in Increased Values	Factors Resulting in Decreased Values
Albumin	18–20	Maintains plasma oncotic pressure; transports small molecules	Dehydration, anabolic steroids, insulin, infection	Overhydration, edema, kidney dysfunction, nephrotic syndrome, poor dietary intake, impaired digestion, burns, congestive heart failure, cirrhosis, thyroid/adrenal/pituitary hormones, trauma, sepsis
Transferrin (TFN)	8–9	Binds Fe in plasma; transports Fe to bone	Fe deficiency, pregnancy, hypoxia, chronic blood loss, estrogens	Chronic infection, cirrhosis, burns, enteropathies, nephrotic syndrome, cortisone, testosterone
Prealbumin (transthyretin)	2–3	Binds T ₃ and to a lesser extent T ₄ ; carrier for retinol-binding protein	Kidney dysfunction	Cirrhosis, hepatitis, stress, surgery, inflammation, hyperthyroidism, cystic fibrosis, kidney dysfunction, zinc deficiency

Fe, iron; T₃, triiodothyronine; T₄, thyroxine.

serum ALB concentrations and poor clinical outcome has been demonstrated in most of the above mentioned settings. Additionally, serum ALB concentrations of 2.5 g/dL or less can be expected to exacerbate ascites and peripheral, pulmonary, and GI mucosal edema as a result of decreased colloid oncotic pressure.

TFN is a glycoprotein that binds and transports ferric iron to the liver and reticuloendothelial system for storage. As a surrogate marker of nutrition status, TFN will decrease in response to protein depletion before serum ALB concentrations decrease because it has a shorter biologic half-life (8 days), and there is less of it in the body (less than 100 mg/kg of body weight). Serum TFN concentrations may be determined by direct measurement or can be estimated indirectly from measurement of total iron-binding capacity, where $TFN = (total\ iron\text{-}binding\ capacity \times 0.8) - 43$. Critical illness, hydration status, and iron stores affect the serum TFN concentration. In iron deficiency, hepatic TFN synthesis is increased, resulting in increased serum TFN concentrations unrelated to protein status.

Prealbumin is the transport protein for thyroxine and a carrier for retinol-binding protein. The body’s content of prealbumin is low (10 mg/kg of body weight), and it has a very short biologic half-life (2 to 3 days). Prealbumin may be reduced in as few as 3 days after calorie and protein intake is significantly decreased, or when hypercatabolism or severe metabolic stress (trauma or burns) is present. Because of its short half-life, it is most useful in monitoring the short-term, acute effects of nutrition support or deficits. As with ALB and TFN, serum prealbumin concentrations are depressed in those with liver disease as a consequence of decreased hepatic synthesis. Increased serum prealbumin concentrations have been noted in patients with kidney disease as a result of impaired excretion.

Serum visceral proteins are of greatest value in assessing uncomplicated semistarvation and recovery. During severe acute stress (trauma, burns, or sepsis), these proteins are relatively poor markers of nutrition status because their synthesis is downregulated as the liver increases the production of acute-phase reactants such as C-reactive protein, α_1 -acid glycoprotein, and α_1 -antitrypsin.

IMMUNE FUNCTION TESTS

The frequency of impaired immunocompetence and an increased incidence of infection in malnourished patients suggests that certain immune function tests can be used as nutrition status markers. Nutrition affects immune status either directly, affecting primarily the lymphoid system, or indirectly by affecting cellular metabolism or organ systems that are involved with immune system regulation. Immune function tests used in nutrition assessment are the total lymphocyte count and DCH reactions. Both tests are simple, readily available, and inexpensive. Total lymphocyte count reflects the number of circulating T and B lymphocytes. Tissues that generate T cells are very sensitive to malnutrition and undergo involution resulting in decreased T-cell production and eventually lymphocytopenia. Total lymphocyte count is calculated from a complete

blood count with differential: $total\ lymphocyte\ count = (\% \text{ lymphocytes} \times total\ number\ of\ white\ blood\ cells)$. Values of less than 1,500 cells/mm³ and 900 cells/mm³ are associated with moderate and severe nutrition depletion, respectively.²⁴

DCH is commonly assessed using antigens to which the patient was previously sensitized. The recall antigens used most frequently in nutrition assessment are mumps, *Candida albicans*, streptokinase-streptodornase, *Trichophyton*, coccidioidin, and purified protein derivative. Anergy is associated with severe malnutrition, and immune response may be restored with nutrition repletion. Other more sophisticated immune function tests have been used to evaluate nutrition status in research settings, including lymphocyte surface antigens (CD4 and CD8 counts, CD4:CD8 ratio), T-lymphocyte responsiveness, and serum interleukin concentrations. Nonnutrition factors that affect total lymphocyte count include infection (e.g., human immunodeficiency virus/acquired immunodeficiency syndrome, pertussis, viruses, and tuberculosis), immunosuppressive drugs (e.g., corticosteroids, cyclosporine, chemotherapy, and anti-lymphocyte globulin), leukemia, and lymphoma. DCH can be affected by a number of factors, including fever, viral illness, recent live virus vaccination, critical illness, irradiation, immunosuppressive drugs, diabetes mellitus, human immunodeficiency virus/acquired immunodeficiency syndrome, cancer, and surgery. This lack of specificity currently limits the usefulness of these tests as nutrition status markers. Nutrients such as arginine, omega-3 fatty acids, and nucleic acids given in pharmacologic doses have been shown to improve immune function. Monitoring the efficacy of a nutrition care plan that includes these potentially immunomodulating nutrients may need to include immune function assessment with these or other immune function indicators.^{25,26}

SPECIFIC NUTRIENT DEFICIENCIES

7 A comprehensive nutrition assessment must include an evaluation of possible trace element, vitamin, and essential fatty acid deficiencies. Because of their key role in metabolic processes (as coenzymes and cofactors), a deficiency of any of these nutrients may result in altered metabolism and cell dysfunction and may interfere with metabolic processes necessary for nutritional repletion. The evaluation of single nutrient deficiency states includes an accurate history to identify symptoms and risk factors that may indicate deficiency or predispose the patient to developing a deficiency state. A nutrition-focused physical examination for signs of deficiencies and biochemical assessment to confirm a suspected diagnosis also should be done. Ideally, biochemical assessment would be based on the nutrient’s function (e.g., metalloenzyme activity) rather than simply measuring the nutrient’s serum concentration. Unfortunately, few practical methods to assess micronutrient function are available, and most assays measure serum concentrations of the individual nutrient.

TABLE 143-6 Assessment of Trace Element Status

Trace Element	Signs of Deficiency	Signs of Toxicity	Factors Associated with Altered Plasma Concentrations
Chromium	Glucose intolerance, peripheral neuropathy, increased free fatty acid concentrations, low RQ, weight loss, increased LDL-C, glucosuria, impaired protein utilization	Industrial exposure: skin/nasal septum lesions, allergic dermatitis, increased incidence of lung cancer	Decreased: long-term inadequate intake Increased: kidney failure
Copper	Neutropenia, leukopenia, hypochromic anemia, osteoporosis, hair/skin depigmentation, dermatitis, anorexia, diarrhea, mental deterioration, hypercholesterolemia	Wilson's disease: liver cirrhosis, diarrhea, vomiting, metallic taste	Decreased: high iron or vitamin C intake, corticosteroid use Increased: infection, rheumatoid arthritis, pregnancy, oral contraceptives, decreased biliary excretion Decreased: long-term inadequate intake
Iodine	Hypothyroid goiter, neuromuscular impairment, deaf-mutism, increased embryonic and postnatal mortality, cognitive impairment, impaired fertility, cretinism (severe cases)	Thyrotoxicosis: nodular goiter, weight loss, tachycardia, muscle weakness, warm skin	
Iron	Microcytic, hypochromic anemia (weakness, pallor, fatigue), glossitis, headache, dysphagia, nail changes, gastric atrophy, paresthesia, decreased cognitive function	Liver cirrhosis, cardiomyopathy, pancreatic damage, skin pigmentation	Increased: blood transfusion Decreased: blood loss
Manganese	Nausea, vomiting, dermatitis, hair color changes, hypocholesterolemia, growth retardation, defective carbohydrate and protein metabolism	Parkinsonian-like symptoms, hyperirritability, hallucinations, libido disturbances, ataxia	Increased: decreased biliary excretion, high iron or vitamin C intake
Molybdenum	Tachycardia, tachypnea, altered mental status, visual changes, headache, nausea, vomiting	Gout-like syndrome, increased urinary copper	Decreased: low birth weight, excessive GI losses
Selenium	Muscle weakness/pain, cardiomyopathy	Nausea, vomiting, hair/nail loss, tooth decay, skin lesions, irritability, fatigue, peripheral neuropathy	Decreased: malignancy, liver failure, pregnancy Increased: reticuloendothelial neoplasia
Zinc	Dermatitis, hypogeusia, alopecia, diarrhea, apathy, depression, growth retardation, impaired wound healing, immunosuppression, acrodermatitis enteropathica	Acute: gastric distress, nausea, dizziness, death with large intravenous doses Chronic: immunosuppression, decreased HDL-C, copper deficiency	Decreased: infection, burns, stress, hypoalbuminemia, corticosteroids, pregnancy, inflammation Increased: tissue injury, hemolysis, contaminated collection tube

HDL-C, high-density-lipoprotein cholesterol; LDL-C, low-density-lipoprotein cholesterol; RQ, respiratory quotient.

TRACE ELEMENTS

Clinical syndromes are associated with deficiency states of the essential trace elements zinc, copper, manganese, selenium, chromium, iodine, fluoride, molybdenum, and iron in children and adults. Each element is involved in a variety of biologic functions and is necessary for normal metabolism, serving as a coenzyme and/or playing a role in hormonal metabolism or erythropoiesis. Other essential trace elements for which deficiency states have not been recognized include tin, nickel, vanadium, cobalt, gallium, aluminum, arsenic, boron, bromine, cadmium, germanium, and silicon. Toxicities can occur with excess intake of some trace elements. With the current public interest in alternative and complementary medicine, clinicians must ask patients about their use of nutrition supplements and assess for signs and symptoms of toxicities (overdose) as well as deficiencies (Table 143–6).

Zinc is a component of many enzymes and proteins and is involved in the regulation of gene expression. Zinc deficiency is characterized by several signs and symptoms, including a moist eczematous dermatitis that is most apparent in the nasolabial folds and around orifices (see Table 143–6).^{27,28} Zinc deficiency occurs most frequently with abnormal GI losses, such as in Crohn's disease, malabsorptive states (e.g., short-bowel syndrome), and extensive ostomy or fistula losses, or from prolonged inadequate intake, such as with zinc-free or inadequately zinc-supplemented parenteral nutrition. Zinc deficiency can be documented by the presence of low plasma zinc concentrations. However, plasma zinc concentrations decrease in acute stress states such as trauma, surgery, burns, or sepsis and generally remain depressed until stress resolves. Also, because zinc is a normal contaminant of most blood collection tubes, special zinc-free collection tubes must be used for plasma assays. Hair zinc analysis by atomic absorption spectroscopy or neutron activation analysis may be a good indicator of zinc status in children,²⁹ and lymphocyte 5'-nucleotidase activity and leukocyte

zinc content are better indicators of zinc status in adults, but these assays are not widely available.

Copper is a component of enzymes involved in iron metabolism. The signs and symptoms of copper deficiency include anemia, skeletal demineralization, and hypercholesterolemia (see Table 143–6).^{27,28} In severe cases, such as in Menkes syndrome, copper deficiency is further manifested as hypothermia, hair and skin depigmentation, progressive mental deterioration, and growth retardation. Factors predisposing to copper deficiency include malabsorption states, protein-losing enteropathy, nephrotic syndrome, and copper-free parenteral nutrition.^{30,31} The chronic ingestion of too much copper or inadequate elimination can result in liver cirrhosis (e.g., Wilson disease). Copper deficiency is assessed most frequently using plasma copper or ceruloplasmin concentrations. As with zinc, serum copper concentrations may not accurately reflect total body copper status because serum concentrations may be altered by a variety of conditions and may remain normal even when hepatic stores are deficient (see Table 143–6). Copper function also may be assessed by measuring activity of the cuproenzymes—erythrocyte superoxide dismutase or cytochrome-C oxidase—in platelets or leukocytes. Enzyme activity is decreased significantly in copper deficiency. However, measurement of enzyme activity is method and technique sensitive and not routinely available.

Chromium is an important cofactor, along with insulin, in the maintenance of normal blood glucose concentrations. Chromium deficiency is characterized by glucose intolerance and impaired protein utilization. Patients with chromium deficiency also may have increased free fatty acid concentrations and a low respiratory quotient (RQ) (see Table 143–6). Chromium deficiency has only been identified in patients receiving long-term parenteral nutrition with inadequate chromium intake.^{27,28,32,33} Plasma chromium concentrations do not accurately reflect total body chromium status, presumably because the biologically active form of chromium is an organic substance known as the glucose tolerance factor. Chro-

mium toxicity is not a common clinical concern and has been reported only with contaminated drinking water or industrial exposure. Chromium picolinate supplementation as an adjunct for weight loss has not been proven effective. Manganese is important in the function of many enzymes, including arginase (amino acid metabolism), pyruvate carboxylase (carbohydrate metabolism), and superoxide dismutase (cholesterol metabolism; antioxidant), and in bone formation. Manganese deficiency has only been reported in association with the ingestion of chemically defined manganese-deficient oral diets.^{27,28} Table 143–6 lists common symptoms associated with manganese deficiency. Manganese toxicity is more concerning and has been described in several patients receiving long-term parenteral nutrition supplemented with a standard trace element preparation.^{34–38} Manganese appears to accumulate in brain tissue, especially in the setting of chronic cholestasis and short-bowel syndrome. Clinical toxicity is evidenced primarily by extrapyramidal symptoms mimicking Parkinson's disease. Serum manganese concentrations do not correlate well with the clinical presentation, but magnetic resonance imaging of the basal ganglia may show hyperintensity areas, especially in the globus pallidus. In most reported cases, discontinuation of manganese in the parenteral nutrition solution resulted in resolution of neurologic symptoms in 6 months with partial or total normalization of the magnetic resonance image after 1 to 2 years. Other methods of evaluating manganese status include measuring the manganese content of mononuclear blood cells³⁷ and the activity of manganese superoxide dismutase, a mitochondrial antioxidant enzyme.³⁷ These methods are good indicators of manganese status but are not widely available.

Selenium, as selenocysteine, is incorporated into several enzymes: glutathione peroxidase (antioxidant), iodothyronine deiodinase (thyroid hormone regulation), and selenoprotein P (vitamin C metabolism). Prematurity, acute illness, chronic GI losses, and long-term selenium-free parenteral nutrition are associated with low serum selenium concentrations and decreased glutathione peroxidase activity.^{27,28,39–43} The clinical significance of reduced serum selenium concentrations is unclear. Selenium deficiency has been described in patients receiving long-term selenium-free parenteral nutrition. Muscle pain and weakness are the most frequently observed signs and symptoms (see Table 143–6), but severe biochemical deficiency is not always accompanied by these symptoms. Fatal cardiomyopathy has been reported in several cases.

Selenium toxicity or selenosis generally only occurs in those with long-term exposure to foods grown in selenium-rich soil (e.g., Great Plains area of the United States) and may occur when intake exceeds 400 mcg per day for prolonged periods. Selenium status may be assessed by measuring plasma selenium concentrations, which will reflect recent selenium intake. Decreased concentrations may indicate selenium deficiency, but reductions also have been observed in patients with malignancies, liver failure, and pregnancy. Assays that measure the activity of the selenium-containing enzyme glutathione peroxidase in erythrocytes or the plasma concentration of selenoprotein P may be more sensitive indicators of selenium status because they reflect chronic ingestion, but neither is widely available.

Molybdenum is a cofactor for enzymes involved in catabolism of sulfur amino acids, purines, and pyrimidines (i.e., xanthine, aldehyde, and sulfite oxidases). Molybdenum deficiency is rare. One case of molybdenum deficiency has been reported in a patient receiving long-term parenteral nutrition who presented with symptoms that included tachycardia, tachypnea, headache, night blindness, nausea, vomiting, central scotomas, lethargy, disorientation, and ultimately coma (see Table 143–6). Symptoms were reversed when molybdenum was added to the parenteral nutrition solution.⁴⁴ Factors predisposing to molybdenum deficiency appear to be low birth weight, excessive loss via the GI tract, such as with short-bowel syndrome, and long-

term inadequate intake, such as with molybdenum-free parenteral nutrition. Biochemical abnormalities expected in molybdenum deficiency include very low serum and urine uric acid concentrations (low xanthine oxidase activity) and low urine inorganic sulfate concentrations (low sulfate oxidase activity).⁴⁵

Deficiency of iodine, a component of thyroid hormones, may result in goiter formation (see Chap. 78). However, not everyone with an iodine-deficient diet will develop a goiter. Thyroxine (T_4) and triiodothyronine (T_3) can be used to assess iodine status (see Table 143–6). Intravenous iodine supplements typically are not necessary except during long-term parenteral nutrition with minimal enteral intake. Iodine needs generally are met by cutaneous absorption of iodine from germicides (e.g., povidone-iodine) used in catheter care or consumption of iodized salt.^{46,47} Use of povidone-iodine as a topical antiseptic has decreased with the increased use of chlorhexidine for catheter care, thus the need for iodine supplementation must be individualized. Iodine excess is rarely a clinical concern when thyroid function is normal.

Iron is an important component of hemoglobin, myoglobin, and cytochrome enzymes; it is important in oxygen transport, muscle iron storage, and cellular energy production. Patients with iron-deficiency anemia generally present with fatigue, weakness, and pallor, but they may have other symptoms (see Chap. 104). Inadequate iron intake, malabsorption, and blood loss are the principal causes of iron-deficiency anemia. Iron toxicity (overload) with possible organ damage can occur when chronic iron intake exceeds requirements such as in patients receiving frequent blood transfusions. Iron deficiency or overload is confirmed by assessment of body iron stores, as reflected indirectly by measurement of hemoglobin, serum iron, total iron-binding capacity, and serum ferritin, or directly by marrow staining and liver biopsy. Although the direct methods are the most accurate, they are invasive, and indirect measurements are used more commonly. Because indirect parameters may be altered by chronic illness independent of iron stores, concomitant illness must be considered in their interpretation.

VITAMINS

Vitamins act as both catalysts (cofactors) and substrates in essential metabolic reactions in the body. A comprehensive nutrition-focused history and physical examination is the most valuable means of assessing patients for vitamin deficiency or toxicity (Table 143–7). A thorough review of all the complex interrelationships of vitamins and their effects on nutrition and metabolism, however, is beyond the scope of this chapter.⁴⁸ Although it is uncommon to see a single-vitamin deficiency as multiple vitamin deficiencies are most often associated with generalized malnutrition, single-vitamin deficiencies may occasionally be noted. Thiamine deficiency may result in lactic acidosis and encephalopathy,⁴⁹ whereas pernicious anemia caused by vitamin B_{12} (cyanocobalamin) deficiency has been reported with increasing frequency, especially in the elderly, as a consequence of decreased gastric acidity. Recently, the incidence of vitamin D deficiency was reported to be increased, especially in children⁵⁰ and the elderly.^{51,52} Laboratory assessment may be useful to confirm the clinical suspicion of a deficiency state. The first indication of a deficiency is usually a fall in circulating serum concentrations of the vitamin or its coenzyme. Subsequently, there is a decrease in urinary excretion of the vitamin, which, in turn, is followed by diminished tissue concentrations of the vitamin. The most common measurements of vitamin status are assays of circulating amounts in plasma or serum. Assays of biochemical or metabolic function of the vitamin are more likely to reflect body stores than are serum concentrations. Most of these functional assays use erythrocyte or leukocyte extracts to determine apoenzyme activity, which is dependent on the vitamin coenzyme (Table 143–7). Vitamin toxicity can occur, especially with

TABLE 143-7 Assessment of Vitamin Status

Vitamin	Signs of Deficiency	Laboratory Assay	Comments
Water-soluble vitamins			
Thiamine (B ₁)	Early: anorexia, fatigue, depression, impaired memory/concentration Late: paresthesia, nystagmus, lactic acidosis, congestive heart failure, Wernicke-Korsakoff's syndrome, peripheral neuritis, beriberi	Whole blood or erythrocyte transketolase activity Blood thiamin	Increased need with hemodialysis, peritoneal dialysis, alcoholism, malabsorption, hypermetabolism
Riboflavin (B ₂)	Mucositis, dermatitis, cheilosis, photophobia, corneal vascularization, lacrimation, decreased vision, impaired wound healing, normocytic anemia	Urinary riboflavin	
Pantothenic acid	Fatigue, malaise, headache, insomnia, vomiting, abdominal cramps	Serum pantothenic acid	
Niacin	Pellagra: dermatitis, dementia, glossitis, diarrhea, memory loss, headaches	Urinary niacin metabolites	Flushing and GI distress can be seen with supplements; increased need with hemo- and peritoneal dialysis, malabsorption
Pyridoxine (B ₆)	Dermatitis, glossitis, distal limb numbness/paresthesia, convulsions, sideroblastic anemia	Serum pyridoxal 5'-phosphate Plasma B ₆	Sensory neuropathy with high supplement intake
Folic acid	Megaloblastic anemia, diarrhea, glossitis, cheilosis, angular stomatitis, fatigue, difficulty concentrating, irritability, headache, palpitations, shortness of breath, heart failure, tachycardia, postural hypotension, lactic acidosis, neural tube defects	Serum folate Serum homocysteine	Decreased with increased cellular/tissue turnover (pregnancy, malignancy, hemolytic anemia); masks neurologic complications of vitamin B ₁₂ deficiency; decreases risks of neural tube defects
Cyanocobalamin (B ₁₂)	Pernicious anemia, glossitis, spinal cord degeneration, peripheral neuropathy	Serum B ₁₂ Serum methylmalonic acid	Decreased absorption in the elderly, distal ileal resection, loss of gastric intrinsic factor
Biotin	Dermatitis, depression, lassitude, somnolence	Urinary biotin	
Ascorbic acid (C)	Enlargement/keratosis of hair follicles, impaired wound healing, anemia, lethargy, depression, bleeding, ecchymosis	Plasma ascorbic acid	GI disturbances, kidney stones, excess iron absorption with excess intake; smokers need 35 mg/day more than non-smokers
Fat-soluble vitamins			
Retinol (A)	Dermatitis, night blindness, xerophthalmia, Bitot spots, ^a pruritus, follicular hyperkeratosis, excessive deposition of periosteal bone, hair changes, poor growth Irreversible: punctate keratopathy, keratomalacia, corneal perforation	Serum vitamin A	Teratogenic effects, liver toxicity with excessive intake; alcohol intake, liver disease, hyperlipidemia, and severe protein malnutrition increase susceptibility to adverse effects of high intake; β -carotene supplements recommended only for those at risk of deficiency (fat malabsorption)
D	Rickets, osteomalacia, muscle weakness, poor growth, hypocalcemia	Plasma 25-hydroxy vitamin D	Elevated intake causes hypercalcemia; decreased in uremia, elderly (especially in winter), fat malabsorption
α -tocopherol (E)	Hemolysis	Serum vitamin E	Excess intake: hemorrhagic toxicity; increased risk of bleeding with anticoagulants
K	Bleeding (ecchymosis, petechiae, hematomas)	Prothrombin time	Anticoagulant therapy can be affected by supplements or diet

^aBitot spots are spots located superficially in the conjunctiva, which are oval, triangular, or irregular in shape.

the fat-soluble vitamins (A, D, E, and K), which are stored in the body. Excessive dietary intake of vitamin A (hypervitaminosis A) is linked to an increased risk of hip fractures in both men and women.^{53–55} With the exception of cyanocobalamin, which is stored in the liver, water-soluble vitamins are not stored in the body; consequently, the risk of toxicity is considered minimal unless ingested in very high individual doses. Recent evidence, however, suggests that even water-soluble vitamins may be associated with adverse events when taken chronically in high doses. Although administration of folic acid is definitively associated with a reduction in neural tube defects, its ability to improve some cardiac outcomes (a result of its effect on homocysteine concentrations) is less-well established.^{56,57} The administration of folic acid, vitamin B₆ (pyridoxine), and vitamin B₁₂ after coronary artery stenting is associated with an increase in the risk of in-stent restenosis.⁵⁸ With the current use of nutrition supplements by Americans, the clinician should be alert for the signs of hypervitaminosis (Table 143–7).

ESSENTIAL FATTY ACIDS

The body can synthesize all fatty acids except α -linoleic acid (an omega-6 fatty acid) and linolenic acid (an omega-3 fatty acid). Consequently, intake of approximately 2% to 4% of total calories as these fatty acids is essential to prevent deficiency. Symptoms of

essential fatty acid deficiency include dermatitis (dry, cracked, scaly skin), alopecia, impaired wound healing, growth failure, thrombocytopenia, and anemia. Essential fatty acid deficiency is rare in adults and children but can occur with prolonged use of lipid-free parenteral nutrition, with severe fat malabsorption, with very-low-fat enteral feeding formulations or diets, and with severe malnutrition, especially in stressed patients.^{59,60} In critically ill adults and older children with increased metabolic demands, biochemical evidence of essential fatty acid deficiency can occur within 1 week of starting lipid-free parenteral nutrition.^{59,60} Because newborns, especially those born prematurely, have limited fat stores, they may develop essential fatty acid deficiency more rapidly than adults. Biochemical essential fatty acid deficiency has been noted within 72 hours after birth in preterm infants receiving fat-free intravenous solutions.⁶¹

Linoleic acid normally is converted to arachidonic acid (a tetraene fatty acid). If linoleic acid is unavailable, oleic acid will be substituted, which results in production of eicosatrienoic acid (a triene fatty acid) as the metabolic end product, enabling an essential fatty acid deficiency to be detected on the basis of decreased tetraene production and increased triene production. Normally, the ratio of trienes to tetraenes is less than 0.4; when this ratio becomes greater than 0.4, the diagnosis of essential fatty acid deficiency is established. However, because analysis of plasma fatty acids is expensive and not widely available, diagnosis is generally made on clinical findings.

CARNITINE

Carnitine is a quaternary amine required for transport of long-chain fatty acids into the mitochondria for β -oxidation and energy production. Carnitine also binds acyl residues and helps in their elimination (detoxification), thereby decreasing the number conjugated with coenzyme A and increasing the ratio of free to acetylated coenzyme A. Carnitine is available from a wide variety of dietary sources (especially meats) and can be synthesized by the liver and kidneys from lysine and methionine. Hepatic synthesis is decreased in premature infants, and low plasma carnitine concentrations and/or overt carnitine deficiency have been documented in premature infants receiving parenteral nutrition or carnitine-free diets, as well as in those with inborn errors of metabolism.^{62–64} Other predisposing factors for carnitine deficiency include chronic kidney or liver disease, vitamin C deficiency, chronic use of valproic acid and zidovudine, and a vegetarian diet.

The clinical presentation of carnitine deficiency includes generalized skeletal muscle weakness, fatty liver, and fasting hypoglycemia. Carnitine status can be assessed by measurement of plasma, urine, or red blood cell total and free carnitine concentrations. Plasma and urine carnitine concentrations are most helpful in primary carnitine deficiency (an inborn error of metabolism). Plasma concentrations constitute less than 1% of the total body carnitine.⁶³ Acylcarnitine concentrations are more helpful in secondary causes of carnitine deficiency. When only total and free concentrations are available, the free is subtracted from the total to give the acylcarnitine concentration.

MUSCLE FUNCTION TESTS

A relatively new approach in nutrition assessment is evaluation of muscle function as an end-organ response. Hand-grip strength (forearm muscle dynamometry), respiratory muscle strength, and muscle response to electrical stimulation have been used. Measuring hand-grip strength is a relatively simple, noninvasive, and inexpensive (most hand-grip dynamometers cost less than \$400) procedure that correlates with patient outcome.^{65–67} Ulnar nerve stimulation causes measurable muscle contraction and is currently used in the intensive care unit to monitor the adequacy of neuromuscular blockade. In the setting of malnutrition, increased fatigue and a slowed muscle relaxation rate have been noted; these indices return to normal after refeeding. Both these parameters have the advantage of being indicators of tissue function rather than composition. Their usefulness in clinical practice is currently hampered by a lack of appropriate reference standards and limited data confirming their sensitivity and specificity for nutrition assessment.

OTHER NUTRITION ASSESSMENT TOOLS

Various methods to determine body composition have been used in the research setting. These methods generally are complex, require expensive technology, and at present are limited to research centers. One of the most promising for routine clinical practice is dual-energy x-ray absorptiometry (DXA). DXA is best known for its use in measuring bone density for the evaluation of osteoporosis, but DXA can be used to quantify the mineral, fat, and LBM compartments of the body.^{68–71} DXA is available in most hospitals and many clinics. Equipment for central DXA scans requires a fair amount of space and is expensive; that is, \$40,000 to \$160,000 depending on complexity of the scanner. Portable (or peripheral) DXA devices that use ultrasound and infrared interactance can be used to measure bone density in peripheral bones such as the wrist, fingers, or heel, and have also been used to assess subcutaneous fat. These portable DXA scanners are much less expensive (\$10,000 to \$20,000 or less) and are amenable for use in community screenings in malls,

health fairs, and pharmacies. Further research is needed to determine if DXA will be useful clinically in nutrition assessment.

Magnetic resonance imaging and computed tomography can measure subcutaneous, intraabdominal, and regional fat distribution. Neutron activation is a means of measuring body nitrogen, calcium, sodium, chloride, and phosphorus. These measurements can then be used to calculate total body fat, bone, and protein. Isotope dilution methods determine TBW and underwater weighing determines density. In addition, these methods can be used to estimate LBM and body fat. LBM also can be estimated using total body electrical conductivity and by measuring the naturally occurring isotope ⁴⁰K. These techniques are used primarily in research and seldom in clinical practice.

ASSESSMENT OF NUTRIENT REQUIREMENTS

8 Nutrition requirements depend on an individual's clinical condition and the need for continued maintenance of adequate nutrition, or whether starvation or ongoing metabolic stress dictates a need for repletion. For obese patients, usual nutrition requirements may be altered because of the need for weight loss. In children, there is the added consideration of sustaining or reestablishing normal growth and development. Organ function (e.g., intestine, kidney, liver, and pancreas) may affect nutrient utilization.

Nutrient requirements vary with age, gender, size, disease state, clinical condition, nutrition status, and physical activity level. An estimate of nutrient requirements must be made using guidelines interpreted in the context of these patient-specific factors. The recommended dietary allowances (RDAs) initially were intended as guidelines for preventing nutrition deficiencies in a healthy population of individuals, but they have often been used inappropriately to evaluate the diets of individuals. In the early 1990s, the Food and Nutrition Board began the task of revising the RDAs and created a new family of nutrition reference values, the dietary reference intakes (DRIs) which include seven nutrient groups.⁷²

The four categories of the new DRIs are estimated average requirements, RDAs, adequate intakes, and tolerable upper intake levels. Estimated average requirements can be used for planning nutrient intakes for groups, as they are defined as the amount of the nutrient that meets the needs of 50% of persons in a given group. The RDA is designated as nutrient intake that meets the needs of almost all persons in the designated group. The RDA is approximately two standard deviations above the estimated average requirement for nutrients for which the requirement is well defined, and 1.2 times the estimated average requirement for nutrients for which there is more variability. To evaluate an individual's daily intake, the RDA is the most appropriate comparator. Adequate intakes are defined as the average intake of a designated group that appears to sustain a particular nutrition state, growth, or other functional indication of health. This category is reserved for nutrients for which no estimated average requirement or RDA has been determined. Finally the tolerable upper intake level is the maximum nutrient intake that is unlikely to pose adverse effects in almost all persons in a designated group. DRIs have been established for six of the seven established nutrient groups: (a) calcium, phosphorus, magnesium, vitamin D, and fluoride; (b) folate and other B vitamins; (c) antioxidants (e.g., selenium and vitamins C and E); (d) trace elements; (e) macronutrients (e.g., protein, fat, carbohydrates, and fiber); and (f) electrolytes and water.⁷² Recommendations for group seven, which includes other food components (e.g., phytoestrogens), are still in development.

ENERGY REQUIREMENTS

The DRIs for macronutrients recommend that adults consume 45% to 65% of their total calories as carbohydrates, 20% to 35% as fat,

and 10% to 35% as protein.⁷³ The recommendations for children are similar: carbohydrate, 45% to 65%; fat, 30% to 40%; and, protein, 10% to 30%. Infants, especially premature infants, need a higher proportion of fat (approximately 40% to 50% of total calories) in their diets to ensure normal neurologic development. An RDA for total carbohydrates of 130 g/day for adults and children is included in the most recent DRIs.^{72–74}

CLINICAL CONTROVERSY

Clinicians continue to debate whether an individual's energy requirements should be expressed as total or nonprotein calories. Proponents of nonprotein calories argue that sufficient energy must be provided from nonprotein sources (dextrose and fat) to spare protein from conversion to energy to be used for wound healing and LBM maintenance. Supporters of total calories state that the nonprotein calorie approach overestimates energy needs because 15% of daily energy expenditure is derived from protein breakdown. Even with adequate energy intake, protein metabolism is not necessarily prioritized for anabolism, especially during stress. Additionally, standard equations for estimating energy needs were derived using total energy-expenditure measurements. Regardless of the method chosen, the practitioner should consistently document which method was used.

Estimating Energy Expenditure

There are numerous published methods for determining an individual's total energy or calorie (kcal) requirement. The most commonly used methods to determine energy requirements use population estimates of calories per kilogram of body weight (kcal/kg), equations that estimate an individual's energy expenditure, or indirect calorimetry. The simplest method to assess energy requirements is to use population estimates of calories required per kilogram of body weight. This method assumes standard values for the energy requirements associated with various disease states or clinical conditions, as well as the additional requirements for repletion of a malnourished individual. It does not take into consideration age- or gender-related differences in energy needs. Daily adult requirements determined by this method, using ABW or adjusted IBW in kilograms, are accepted to be:

Healthy, normal nutrition status: 20 to 25 kcal/kg per day

Malnourished or metabolically stressed: 25 to 30 kcal/kg per day

Major burn injury (>50% total body surface area): 30 to 40 kcal/kg per day

Table 143–8 shows suggested calorie intakes for maintenance and normal growth of healthy infants and children.^{72,73} For children, these maintenance energy requirements are approximately 150% of basal metabolic rate, with the additional calories needed to support activity and growth. Caloric requirements increase with fever, sepsis, major surgery, trauma, burns, and long-term growth failure, and in the presence of chronic conditions such as bronchopulmonary dysplasia, congenital heart disease, and cystic fibrosis. Energy needs may decrease with obesity and neurologic disability (e.g., cerebral palsy). Clinical judgment and close monitoring are essential to ensure that the desired nutrition therapy outcomes are attained.

Various equations are used to estimate energy needs of adults and children (see Table 143–9).^{60,73,75} The Harris-Benedict equations are a popular means for assessing energy requirements in adults. They have the advantage of taking into consideration the patient's age, height, weight, gender, and clinical condition. These equations were derived from oxygen (O₂) consumption measurements made on normally nourished individuals who were in a fasting and resting state. Although these equations are commonly referred to as the

TABLE 143-8 Dietary Reference Intakes for Energy and Protein in Healthy Children

Age (Reference Age/Weight)	Estimated Energy Requirement (kcal/day)		Protein RDA (g/kg/day) ^a
	Boy	Girl	
0–6 months (3 months/6 kg)	570	520	1.52 ^b
7–12 months (9 months/9 kg)	743	676	1.5
1–2 years (24 months/12 kg)	1,046	992	1.1
1–3 years (24 months/12 kg)			
3–8 years (6 years/20 kg)	1,742	1,642	0.95
4–8 years (6 years/20 kg)			
9–13 years (11 years/M: 36 kg; W: 37 kg)	2,279	2,071	0.95
14–18 years (16 years/M: 61 kg; W: 54 kg)	3,152	2,368	0.85

M, men; RDA, recommended dietary allowance; W, women.

^aProtein requirements in metabolically stressed children increase by 50% or more.

^bAdequate intake (AI).

Adapted from Food and Nutrition Board.^{72,73}

“BEE (basal energy expenditure) equations,” they actually estimate resting energy expenditure (REE), the amount of energy expended at rest by a fasting, awake individual in a temperature-controlled environment performing only basal functions such as breathing, circulation, and metabolic processes. Table 143–9 shows the Harris-Benedict equations.

Because these equations approximate REE, their results must be modified by a factor that is most representative of the individual's clinical condition. For example, an individual who is confined to bed

TABLE 143-9 Equations to Estimate Energy Expenditure in Adults and Children^a

Adults

Harris-Benedict (kcal/day)

Men: BEE = 66 + [(13.7W(kg)) + [5H(cm)] – (6.8A)]

Women: BEE = 655 + [(9.6W(kg)) + [1.8H(cm)] – (4.7A)]

DRI equations (kcal/day)

Men: EER = 662 – 9.53A + (PA × 15.91W) + 539.6H(m)

Women: EER = 354 – 6.91A + (PA × 9.36W) + 726H(m)

PA = 1 if sedentary; 1.12 if low active; 1.27 if active; and 1.45 if very active.

Children

FAO/WHO/UNU (kcal/day)

0–3 years of age

Boys: BMR = 60.9W – 54

Girls: BMR = 61W – 51

4–10 years of age

Boys: BMR = 22.7W + 495

Girls: BMR = 22.5W + 499

11–18 years of age

Boys: BMR = 17.5W + 651

Girls: BMR = 12.2W + 746

DRI equations (kcal/day)

Birth through 2 years of age

EER = (89W – 100) + GF

GF = 175 kcal if 0–3 months; 56 kcal if 4–6 months; 22 kcal if 7–12 months; 20 kcal if 13–35 months

3–18 years of age

Boys: EER = 88.5 – (61.9A) + PA [26.7W + 903H(m)] + GF

Girls: EER = 135.3 – (30.8A) + PA [10W + 934H(m)] + GF

GF = 20 kcal if 3–8 years; 25 kcal if 9–18 years.

PA = 1 if sedentary; 1.13–1.16 if low activity; 1.26–1.31 if normal activity; and 1.42–1.56 if very active

A, age in years; BEE, basal energy expenditure; BMR, basal metabolic rate; DRI, Dietary Reference Intakes; EER, estimated energy requirement; FAO/WHO/UNU, Food and Agriculture Organization/World Health Organization/United Nations University; GF, growth factor, H, height in centimeters (cm) or meters (m), as indicated; PA, physical activity factor; W, weight in kilograms.

^aNo real consensus exists as to which formula is best in all situations. Many clinicians use both to calculate a range of acceptable intakes.

TABLE 143-10 Stress Factors for Use in Children and Adults

Condition	Factor
No stress	
Confined to bed	1.2
Out of bed: normal activity	1.3
Catch-up growth	1.5
Mild stress	
Postoperative recovery: uncomplicated surgery	1
Trauma: mild (e.g., long-bone fracture)	1.2
Moderate stress	
Sepsis (moderate)	1.3
Trauma: central nervous system (sedated)	1.3
Trauma: moderate to severe	Children: 1.5 Adults: 1.3
Severe stress	
Sepsis (severe)	Children: 1.6 Adults: 1.3
Trauma: central nervous system (severe)	Children: Up to 2.0 Adults: up to 1.3
Burns (proportionate to burned area)	Up to 2.0

may require a calorie intake that is only 20% to 30% above the REE, whereas a person who is suffering from a severe burn injury may require 150% to 200% of the calculated REE. Some clinicians multiply the calculated REE by both a stress factor and an activity factor. Because in validation studies in healthy subjects these equations have been shown to overestimate REE by 6% to 15%, the calculated REE should be multiplied by either a stress factor or an activity factor to avoid further overestimation of the individual's energy needs.⁷² It should also be noted that ABW (up to a BMI of 57 kg/m² in men and 40 kg/m² in women), not IBW or adjusted IBW, was used to generate the original data with these equations.⁷² The metabolic response to stress in children appears to be similar to that seen in critically ill adults, and the “stress factors” used in adults and shown in Table 143-10 can be used in children once the REE has been determined using one of the equations shown in Table 143-9.^{76,77} Controversy exists over the accuracy and reliability of predicting energy expenditure based on these equations because clinical judgments of stress level or activity level will vary between clinicians.^{69,77}

Measuring Energy Expenditure

The most accurate method to determine energy expenditure is to measure it using indirect calorimetry, also referred to as metabolic gas monitoring. Indirect calorimetry methodology is based on the fact that when substrates (carbohydrates, fat, and protein) are oxidized, O₂ is consumed and carbon dioxide (CO₂) is produced in varying amounts depending on the substrate being oxidized. Indirect calorimetry is a noninvasive procedure where oxygen consumption (VO₂, mL/min) and carbon dioxide production (VCO₂, mL/min) are measured, and the measured resting energy expenditure (MREE; kcal/day) is calculated using the abbreviated Weir equation as $(MREE = 3.9VO_2 + 1.1VCO_2) \times 1.44$.⁷⁷⁻⁸⁰

MREE represents the total energy expended by the patient during the time period over which the measurements were taken. It is often extrapolated to a 24-hour period to approximate daily energy requirements. MREE reflects alterations in energy requirements as a result of disease or clinical condition, but does not include energy required for nutritional repletion of a malnourished individual or growth in a child. The energy intake required for these functions is accounted for by multiplying MREE by a metabolic or activity factor: mechanically ventilated, critically ill, 1; critically ill, no mechanical ventilation, 1 to 1.1; adult acute noncritically ill, 1.1 to 1.4 depending on activity; adult needing repletion or a child, 1.3 to 1.5; adult outpatient, 1.1 to 2 depending on activity; and adult depletion (weight loss), less than 1.⁷⁹

The data obtained from indirect calorimetry also can be used to determine an RQ which reflects substrate oxidation, characterizes substrate use, and is calculated as VCO₂/VO₂. RQ values for nutrient substrates are fat, 0.7; carbohydrate, 1; protein, 0.8; and mixed substrate (fat, carbohydrate, and protein), 0.85. An RQ value of greater than 1 represents either lipogenesis or hyperventilation; an RQ value of less than 0.7 may indicate a ketogenic diet, fat gluconeogenesis, or ethanol oxidation. Values outside the 0.67 to 1.3 range should raise doubts as to the test's validity. Clinically, the RQ is used to determine if a patient is being overfed, which is indicated by an RQ value greater than 1.

CLINICAL CONTROVERSY

Clinicians do not agree on the best method for estimating energy requirements for a specific individual. Numerous equations and “stress” factors have been published, but none has been shown to be superior in all situations. These equations are probably adequate, however, for determining most individuals' needs. Measuring energy expenditure with indirect calorimetry is potentially more accurate, especially for the stressed, hospitalized, and ventilated patient, but it is neither appropriate nor available for all patients. Regardless of the method chosen, careful monitoring of the response to nutrition intervention is imperative.

There are limitations to the use of indirect calorimetry.^{60,78,79} Not all institutions have metabolic carts available or personnel trained to use them. Calibration errors are common, and indirect calorimetry overestimates REE for patients with hyperventilation, metabolic acidosis, overfeeding, and air leaks anywhere in the system. Underestimates of REE are likely with hypoventilation, metabolic alkalosis, underfeeding, and gluconeogenesis. Mechanically ventilated patients are technically easier to study because the indirect calorimeter circuit can be integrated into the ventilator circuit. The patient must be at complete rest for 1 hour, must not receive bolus feedings either by feeding tube or orally for 4 hours, should have no changes in substrate delivery for 12 hours, must be on a fraction of inspired O₂ of less than 0.6, and the positive end-expiratory pressure must be less than 5 cm H₂O to ensure a steady-state reading. Unfortunately, many of the patients in whom indirect calorimetry would be most useful will not meet these requirements.

PROTEIN

Daily protein requirements are based on age, nutrition status, disease state, and clinical condition. Table 143-8 lists the RDA for protein for children; for individuals older than 18 years of age, the RDA is 0.8 g/kg per day, which is less than most people typically consume.^{72,73} In adults older than 60 years of age, protein needs are increased to 1 g/kg per day to help reduce loss of LBM that occurs with aging, and up to 1.5 to 2 g/kg per day may be needed in states of metabolic stress, such as infection, trauma, and surgery, to prevent loss of LBM.^{73,81} Protein requirements are also higher in pregnant and lactating women (1.1 g/kg per day).^{72,73}

Protein metabolism depends on both kidney and liver function; and protein requirements are altered with kidney or liver dysfunction (see Chap. 147). Critical illness (e.g., sepsis, burns, or trauma) results in a hypercatabolic state in which there is increased protein synthesis and degradation. Consequently, protein requirements are increased to 1.5 to 2 g/kg per day. In burned patients, protein requirements may be as high as 2.5 to 3 g/kg per day or 20% to 25% of total calories in children. Liver failure typically results in the need for protein restriction (0.5 g/kg per day) except if a hypercatabolic state is also present, in which case the requirement may be increased to 1.5 g/kg per day. Protein needs in kidney failure are variable and

affected by the various kidney replacement therapies available. The application of these guidelines requires both clinical judgment and frequent monitoring of kidney and liver function, serum chemistries, clinical condition, and nutrition outcomes (see Chap. 147).

Nitrogen is found only in protein and at a relatively constant ratio of 1 g nitrogen per 6.25 g protein. This ratio may vary somewhat for enteral and parenteral feeding formulations, depending on the biologic value of the protein source. Adequacy of protein intake can be assessed clinically by measuring urinary nitrogen excretion and comparing it with nitrogen intake—a nitrogen balance study. Nitrogen balance indirectly reflects an individual's protein use or protein catabolic rate, which increases with hypercatabolism. As the stress level increases, a concomitant increase in protein catabolism results in an increase in urinary nitrogen excretion. Usually the amount of urea nitrogen is measured in a 24-hour urine urea collection. In healthy individuals, the quantity of urine urea nitrogen accounts for 80% to 90% of the total urine nitrogen excreted. Nitrogen output (g/day) can be approximated as 24-hour urine urea nitrogen + 4, where 4 is a factor representing usual skin, fecal, and respiratory nitrogen losses.⁸² Alternatively, if available, total urine nitrogen can be measured and may be more accurate. If total urine nitrogen is used, then the best estimate of nitrogen output is total urine nitrogen \times 1.05.⁸² In patients with kidney failure, in which case neither urine urea nitrogen nor total urine nitrogen represents nitrogen generation, protein turnover can be approximated with equations based on urea kinetics that estimate the rate of urea production.²²

FAT

The daily adequate intake for men and women for α -linolenic acid is 1.6 and 1.1 g, respectively; for linoleic acid, it is 14 to 17 g/day for men and 11 to 12 g/day for women. Overall, fat should represent no more than 10% to 35% of total calories, with the recommendation that saturated fatty acids, *trans* fatty acids, and dietary cholesterol intake be kept as low as possible while consuming a nutritionally adequate diet.^{72,73} As mentioned previously, fat intake in children younger than 2 years of age is critical for proper central nervous system growth and development; generally, no fat restriction (e.g., skim milk) should be imposed until after the age of 2 years.

FIBER

Maintenance of normal bowel habits, lower blood pressure, and lower cholesterol serum concentrations is attributed to dietary fiber intake. Some evidence also suggests that fiber has a role in the prevention of colon cancer and promotion of weight control through its effect on satiety. Men and women 50 years of age and younger should ingest 38 g/day and 25 g/day, respectively, of total fiber. For men and women older than 50 years of age, the recommended intakes are 30 g/day and 21 g/day, respectively.^{72,73,81} For children younger than 16 years of age, the “age + 5” rule is often used. The recommended daily intake of fiber is calculated by adding 5 g to the child's age in years. For example, a 6-year-old child should ingest 11 g/day of dietary fiber.^{72,73,83,84}

FLUID

The daily fluid requirement for an adult depends on many factors but is generally 30 to 35 mL/kg. It also can be estimated as 1 mL/kcal ingested or as 1,500 mL/m² per 24 hours. Fluid requirements per kilogram are higher for children and even higher for preterm infants because of their higher percentage of TBW and basal energy needs. Additionally, premature neonates have increased fluid requirements because of greater insensible losses and the kidney's inefficiency in concentrating urine. The Holliday-Segar method is a commonly

TABLE 143-11 Factors That Alter Fluid Requirements

Increased Requirements	Decreased Requirements
Fever	Fluid overload
Radiant warmers	Cardiac failure
Diuretics	Decreased urinary output
Vomiting	Heat shields
Nasogastric suction	Relatively high humidity
Ostomy/fistula drainage	Humidified air via endotracheal tube
Diarrhea	Kidney failure
Glycosuria	Hypoalbuminemia with starvation
Phototherapy	Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)
Increased ambient temperatures	
Hyperventilation	
Prematurity	
Excessive sweating	
Increased metabolism (e.g., hyperthyroidism)	
Diabetes insipidus	

employed, quick, and simple method for estimating minimum daily fluid needs of children that also can be applied to adults. Children who weigh less than 10 kg should receive at least 100 mL/kg per day. An additional 50 mL/kg per day should be provided for each kilogram of body weight between 11 kg and 20 kg, and 20 mL/kg per day for each kilogram above 20 kg. Thus daily fluid needs for a child weighing 8 kg would be at least 800 mL/day, whereas at least 1,350 mL/day would be needed for a 17-kg child.

Table 143-11 lists factors that alter fluid needs for both adults and children. All sources of fluid intake should be assessed (e.g., fluid vehicles for intravenous medications and intravenous or feeding tube flushes) when determining fluid requirements. Monitoring of urine output and specific gravity as well as serum electrolytes and weight changes can be used to assess fluid status. A urine output of at least 1 mL/kg per hour (in children) and approximately 50 mL per hour (in adults) is considered adequate to ensure tissue perfusion. Urine output should be higher if large fluid volumes or high renal solute loads (e.g., parenteral nutrition or concentrated enteral feeding formulations) are being administered. Urine specific gravity depends on the kidney's concentrating and diluting capabilities. Concomitant diuretic therapy as a result of increased solute excretion limits the usefulness of urine specific gravity as an index of fluid status.

MICRONUTRIENTS

Requirements for micronutrients (e.g., electrolytes, trace elements, and vitamins) vary with age, gender, and the route by which the nutrient is ingested (Table 143-12).^{5,72,85} The variability between oral and parenteral requirements is a result of bioavailability considerations. Micronutrients poorly absorbed via the GI tract usually are required in greater doses enterally than parenterally. However, many water-soluble micronutrients are excreted more rapidly via the kidneys when administered intravenously. In these situations, the intravenous dose is greater than the oral dose. Other factors that affect micronutrient requirements include GI losses through diarrhea, vomiting, or high-output fistula; wound healing; and hypermetabolism/catabolism. Cutaneous micronutrient losses (e.g., zinc, copper, and selenium) also may be significant after major burn injury. Sodium, potassium, magnesium, and phosphorus are particularly dependent on kidney function, and in the setting of kidney failure, intake will likely need to be restricted. Calcium needs, on the other hand, may be increased in these patients. Patients who are severely malnourished will have increased electrolyte requirements during early refeeding owing to preexisting deficiencies and/or rapid intracellular uptake with anabolism. Failure to provide adequate electrolytes during refeeding has resulted in death from the refeeding syndrome.⁸⁶

TABLE 143-12 Recommended Daily Electrolytes, Trace Elements, and Vitamins^a

Nutrient	Adult (≥19 years of age)		Pediatric	
	Enteral	Parenteral	Enteral	Parenteral
Electrolytes and minerals				
Acetate ^b	—	—	—	—
Calcium	1,000–1,200 mg	0–15 mEq	0–12 months: 210–270 mg 1–3 years: 500 mg 4–8 years: 800 mg 9–18 years: 1,300 mg	Premature: 2–4 mEq/kg Other: 1–2.5 mEq/kg
Chloride ^b	—	—	—	2–6 mEq/kg
Magnesium	M: 400–420 mg W: 310–320 mg	10–20 mEq	0–6 months: 30 mg 7–12 months: 75 mg 1–3 years: 80 mg 4–8 years: 130 mg 9–18 years: 240–410 mg	0.25–1 mEq/kg
Phosphorus	700 mg	20–45 mmol	0–6 months: 100 mg 7–12 months: 275 mg 1–8 years: 460–500 mg 9–18 years: 1,250 mg	Premature: 1–2 mmol/kg Others: 0.5–1 mmol/kg
Potassium ^{c,d}	4,700 mg	60–100 mEq (1–2 mEq/kg)	0–6 months: 400 mg 7–12 months: 700 mg 1–8 years: 3,000–3,800 mg 9–18 years: 4,500–4,700 mg	2–5 mEq/kg
Sodium ^{c,d}	1,200–1,500 mg	60–100 mEq (1–2 mEq/kg)	0–6 months: 120 mg 7–12 months: 370 mg 1–8 years: 1,000–1,200 mg 9–18 years: 1,500 mg	2–6 mEq/kg
Trace elements				
Chromium ^e (mcg)	20–35	10–15	0–6 months: 0.2 7–12 months: 5.5 1–8 years: 11–15 9–18 years: 21–35	0.14–0.2 mcg/kg (max 5 mcg)
Copper ^f (mcg)	900	0.3–1.5	0–12 months: 200–220 1–8 years: 340–440 9–18 years: 700–890	20 mcg/kg (max 300 mcg)
Fluoride	3–4 mg	—	0–6 months: 0.01 mg 7–12 months: 0.5 mg 1–8 years: 0.7–1 mg 9–18 years: 2–3 mg	—
Iodine ^g (mcg)	150	70–140 (not well defined)	0–12 months: 110–130 1–8 years: 90 9–18 years: 120–150	1 mcg/kg

Selenium (mcg)	55	20–60	0–12 months: 15–20 1–8 years: 20–30 9–18 years: 40–55	1.5–3 mcg/kg (maximum 30 mcg)
Zinc ^h (mg)	8–11	2.5–5	0–12 months: 2–3 1–8 years: 3–5 9–18 years: 8–11	Premature: 300–400 mcg/kg Other: 50–250 mcg/kg
Vitamins				
Ascorbic acid (mg) (Vitamin C)	75–90	100	0–12 months: 40–50 1–8 years: 15–25 9–18 years: 45–75	80
Biotin (mcg)	30	60	0–12 months: 5–6 1–8 years: 8–12 9–18 years: 20–25	20

(continued)

TABLE 143-12 Recommended Daily Electrolytes, Trace Elements, and Vitamins^a (continued)

Nutrient	Adult (≥19 years of age)		Pediatric	
	Enteral	Parenteral	Enteral	Parenteral
Choline (mg)	425–550	Not established	0–12 months: 125–150 1–8 years: 200–250 9–18 years: 375–550	Not established
Cobalamin (mcg) (Vitamin B ₁₂)	2.4	5	0–12 months: 0.4–0.5 1–8 years: 0.9–1.2 9–18 years: 1.8–2.4	1
Folic acid (mcg)	400	400	0–12 months: 65–80 1–8 years: 150–200 9–18 years: 300–400	140
Niacin (mg NE)	14–16	40	0–12 months: 2–4 1–8 years: 6–8 9–18 years: 12–16	17
Pantothenic acid (mg)	5	15	0–12 months: 1.7–1.8 1–8 years: 2–3 9–18 years: 4–5	5
Pyridoxine (mg) (Vitamin B ₆)	1.3–1.7	4	0–12 months: 0.1–0.3 1–8 years: 0.5–0.6 9–18 years: 1–1.3	1
Riboflavin (mg)	1.1–1.3	3.6	0–12 months: 0.3–0.4 1–8 years: 0.5–0.6 9–18 years: 0.9–1.3	1.4
Thiamin (mg)	1.1–1.2	3	0–12 months: 0.2–0.3 1–8 years: 0.5–0.6 9–18 years: 0.9–1.2	1.2
Vitamin A (mcg RE) (Retinol)	700–900	600–1,000 (3,300–5,500 international units)	0–12 months: 400–500 1–8 years: 300–400 9–18 years: 600–900	700 (2300 international units)
Vitamin D (mcg)	≤50 years: 5 (200 IU) 51–70 years: 10 (400 international units) >70 years: 15 (600 international units)	5 (200 international units)	All ages: 5 (200 international units)	5–10 (200–400 international units)
Vitamin E (mg TE) (α -tocopherol)	15 (15 international units)	10 (10 international units)	0–12 months: 4–5 (4–5 international units) 1–8 years: 6–7 9–18 years: 11–15	7 (7 international units)
Vitamin K (mcg)	90–120	0.7–2.5 mg	0–12 months: 2–2.5 1–8 years: 30–55 9–18 years: 60–75	200

M, men; NE, niacin equivalents; RE, retinol equivalents; TE, tocopherol equivalent; W, women.

^aData from references 5, 49, and 55. Data represent either the recommended dietary allowance or the adequate intake for each nutrient where established.

^bNot established; as needed to maintain acid–base balance.

^cNewborns and low-birth-weight or very-low-birth-weight infants or with concomitant disease (e.g., necrotizing enterocolitis) may have higher requirements. Intake in nonhealthy children must be individualized.

^dNo recommended dietary allowance or adequate intake has been established.

^eAn additional 20 mcg of chromium per day is recommended in patients with significant intestinal losses.

^fMay accumulate in cholestasis.

^gLong-term parenteral nutrition only if no topicals containing iodide or iodized table salt are used.

^hAn additional 12.2 mg zinc/L of small bowel fluid lost and 17.1 mg zinc/kg of stool or ileostomy output is recommended; add an additional 2 mg zinc per day for acute catabolic stress.

DRUG–NUTRIENT INTERACTIONS

9 Drug-induced nutrient deficiency, poor therapeutic response, enhanced drug toxicity, and failure to achieve desired nutrition outcomes can occur if either nutrition support or drug therapy is stopped as a consequence of adverse effects.^{87–91} Patient outcomes may be enhanced when an effective screening method to identify significant drug–nutrient interactions is coupled with a patient-counseling program. An important part of the screening process is to recognize risk factors that influence drug–nutrient interactions. The potential for drug–nutrient interactions is greatest in pediatric and elderly individuals, those with poor nutrition status (obesity and marasmus), those receiving multiple drug therapies, and those receiving tube feedings.

Mineral and electrolyte serum concentrations may change because of drug therapy. For example, with diuretics, urine sodium, potassium, and magnesium wasting may occur, causing a reduction

in their respective serum concentrations (see Chaps. 52 to 54). Serum electrolyte concentrations also may increase as a direct result of the drug's mechanism (e.g., potassium-sparing diuretics) or because of the drug's salt form. Corticosteroids and cyclosporine are known to cause hyperglycemia, whereas other drugs are prescribed to pharmacologically lower blood glucose concentrations, for example, insulin and oral hypoglycemics (see Chap. 77).

Vitamin status also may be affected by drugs (Table 143-13). For example, sulfasalazine therapy causes a decrease in folic acid, isoniazid therapy causes pyridoxine deficiency, and furosemide therapy may result in decreased thiamin concentrations. Drug therapy outcomes also may be affected by vitamin intake. The ingestion of high doses of folic acid may decrease methotrexate's therapeutic effect, whereas changes in an individual's usual vitamin K or vitamin E intake may cause variability in warfarin's anticoagulation effects.

Drug-delivery vehicles also may contain nutrients. Most intravenous therapies (maintenance intravenous fluids, drugs, and electro-

TABLE 143-13 Drug Effects on Vitamin Status

Drug	Effect
Antacids	Thiamin deficiency
Antibiotics	Vitamin K deficiency
Anticonvulsants	Vitamin D and folic acid malabsorption
Antineoplastics	Folic acid antagonism and malabsorption
Antipsychotics	Decreased riboflavin
Cathartics	Increased requirements for vitamins D, C, and B ₆
Cholestyramine	Vitamins A, D, E, and K, β -carotene malabsorption
Colestipol	Vitamins A, D, E, and K, β -carotene malabsorption
Corticosteroids	Decreased vitamins A, D, and C
Diuretics (loop)	Thiamin deficiency
Histamine ₂ antagonists	Vitamin B ₁₂ deficiency
Isoniazid	Vitamin B ₆ deficiency
Mineral oil	Vitamins A, D, E, and K malabsorption
Orlistat	Vitamins A, D, E, and K malabsorption
Pentamidine	Folic acid deficiency
Proton pump inhibitors	Vitamin B ₁₂ deficiency

lyte replacements) are delivered using either dextrose (e.g., dextrose 5% in water) or sodium (e.g., 0.9% normal saline) in the admixture. Lipid emulsion (10%) is used as the vehicle for the anesthetic agent propofol and may contribute a large amount of fat calories when continuous propofol infusions are used. In these instances, nutrition-support regimens must be adjusted to accommodate the calories and other nutrients delivered through these therapies.

PRACTICAL GUIDELINES FOR NUTRITION ASSESSMENT

10 The value of any given marker used for nutrition assessment is only as great as its ability to accurately identify the patient with malnutrition and to correlate with malnutrition-associated complications. Most of the currently available markers of nutrition status were first used in epidemiologic studies to define large populations suffering from malnutrition caused by famine. The response of the various nutrition status markers to nutrition therapy and the correlation between improvement in these markers and decreased morbidity and mortality further support their validity. However, when applied to an individual, most of these markers lack specificity and sensitivity, which makes the development of a clinically useful, cost-effective approach to individual patient nutrition assessment challenging.

The importance of the nutrition-focused history and physical examination in both nutrition screening and nutrition assessment cannot be overemphasized. The least amount of objective data that can further substantiate the clinical impression and provide a baseline for subsequent monitoring are those markers that show the best correlation with outcome: weight and serum albumin concentration. The cost-effectiveness of the addition of further biochemical parameters is yet to be determined. The assessment of other anthropometric measures is most useful in the setting of anticipated long-term nutrition support in which these measurements will serve as a longitudinal marker of an individual's response to the nutrition care plan.

Initially, nutrition requirements are determined on the basis of assumptions made about the patient's clinical condition and the nutrition needs associated with repletion or growth, if needed. Once a nutrition intervention has been initiated, periodic reassessment of nutrition status is critical to determine the accuracy of the initial estimate of nutrition requirements. Also, nutrition requirements are dynamic in the setting of acute or critical illness—as the patient's clinical status changes, so will protein and energy requirements, further emphasizing the need for continued reassessment.

Better markers of nutrition status and methods for determining patient-specific nutrition requirements are needed to allow further refinement of estimates of an individual's nutrition needs. Functional tests and simple, noninvasive tests for body composition analysis hold promise for the future. However, until better methods of assessment become available clinically and are demonstrated to be cost-effective, the currently available battery of tests will continue to be the mainstay of nutrition assessment.

Information in this chapter can be used to establish empiric goals for a nutrition care plan. However, as with other forms of therapy, continuous monitoring and reassessment are required to determine if these goals are appropriate for an individual patient.

ABBREVIATIONS

- ABW: actual body weight
- ALB: albumin
- BIA: bioelectrical impedance analysis
- BMI: body mass index
- DCH: delayed cutaneous hypersensitivity
- DRI: dietary reference intake
- DXA: dual-energy x-ray absorptiometry

Prevalence and Significance of Malnutrition

GORDON SACKS AND CATHERINE M. CRILL

KEY CONCEPTS

- 1 Weight loss is a hallmark sign of malnutrition in the cancer patient and correlates with decreased survival for some cancer types.
- 2 Nutritional problems in human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) patients have shifted from complications of severe wasting to metabolic changes associated with subcutaneous fat atrophy, visceral fat accumulation, hypertriglyceridemia, and insulin resistance.
- 3 Immune function, growth, and survival can be improved in HIV-positive children with aggressive nutritional and antiviral therapy.
- 4 Enteral nutrition (EN) decreases septic complications when compared with parenteral nutrition (PN) in severely injured trauma patients.
- 5 EN promotes remission in the majority of patients with acute Crohn's disease.
- 6 Adults with less than 60 cm remaining of small bowel after massive surgery will require PN for months to years.
- 7 EN supplemented with immune-enhancing nutrients lowers metabolic and infectious complications in adult surgical patients.
- 8 Maintaining adequate nutrition status contributes to improved outcomes in patients with cystic fibrosis (CF).
- 9 Optimizing nutritional status of pediatric solid organ transplant patients pre- and posttransplantation can improve outcomes and reduce morbidity.
- 10 Malnutrition is associated with increased use of healthcare resources and nutritional interventions can contribute to cost savings by reducing length of hospital stay and morbidity associated with malnutrition.

The term malnutrition has been used to characterize a broad range of altered nutritional states. Overnutrition is the term used to describe excess nutrient intake, whereas undernutrition is used to describe insufficient intake or substrate use. Both of these nutritional states can contribute to the poor outcome of many disease states. Unless specifically stated otherwise, in this chapter malnutri-

tion is considered to be synonymous with undernutrition (refer to Chap. 148 for a discussion on overnutrition/obesity). In children, malnutrition is defined by a variety of criteria. Stages (e.g., Waterlow stages) were developed to define the severity of protein-energy malnutrition. Anthropometric evaluations, using established age-based growth curves, can also be used to define acute and chronic malnutrition using either Z scores or height and weight percentiles. In general, malnutrition in children is defined as growth that is below the fifth percentile for age or less than 90% to 95% of the median value for age. In this chapter, the prevalence of malnutrition is characterized and the significant impact of abnormalities in nutrition assessment parameters on the morbidity and mortality of adult and pediatric patients with selected disease states is presented. Interventional strategies for the prevention and management of malnutrition are characterized and the economic consequences of malnutrition are also presented.

PREVALENCE

Although malnutrition occurs throughout the world, it is most prevalent in underdeveloped countries, where food supply, ignorance, poverty, overcrowding, and poor sanitation are contributing factors. The most susceptible individuals in developed and underdeveloped countries are infants (especially premature infants), pregnant or lactating women, and the elderly. The predominant factors that contribute to malnutrition in developed countries include poor maternal nutrition before and during pregnancy, misconceptions about the use of certain foods, fad diets, maternal illiteracy, household poverty, and alcohol or drug abuse. The relationship between malnutrition and breast-feeding is time-dependent. The benefit of breast-feeding during the first 6 months of life in reducing mortality and improving growth is well known and advocated by the American Academy of Pediatrics. Prolonged breast-feeding (beyond 6 months to 1 year), however, has been associated with an increased risk of malnutrition. This association may be a result of the lower use of complementary foods in economically and educationally disadvantaged households, rather than breast-feeding per se.¹

Malnutrition in adults is associated most commonly with exacerbations of chronic disease or an onset of an acute illness and thus is quite prevalent in the hospital setting. Recognition of the scope of the problem coincides with the systematic application of nutrition assessment techniques to hospitalized individuals in the last three decades. The heightened awareness of nutritional disease and better in-hospital nutrition management since the mid-1970s has contributed to a decline in its prevalence.² The prevalence of previously unrecognized malnutrition in hospitalized adult patients from varying socioeconomic backgrounds is still high and ranges from 40% to 55% in a variety of institutions.³ Worldwide, approximately 200 million children are moderately to severely underweight, while 70 million are severely malnourished.⁴ The overwhelming majority of

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

these children live in South Asia or sub-Saharan Africa.⁵ More than one-half of global childhood deaths of children younger than 5 years of age is attributable—directly or indirectly—to malnutrition.^{6,7} Chronic malnutrition in children younger than 2 years of age is an independent predictor of poor cognitive development lasting up to 11 years of age.⁸ Severe malnutrition is both a medical and social disorder and successful management requires attention to both of these factors. The first of the United Nations’ Millennium Development Goals, drafted in 2002, was to halve the number of people suffering from hunger.⁶ Fortunately, the global trend indicates a modest but consistent decline in malnutrition-associated mortality in children younger than 5 years of age.⁹

Because children have both limited body stores and high metabolic demands, they are at particular risk for developing malnutrition, especially during illness. Although the majority of undernourished children are from underdeveloped countries, malnutrition is also prevalent in the United States and other industrial countries. In 1974, a publicly funded health and nutrition program known as the Pediatric Nutrition Surveillance System was established to generate data on the prevalence of malnutrition in low-income U.S. children (<5 years of age). Several advances were observed during the period of 1995 through 2004, most notably a decrease in high birth weight and anemia and an increase in the percentage of infants ever breastfed and those breastfed for at least 6 months.¹⁰ Prevalence of short stature (height for age) and low birth weight remained stable. The prevalence of underweight status of 4.7%, which is lower than the expected value of 5%, suggests that the prevalence of acute malnutrition in this population is low. The prevalence of overweight children, however, increased from 11% in 1995 to 14.8% in 2004. The focus on malnutrition has now been shifted to the prevention and treatment of childhood obesity, which has reached epidemic proportions (see Chap. 148).

Children with chronic disease and those in periods of rapid growth have the highest prevalence of malnutrition. Hendricks et al. characterized the change in prevalence of protein-energy malnutrition in hospitalized children over a 15-year period.¹¹ Overall prevalence was high, but significant reductions were detected in acute malnutrition (weight for height <90% of median) from 33.6% to 24.5%, and chronic malnutrition (weight for height <95% of median) from 46.8% in 1976 to 27.3% in the 1990s.

PHYSIOLOGIC RESPONSE TO STARVATION

During the first few days of starvation, hepatic glycogen stores are used for energy and skeletal muscle proteolysis provides amino acids as a source for new glucose production (i.e., gluconeogenesis) creating fuel substrates for glucose-dependent tissues, such as the brain, renal medulla, and red blood cells. When glycogen stores are depleted, skeletal muscle is scavenged for amino acids and fatty acids are mobilized from adipose tissue. With prolonged starvation (i.e., >5 days), metabolic pathways shift to derive energy from ketone production (i.e., β -hydroxybutyrate and acetoacetate) as a result of free fatty acid oxidation while sparing protein mobilization from skeletal muscle. Protein conservation is evidenced clinically by a reduction in urinary urea nitrogen from a normal value of 12 g/day to 3 to 5 g/day by 5 to 6 weeks.¹² Inadequate nutrient intake is accompanied by reductions in basal metabolic rate and the synthetic capacity of the liver. Endocrine adaptive functions occur in response to severe energy and protein deficiencies, including a decline in insulin secretion and increases in glucagon and epinephrine concentrations.

The outcome of prolonged malnutrition is an inappropriate reduction in lean body mass resulting in alterations in the function of essentially every organ. The clinical significance of the effect will depend on the specific anatomic structure or system and on the degree of malnutrition. For example, with mild malnutrition, loss of

TABLE 144-1 Immune Response Mechanisms in Malnutrition

Parameter	Observation in Malnutrition
Cell-mediated immune response	
Delayed cutaneous hypersensitivity	Decreased
Lymphocyte transformation	Decreased
Polymorphonuclear leukocyte response	
Phagocytosis	Normal or decreased
Metabolism	Decreased
Bactericidal capacity	Decreased
Chemotaxis	Decreased
Total lymphocyte count	Decreased
T cells	
CD4	Decreased
CD8	Decreased
Helper to suppressor ratio	Decreased
Humoral response	
Complement activity (CH50)	Decreased
Secretory immunoglobulin A	Decreased
Serum complement	Decreased or normal
Serum immunoglobulins	Normal
Serum opsonization	Normal

skeletal muscle mass may be apparent as weakness or a decreased level of physical activity. However, alterations in cardiac function, circulatory failure and decreased cardiac output which usually are only seen in advanced malnutrition and can result in impaired renal plasma flow and glomerular filtration rates. Major defects in T-lymphocyte function and the complement system result from atrophy of the thymus gland. Ultimately, the malnourished patient becomes more susceptible to infections (Table 144–1). Until recently, the effect of early malnutrition (fetal and neonatal) on organ and cellular function was only recognized in terms of short-term growth and development outcomes. Now it is known that “fetal programming” or “metabolic imprinting” is linked to adult health. Specifically, maternal body composition and dietary balance during pregnancy can influence the risk of adult-onset cardiac disease, type 2 diabetes, and obesity.^{9,13,14}

Malnourished patients have an increased likelihood of developing wound infections and the wound healing rates have also been noted to be slower in those with poor nutritional status.¹ Protein is essential for the integrity of the structural components of skin (i.e., collagen) and severe protein deficiency can result in edema secondary to the reduction in circulating proteins, such as albumin.¹⁵ Deficiency of arginine, vitamin C, vitamin A, or zinc also may contribute to decreased wound healing (Table 144–2). Supplemental vitamin A promotes wound healing in animal models in the presence of deficiency, and arginine has improved markers of wound healing (i.e., protein and hydroxyproline in the wound bed) in elderly healthy human volunteers.¹⁶ However, supplementation of these nutrients is

TABLE 144-2 Nutritional Disorders and Wound Healing

Nutritional Disorder	Effect on Wound Healing
Arginine deficiency	Altered collagen formation
Copper deficiency	Impaired lysyl oxidase activity
Protein-energy malnutrition	Decreased wound strength because of reduced hydroxyproline content of wound; decreased rate of wound healing; increased incidence of wound infection
Vitamin C deficiency	Decreased fibroblast maturation with failure of collagen synthesis; decreased angiogenesis
Vitamin A deficiency	Decreased collagen accumulation; formation of abnormal collagen
Zinc deficiency	Impaired DNA and protein synthesis; impaired mitosis and cell proliferation

only recommended in the presence of documented deficiencies as supplementation in nondeficient individuals may actually be harmful. For example, excess vitamin E antagonizes the promotion of wound healing by vitamin A, and excess zinc will displace copper and interfere with lysyl oxidase (the enzyme necessary for collagen cross-link formation). Finally, ingestion of excessive amounts of vitamin A may cause liver damage, hemorrhage, and even coma.¹⁵

DISEASE-SPECIFIC CONSEQUENCES

Malnutrition seldom exists as an isolated disease state; rather, it is usually found in patients with other preexisting illnesses. Often the primary disease or complications of the disease predispose an individual to the development of malnutrition. The primary factors that enhance the likelihood of developing malnutrition include decreased dietary intake (e.g., as a consequence of nausea, vomiting, or anorexia), malabsorption (e.g., as a result of short-bowel syndrome, severe diarrhea, or high-output fistula), and altered metabolism (hypermetabolic and catabolic states caused by sepsis, trauma, cancer, or AIDS). Malnutrition is also associated with the failure of major organs such as the kidney, liver, heart, and lungs (see Chap. 147).

CANCER

1 Patients with cancer have many factors that contribute to their increased likelihood of developing malnutrition (Table 144-3). The frequency is highest (>80%) in patients with gastric and pancreatic tumors, and lowest in patients with hematologic malignancies.¹⁷ Unintentional weight loss, a sign of malnutrition, occurs in 30% to 80% of adult cancer patients. A significant relationship between weight loss and reduced survival has been demonstrated for some (lung, prostate, and colon cancer), but not all tumor types.¹⁷ The degree of reduction in median survival is statistically significant for many cancers and ranges from 49% to 79%.

Current clinical practice guidelines state that routine use of enteral and parenteral nutrition (i.e., specialized nutrition support [SNS]) is

not indicated in well-nourished or mildly malnourished patients undergoing surgical interventions, chemotherapy, or radiation therapy for neoplastic disease. Use of parenteral nutrition (PN) in this population may actually result in more complications and a poor response to cancer treatment.¹⁸ Specialized nutrition support is indicated in malnourished cancer patients who have a life expectancy of at least 3 to 6 months and who have been unable to ingest and/or absorb adequate nutrients for longer than 7 days.¹⁹ In addition, PN may be of benefit in a select group of patients with inoperable malignant bowel obstruction (i.e., ovarian cancer) who lack significant involvement of vital organs, have a good performance status, and are expected to survive longer than 6 months.²⁰

Malnutrition in children with cancer is common, and the prevalence is greater in those with Ewing sarcoma and neuroblastoma, than in those with leukemias and lymphomas.^{21,22} While undernutrition has historically been an independent prognostic factor in the long-term outcome of children with certain cancers, not all researchers agree and it remains an area of continued research.²³⁻²⁵ Although advancements in cancer treatment strategies have greatly improved outcomes for children, many of the complications of treatment protocols, including surgery, combination chemotherapy, and radiation therapy, are associated with an increased prevalence of malnutrition.^{19,26} Theoretically, early recognition and aggressive management of malnutrition may minimize the nutritional consequences, improve tumor response, reduce side effects of therapy, and improve survival. Indeed cancer patients treated with bone marrow transplantation have shown improved tumor response and clinical outcome with PN compared with those who were not receiving PN.²⁷ Of note, survivors of childhood acute lymphoblastic leukemia, particularly those who received cranial irradiation therapy, are at increased risk for obesity later in life.²⁸

Improved nutrition status enhances survival and improves treatment tolerance in many but not all children.^{26,29} Malnutrition as a consequence of simple starvation, characterized by normal metabolism but inadequate nutrient intake or malabsorption, appears to be more responsive to nutrition intervention³⁰ than malnutrition as a result of cancer cachexia, which is characterized by altered nutrient use despite adequate supply.^{31,32}

TABLE 144-3 Risk Factors for Malnutrition in Cancer Patients

Risk Factor	Nutrition Consequence
Primary disease	
Tumor type	Weight loss, anorexia, altered taste, altered metabolism
Complicating conditions	
Malabsorption	Impaired absorption of all or selected nutrients, diarrhea
Bowel obstruction	Nausea and vomiting, inability to ingest nutrients orally or by enteral nutrition
Infection	Increased energy expenditure and protein requirements, altered metabolism, anorexia, malabsorption
Psychological response	Anorexia, food aversion
Treatments	
Chemotherapy	Taste and appetite alterations, nausea and vomiting, mucositis, esophagitis, diarrhea, constipation
Surgery	
Radical resection of oropharyngeal region	Problems with chewing and swallowing
Esophageal reconstruction	Gastric stasis and hypochlorhydria secondary to vagotomy; diarrhea and steatorrhea
Gastrectomy	Dumping syndrome, malabsorption, lack of intrinsic factor, hypoglycemia
Intestinal resection	Malabsorption, renal oxalate stones, metabolic acidosis, diarrhea
Pancreatectomy	Malabsorption, diabetes mellitus
Radiation	
Head and neck	Stomatitis, dysgeusia, xerostomia
Abdomen and pelvis	Bowel obstruction, fistulae, radiation enteritis (diarrhea, protein-losing enteropathy, malabsorption)

CLINICAL CONTROVERSY

The goal of enteral nutrition (EN) and PN support in patients with cancer is to prevent or reverse protein-calorie malnutrition and cancer cachexia. In terminally ill children and adults, the use of EN and PN is controversial. Some clinicians believe their use is warranted in these patients only if an improved quality of life can be attained.

AIDS

2 Generalized wasting and malnutrition were common characteristics of HIV/AIDS during the early years of this epidemic. In many patients, weight loss and wasting were often the earliest symptoms, along with opportunistic infection. Malnutrition was often progressive and contributed to death in some patients.^{19,33} Poor nutrition status as indicated by weight loss and decreased serum prealbumin concentrations has been shown to be a predictor of mortality in adult AIDS patients.^{34,35} Furthermore, simultaneous micronutrient deficiencies such as vitamin A, vitamin B₁₂, zinc, and selenium are significantly associated with HIV-related mortality, independent of CD4 counts and changes in CD4 over time. When the individual effect of these micronutrient deficiencies is further delineated, selenium deficiency was found to be the only independent predictor of HIV-related prognosis.³⁵ Recently, nutritional problems have shifted from the characteristic lethal wasting associated with oppor-

tunistic infections to a syndrome of subcutaneous fat atrophy (lipoatrophy), fat accumulation (lipohypertrophy) in the abdomen or over the back of the neck (“buffalo hump”), hypertriglyceridemia, and insulin resistance.³⁶ The etiology is unclear but appears to be associated with both protease inhibitor and nucleoside analog therapy, particularly when these drugs are combined.³⁷ The implications of these metabolic and body compositional changes on outcome and development of comorbidities (i.e., atherosclerosis) are unclear at this time.

③ Most HIV-positive children will experience nutritional deficits and growth abnormalities.³⁸ Infants with perinatal-acquired HIV have normal birth weights, but show signs of growth delay as early as 4 months.³⁹ Failure to thrive is reported in up to 33% of HIV-infected children.⁴⁰ Impaired linear growth also appears to correlate with periods of rapid viral replication and lower CD4 T-lymphocyte counts during the first 18 months of life.^{41,42} There is a direct relationship between these growth abnormalities and morbidity and mortality.³⁸ Prior to the use of highly active antiretroviral therapy, EN rehabilitation increased CD4 count and body weight in children with AIDS.⁴⁴ Fortunately, immune function, growth velocity, and survival can be improved markedly if aggressive nutritional therapy and antiviral therapy are initiated.³⁸

The response to nutrition intervention in adults with AIDS is variable. Supplemental dietary intake of selected micronutrients is associated with a reduction in mortality in HIV-1 seropositive homosexual/bisexual men. High intakes of B-group vitamins (B₁, B₆, and niacin) and β -carotene are associated with improved survival, whereas an increased intake of zinc is associated with worse survival.⁴⁵ Cyanocobalamin (vitamin B₁₂) deficiency is common among HIV patients and is associated with neurologic changes, peripheral neuropathy, and decreased performance in problem-solving skills. Whether the deficiency is a result of malabsorption or protease inhibitor therapy, yearly determinations of serum cyanocobalamin are recommended and cyanocobalamin parenteral therapy should be initiated for those with serum concentrations <350 pg/mL.⁴⁶ In the presence of persistent weight loss, nutritional counseling with oral supplements may improve caloric intake and lean body mass.⁴⁷ If weight loss persists despite aggressive dietary oral intake, EN via a feeding tube can be attempted. Lean body mass repletion in AIDS patients with weight loss and inadequate food intake has been reported when EN was the sole source of nutrient intake.⁴⁷ Kotler et al. compared the effects of PN and an oral semielemental diet on body weight, body composition, survival, quality of life, and medical costs in AIDS outpatients with malabsorption syndromes.⁴⁸ At the end of 3 months, the PN group gained more weight and significantly more fat, but body cell mass measurements and survival did not differ between the groups. However, the group receiving an oral diet scored significantly better on the quality-of-life physical-functioning subscale. The most dramatic differences were in medical costs, with a fourfold cost increase in patients receiving PN versus oral diet therapy.⁴⁹

With earlier diagnosis and initiation of treatment for HIV-positive status prior to the full development of AIDS, the prevalence of malnutrition may ultimately decline. New treatment modalities for AIDS are also being developed that may affect the prevalence of malnutrition and the response to nutrition intervention in this patient population. For example, 12 weeks of recombinant human growth hormone treatment was evaluated in 178 HIV-infected patients with unintentional weight loss of $\geq 10\%$. In this trial, growth hormone administration resulted in a mean increase of 3 kg of lean body mass with a decrease of about 1.7 kg of body fat. These changes in body composition were accompanied by an improvement in functional performance, reflected by treadmill work output.⁵⁰ However, concerns regarding the development of hyperglycemia and diabetes associated with long-term use of growth hormone have

tempered its use. Other agents, including thalidomide,⁵¹ testosterone,⁵² nandrolone decanoate,⁵³ and oxandrolone,⁵⁴ also show promise in reversing cachexia associated with AIDS.

CRITICAL ILLNESS, TRAUMA, AND BURN INJURY

Trauma, burn injury, and sepsis are all catalysts for the release of mediators that initiate and regulate the hypermetabolic response. The metabolic consequences of this response include altered carbohydrate metabolism, increased protein synthesis and degradation, and increased lipid oxidation, which ultimately result in net loss of protein and lean body mass.⁵⁵ In a previously well-nourished individual, critical illness can result in the onset of kwashiorkor-like malnutrition within 5 to 7 days, whereas in a previously malnourished individual, critical illness can precipitate severe mixed marasmus-kwashiorkor within 3 to 5 days. In a prospective study of 129 adult patients admitted to the intensive care unit, 43% were malnourished.⁴⁹ Malnourished patients had an increased length of stay in the intensive care unit (a mean of 27 vs. 19 days) and a statistically significantly increased incidence of complications (55% vs. 40%) compared with well-nourished patients with a similar severity of illness.

④ The goal of nutrition support in critically ill patients is to prevent the development of or worsening of malnutrition as positive patient outcomes such as better tissue repair and organ function may be improved when SNS is initiated for these patients.⁵⁵ EN initiated within 24 to 48 hours of injury may attenuate the hypermetabolic response.⁵⁷ EN also results in fewer septic complications than does PN.⁵⁸ Three meta-analyses suggest that critically ill patients derive the greatest benefit when enterally fed an immune-enhanced formula that contains pharmacologic doses of immune-modulating nutrients such as arginine, glutamine, nucleic acids, and omega-3 fatty acids.^{59–61} Supplementation of micronutrients, such as zinc and selenium, early in the recovery phase of burn and traumatic injuries also improves outcomes. Clinical benefits are most likely linked to enhancement of antioxidant defense mechanisms and immunity.⁶²

During critical illness in the pediatric population, the catabolic response limits the capacity for somatic growth.^{19,63,64} To avoid overfeeding during acute illness, the American Society for Parenteral and Enteral Nutrition (ASPEN) recommends that requirements for growth (i.e., caloric provision above measured or predicted energy requirements) not be included in daily caloric provision.¹⁹

INFLAMMATORY BOWEL DISEASE

Malnutrition has been reported in 20% to 85% of patients with inflammatory bowel disease: malabsorption, increased gastrointestinal losses, and poor oral intake are the predominant causes of malnutrition. The risks are not the same with all diseases in this category as evidenced by the findings that the nutrition consequences in patients with ulcerative colitis tend to be less severe than those with Crohn's disease.⁶⁵ Decreased food intake may be a result of pain, anorexia, or altered taste; malabsorption may be caused by mucosal abnormalities, bacterial overgrowth, or diminished absorptive surface area after surgical resection of diseased bowel; and hypermetabolism may be a consequence of fever and infection. Various nutrient abnormalities, such as anemia, metabolic bone disease, and vitamin and trace mineral deficiencies, have been observed in inflammatory bowel disease patients.⁶⁵ Growth failure, characterized by retarded skeletal maturation and delayed development of secondary sex characteristics, occurs in as many as 35% of children with Crohn's disease and up to 10% of children with ulcerative colitis.^{66,67}

⑤ Specialized nutrition support, including both EN and PN, has been used in the past as supportive and primary treatment modalities. Use of supportive SNS has been directed at reversing nutritional

deficiencies associated with Crohn's disease. Enteral nutrition as a primary therapy has been investigated in limited clinical trials and via meta-analyses of available data. The results have consistently shown that conventional corticosteroids are more effective than exclusive use of a liquid diet, either orally or enterally, in the treatment of active Crohn's disease.⁶⁸ The response rate to standard EN was, however, greater than the 18% to 42% placebo-response rate observed in many controlled clinical trials. Although the reasons for the therapeutic effects of EN are not well understood, it seems unlikely that the mechanism is merely the consequence of nutrition repletion. Proposed hypotheses include alteration in intestinal microbial flora, elimination of dietary antigen uptake, and reduction of intestinal synthesis of inflammatory mediators.⁶⁸ A unique oral nutrient supplement combining omega-3 fatty acids and fructooligosaccharides when given to patients with mild to moderate ulcerative colitis for 6 months has been shown to be associated with a significant decrease in the dose of prednisone required to control clinical symptoms as compared with a placebo group.⁶⁹ As a result some clinicians now believe that dietary manipulation may not only interrupt the inflammatory process but also serve as a useful adjunct in the management of patients with active inflammatory bowel disease.

In addition, EN therapy has been shown to improve linear growth and mucosal healing in pediatric patients with Crohn's disease and to induce response rates of 50% to 60% in those with active Crohn's disease.^{19,68} Although SNS may be used to maintain weight and nutrition status in patients with ulcerative colitis, it has not been shown to induce or maintain remission.

CHRONIC INTESTINAL PSEUDOObSTRUCTION

The patient with pseudoobstruction, a hypomotility or dysmotility disorder of the gastrointestinal tract that is thought to be a neuromuscular disorder of the smooth muscle and/or its innervation, often presents with symptoms indistinguishable from those associated with a bowel obstruction. Prolonged dysmotility can result in malnutrition, as well as growth failure, in children.⁷⁰ Primary factors contributing to a risk of malnutrition are anorexia, nausea, vomiting, and obstruction, which may recur over years. Approximately 15% to 30% of patients with pseudoobstruction require SNS with either PN or EN.⁷⁰

SHORT-BOWEL SYNDROME

Short-bowel syndrome is the result of the surgical resection or disease-associated functional loss of a large portion of the intestinal tract. The degree of nutrition impairment depends on the amount and location of excised bowel. Malabsorption is present to some extent immediately following surgery and may be permanent. Bowel adaptation will occur over time (up to 1 to 2 years), but may not result in restoration of the full absorptive capacity of the intestine.^{19,71} Intestinal adaptation occurs more frequently in children than in adults.⁷² Two institutions reported longitudinal experience with intestinal adaptation in infants and children with short-bowel syndrome.^{73,74} Premature infants may have the best adaptive response to short-bowel syndrome due to rapid intestinal growth during late gestation, when the jejunum, ileum, and colon more than double in length.⁷⁵ For this reason, the use of a percentage of expected small-bowel length, rather than absolute remnant length, for assessing the ability for adaptation and successful wean from PN might be more appropriate in infants with short-bowel syndrome.⁷³

6 Adults who have 600 to 700 cm of ileum remaining after surgical resection (i.e., 100 to 200 cm of ileum resected) require vitamin B₁₂, calcium, and magnesium supplementation. Massive resection of the small bowel, leaving less than 60 cm in adults and less

than 10 cm in children, results in severe malabsorption of all nutrients and these patients require total or supplemental PN for months or years postoperatively.^{72,76,77} Removal of the colon with the retention of <50 cm of jejunum and ileum may require that patients remain on PN for life.⁷⁶ One long-term study of 124 adults with nonmalignant short-bowel syndrome maintained on PN demonstrated that the presence of terminal ileum in continuity with the colon enhanced the probability of weaning from PN and survival.⁷⁸ In the absence of SNS, malnutrition is inevitable and can be life-threatening. For those children with intestinal failure resulting from extensive bowel loss or life-threatening complications from prolonged PN, innovative surgical procedures including bowel lengthening, serial transverse enteroplasty, and transplantation (small bowel with or without a liver) can improve the gut's adaptive process and reduce the need for PN.^{72,79–81}

SURGICAL PATIENTS

7 Malnourished patients tend to have a greater risk of postoperative morbidity and mortality than do well-nourished patients. Several nutrition assessment parameters predict morbidity and mortality in surgical patients. In a classic study by Mullen et al., the value of 16 nutritional and immunologic variables was examined and serum concentrations of albumin and transferrin, as well as delayed cutaneous hypersensitivity reactions, were found to be the most reliable predictors of outcome.⁸² These factors have been confirmed by several authors to correlate with morbidity and mortality.^{83,84} A retrospective study by Kudsk et al.⁸⁵ extended these findings by showing that operative site, in addition to the preoperative albumin concentration, was an independent risk factor in predicting clinical outcome: patients who underwent a colectomy and gastrectomy tolerated greater degrees of hypoalbuminemia than did those patients who underwent esophagectomy or pancreatectomy. The subjective global assessment, developed by Detsky et al., is a clinical method that can aid in the recognition of undernutrition by evaluating a patient's nutritional status based on features of the medical history and physical examination.⁸⁶ In prospective studies, subjective global assessment was very successful in predicting complications in surgical patients. The use of preoperative PN in patients with malnutrition, particularly when associated with a low serum albumin concentration, reduced the incidence of major postoperative complications in several patient populations.⁸⁷ Parenteral nutrition administered solely after surgery is actually associated with an increased incidence of complications in approximately 10% of patients. However, perioperative SNS delivered prior to and following major abdominal or thoracic surgical procedures is beneficial in malnourished patients.⁸⁸ In a multiinstitutional Veterans Administration Cooperative Study, 395 malnourished patients were randomly assigned to receive PN administered 1 to 2 weeks before surgery and up to 3 days afterward or no perioperative PN (control group). Differences in mortality at 30 and 90 days were not statistically significant, and there was no significant reduction in complication rate. The incidence of noninfectious complications was higher in those with the greatest degree of malnutrition. In the PN group, the highest incidence of infectious complications was in the borderline or mildly malnourished patients, but severely malnourished PN patients had significantly less noninfectious complications than controls (5% vs. 49%, $P = 0.03$). The investigators concluded that perioperative PN did not result in an improved postoperative course except in patients who were severely malnourished preoperatively. In patients who were mildly to moderately malnourished, the incidence of infectious complications associated with the use of PN outweighed the benefits. As with critically ill patients, EN with immune-enhanced formulas appears to promote the best nutrition and clinical outcome with fewer metabolic and infectious complications for surgical patients.⁸⁹

CYSTIC FIBROSIS

8 The predominant clinical findings of cystic fibrosis (CF) are related to altered pulmonary function and pancreatic exocrine function. Historically, growth retardation and failure to thrive have been classic features of CF. Over the past decade, the nutritional status of children with CF has improved, largely as a result of nutritional interventions aimed at improving pulmonary function and clinical outcome. However, the most recent Patient Registry data from 2004 reported that 15% of children with CF were still below the 5th percentile in height for age and another 15% below the 5th percentile in weight for age.⁹⁰

A longitudinal study confirmed that nutrition and lung function are codependent variables in CF.⁹¹ Other factors that contribute to nutrition disorders associated with CF include an increased energy expenditure, malabsorption, anorexia, gastroesophageal reflux, pharmacotherapy, CF-related diabetes, ineffective pancreatic enzyme supplementation, and inadequate pulmonary toilet.⁹² Increased energy requirements in CF patients are the result of the increased amount of work required to breathe and an elevated resting energy expenditure during pulmonary exacerbations. Children with mild to moderate lung disease may be spared from this rise in resting energy expenditure during an acute exacerbation.⁹³ It is also theorized that the genetic defect that causes CF affects metabolism causing an increase in energy requirements. The physical pounding on the back of the patient while in a partially inverted position (i.e., pulmonary toilet) is designed to loosen the thickened bronchial secretions that impair breathing. It may be performed numerous times throughout the day and may result in an increase in energy expenditure. It also interferes with the feeding schedule, which needs to be designed to ensure that the stomach is empty or nearly empty before the pulmonary toilet process begins, to prevent pulmonary aspiration of stomach contents.

As life expectancy of patients with CF increases, the recognition of CF-associated diseases has also increased. Cystic fibrosis-related diabetes mellitus is now a well-recognized problem and further complicates the nutritional management of these individuals.⁹⁴ Altered pancreatic function is common and more than 90% of CF patients need pancreatic enzyme supplementation. Insufficiency of pancreatic enzyme secretion into the intestine reduces the absorption of fat and fat-soluble vitamins. Consequently, more than two-thirds of CF centers in North America use a hydrolyzed (semielemental) enteral formula with low fat content for CF infants. However, the nutrition benefits of this expensive hydrolyzed formula over a conventional cow's milk formula have been challenged.^{95,96} Nutritional management typically focuses on the use of oral pancreatic enzymes (e.g., Viokase and Pancrease), supplemental fat-soluble vitamins, and a high-protein, high-calorie diet.⁹² If nutrition status cannot be maintained with these measures, supplemental EN or PN may be indicated.

SOLID-ORGAN FAILURE

9 Malnutrition with growth impairment is a well-recognized complication of renal, hepatic, and cardiac failure in children that is associated with an increased risk of morbidity and mortality. Mechanisms responsible for malnutrition include reduced energy intake, increased resting energy rates, and increased total energy expenditure.⁹⁷⁻⁹⁹ Early clinical onset of organ failure can have profound effects on growth and development, especially in children with end-stage liver disease. Among children diagnosed with hereditary renal disorders, 50% had marked growth retardation (mean age at observation: 10 years).⁹⁹ Prevalence of malnutrition in hospitalized children with cardiac disease varies with age and type of cardiac lesion. Seventy-nine percent of infants with heart disease had evidence of

acute malnutrition, compared with less than 30% in all other age groups. The prevalence of chronic malnutrition was common in all age groups. An inverse relationship to age was observed with 82%, 84%, 61%, 58%, and 38% of infants, toddlers, preschool children, school-age children, and adolescents, respectively, being malnourished.¹⁰⁰ Children with complex cardiac disease or left-to-right intracardiac shunts had the highest prevalence of both acute and chronic malnutrition (38% to 80%). Catch-up growth in children with chronic renal failure, complex congenital heart lesions, and advanced cirrhosis can be attained with aggressive feeding regimens, including EN.¹⁰¹ Optimizing nutritional status during the pre- and posttransplantation phase can improve outcomes and reduce morbidity.^{102,103} After liver transplantation, catch-up growth can occur, but final height often remains 0.5 to 1 standard deviation below normal.¹⁰⁴

FAILURE TO THRIVE

Pediatricians have traditionally used the term failure to thrive to characterize children who do not achieve normative weight and height milestones. Geriatricians recently transposed this term to describe elderly patients who fail to maintain their functional status, as reflected by weight loss, declines in physical and cognitive function, and the general appearance of hopelessness.¹⁰⁵ Estimates of undernutrition as high as 65% in residents of long-term care facilities have been noted, compared with a rate of 5% to 15% in community-dwelling persons older than 65 years of age. Factors contributing to this anorexia and weight loss include underlying medical conditions, such as cardiac failure and gastritis, which are associated with decreased oral intake. A variety of medications may interfere with taste and sense of smell, resulting in a lack of appetite. Distortion of a taste sensation has been reported with angiotensin-converting enzyme inhibitors and calcium channel blockers. β -Blockers and the quinolones alter sense of smell in the elderly.¹⁰⁶ Management strategies may include sugarless chewing gum, lozenges, or substituting a different medication in the same therapeutic class. Nutritional intervention is reserved for individuals who are unable to reverse their unintentional weight loss and have a body mass index less than 18 kg/m². Commercially available oral supplements successfully improve caloric intake and promote weight gain in undernourished homebound elders. Enteral nutrition administered through a feeding tube should only be considered for older individuals who are unable to orally consume adequate nutrients. Parenteral nutrition is appropriate for older persons with intestinal failure who are undernourished but who have a reasonable expectation of recovery from the underlying problem (e.g., Crohn's disease, bowel obstruction, severe pancreatitis). Enteral or parenteral nutrition used solely for the purpose of postponing death is strongly discouraged. Specialized nutrition support is justified in older individuals with a reasonable duration and quality of life.

Infants and children not meeting expected growth parameters are typically given the diagnosis of failure to thrive. A recent study evaluated the definitions of failure to thrive in the medical literature and found that, consistent with a 1985 Consensus recommendation, the definition of failure to thrive in all of the evaluated sources was based on anthropometrics alone; however, many dissimilarities existed as to which anthropometric parameters were used.¹⁰⁷ Failure to thrive has been suggested to be either organic (medical), nonorganic (psychosocial), or mixed in etiology.¹⁰⁷ There are numerous medical and psychosocial causes of failure to thrive (Table 144-4). ASPEN recommends that the term pediatric undernutrition be used in place of failure to thrive and that the degree of undernutrition be assessed as either moderate or severe.¹⁹ Evaluation should include a thorough patient history, including nutrition, social, and family history, and physical examination to rule out medical causes. To optimize nutrition and improve growth velocity, patients with failure

TABLE 144-4 Causes of Pediatric Undernutrition

Medical	Psychosocial
Prematurity	Family stress
Gastroesophageal reflux disease	Poverty
Feeding difficulty	External demands
Colic	Parental Issues
Orofacial abnormality	Maternal physical and emotional deprivation
Chronic diarrhea	Maternal depression
Excessive juice intake	Beliefs on feeding/nutrition practices
Food allergy	Education level
Gastroenteritis	Mental capacity
Parasitic infection	Emotional disturbance
Malabsorption syndromes	History of drug/alcohol abuse
Gluten sensitivity (celiac disease)	History of childhood abuse/neglect
Lactase deficiency	Child neglect
Milk-protein allergy	Child abuse
Pancreatic enzyme deficiency	
Protein-losing enteropathy	
Delayed introduction of complementary foods	
Cystic fibrosis

Anorexia/bulimia	

to thrive should be closely monitored on a designated nutrition plan, with routine assessment of anthropometrics using growth curves.¹⁹

NEONATES

Regardless of the disease process, pediatric patients, particularly neonates and infants, are at greater risk for nutrition disorders and develop the most severe consequences more frequently. Pharmacologic and technologic advances in neonatal medicine have improved the survival of premature, extremely low birth weight infants (<1,000 g). These premature neonates are at increased risk for malnutrition as well as developing disease states such as necrotizing enterocolitis and bronchopulmonary dysplasia (BPD) that may further complicate nutrition status.

Premature neonates have decreased protein and fat stores and have an increased protein catabolic rate, which may be further increased by sepsis and critical illness. Early administration (i.e., within the first 24 hours) of amino acids has been found to result in positive nitrogen balance, as well as a decreased incidence of hyperglycemia.^{109–111} Because hyperglycemia is also associated with increased morbidity and mortality during the neonatal period, attempts to prevent and/or treat hyperglycemia should be taken.^{112–114}

Although the successful achievement of catch-up growth has been related to improved neurodevelopmental outcomes,^{115,116} recent data suggest that rapid early weight gain may be associated with cardiovascular disease later in life (abnormal lipid profile, insulin and leptin resistance, increased blood pressure).¹¹⁷ Barker's hypothesis of "fetal origins of adult disease" suggests that adaptations the infant makes when malnourished or stressed (i.e., toward energy conservation) may result in central obesity, diabetes, and cardiovascular disease later in life.¹¹⁸

Bronchopulmonary Dysplasia

BPD or chronic lung disease is a clinical, pathologic, and radiographic disease of the newborn resulting from prolonged exposure to positive-pressure ventilation and elevated oxygen concentrations. Risk factors for developing BPD include the degree of prematurity, nutrition, and immunologic status. Characteristics of BPD include pulmonary edema and tissue destruction with subsequent repair, fibrosis, and inflammation. Growth failure and altered body composition are common in infants with BPD when compared with their peers without BPD.¹¹⁹ The persistence of this altered body composition can last into the first years of life. Estimates of growth failure after hospital discharge range between 30% and 67%.¹²⁰ The origin of growth failure is multifactorial and is associated with elevations in both resting and total energy expenditure, use of corticosteroids, intrauterine growth retardation, and feeding problems.^{121,122} Given that pulmonary edema is common, fluid restriction is often necessary. This restriction further impedes provision of adequate calories and may contribute to poor growth.¹²¹ Optimal oxygen therapy during the first year of life in infants with BPD can result in growth patterns similar to those seen in infants without BPD.¹²³ Growth failure during the first 2 years of life, early childhood, and beyond has been reported, but it appears that prematurity and sociodemographic factors rather than BPD per se are most predictive of future growth.^{124,125} Catch-up growth can be attained faster when infants are fed higher intakes of protein, calcium, phosphorus, and zinc.¹²⁶ Because vitamin A deficiency is associated with BPD, supplementation is given for the prevention of BPD and sepsis in preterm infants.^{127,128} Benefits of vitamin A supplementation (i.e., a trend toward reduction in ventilatory support) must be weighed against the risks of repeated intramuscular injections and the potential for vitamin A toxicity (i.e., posthemorrhagic hydrocephalus or liver disease). The concern over these risks has prevented its widespread use at this time.

THERAPEUTIC OPTIONS TO MINIMIZE THE SIGNIFICANCE OF MALNUTRITION

The increased awareness of the prevalence and significance of untreated protein-calorie malnutrition has provided a strong incentive for a more rigorous evaluation of abnormalities of nutrition status and prompt initiation of SNS for malnourished patients. If nutrition assessment (see Chap. 143) reveals no malnutrition, then the patient or the patient's caregiver should be counseled on appropriate maintenance goals for nutrition intake.

If mild to moderate malnutrition is present, an anabolic feeding regimen should be initiated using oral supplements. If anorexia is a major contributing factor, EN may be indicated. Intact nutrients can be administered enterally when normal bowel function is present, but a specially designed formula that has a modified fat content, is lactose-free, contains fiber, and/or is calorie or protein enriched may be indicated if intestinal function is compromised (see Chap. 146). If malabsorption is a major contributing factor, EN using a disease-specific formula, or, alternatively, supplemental PN, may be indicated. In the presence of severe malnutrition, an anabolic feeding regimen should be initiated either enterally or parenterally depending on intestinal function and malabsorption.¹⁹ Data from international studies show the median mortality rate secondary to severe malnutrition in children younger than 5 years of age is 25% and has not changed for the last five decades.¹²⁹ The findings in some institutions of a mortality rate of less than 5% suggests that treatment strategy and practices employed are critical to optimize patient outcomes. The World Health Organization has published guidelines for the management of severe malnutrition in children.¹²⁹ Table 144-5 summarizes the management principles endorsed in these guidelines.

TABLE 144-5 Management Principles for Severe Pediatric Malnutrition

- 1. Recognize the physiologic effects of reductive adaptation. Every organ system has adapted to starvation and cannot tolerate aggressive reintroduction of nutrition.
- 2. Treat or prevent hypoglycemia, hypothermia, and dehydration (days 1 to 3). Initiate small, frequent feedings (every 2 to 3 hours) and provide only enough calories to meet basic metabolic demands.
- 3. Avoid a high-protein diet (days 1 to 3) secondary to liver incompetence.
- 4. Correct electrolyte imbalance (day 1 through week 6).
- 5. Assume the child has an infection and empirically treat with antibiotics (days 1 to 7).
- 6. Avoid cardiac failure secondary to aggressive rehydration. Parenteral rehydration should be avoided at all costs and only used if the child is in shock. Avoid diuretics during the first 1 to 5 days even if edema is evident.
- 7. Advance enteral feeding to recover lost weight and provide for “catch-up growth” (day 7 through week 26).
- 8. Correct micronutrient deficiencies with vitamins and minerals (without iron on days 1 to 7 and with iron on day 7 through week 6).
- 9. Correct emotional and social disorders.

When bowel obstruction or short-bowel syndrome is present, PN is indicated. Equivocal data exist whether EN is absolutely contraindicated in hypoperfusion of the gut. The most recent recommendations advocate holding EN when patients have sustained hypotension (<70 mm Hg), a need for increasing doses of pressor agents to maintain the mean arterial pressure ≥70 mm Hg, increasing ventilatory support requirements, or worsening signs of GI intolerance to the enteral nutrition (i.e., sudden abdominal distension, abrupt increases in nasogastric output, and sudden abdominal pain).¹³⁰ The anticipated duration of the need for parenteral support will dictate whether one uses the peripheral or central venous route of administration (see Chap. 145). Routine reevaluation of the response to nutrition therapy and attainment of nutrition goals should be incorporated into the overall patient care plan.

PHARMACOECONOMIC CONSIDERATIONS

10 Malnourished patients have increased complications during their hospital course, among them an increased length of stay, thereby incurring increased healthcare costs.^{3,131} Although the evidence is strong that malnutrition is associated with increased healthcare costs, it has been more difficult to establish the cost-to-benefit or cost savings of nutrition intervention. Tucker and Miguel confirmed the association between poor nutritional status and prolonged length of hospital stay, and also determined that when nutrition intervention occurred (oral, enteral, or parenteral nutrition), the average length of stay was decreased by 2.1 days.¹³¹

Trauma patients are at an unusually high risk for developing malnutrition because of the hypermetabolic and hypercatabolic state associated with underlying injury. Although several clinical trials have compared the efficacy of EN versus PN, little data are available regarding the cost-effectiveness of these two routes of administration. Trice et al.¹³² assessed the economic impact of the delivery of EN versus PN to trauma patients. Their evaluation of the data from nine prospective, randomized clinical trials revealed that postoperative PN was associated with an almost fourfold increased risk of infectious complications and 15-fold greater risk of catheter sepsis compared with EN. Estimated total costs were 4- to 12.5-fold greater in patients receiving PN than in those receiving EN. Thus the decision to prescribe PN over EN should be evaluated carefully.

Economic savings also have been achieved when SNS teams are involved with the provision of EN.¹³³ A benefit of \$4.20 was realized for every \$1 invested in nutrition support team management. Furthermore, management by the nutrition support team resulted in reductions in mortality rate, length of hospital stay, readmission rates, and complications, compared with management by a nonteam

group. Thus intervention by specially trained healthcare practitioners, including pharmacists, can lower costs associated with nutrition intervention without compromising the quality of patient care.

CONCLUSIONS

Although the cost-to-benefit analysis of nutrition intervention is weak, the issue that seems clear is that malnutrition is associated with significant morbidity and mortality in numerous disease states and clinical settings. Furthermore, it is likely that improved patient outcomes can be achieved by a systematic approach to identify the presence of risk factors for malnutrition, quantitate the degree of malnutrition, and initiate nutrition management.¹⁹ The clinician’s responsibilities in the management of nutrition disease include the following: identifying patients at risk for malnutrition; identifying candidates for nutrition intervention; designing patient-specific nutrition-support regimens; evaluating and managing drug–nutrient interactions; and, finally, initiating a monitoring plan to evaluate all clinical and laboratory data so as to optimize the safety and efficacy of the specialized nutrition support regimen.

ABBREVIATIONS

- AIDS: acquired immunodeficiency syndrome
- BPD: bronchopulmonary dysplasia
- CF: cystic fibrosis
- EN: enteral nutrition
- HIV: human immunodeficiency virus
- PN: parenteral nutrition
- PNI: prognostic nutritional index

TODD W. MATTOX AND PAMELA D. REITER

KEY CONCEPTS

- 1 Four steps to developing a successful nutrition plan include definition of nutrition goals, determination of nutrition requirements, determination of appropriate route of nutrient delivery, and subsequent monitoring of the nutrition regimen to evaluate suitability of the regimen as a patient's clinical condition changes and to minimize or treat complications early.
- 2 The appropriate route of nutrition support depends on the functional condition of the patient's gastrointestinal (GI) tract, risk of aspiration, expected duration of nutrition therapy, and clinical condition.
- 3 Identifying the patient who is most likely to benefit from parenteral nutrition (PN) therapy includes consideration of the patient's age, nutrition status, expected duration of GI dysfunction, and potential risks of initiating therapy.
- 4 PN formulations include intravenous sources of protein, dextrose, fat, water, electrolytes, vitamins, trace elements, and other additives.
- 5 PN solutions may be appropriately formulated for administration by peripheral or central venous access.
- 6 PN solutions may be infused continuously or intermittently.
- 7 Biochemical and clinical measurements considered necessary for effective monitoring of patients receiving PN include serum chemistries, vital signs, weight, total daily fluid intake and losses, and nutritional intake.
- 8 Non-catheter-related complications of PN therapy are minimized with application of age-appropriate nutrient dosing guidelines, frequent monitoring, and rational adjustments to the PN regimen when metabolic abnormalities occur.
- 9 Expenses associated with PN therapy may be minimized by using PN in appropriate patients, appropriate use of laboratory measurements associated with PN therapy, maximizing efficient purchasing practices for PN solutions and compounding supplies, streamlining compounding procedures, and minimizing PN waste.

Maintenance of adequate nutrition status during illness has been recognized for more than 50 years as an integral part of the medical

treatment plan for patients who are unable to use normal physiologic means of nourishment. Successful techniques for providing intravenous (IV) nutrition support were introduced to clinical practice in adults and subsequently, infants in the late 1960s.¹ Use of central venous access was investigated to reduce risk of metabolic complications associated with fluid overload and electrolyte imbalances. The use of larger vessels permitted infusion of concentrated formulas, which decreased the fluid volume required and avoided the phlebitis that commonly occurred when hypertonic infusions were given peripherally.

Further clinical experience and research fostered development of protocols that promoted better patient care and resulted in a decline in complications associated with parenteral nutrition (PN) therapy.² The scope of practice for nutrition support clinicians has broadened as a result of increasing knowledge regarding the metabolic consequences associated with acute injury and chronic disease states. The pharmacist's role in providing safe and effective nutrition-support care requires knowledge of the principles of patient selection, initial therapy design, preparation and dispensing of the nutritional formulations, and outcome monitoring. Other responsibilities of the nutrition support pharmacist may include development of policy and procedures, as well as quality improvement activities for patient care and operational processes associated with providing parenteral and enteral nutrition.³⁻⁶ However, the role of other healthcare professionals may be similar because of the evolving interdisciplinary approach to nutritional support.⁵⁻¹⁰ This chapter reviews indications for PN, components of PN formulations, routes of IV administration, practical aspects of regimen design, solution admixture, outcome monitoring, and management of complications for both adult and pediatric (neonates, infants, and children) patients.

DESIRED OUTCOMES

- 1 The primary objective of nutrition support therapy is to promote positive clinical outcomes of an illness and improve a patient's quality of life. Four fundamental steps are key to providing optimal care for patients who require nutrition support. They are definition of nutrition goals, determination of nutrient requirements for achievement of the nutrition goals, delivery of the required nutrients, and subsequent assessment of the nutrition regimen.⁵⁻⁷

A patient's nutrition goals can be established after a thorough nutritional assessment (see Chap. 143). Nutrient requirements and an appropriate route for delivery of the required nutrients can then be determined (see Chaps. 144 and 146). Nutrition support goals include correction of the patient's caloric and nitrogen imbalances, and any fluid or electrolyte abnormalities, or known vitamin or trace element abnormalities. An additional goal is to lessen the metabolic response to injury by minimizing oxidant stress and favorably modulating immune response. These interventions should not cause or worsen other metabolic complications.

Learning objectives, review questions, and other resources can be found at
www.pharmacotherapyonline.com.

Specific caloric goals include (a) adequate energy intake to promote normal growth and development in neonates, infants, and children, (b) energy equilibrium and preservation of fat calorie stores in well-nourished adults, and (c) positive energy balance in malnourished patients with depleted endogenous fat stores. Obese patients with excess endogenous fat stores (greater than 120% of ideal body weight) may require less caloric support than nonobese patients with the same clinical condition.¹¹ Specific nitrogen goals are positive nitrogen balance or nitrogen equilibrium and improvement in the serum concentration of visceral protein markers such as transferrin or prealbumin.

2 The gastrointestinal (GI) tract is the optimal route for providing nutrients unless obstruction, severe pancreatitis, or other GI complications are present (see Chap. 143).¹² Other considerations that may impact determination of an appropriate route for delivery of nutrition support include expected duration of nutrition therapy and risk of aspiration. Patients who have nonfunctional GI tracts or are otherwise not candidates for enteral nutrition may benefit from PN. Nutrition support provide by the IV route is also commonly referred to as total parenteral nutrition or hyperalimentation. Routine monitoring is necessary to ensure that the nutrition regimen is suitable for a given patient as the patient’s clinical condition changes and to minimize or treat complications early.

INDICATIONS FOR PARENTERAL NUTRITION SUPPORT

The association between malnutrition and development of complications and mortality is well documented in adult and pediatric patients.^{13,14} Although improvement in nutrition status as defined by various clinical nutrition markers has been reported in patients who received PN, the impact on clinical outcome is difficult to demonstrate in many adult populations. Several investigations have reported a positive effect of PN on complications and mortality, whereas others have failed to demonstrate any difference.^{13,15} Early studies have been criticized for defects in study design, such as small sample sizes, inappropriate randomization, and inconsistent baseline nutrition status among the study group, which hindered demonstration of the effectiveness of PN therapy. The impact of PN on clinical outcome has been more successfully demonstrated in critically ill infants and children, particularly those with acquired or congenital GI tract anomalies.¹⁷ Consensus guidelines for PN use in adults (Table 145–1) and pediatric (Table 145–2) patients are based on clinical experience and investigations in specific patient populations.^{15,17,18} Unfortunately, conflicting data have resulted in a lack of consistency in published guidelines from different sources, which complicates identification of the patient who is most likely to benefit from PN. However, these published reports may serve as resources for development of institution-specific standards.

3 The decision to initiate PN is based on the assessment that the patient cannot meet his or her nutritional requirements through the GI tract. This assessment must include an evaluation of the patient’s nutrition status, clinical status, age, and potential risks of initiating therapy, such as infection and other metabolic abnormalities. The appropriate length of time to wait prior to starting PN therapy is not well defined.¹²

CLINICAL CONTROVERSY

The most appropriate time to initiate PN in adults differs between various consensus reports because few data specifically address this issue. Some recommend initiating PN in patients who are not candidates for enteral nutrition as early as after 7 days of inadequate oral intake, whereas others recommend waiting up to 14 days in previously well-nourished or moderately malnourished patients.

TABLE 145-1 Indications for Adult Parenteral Nutrition

- 1. Inability to absorb nutrients via the GI tract because of one or more of the following:
 - a. Massive small bowel resection: usually patients with less than 100 cm of small bowel distal to the ligament of Treitz without a colon, or less than 50 cm of small bowel with an intact colon
 - b. Intractable vomiting when adequate EN is not expected for 7–14 days.
 - c. Severe diarrhea
 - d. Bowel obstruction
 - e. GI fistulae: PN is indicated in patients with prolonged inadequate nutritional intake longer than 5–7 days who are not candidates for EN
- 2. Cancer: antineoplastic therapy, radiation therapy, or HSCT
 - a. PN may be used in moderately to severely malnourished patients receiving active anticancer treatment who are not candidates for EN
 - b. PN is not routinely indicated for well-nourished or mildly malnourished patients undergoing surgery, chemotherapy, or radiation therapy
 - c. PN is unlikely to benefit patients with advanced cancer whose malignancy is unresponsive to treatment. However, use may be appropriate for carefully selected patients who have failed trials of less-invasive medical therapies and have good performance status, an estimated life expectancy of longer than 40–60 days, and strong social and financial support
- 3. Pancreatitis: PN may be used in patients with severe pancreatitis with prolonged inadequate nutritional intake longer than 5–7 days who are not candidates for EN. PN should be used when EN exacerbates abdominal pain, ascites, or fistula output
- 4. Critical Care
 - a. PN should be used in those patients in whom EN is contraindicated or is unlikely to provide adequate nutritional requirements within 5–10 days
 - b. Organ failure (liver, renal, or respiratory): PN should be used in patients with moderate to severe catabolism when EN is contraindicated
 - c. Burns: PN should be used in those patients in whom EN is contraindicated or is unlikely to provide adequate nutritional requirements within 4–5 days
- 5. Perioperative PN
 - a. Preoperative: for 7–14 days for patients with moderate to severe malnutrition who are undergoing major GI surgery, if the operation can be safely postponed
 - b. Postoperative: PN should be used in patients in whom EN is contraindicated or is unlikely to provide adequate nutritional requirements within 7–10 days
- 6. Hyperemesis gravidarum: when EN is not tolerated
- 7. Eating disorders: PN should be considered for patients with anorexia nervosa and severe malnutrition who are unable or unwilling to ingest adequate nutrition

EN, enteral nutrition; GI, gastrointestinal; HSCT, hematopoietic stem cell transplantation; PN, parenteral nutrition; SBS, short-bowel syndrome.
From references 12 and 17.

Adult PN therapy is not an emergent intervention and should not be initiated until the patient is hemodynamically stable.¹² In general, adults who are not candidates for enteral nutrition should be considered candidates for PN after 7 to 14 days of suboptimal nutritional intake.¹² Guidelines for use in infants and children are primarily influenced by age. The most appropriate time to initiate therapy in infants and children varies with age and nutritional status. Early PN

TABLE 145-2 Indications for Pediatric Parenteral Nutrition

- 1. When enteral nutrition is unlikely to provide adequate nutritional requirements
 - a. Premature infant within 24–48 hours
 - b. Other pediatric patients within 5–7 days
- 2. When the GI tract is not functional or cannot be assessed
 - a. Massive small bowel resection resulting in short-bowel syndrome
 - b. Neonatal necrotizing enterocolitis
 - c. Severe inflammatory bowel disease
 - d. Intractable diarrhea and/or vomiting
 - e. Graft-versus-host disease
 - f. Postchemotherapy
- 3. Infants and children requiring extracorporeal membrane oxygenation
- 4. Organ failure (liver, renal, pulmonary, pancreas) when enteral nutrition is contraindicated and child is catabolic

From references 16 and 18.

within the first 24 hours of life has been recommended for infants with a birth weight less than 1,500 grams.^{19–21} Protein loss in extremely low-birth-weight infants can be twofold higher than in term infants, and frequently results in a negative nitrogen balance that cannot be corrected by glucose as a sole nutrient. Early aggressive PN in neonates can enhance protein accretion and somatic growth.²² However, many clinicians hesitate to initiate early PN because of concern of adverse effects associated with protein intolerance. Withholding PN for 2 to 3 days after birth, coupled with a slow advancement of substrate, only appears to contribute to the acute semistarvation and growth failure seen in many neonates.^{21,23} PN should be initiated within 5 to 7 days in other pediatric patients who are unable to meet their nutrient requirements with enteral nutrition.^{16,20} Earlier intervention should be considered in term infants (within 2 to 3 days), critically ill children (within 3 to 5 days), and children with preexisting malnutrition. Guidelines for older children are similar to those in adults.

COMPONENTS OF PARENTERAL NUTRITION

4 PN formulations include intravenous sources of protein, dextrose, fat, water, electrolytes, vitamins, trace elements, and other additives. PN solutions should provide the optimal combination of macro- and micronutrients to provide a patient's specific nutritional requirements. Macronutrients include water, protein, dextrose, and intravenous fat emulsion (IVFE) (Table 145–3). Micronutrients include vitamins, trace elements, and electrolytes. Both macronutrients and micronutrients are necessary for maintenance of normal metabolism. In general, macronutrients are used for energy (dextrose and fat) and

as structural substrates (protein and fat). Micronutrients are required to support a variety of metabolic activities necessary for cellular homeostasis such as enzymatic reactions, fluid balance, and regulation of electrophysiologic processes. These components usually require individualized adjustments as the patient's clinical condition affects changes in metabolic stress, organ function, fluid and electrolyte balance, and acid–base status.

AMINO ACIDS

Protein in PN solutions is provided in the form of crystalline amino acids (CAAs), which are used primarily for protein synthesis. When oxidized for energy, 1 g of protein yields 4 calories. However, including the caloric contribution from protein when calculating calories provided by the PN regimen is controversial.²⁴

CLINICAL CONTROVERSY

Although sufficient energy substrate should be provided to support amino acid use for protein synthesis, amino acid oxidation for energy has been demonstrated in critically ill patients and is thought to occur because of altered metabolism associated with severe metabolic stress. Hence some practice settings may express calories provided by PN as total calories (protein, carbohydrate, fat calories), whereas others may use nonprotein calories (carbohydrate and fat).

Commercially available CAA solutions may be categorized as standard amino acid solutions or modified amino acid solutions. Standard CAA solutions are designed for use in patients with “normal” organ function and nutritional requirements (see Table 145–3). Although standard CAA solutions differ in the proportion of specific amino acids, they contain a balanced profile of essential, semiessential, and nonessential L-amino acids. Despite these differences, similar effects on markers of protein use have been reported.²⁵ The protein concentration, total nitrogen, and electrolyte content is also different between products. Because the nitrogen concentration of dietary protein is approximately 16%, 6.25 (100 g protein/16 g nitrogen) is commonly accepted as the conversion figure for calculating the nitrogen amount provided by CAA protein. Differences in nitrogen content per gram of amino acids among CAA products may affect calculation of nitrogen amounts infused when determining nitrogen balance.^{25,26} The clinical significance of these differences in determining nitrogen balance for routine clinical use is unknown.²⁶

Electrolyte composition of standard CAA solutions varies from small, obligatory amounts, to the provision of maintenance requirements of most electrolytes for an adult. Electrolytes provided by CAA solutions must be considered when determining a patient's individual requirements. CAA are available in several different concentrations, which facilitates compounding of patient-specific PN regimens. Highly concentrated products (15% to 20%) are attractive for use in critically ill patients who typically require fluid restriction but have large protein needs. Modified amino acid solutions are designed for use in patients who have altered protein requirements, such as those with hepatic encephalopathy, renal failure, and metabolic stress or trauma, as well as neonates and pediatric patients (see Table 145–3). These solutions tend to be more expensive than standard CAA solutions. The rationale for and clinical efficacy of modified amino acids in disease-specific PN regimens is controversial (see Chap. 147).

Several commercially available CAA solutions are designed to provide conditionally essential amino acids, which are considered nonessential during health because they are produced from other amino acids. However, under certain physiologic conditions, such as prematurity or sepsis, these amino acids cannot be synthesized in

TABLE 145-3 Macronutrient Components of PN Solutions

Nutritional Substrate	Intravenous Source	Description
Fluid	Sterile water for injection USP	
Nitrogen	Crystalline amino acids	
	Standard solutions	Contain a balanced profile of essential, semiessential, and nonessential L-amino acids
	Disease-specific solutions	
	Hepatic encephalopathy	Amino acid profile includes higher BCAA concentrations and lower AAA and methionine concentrations
	Renal failure	Amino acid profile includes higher EAA and histidine concentrations
Energy	Metabolic stress/trauma	Amino acid profile provides standard essential, semiessential, and nonessential amino acids with higher BCAA concentrations
	Pediatrics	Amino acid profile includes standard essential, semiessential, and nonessential amino acids with lower methionine, phenylalanine, and glycine concentrations; these solutions also contain taurine, glutamate, and aspartate
Carbohydrate	Dextrose	
	Glycerol	Used in ProcalAmine (B. Braun Medical, Inc.)
Fat	Intravenous fat emulsion LCT emulsions	Oil source is soybean or soybean and safflower combination

AAA, aromatic amino acids (includes phenylalanine and tyrosine); BCAA, branched-chain amino acids (leucine, isoleucine, and valine); EAA, essential amino acids (leucine, isoleucine, valine, phenylalanine, tryptophan, methionine, threonine, and lysine); LCT, long-chain triglycerides; PN, parenteral nutrition.

sufficient quantities.²⁵ CAA solutions specifically designed for use in neonates and pediatric patients contain increased amounts of taurine, aspartic acid, and glutamic acid. Other conditionally essential amino acids, such as cysteine, carnitine, and glutamine, are not available in commercial CAA solutions in pharmacologic amounts because they are relatively unstable or poorly soluble.²⁵

Consequently, PN solutions may need to be modified by clinicians to provide the desired amount of supplemental conditionally essential amino acids. Cysteine is a conditionally essential amino acid in preterm and term infants that may be added to PN solutions at the time of compounding. Cysteine supplementation also enhances calcium and phosphate solubility in PN solutions by decreasing the solution's pH.²⁷ Carnitine is a quaternary amine required for free fatty acid transport into the mitochondria for β -oxidation and energy production. Newborns are at risk for carnitine deficiency because of their immature synthetic and conservation mechanisms. Decreased plasma carnitine concentrations are associated with impaired lipid metabolism in patients receiving IVFE.²⁸ Supplemental carnitine may be added to the PN solution at the time of compounding. Carnitine use in neonatal PN regimens is generally reserved for patients receiving sole PN support for more than 2 weeks because the effect of short-term carnitine supplementation on clinical outcomes such as weight gain and lipid use is not clear.²⁸

Glutamine is the most abundant free amino acid in the body and is an important intermediate for many metabolic processes. Glutamine is reported to have an important role in maintaining intestinal integrity, immune function, and protein synthesis during conditions of metabolic stress.^{25,29} Investigations in humans and animals have reported positive effects on nutritional markers such as nitrogen balance, whereas others have reported significant improvement in other outcome markers, such as decreased length of hospitalization, incidence of infections, and GI toxicities associated with chemotherapy or radiation.³⁰ However, the best adult candidate for response to glutamine therapy has not been clearly identified.³⁰ The clinical usefulness of glutamine in neonates is less clear.³¹ Plasma glutamine concentrations increase with supplementation, but no beneficial effect on sepsis, enteral feeding tolerance, necrotizing enterocolitis, growth or mortality has been reported.^{29–33} The clinical use of glutamine is further complicated because there is no commercially available IV glutamine formulation. Currently available CAA solutions do not contain glutamine because of poor solubility and instability. Use of IV glutamine requires special manufacturing techniques not readily available in many institutional pharmacies.³⁴ Additional controlled trials are warranted to characterize the risks and costs associated with extemporaneous compounding before routine IV glutamine use can be recommended.^{30,34} Dipeptide amino acids are a potential parenteral source for conditionally essential amino acids that may provide a solution to the instability and solubility limitations. Dipeptides are synthesized by combining two amino acids with a peptide bond. The resulting protein is more soluble and stable than the individual amino acids.²⁵ Intravenous dipeptide formulations would be advantageous clinically because they incorporate higher concentrations of some specific amino acids, as well as some low-solubility, low-stability amino acids that are omitted or present in small quantities in current CAA solutions. In addition, dipeptide use would allow formulation of CAA solutions with a higher nitrogen content. Further studies are needed to assess long-term safety and optimal combinations of amino acids in different disease states.

DEXTROSE

The primary energy source in PN solutions is carbohydrate, usually in the form of dextrose monohydrate, which is available in concentrations ranging from 5% to 70%. When oxidized, each gram of hydrated dextrose provides 3.4 kcal. The appropriate IV dextrose

dose depends on the patient's age, estimated caloric requirements, and clinical condition. For example, minimum dextrose requirements in neonates is estimated to be approximately 6 to 10 mg/kg/min.³⁵ However, IV dextrose infusion rates should not exceed 12 to 14 mg/kg per minute in infants and 4 to 7 mg/kg per minute in adults.^{35–37} The recommended dextrose dose for routine clinical care rarely exceeds 5 mg/kg per minute in older critically ill children (1 to 11 years old) and adults.^{38,39} Maintaining an age-appropriate dextrose infusion rate is necessary to minimize risk of adverse effects. If the dextrose infusion rate exceeds the glucose oxidation rate, metabolically expensive pathways, such as glycogen repletion and lipid synthesis, are favored, resulting in increased energy expenditure, increased oxygen consumption, and increased carbon dioxide production. Excessive dextrose infusion rates also may contribute to the development of hyperglycemia, excess carbon dioxide production, and increased biochemical markers for liver function associated with fatty infiltration of the liver.^{38–40}

Non-insulin-dependent carbohydrate sources have been investigated as an alternative to dextrose to improve glycemic control in patients with impaired insulin secretion or activity who require PN. Glycerol, a sugar alcohol that provides 4.3 kcal/g, is the only dextrose alternative commercially available for clinical use. It is available as an isotonic, 3% solution in combination with 3% amino acids and supplemental electrolytes (ProcalAmine, B. Braun Medical, Irvine, CA). Although the solution may be peripherally infused, a major disadvantage of this formula is the dilute amino acid and carbohydrate concentrations. Most adult patients require up to 3 to 4 L/day of ProcalAmine solution together with IVFE as a caloric source to provide minimum energy requirements.⁴¹ Intravenous glycerol use in catabolic adults is safe and effective, but similar data are not available for infants and children.⁴²

INTRAVENOUS FAT EMULSION

IVFE is used as a concentrated source of calories and essential fatty acids. Commercially available IVFE products differ in triglyceride source (soybean oil or a combination of soybean oil and safflower oil), fatty acid content, and commercially available concentrations (10%, 20%, and 30%). These products also contain egg phospholipids as an emulsifying agent and glycerol to make the emulsion isotonic. Although the caloric contribution of fat is 9 kcal/g, the caloric content of IVFE is 1.1 kcal/mL for 10% emulsion, 2 kcal/mL for 20% emulsion, and 3 kcal/mL for 30% emulsion because of the caloric contribution of the egg phospholipid and glycerol.⁴³ The triglyceride source of IVFEs differ in fatty acid composition. Emulsions containing soybean oil are made of approximately 50% to 55% linoleic acid and 4% to 9% linolenic acid, whereas IVFEs that contain safflower oil are made of approximately 66% linoleic acid and 4% linolenic acid.⁴³ Linolenic acid, an omega-3 fatty acid, and linoleic acid, an omega-6 fatty acid, are both polyunsaturated long-chain triglycerides (LCTs).⁴⁴ IVFE products also differ in phospholipid and triglyceride concentrations. Higher-concentrated IVFEs (20% and 30%) have a lower phospholipid-to-triglyceride ratio compared with 10% IVFE.⁴⁵ Because higher amounts of circulating phospholipids are associated with impaired triglyceride clearance in neonates and infants, 20% IVFE is the preferred product for this population.^{34,40,45,46}

Both IVFE types are effective for treatment or prevention of essential fatty acid deficiency (EFAD). EFAD is the result of a biochemical deficiency of linoleic acid and arachidonic acid, which are considered essential in humans.⁴⁷ Since linolenic acid may be essential, all commercially available IVFEs contain soybean oil as a predominant linolenic acid source. These fatty acids are important for a variety of functions such as cellular integrity, platelet function, postnatal brain development, and wound healing.⁴⁷ Normally, linoleic acid is converted to the tetraene arachidonic acid. When

linoleic acid is not present in sufficient amounts, oleic acid is converted to the triene 5,8,11-eicosatrienoic acid, a fatty acid of lesser physiologic integrity, and EFAD occurs. EFAD may be prevented by providing 2% to 5% of total calories as linoleic acid and 0.25% to 0.5% of total calories as linolenic acid.³⁴ This may be achieved in most adult patients by giving approximately 100 g IVFE weekly.^{34,48} Neonates and infants require a minimum of 0.5 to 1 g/kg daily.⁴⁰

Plasma IVFE clearance is directly related to gestational age of infants and appears to be influenced by the infusion rate and the patient's clinical status.^{45,46} The risk of developing hypertriglyceridemia decreases with longer infusion times.^{34,40,45} Rapid IVFE infusions are reported to contribute to decreased oxygenation in neonates.⁴⁰ Adverse pulmonary effects are thought to be caused by polyunsaturated fatty acid (PUFA)-driven prostaglandin production, which results in altered vascular tone. However, the association between IVFE and pulmonary dysfunction is not clear.⁴⁰ In addition, data in animals and humans also suggest that rapid infusion of long-chain fatty acid formulations may have a negative impact on immunocompetence by saturating the reticuloendothelial system.^{44,46}

CLINICAL CONTROVERSY

Initiation of IVFE earlier than 4 to 7 days of life in infants with a birth weight less than 800 g remains controversial because of the potential increased risk of chronic lung disease and death. Some clinicians advocate initiating IVFE at 1 to 1.5 g/kg/day within the first week of life and advancing the dose after the second week of life.

As a caloric source, IVFE use may facilitate provision of adequate calories and minimize complications of nutrition therapy such as hyperglycemia, hepatotoxicity, or increased carbon dioxide production.⁴⁴ Although the frequency of acute adverse effects is reported to be less than 1% with current formulations, patients receiving their first IVFE dose should be monitored for dyspnea, chest tightness, palpitations, and chills. Headache, nausea, and fever also have been reported and might be associated with a rapid infusion rate. In general, IVFE use is contraindicated in patients with an impaired ability to clear fat emulsion, such as patients with pathologic hyperlipidemia and hypertriglyceridemia associated with pancreatitis.⁴⁶ Finally, patients with a reported egg allergy should be evaluated carefully for the nature and severity of the reaction before deciding to initiate a fat-based PN regimen.

Commercially available 10% and 20% IVFE products may be administered either by the central or peripheral route. They may be added directly to the PN solution as a total nutrient admixture (TNA) or 3-in-1 system (lipids, protein, glucose, and additives), or they may be piggybacked with the CAA-dextrose solution.^{34,43,44} The more concentrated 30% IVFE is only approved for use in the preparation of TNA and is not intended for direct IV administration.

The negative effects of LCTs on immune function have stimulated a search for new lipid sources.⁴⁴ Medium-chain triglycerides (MCTs) may offer several advantages, especially for critically ill patients. MCTs are hydrolyzed and cleared more rapidly than LCTs, and they do not accumulate in the liver. In addition, MCTs do not require carnitine for entrance into mitochondria for oxidation. However, MCTs are not a source of essential fatty acids. Subsequent studies of IV MCT-LCT mixtures in a number of patients demonstrate safety and efficacy comparable with standard LCT emulsions.^{44,47,49} Several MCT-LCT products are available in Europe, although no IV MCT formulations are currently available commercially in the United States. Other IV lipid formulations currently being investigated contain omega-3 PUFAs.⁴⁴ Current IVFEs contain omega-6 PUFAs as linoleic acid and omega-3 PUFAs as linolenic acid. Omega-3 PUFAs are metabolized to cytokine media-

tors, which may be less inflammatory and immunosuppressive than those derived from omega-6 PUFAs. The effect of IVFE administration on immune function, as well as patient morbidity and mortality, is not clear.^{40,50,51} However, investigations of enteral solutions with a higher concentration of omega-3 PUFAs have reported decreased infections and improvement in in vitro immunologic indices in critically ill patients.^{47,52} Although IVFE products remain the most common source of parenteral fat, a number of drugs have been introduced that contain lipid as either a vehicle for delivery or as a portion of the drug molecular formulation. Propofol, an IV anesthetic, is delivered in a soybean oil-in-water emulsion that is essentially the same as Intralipid 10%. This agent is used commonly for continuous sedation of ventilated patients and should be considered a potentially significant source of calories that may require adjustment of a patient's nutrition regimen.⁵³ The antifungal amphotericin B is available in several lipid-containing combinations such as liposomal and lipid complex formulations. The caloric contribution from these products when used in standard doses generally is small and is not relevant clinically.

VITAMINS

Maintenance guidelines for daily parenteral vitamin supplements have been established by the Nutrition Advisory Group of the American Medical Association (NAG-AMA) for adults, children, and infants.⁵⁴ The NAG-AMA identified 13 essential vitamins that include 4 fat-soluble vitamins and 9 water-soluble vitamins. These guidelines are based on the recommended daily allowances, which are designed to meet requirements of healthy people. Vitamin requirements for preterm infants and patients with metabolic stress or specific organ failures are controversial.^{40,55-57} Revised NAG-AMA recommendations for parenteral vitamin requirements in infants and children primarily reflect changes for preterm infants requiring PN.⁵⁷

Adult parenteral multiple-vitamin products formulated to comply with the NAG-AMA guidelines are available commercially, while there are two commercially available parenteral vitamin products for use in pediatric patients. MVI-Pediatric (Mayne Pharma, Paramus, NJ) and Infuvite Pediatric (Baxter Healthcare Corporation, Deerfield, IL) are formulated to meet the revised NAG-AMA guidelines for infants weighing less than 1 kg to children up to 11 years old. However, there are no commercially available IV multivitamin products designed to specifically meet the unique requirements of premature infants, including higher vitamin A and lower doses of vitamins B₁, B₂, B₆, and B₁₂ compared to recommendations for term infants and older children.

In the past, parenteral multiple-vitamin formulations for adults contained only 12 essential vitamins. Vitamin K was not included to minimize the risk of a drug-nutrient interaction in patients receiving anticoagulants, which antagonize vitamin K-dependent coagulation factors. However, in 2000, the U.S. Food and Drug Administration (FDA) mandated reformulation of adult parenteral multiple-vitamin products to include 150 mcg of vitamin K in addition to higher doses of vitamins B₁, B₆, and C.⁵⁸ The NAG-AMA recommendation for vitamin K in adults is 2 to 4 mg weekly. Other practitioners recommend larger doses of 0.5 to 1 mg/day or 5 to 10 mg weekly.³⁴ An investigation of patients receiving long-term IVFE-containing PN with vitamin K-free parenteral multivitamins at home suggests that supplemental vitamin K may not be necessary to maintain normal prothrombin times and plasma vitamin K concentrations.⁵⁹ Vegetable oils such as soybean and safflower oils used in IVFEs are a natural source of phyloquinone (vitamin K₁). However, the vitamin K concentration depends on the type and concentration of vegetable oil in the IVFE.⁵⁸⁻⁶⁰ Mean concentrations of 13.2 and 26.5 mcg/100 mL were reported for 10% and 20% Liposyn II (Abbott Laboratories, Abbott Park, IL), which contains both soybean and safflower oil.⁶⁰

Mean concentrations of 30.9 and 67.5 mcg/100 mL were reported for 10% and 20% Intralipid (Baxter Healthcare Corporation, Deerfield, IL), which contains only soybean oil. The bioavailability of vitamin K₁ from IVFEs is unknown. Although hospitalized patients who received no additional vitamin K supplementation during short-term PN that included a low vitamin K-containing IVFE experienced minimal effects on international normalized ratio, supplemental vitamin K may be given intramuscularly or subcutaneously or added to the PN solution if needed.^{58,61} Current recommendations suggest supplemental vitamin K is unnecessary when a vitamin K-containing multiple-vitamin product is used.³⁴ A parenteral multiple-vitamin formulation containing no vitamin K is commercially available for use in patients receiving home parenteral nutrition and warfarin anticoagulation. (MVI-12, multi-vitamin infusion without vitamin K, Mayne Pharma, Paramus, NJ.)

Vitamin requirements may be altered in malnutrition and other specific disease states or with certain drug therapies. Individual and combination products are available to provide additional or tailored supplementation, which may be necessary to prevent development of vitamin toxicities or deficiencies caused by altered metabolism or drug therapy.

TRACE ELEMENTS

Many trace elements are an important part of metalloenzymes and also function as cofactors in a variety of regulatory metabolic pathways.^{55,57} Although 17 trace elements have demonstrated biologic importance, clear deficiency syndromes in humans have been described only for iron, iodine, cobalt (as vitamin B₁₂), zinc, and copper.^{57,62,63} The NAG-AMA recognized zinc, copper, and chromium as being essential for IV supplementation in patients receiving PN.⁶⁴ Although a clear deficiency syndrome for manganese has not been reported in humans, the NAG-AMA considered manganese essential based on case reports of patients receiving PN with metabolic complications that corrected after manganese supplementation.⁶⁴ Reports of syndromes associated with selenium and molybdenum deficiency suggest that they also may be essential.^{57,62} Recommendations for trace elements in pediatric patients receiving PN have been revised as well.⁵⁷

Intravenous trace elements are available as single-mineral solutions and as multiple-mineral combinations with or without electrolytes. Most products provide the daily requirements for the trace minerals considered essential by the NAG-AMA (zinc, copper, chromium, and manganese), whereas some also include iodide, molybdenum, or selenium. Combination products are available for pediatric patients that provide manganese, copper, chromium, zinc, and selenium.

Requirements for trace elements also change depending on the clinical condition of the patient. For example, higher doses of supplemental zinc likely are necessary in patients with high-output ostomies or diarrhea because the GI tract is the predominant excretion route for zinc. Manganese and copper are excreted through the biliary tract, whereas chromium, molybdenum, and selenium are excreted renally. Hence these trace elements should be restricted or withheld from PN solutions in patients with cholestatic liver disease and renal failure, respectively.

ELECTROLYTES

Electrolytes such as sodium, potassium, calcium, magnesium, phosphorus, chloride, and acetate are necessary PN components for the maintenance of numerous cellular functions. Electrolytes may be given to maintain normal serum concentrations or to correct deficits. Patients who have “normal” organ function and relatively normal serum concentrations of any electrolyte should receive

normal maintenance electrolyte doses when PN is initiated and daily thereafter. Specific electrolyte requirements vary according to the patient’s age, disease state, organ function (see Chap. 147), previous and current drug therapy, nutrition status, and extrarenal losses. Electrolytes are available commercially as single- and multiple-nutrient solutions. Multiple-electrolyte solutions are useful in stable patients with normal organ function who are receiving PN. Concentrated multiple-electrolyte solutions designed for addition to PN solutions generally contain only sodium, potassium, calcium, and magnesium. Phosphorus must be added as a separate additive. Further information regarding metabolism and requirements of vitamins, trace elements, and electrolytes is given elsewhere.^{34,65}

DESIGNING A PARENTERAL NUTRITION REGIMEN

6 Several factors, including the patient’s venous access, fluid status, and macronutrient and micronutrient requirements, are important considerations when designing the PN regimen. A patient’s venous access and fluid status determines how concentrated the PN solution may be compounded and hence have an impact on the nutrient amount that may be provided. PN solutions may be administered by central or peripheral venous access. The patient’s clinical condition determines which route is most appropriate (Fig. 145–1).

PN solutions may be provided as a 2-in-1 formulation that contains dextrose, CAA, and other necessary micronutrients, or as a TNA that contains dextrose, CAA, and IVFE, as well as other necessary micronutrients. Use of TNA solutions offers several potential advantages, including reduced inventory (infusion pumps, tubing, and other related supplies), decreased time for compounding and administration, a potential decrease in manipulations of the infusion line (which should correspond with a decreased risk of catheter contamination), and ease of delivery and storage for patients receiving home PN.⁶⁶ Potential disadvantages include increased risk of infections and stability and compatibility concerns. For example, the stability of TNA solutions is less predictable than that of 2-in-1 solutions, which makes their use less desirable in specific patient populations such as neonates and infants.³⁴

ROUTES OF PARENTERAL NUTRITION ADMINISTRATION

Peripheral Route

Peripheral parenteral nutrition (PPN) is an option for mild to moderately stressed patients in whom central access is unavailable or undesirable and function of their GI tract is expected to return within 10 to 14 days.⁶⁷ Potential PPN candidates should not be fluid restricted or require large nutrient amounts. Lower concentrations of amino acid (3% to 5% final concentration), dextrose (5% to 10% final concentration), and micronutrients compared to central parenteral nutrition (CPN) are necessary for peripheral administration. Because PPN solutions are relatively dilute, larger volumes are usually necessary to provide nutrient requirements. Additionally, many patients who receive PPN likely will require the use of IVFE to increase caloric support to levels more consistent with CPN regimens. The primary advantages of PPN include a lower risk of infectious, metabolic, and technical complications.⁶⁷ However, several other factors may complicate PPN use in many patient populations. Patients who have received multiple courses of chemotherapy, malnourished patients, premature infants, elderly patients, and others with an illness of long duration who have already been subjected to multiple venous accesses for fluid and medication administration are likely to have limited peripheral venous access. PPN use is also

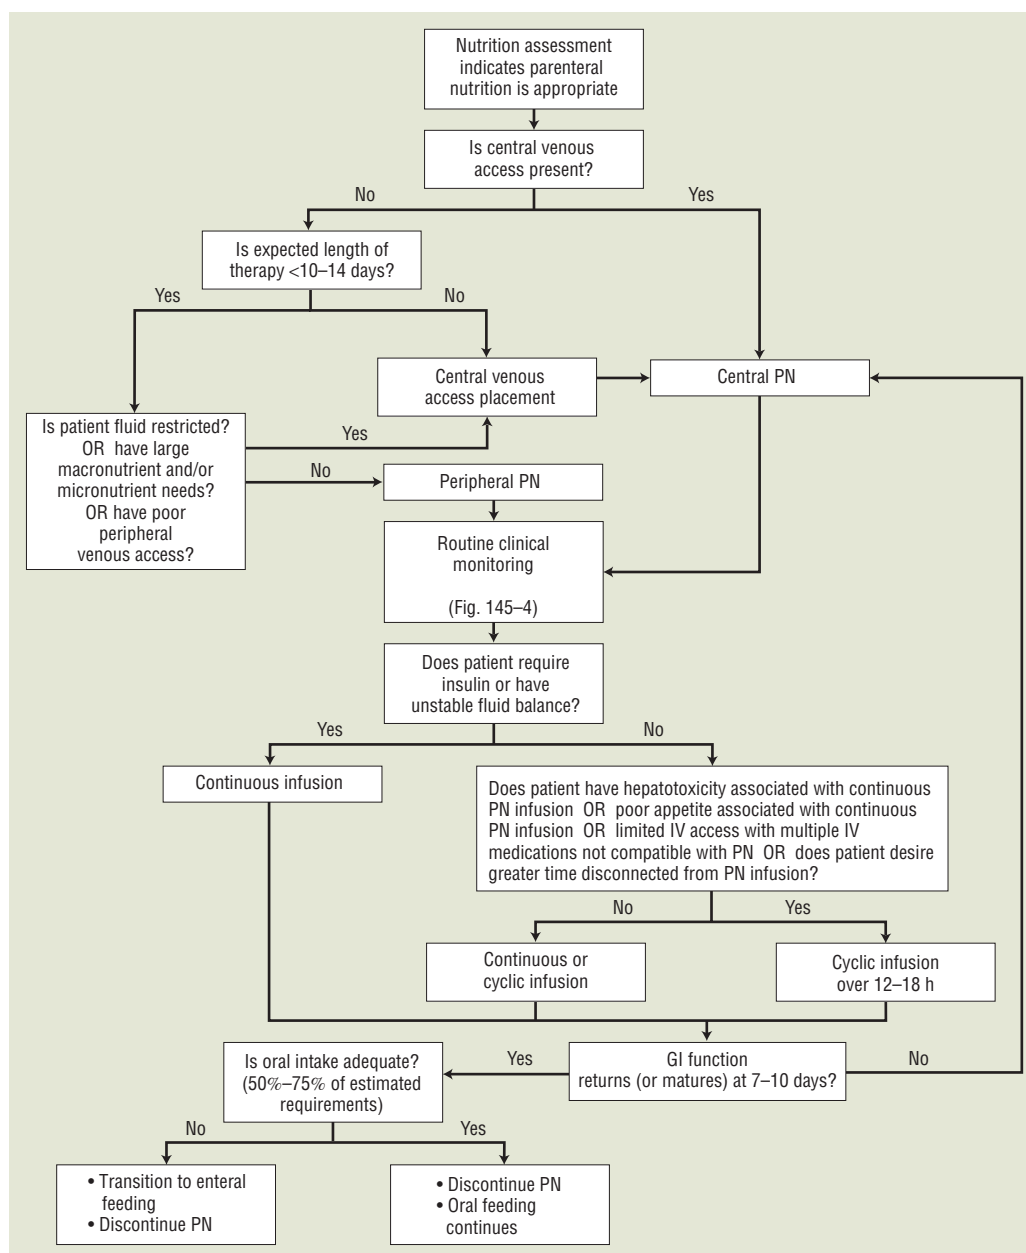

FIGURE 145-1. The route of parenteral nutrition (PN) and the infusion type depend on the patient's clinical status and the expected length of therapy.

limited by relatively poor peripheral vein tolerance to hypertonic solutions. Thrombophlebitis is a commonly reported complication in patients receiving PPN. Although the risk of developing phlebitis is greater with solution osmolarities greater than 600 to 900 mOsm/L, peripherally administered TNA with much higher osmolarities have been associated with low infusion-site complications in some centers.⁶⁷ Efforts to minimize development of phlebitis and/or infiltration sequelae in patients receiving PPN include addition of IVFE to the regimen as a possible venous lumen protectant, subtherapeutic heparin doses (0.5 to 1 unit/mL) to prevent thrombus formation, and/or small doses of hydrocortisone (5 mg/L) to minimize access site inflammation.⁶⁷ Midline catheter use may offer some advantage with reducing the risk of thrombophlebitis.⁶⁸ Although these catheters are not central venous access devices, they are longer and infuse into larger venous vessels which may dilute the PN solution to a more tolerable osmolarity. The osmolarity of a PN solution may be estimated by using the guidelines for osmolarities of selected PN components in Table 145-4.

Central Route

CPN is the preferred choice for PN delivery and is used predominantly for patients who require PN for periods of greater than 7–14 days during hospitalization or indefinitely at home.⁶⁸ These patients may have large nutrient requirements, poor peripheral venous access, and/or fluctuating fluid requirements, such as metabolically stressed

TABLE 145-4 Osmolarities of Selected Parenteral Nutrients

Nutrient	Osmolarity
Amino acid	100 mOsm/%
Dextrose	50 mOsm/%
Lipid emulsion	1.7 mOsm/%
Sodium (acetate, chloride, phosphate)	2 mOsm/mEq
Potassium (acetate, chloride, phosphate)	2 mOsm/mEq
Magnesium sulfate	1 mOsm/mEq
Calcium gluconate	1.4 mOsm/mEq

patients with extensive surgery, trauma, sepsis, multiple-organ failure, or malignancy. CPN solutions are highly concentrated hypertonic solutions that must be administered through a large central vein. Unlike peripheral veins, central veins have a higher blood flow, which quickly dilutes the hypertonic solutions. Disadvantages of CPN include risks associated with catheter insertion, routine catheter use, and care of the access site. Relative to peripheral venous access, central venous catheter access is associated with a greater potential for infection. In addition, the risk of more serious catheter-induced trauma and related sequelae and other serious technical or mechanical problems is greater than with peripheral access.

The choice of central venous access site depends on a number of factors, including the patient's age and anatomy. Central venous catheters vary in composition, lumen size, number of injection ports, and other special features that affect ease or convenience of care and maintenance. Central venous catheters for short-term use in adults are commonly inserted percutaneously into the subclavian vein and advanced so that the tip is at the superior vena cava.⁶⁸ If this approach is not possible, the internal jugular vein can be used. Frequently, short-term central venous access is obtained in critically ill neonates via a catheter placed in the umbilical vein. Other sites for central venous access in infants and older children are similar to those in adults. When therapy is expected to last longer than 4 weeks, the catheter usually is tunneled subcutaneously before entering the central vessel, secured initially with retaining sutures, and anchored in place with a felt cuff that promotes subcutaneous fibrotic tissue growth around the catheter. The injection port may remain external or be concealed entirely beneath the skin. Implanted central venous catheters have a larger port or reservoir that is surgically placed beneath the skin surface and anchored in the chest wall muscle. Peripherally inserted central catheters are venous access devices that are inserted into a peripheral vein (basilic, cephalic, or brachial) and advanced so that the tip is at the superior vena cava.⁶⁸ Peripherally inserted central catheters are increasingly used for both short- and long-term central venous access in acute or home care settings because of ease and economy of bedside placement.⁶⁹

CONSTRUCTING THE PARENTERAL NUTRITION REGIMEN

Once the route of delivery is chosen, components of the PN regimen are determined based on the patient's nutritional assessment. Some healthcare systems may require the entire PN formula to be written in individual components and additives without the use of a standard order form. More commonly, the ordering process has been simplified by the use of order forms designed specifically for PN. These standardized order forms promote education of practitioners by providing brief guidelines for initiating PN and foster cost-efficient nutrition support by minimizing errors in ordering, compounding, and administration.^{70,71} Standardized order forms also may include options for ordering certain related procedures, laboratory tests, protocols for patient management, or consultations with other medical services related to the patient's nutrition support. Standardized forms and protocols should be reviewed and updated periodically to reflect changes in the practices and patient population of a practice setting and also advances in technology that may affect provision of nutrition support.

Adult Parenteral Nutrition Solutions

In general, there are two methods for ordering adult PN. The "standard formula approach" offers a variety of base formulations with a fixed nonprotein calorie-to-nitrogen ratio. This method usually includes different formulas designed for mild to moderately stressed patients, renal failure patients, fluid-restricted patients, and liver failure patients. Because the nonprotein calorie-to-nitrogen

ratio is fixed, the amount of nutrient delivered depends solely on the infusion rate. The "individualized formula approach" permits compounding of patient-specific solutions. Compounding of the PN solution is limited only by the concentrations of stock solutions and stability of the additives. The nutrient amount delivered depends on the daily volume of the PN solution infused and the nutrient concentrations in the PN solution. The total daily amount of PN solution may be prepared in multiple bags, or more cost-effectively in a single container.³⁴

Traditionally, adult PN solutions have been ordered by expressing the final concentrations of each component in the solution. For example, CAA and dextrose are ordered commonly in final percentage, electrolytes in milliequivalents per liter, and other additives in amount (milliliters or units) per day. This inconsistency may promote confusion and misinterpretation of PN solution contents that may result in harm, especially when patients are transferred between health system environments. To ensure that PN labels in all health system environments clearly and accurately reflect the PN solution contents, guidelines for standardized adult PN labeling have been recommended.³⁴ In addition to including a variety of other information on the label such as dosing weight and administration route, the guidelines recommend expressing PN ingredients in amounts per total volume, which minimizes the need for pharmaceutical calculations to determine the nutrient value of the admixture. Computer software for calculating PN solutions is widely available, and several programs have adapted the recommended labeling guidelines. Pharmaceutical calculations of a 2-in-1 PN regimen are briefly reviewed (Fig. 145–2).

Several guidelines or clinical rules of thumb are available to help simplify calculation of a PN regimen after a patient's nutritional requirements have been decided. For example, adult patients receiving only PN therapy may need larger volumes of fluid to provide maintenance requirements and replace extrarenal losses. However, patients requiring other IV drug therapy may receive adequate fluid from an additional IV maintenance solution (e.g., 0.45% NaCl in 5% dextrose) and/or piggybacked medications. Depending on individual institutional practices, maximally concentrating the PN solution and using an inexpensive maintenance fluid to manage hydration may provide a cost-effective regimen that requires fewer adjustments. Another guideline that may be helpful in designing a PN regimen is to allow a volume of approximately 100 to 150 mL/L of base solution (approximately 200 to 300 mL per day) for electrolytes and other additives. PN regimens for patients who require very small amounts of additives, such as patients with renal failure, may be further concentrated.

Pediatric Parenteral Nutrition Solutions

Pediatric PN solutions are typically ordered using an individualized approach because clinical practice guidelines often recommend nutrient intakes based on the patient's weight. To simplify pediatric PN ordering many institutions use a pediatric-specific PN order form that expresses daily nutrient amount based on weight. For example, protein and fat are ordered as grams per kilogram per day, dextrose as milligrams per kilogram per minute, and electrolytes as milliequivalents per kilogram per day. However, some institutions may order macronutrients by expressing the final concentration of each component in the solution. Current safe practice guidelines suggest that the pediatric PN label identify components as an "amount per day" with a secondary expression of components as "amount per kilogram per day."³⁴ Auxiliary labels may be needed when the format between PN ordering and PN labeling is different. Calculations for determining a pediatric PN solution are reviewed to illustrate fundamental concepts for ordering pediatric PN solutions (Fig. 145–3). Additional features of the pediatric PN label include the dosing weight, administration date and time, expiration date, infu-

Calculation of an Adult Parenteral Nutrition Regimen

Patient case: A patient's daily nutritional requirements have been estimated to be 100 g protein and 2,000 total kcal. The patient has a central venous access and reports no history of hyperlipidemia or egg allergy. The patient is not fluid restricted. The PN solution will be compounded as an individualized regimen using a single-bag, 24-hour infusion of a 2-in-1 solution with intravenous fat emulsion (IVFE) piggybacked into the PN infusion line. Determine the total PN volume and administration rate by calculating the macronutrient stock solution volumes required to provide the desired daily nutrients. The stock solutions used to compound this regimen are 10% crystalline amino acids (CAA), 70% dextrose, and 20% IVFE.

1. Determine the daily IVFE calories and volume

- 2,000 kcal/day \times 30%–40% of total calories as fat = 600–800 kcal/day
Choose IVFE 20% 250 mL/day \times 2 kcal/mL = 500 kcal/day

2. Determine the 70% dextrose stock solution volume

- Determine dextrose calories
Dextrose calories = TOTAL – IVFE – Protein
2,000 kcal – 500 kcal IVFE – (4 kcal/g \times 100 g CAA) = 1,100 kcal
- Calculate required dextrose (grams)
1,100 kcal \div 3.4 kcal/g dextrose = 324 g dextrose
- Determine 70% dextrose volume
70 g/100 mL = 324 g/X mL 70% dextrose; X = 463 mL 70% dextrose

3. Calculate the 10% CAA stock solution volume

- 10 g/100 mL = 100 g/X mL 10% CAA; X = 1,000 mL 10% CAA

4. Determine the 2-in-1 PN volume and administration rate

- Calculate CAA/dextrose volume
463 mL 70% dextrose + 1,000 mL 10% CAA = 1,463 mL CAA–dextrose
- Add 100–200 mL for additives
Total 2-in-1 volume = approximately 1,600–1,700 mL/day
- Calculate the administration rate
1,600–1,700 mL/day \div 24 hours = 67–71 mL/hour; round to 65–70 mL/hour

5. Choose final 2-in-1 PN regimen and determine provided nutrient amounts:

- Final 2-in-1 regimen
100 g CAA/324 gm dextrose in 1,680 mL/day to infuse at 70 mL/hour
+ 20% IVFE 250 mL to infuse at 2 mL/hour
- Calculate macronutrient calories

20% IVFE calories:	250 mL \times 2 kcal/mL =	500 kcal
Dextrose calories:	324 g \times 3.4 kcal/g =	1,102 kcal
Protein calories:	100 g \times 4 kcal/g =	400 kcal
Total kcal:		<u>2,002 kcal</u>
Nonprotein kcal:		1,602 kcal

FIGURE 145-2. Calculation of an adult parenteral nutrition (PN) regimen.

sion rate, and duration of infusion. Because infants and children generally receive daily maintenance fluid from the PN regimen, supplemental IV solutions are rarely needed. Pediatric PN may be provided as a 2-in-1 or TNA formulation. However, the TNA system is not recommended for use when compounding neonatal PN because of IVFE instability with higher calcium and phosphorus concentrations.³⁴ The labeling guidelines for IVFE in children are similar to those in adults.

ADMINISTRATION TECHNIQUES

PN solutions should be administered with an infusion pump. The IV administration line for CAA–dextrose solutions should include a 0.22-micron inline filter to remove particulate matter, air, and any microorganisms that may be present in the solution. IVFEs administered separately from the CAA–dextrose solution must be piggy-

backed into the PN line at a site beyond the inline filter because the average size of IVFE particles is approximately 0.5 microns.³⁴ Routine use of inline filters (greater than 0.22 microns) with TNA solutions is controversial.^{68,72} However, the FDA recommends use of a 1.2-micron filter, which may be effective in preventing catheter occlusion caused by precipitates or lipid aggregates.³⁴ This filter size is also reported to remove *Candida albicans*.

INITIATING AND ADVANCING THE PARENTERAL NUTRITION INFUSION

ADULT PARENTERAL NUTRITION

The patient's nutrition status, current clinical status, history of glucose tolerance, and dextrose concentration in the formula will dictate

Calculation of a Pediatric Parenteral Nutrition Regimen

Patient Case: A 28-week gestational age infant's (weight 1.3 kg) estimated nutritional requirements are 3.5 g/kg/day protein, 3.5 g/kg/day intravenous fat emulsion (IVFE) and 120 nonprotein kcal/kg/day. The infant has central venous access and reports no history of hyperlipidemia or egg allergy. The PN solution will be compounded as an individualized regimen using a single-bag, 24-hour infusion of a 2-in-1 solution with IVFE piggybacked into the PN infusion line. Determine if the desired daily crystalline amino acids (CAA) and dextrose can be provided in the determined daily volume using 10% CAA, and 70% dextrose stock solutions. The IV fat source will be 20% IVFE.

- Determine the 2-in-1 PN volume and administration rate

 - PN volume is based on maintenance fluid requirements
 $150 \text{ mL/kg} \times 1.3 \text{ kg} = 195 \text{ mL/day}$
 - PN Infusion rate
 $195 \text{ mL} \div 24 \text{ hours} = 8.1 \text{ mL/hour}$
- Determine the daily protein amount and the corresponding 10% CAA volume

 - Calculate daily protein amount
 $3.5 \text{ g/kg/day} \times 1.3 \text{ kg} = 4.55 \text{ g/day}$
 - Calculate the 10% CAA stock solution volume
 $10 \text{ g/100 mL} = 4.55 \text{ g/X mL 10\% CAA}$ $X = 45.5 \text{ mL 10\% CAA}$
- Determine the daily dextrose amount and the corresponding 70% dextrose volume

 - Calculate daily dextrose amount to provide approximately 14 mg/kg/day
 $(14 \text{ mg} \times 1.3 \text{ kg} \times 1,440 \text{ minutes/day}) \div 1,000 \text{ mg/g} = 26.2 \text{ g}$
 - Calculate the 70% CAA stock solution volume
 $70 \text{ g/100 mL} = 26.2 \text{ g/X mL 70\% CAA}$ $X = 37.4 \text{ mL 70\% dextrose}$
 - Calculate the dextrose (final) concentration in the volume determined in step 1.
 $26.2 \text{ g/195 mL} = X \text{ g/100 mL}$ $X = 13.4\% \text{ dextrose}$
- Determine the daily IVFE amount, volume, and administration rate

 - Calculate daily IVFE amount
 $3.5 \text{ g/kg} \times 1.3 \text{ kg} = 4.6 \text{ g/day}$
 - Calculate 20% IVFE volume
 $20 \text{ g/100 mL} = 4.6 \text{ g/X}$ $X = 23 \text{ mL/day of 20\% IVFE}$
 - Calculate the IVFE administration rate
 $23 \text{ mL 20\% IVFE} \div 24 \text{ hours} = 0.95 \text{ mL/hour}$
- Determine final 2-in-1 PN regimen and provided nutrient amounts

 - Final PN regimen
 $3.5 \text{ g/kg/d CAA/ 13.5\% dextrose to infuse at } 8.1 \text{ mL/hour}$
 $+ 20\% \text{ IVFE } 3.5 \text{ g/kg/day to infuse at } 0.95 \text{ mL/hour}$
 - Calculate macronutrient calories
20% IVFE calories: $23 \text{ mL} \times 2 \text{ kcal/mL} =$ 46 kcal
Dextrose calories: $26.2 \text{ g} \times 3.4 \text{ kcal/g} =$ 89 kcal
Protein calories: $4.55 \text{ g} \times 4 \text{ kcal/g} =$ 18 kcal
Total kcal: 153 kcal
Nonprotein kcal: 135 kcal

FIGURE 145-3. Calculation of a pediatric parenteral nutrition (PN) regimen.

the infusion rate at which the adult PN solution should be initiated. Stable patients with normal organ function and stable baseline serum glucose concentrations have demonstrated minimal effect on serum glucose concentrations when abruptly initiating or discontinuing PN therapy.^{73–75} However, another approach is to begin the PN infusion and increase the rate gradually over 12 to 24 hours to the desired rate. The infusion rate is likewise reduced in a stepwise fashion, such as decreasing the rate by 50% for 1 hour prior to discontinuation, when the PN therapy ends.⁷⁴ This approach should prevent development of hyperglycemia and rebound hypoglycemia, respectively. Tapered ini-

tiation and cessation has been recommended for patients receiving intermittent subcutaneous regular insulin, patients with severe renal or hepatic disease, patients with other disease states that may increase the risk for development of hypoglycemia, such as severe diabetes or pancreatic malignancy, and patients who are receiving concurrent drug therapy that may predispose to development of hypoglycemia or mask the cardiovascular symptoms of hypoglycemia (β -blockers).⁷³ Although the IVFE dose should not exceed 2.5 g/kg per day or 60% of total daily calories, lower doses of 1 g/kg per day not to exceed 30% of calories have been recommended to minimize nega-

tive effects associated with long-chain fatty acids.³⁴ Manufacturer's information recommends IVFE infusion over 4 to 8 hours for adults. However, infusion over 12 to 24 hours appears to be the best clinical strategy to promote IVFE clearance and minimize risk of negative effects on pulmonary and immune function.^{45,46}

The manufacturer's guidelines recommend initiating IVFE in adults with a test dose of 0.5 to 1 mL/min for the first 15 to 30 minutes because of the potential for an immediate hypersensitivity reaction. In most patients, this is probably not necessary because of the relatively low incidence and benign nature of acute adverse reactions. In addition, infusion over 12 to 24 hours eliminates the need for a test dose because the infusion rate is within the range of the test dose rates recommended by the manufacturer. Appropriate electrolytes should be provided to patients with normal organ function based on standard nutrient ranges.³⁴ Adjustments may be necessary depending on the patient's clinical condition. Adults and children older than 11 years of age should receive daily amounts of trace elements and an adult vitamin formulation.

PEDIATRIC PARENTERAL NUTRITION

Pediatric PN solutions are typically initiated with a volume calculated to provide the patient's daily maintenance fluid requirements on the first day of therapy. Individual substrates are then advanced daily as tolerated with the goal PN regimen generally being achieved by day 3 of therapy. PN should be initiated with the goal protein dose. The initial dextrose dose for older infants and children is based on previous glucose tolerance. Although practices may vary, one approach is to start with (final concentration) 10% dextrose and advance the concentration in 5% increments daily as tolerated to a goal not to exceed 5 to 7 mg/kg per minute. Initial dextrose doses for premature infants should approximate fetal nutrient delivery rates of 5 to 6 mg/kg per minute. Frequently this mathematically translates into a final concentration range of 5% to 10% dextrose. The dextrose concentration for the neonatal PN should be advanced daily by 1% to 2.5% or by 2 to 4 mg/kg/min increments to a goal that does not exceed 12 to 14 mg/kg/min. IVFE is usually initiated at 0.5 g/kg per day in neonates and 0.5 to 1 g/kg per day in older children, and increased daily by 0.5 to 1 g/kg per day to a maximum of 3 to 4 g/kg per day. Incremental increases of IVFE dose allows daily serum triglyceride evaluation and early detection of those with impaired fat clearance. The IVFE dose should not exceed 60% of total daily calories for neonates and 30% of total calories for children. The best clinical strategy for minimizing the risk of adverse effects associated with rapid IVFE administration, and promoting IVFE clearance is to infuse IVFE over 20 to 24 hours or at a rate of 0.15 g/kg per hour.^{45,46} This slow infusion also eliminates the need for a test dose because the infusion rate is less than the test-dose rate recommended by the manufacturer.

CLINICAL CONTROVERSY

Clinical investigations of PN in critically ill neonates report clinical benefits and low risk of adverse effects when PN is initiated within the first 24 hours of life. However, some clinicians continue to withhold PN therapy for 2 to 3 days after birth because of concerns for protein intolerance manifested by hyperammonemia, azotemia, and metabolic acidosis.

Intravenous electrolytes, vitamins, and trace elements should be initiated on the first day of therapy and continued as a daily component of the PN solution.³⁴ Children younger than age 11 years should receive a vitamin product formulated for pediatric patients. Two multivitamin dosing schemas have been suggested for infants and children.³⁴ One method recommends 2 mL/kg per day for infants

weighing less than 2.5 kg and 5 mL per day for infants and children weighing more than 2.5 kg. The other suggests 30% of a vial (1.5 mL/day) for infants weighing less than 1 kg, 65% of a vial (3.25 mL/day) for infants weighing 1 to 3 kg, and 100% of the vial (5 mL/day) for children weighing more than 3 kg (up to 11 years of age). Adult IV vitamin formulations should not be used in infants because of potential neurotoxicity from accumulation of polysorbate and propylene glycol preservatives. Pediatric trace element formulations are dosed based on the child's weight. The usual recommended intake is 0.3 mL/kg for children weighing less than 3 kg and 0.2 mL/kg (maximum 5 mL/day) for children weighing more than 3 kg. Children weighing more than 25 kg should receive an adult trace element formulation. Pediatric patients receiving PN commonly transition from PN support to enteral nutrition by gradually, over a period of days to weeks, decreasing the PN infusion rate while increasing the enteral intake. The PN infusion rate should be reduced for 1 to 2 hours prior to stopping the infusion for neonates and infants because of their immature counterregulatory mechanisms which contribute to an increased risk for developing rebound hypoglycemia.¹⁶ Blood glucose concentrations should be checked within 15 to 60 minutes after the PN infusion ends.

CONTINUOUS VERSUS CYCLIC INFUSIONS

6 Continuous infusions are attractive for use in patients with unstable fluid balance or glucose control (see Fig. 145–1). The intermittent or cyclic infusion of PN over a period of time less than 24 hours, usually for 12 to 18 hours each day, is useful in hospitalized patients with limited venous access in whom administration of multiple other medications requires interruption of the PN infusion.⁷⁴ Cyclic PN also may prevent or treat hepatotoxicities associated with continuous PN therapy. In addition, this delivery mode allows patients receiving PN at home the ability to resume a relatively normal lifestyle.⁷⁴ Various protocols have been reported that suggest incremental increases to the maximum infusion rate for a desired period of time followed by a gradual taper to discontinue the solution.^{16,73,74} However, metabolically stable adults and older children (older than age 2 years) receiving fat-based PN regimens are likely candidates for abrupt initiation and discontinuation of their intermittent PN regimen.^{16,73,74} Cyclic PN is not optimal for all patients and should be used with caution in those with severe glucose intolerance or diabetes, or unstable fluid balance.

EVALUATION OF THERAPEUTIC OUTCOMES

7 Thorough and consistent monitoring of patients who are receiving PN is necessary to ensure that the desired nutritional outcomes are achieved and to prevent the occurrence of adverse effects or complications. Routine evaluation should include the assessment of the patient's clinical condition with a focus on nutritional and metabolic effects of the PN regimen. Serial documentation of a patient's response to a particular regimen is a helpful guide for determining appropriate adjustments in fluid, electrolyte, and nutrient therapies.

Several biochemical and clinical measurements are necessary for effective monitoring of patients receiving PN. Serum concentrations of electrolytes, hematologic indices, and biochemical markers for renal function, liver function, and nutrition status should be measured prior to PN initiation and periodically thereafter depending on the patient's age, nutrition status, and clinical condition. The frequency of blood laboratory measurements in neonates and infants tends to be more conservative as a result of their smaller circulating blood volumes and, in some cases, lack of central vascular access. Other important clinical measurements include vital signs, weight, total fluid intake and losses, and nutritional intakes. Weekly height/

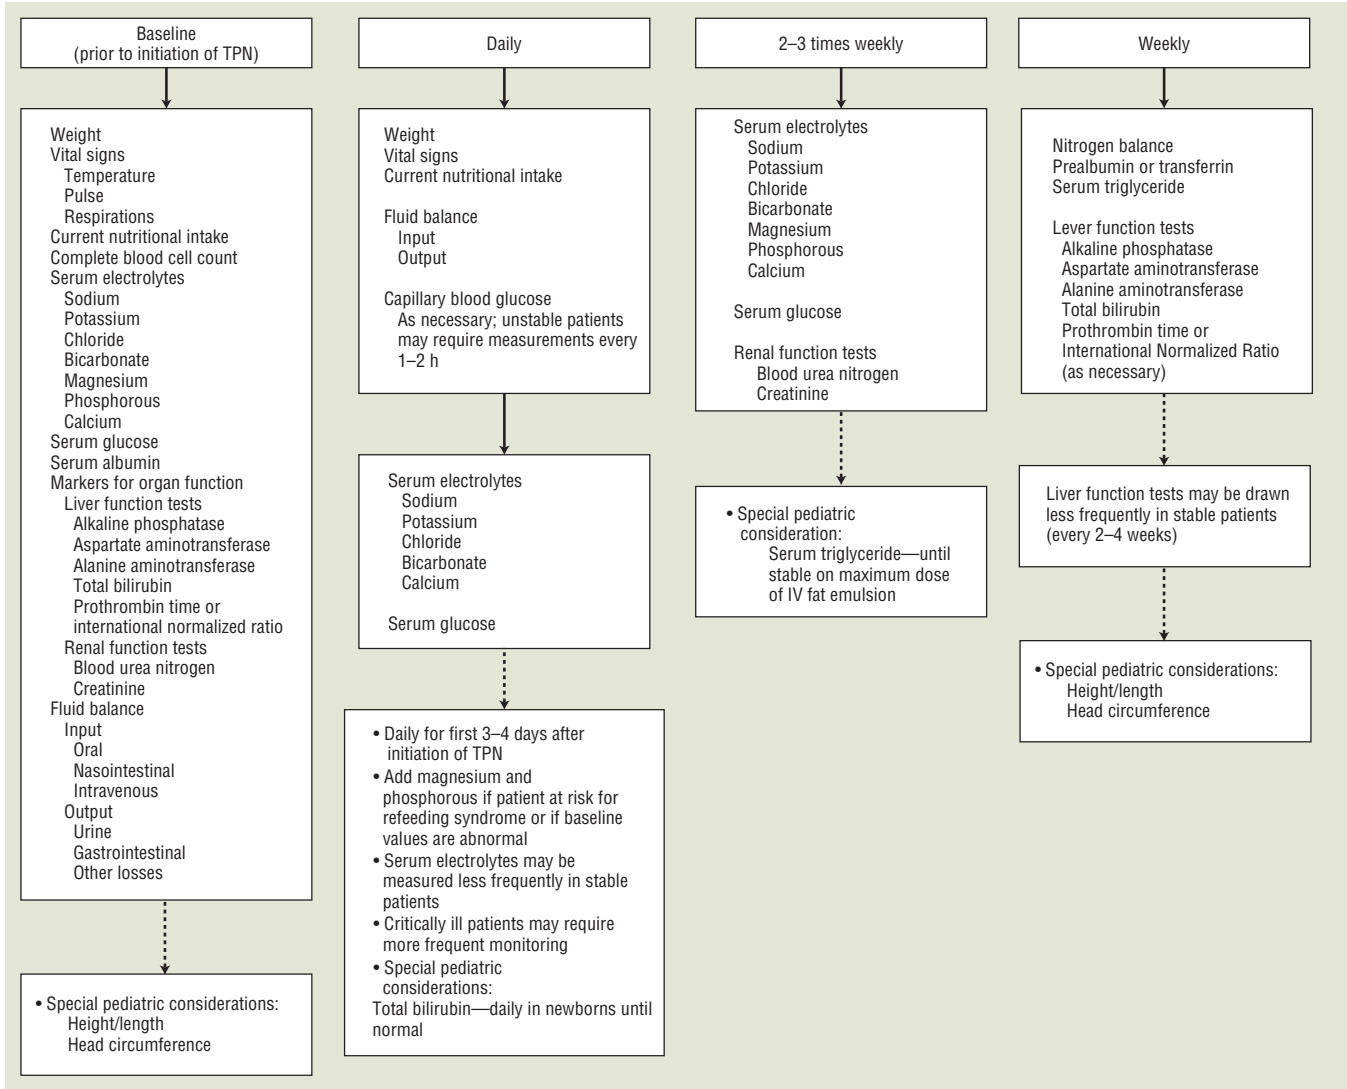

FIGURE 145-4. Monitoring strategy for patients receiving parenteral nutrition (PN).

length and head circumference measurements are helpful for monitoring nutritional changes in neonates. Monitoring parameters considered important for patients receiving PN and the suggested frequency of measurement for each are outlined in Fig. 145-4. Appropriate assessment and evaluation of patient data can identify potential complications that may be avoided or treated early. Monitoring protocols should be developed and tailored for the patient population, medical practices, and resources of individual practice settings.

COMPOUNDING, STORAGE, AND INFECTION CONTROL

The United States Pharmacopeia Chapter 797 details the procedures and requirements for compounding sterile preparations including PN formulations.⁷⁶ These standards apply to all healthcare settings in which sterile preparations are compounded and is used by boards of pharmacy, the FDA, and accreditation organizations such as the Joint Commission. Compounded sterile preparations are defined by risk level (high, medium, low) based on the probability of microbial, chemical, or physical contamination. PN solutions are classified as a medium-risk compounded sterile preparation. In general, PN solutions should be prepared using aseptic technique under a properly maintained laminar flow hood.^{68,76} The hood should be situated such

that the contaminant potential of normal work traffic and air currents is minimized. Personnel must be trained adequately and must practice strict aseptic technique. Supervision by a pharmacist experienced in compounding IV solutions and knowledgeable about stability, compatibility, and storage of PN solutions is also necessary. Quality assurance procedures should be developed to maintain safe and accurate admixture preparation. The potential risk of sepsis associated with PN solution contamination can be decreased greatly when pharmacy-based admixture programs follow specific guidelines developed to ensure proper compounding of PN solutions.⁷⁶

In general, the type of solution being prepared dictates the methods of compounding, storage, and infusion. Currently, the two most commonly used types of PN solutions are 2-in-1 solutions with or without IVFE piggybacked into the PN line, and TNAs. Methods for compounding PN solutions vary based on a healthcare system's patient population and medical practices and the number of PN solutions that need to be prepared. PN base solutions may be prepared by using gravity-driven transfer of CAA stock solutions to partially filled bags of concentrated dextrose stock solutions.^{34,77} Other practice settings may use commercially prepared CAA-dextrose products that are separated within a single bag and then mixed prior to use.³⁴ Advances in compounding technology have facilitated use of automated compounders for preparing PN solutions. Automated compounders are computer-based systems that perform the calculations necessary to determine volumes of nutrient stock solutions

for PN formulations. In addition, most automated compounding systems include software that communicates the determined calculations directly to a transfer pump device that delivers fluid from the source container to the final container by either a volumetric or gravimetric fluid pumping system.⁷⁷ Advantages associated with automated compounders include reduced personnel time and compounding materials and improved compounding accuracy. Disadvantages include the potential for equipment failure and power outages.

Assurance of solution sterility during compounding, storage, and administration is necessary to reduce the risk of infection and related complications. Several studies demonstrated that because of their acidic pH and hypertonicity, CAA-dextrose PN solutions are poor media for bacterial growth.⁷⁸ However, growth of *Pseudomonas aeruginosa*, *Escherichia coli*, and fungi such as *C. albicans* has been reported in CAA-dextrose solutions.⁷⁸ In general, TNA solutions appear to support growth of bacteria less than IVFEs, but more than CAA-dextrose solutions. However, investigations of TNAs hung for up to 24 hours demonstrate that the risk of contamination was no greater than that reported with CAA-dextrose solutions.^{44,68}

Because IVFEs also support growth of gram-positive and gram-negative bacteria as well as fungi, the Centers for Disease Control and Prevention recommend that IVFE infusions not exceed 12 hours, unless volume considerations require more time, in which case IVFE infusions should be completed within 24 hours.⁶⁸ However, these recommendations conflict with FDA-approved guidelines for handling procedures for the IVFE-containing anesthetic agent propofol, which restrict infusion time to 12 hours after the bottle has been spiked and require infusion tubing change every 12 hours.⁷⁹ Other clinical investigations of IVFE solutions infused for up to 24 hours in patients receiving PN demonstrated no correlation between risk of infection and length of hang time, so some institutions allow expiration times of up to 24 hours.⁸⁰ The Centers for Disease Control and Prevention guidelines recommend use of administration sets for 2-in-1 PN for up to 72 hours, but those used for TNA solutions and IVFE should be changed every 24 hours.

Frequently neonates require considerably smaller volumes of IVFE than are commercially available. For some patients, the volumes may be as low as 2 mL/day. To facilitate safe and accurate infusion of these small volumes, some institutions aseptically transfer IVFE into plastic syringes for syringe pump infusion. Use of transferred IVFE preparations has been associated with increased risk of bacteremia because of increased contamination risk during compounding or infusion line manipulation.⁸¹ There are no consistent recommendations for acceptable infusion time of compounded IVFE preparations for non-TNA use. The Centers for Disease Control and Prevention recommendations do not address use of IVFE preparations transferred from the original container.⁶⁸ However, FDA-approved guidelines for propofol handling procedures restrict infusion times for doses provided in syringes to 6 hours.⁷⁹ Recent data reports a contamination risk of less than 0.1% during aseptic compounding of IVFE in syringes.⁸² However, contamination risk during IVFE infusion when tubing is changed at 24-hour intervals is higher, but similar to or less than the contamination rate reported with the use of IVFE in the manufacturer's original container.^{81,82} In view of the lack of consensus for acceptable infusion times for these preparations, and the clinical rationale for longer IVFE infusion times in pediatric patients who are receiving PN therapy, many institutions allow infusion times between 12 and 24 hours.^{68,82}

STABILITY AND COMPATIBILITY

Comprehensive current information regarding compatibility and stability of PN solutions can be found in several reference sources such as *Trissel's Handbook on Injectable Drugs*, which is published

every 2 years with supplements during alternating years, and the *King Guide to Parenteral Admixtures*, which is updated quarterly.^{83,84} In many cases, the exact answer to a compatibility question may not be readily available, and a review of the primary literature may be necessary. When information is not available, clinical judgment and experience must be used carefully to resolve the situation.

CAA-dextrose solutions generally are stable for 1 to 2 months if refrigerated at 4°C (39.2°F) and protected from light.²⁷ However, TNA formulations are complex mixtures that are inherently unstable. Several factors affect stability of TNA solutions, including pH, electrolyte charges, temperature, and time after compounding.²⁷ The United States Pharmacopeia 797 standards recommend storage times of not more than 30 hours at controlled room temperature (15°C [59°F] to 30°C [86°F]) and not more than 9 days at refrigerated temperatures (2°C [35.6°F] to 4°C [39.2°F]) for all medium-risk compounded sterile preparations, including PN solutions.⁸⁵

Because of differences in pH among various CAA products and differences in phospholipid content among IVFE products, specific manufacturers should be consulted for compatibility and stability information prior to routine mixing of components. One approach to compounding TNA formulations manually is to first combine CAA, dextrose, and sterile water (if necessary). Add electrolytes, vitamins, and trace elements and then visually inspect the solution for precipitate or other particulates. Finally, add IVFE and visually inspect the solution to ensure a uniform emulsion exists.^{27,86,87} However, mixing components in this specific order and time sequence may not be possible with the use of automated compounders. The compounder's manufacturer should be consulted for the optimal mixing sequence to ensure safe compounding of TNA solutions.

The precipitation of calcium and phosphorus is a common interaction that is potentially life-threatening.^{27,34} Factors that enhance the risk of precipitate formation include high concentrations of calcium and phosphorus salts, use of the chloride salt of calcium, decreased amino acid and dextrose concentrations, increased solution temperature, increased solution pH, use of an improper sequence when mixing calcium and phosphorus salts, and the presence of other additives including IVFEs.^{27,34} Electrolyte stability in TNA solutions is difficult to assess because of poor visualization of a precipitate should one occur. PN solutions for neonates and infants tend to have larger calcium and phosphorus amounts, as well as other divalent cations, that limit the use of TNA formulations. Because of the relatively limited amount of published stability information, the use of a 2-in-1 formulation with separate administration of IVFEs is recommended for neonates and infants.³⁴ In general, alternative methods of delivering electrolytes or other medications should be pursued in any clinical situation in which compatibility information involving a TNA solution is lacking. Because the addition of bicarbonate to acidic PN solutions may result in the formation of carbon dioxide gas and insoluble calcium and magnesium carbonates, sodium bicarbonate use in PN solutions is not recommended.³⁴ Use of a bicarbonate precursor salt such as acetate usually is preferred.

Vitamins may be affected adversely by changes in solution pH, presence of other additives, storage time, solution temperature, and exposure to light.²⁷ Because of variable stabilities of individual vitamins, IV vitamin solutions should be added to the PN solution as near to the time of administration as is clinically feasible, and should not be in the PN solution longer than 24 hours.

Increased peroxide concentrations have been reported in IVFE and dextrose-amino acid solutions after addition of IV multivitamins and/or exposure to air or light.⁸⁸ Peroxide formation in dextrose-amino acid solutions depends on the concentration of IV multivitamins, CAA, and dextrose, and the presence of IVFEs.⁸⁸ Multiple in vitro experiments have reported negative effects of peroxides and associated metabolites on organ and immune function.^{88,89} Peroxides are associated with neonatal hypoxic-ischemic

encephalopathy, intraventricular hemorrhage, periventricular leukomalacia, chronic lung disease, retinopathy of prematurity, and necrotizing enterocolitis.⁸⁹ Neonates and infants are at increased risk for harmful effects of peroxides because they receive a higher daily peroxide load from PN solutions and they have lower endogenous antioxidant levels compared to adults.⁸⁸ Protecting PN and IVFE solutions from light is recommended to minimize peroxide formation and reduce the risk of negative metabolic effects from peroxide infusion.^{20,88,89}

Many patients receiving PN at home or in a hospital also receive other IV medications. The compatibility of these medications and other intravenous IV solutions is an important concern in delivering safe and effective drug and nutritional therapy. Intravenous medications are infused most often as a separate admixture piggybacked in the PN line. However, some medications may be added directly to the PN solution and administered at the same rate as the PN infusion. Because of the potential for ineffective drug therapy or other complications associated with physiochemical incompatibility and stability of the PN solution, specific criteria should be considered before medications are added directly to the PN solution.⁹⁰ The dosage regimen should be stable for each 24-hour period and should have pharmacokinetic properties appropriate for continuous infusion. There should be documented chemical and physical compatibility of the medication with PN mixture components and other medications that may be piggybacked concomitantly into the PN line. Finally, the PN regimen should be infused continuously over 24 hours. Advantages of using PN admixtures as drug vehicles include consolidation of dosage units, improved pharmacotherapy for certain drugs, conservation of fluid in volume-restricted patients, fewer venous catheter violations, and decreased compounding and administration times.⁹⁰ However, a major disadvantage to the use of PN solutions as drug-delivery vehicles is the lack of compatibility and stability data for the PN solutions that are used commonly in clinical practice. Medications frequently added to PN solutions include regular insulin and histamine₂ antagonists.^{83,84,90}

COMPLICATIONS OF PARENTERAL NUTRITION

MECHANICAL OR TECHNICAL COMPLICATIONS

Mechanical or technical complications include malfunctions in the system used for IV delivery of the solution, such as infusion pump failure, problems with administration sets or tubing, and problems with the catheter. Catheter-related complications are potentially life-threatening. Pneumothorax, catheter misdirection or migration into the wrong vein or improperly positioned within the cardiac chambers, arterial puncture, bleeding, and hematoma formation may occur during surgical placement of the catheter. Many of these complications, in addition to venous thrombosis and air embolism, also can occur after insertion. Catheters occasionally occlude or break during use. If these problems cannot be rectified easily, the catheter may need to be surgically replaced.

INFECTIOUS COMPLICATIONS

Infectious complications can be a major hazard in patients receiving CPN. Often these patients are predisposed to infection as a result of compromised immunity and/or concomitant infection. Frequent use of broad-spectrum antibiotic therapy and malnutrition are also predisposing factors for development of infection. Infection rarely develops secondary to solution contamination.^{68,91} However, strict adherence to specific protocols for preparation of PN solutions should minimize this occurrence.^{76,78} A more common source of

systemic infection is catheter-related infection. Catheter-related bloodstream infection is defined as the presence of bacterial or fungal growth from the catheter tip and peripheral blood cultures. Catheter infection or a colonized catheter is defined as microbial growth from the catheter tip or from a blood culture drawn from the catheter with no growth of the same organism in the peripheral blood culture.⁶⁸ Patients with catheter-related infections may exhibit typical signs of sepsis syndrome such as fever, chills, mental status changes, hypotension, or glucose intolerance. These infections occur when the catheter becomes colonized by direct microbial invasion of the skin at the insertion site or at the infusion site of the catheter. For example, colonization may occur after multiple manipulations of the line used for PN administration, which can occur when the PN line is used to administer other medications. Other examples include failure of in-line bacterial filters, poor placement technique, and poor care of the insertion site.⁶⁸

When no other source of infection is apparent in symptomatic patients, the catheter should be evaluated as the potential source. Blood cultures are usually drawn from a peripheral site and from the central catheter. Appropriate antimicrobial therapy is initiated. The fate of the central catheter depends on the patient's severity of illness, the suspected or identified pathogen and the type of catheter involved. The catheter may be removed and replaced in the same site; the catheter may be removed and replaced at a different anatomic location or it may not be replaced.⁹¹

METABOLIC AND NUTRITIONAL COMPLICATIONS

Metabolic and nutritional complications associated with PN therapy are numerous, and if left untreated, are potentially fatal. Unfortunately, the etiologies of metabolic abnormalities associated with PN are frequently multifactorial. Metabolic abnormalities related to substrate intolerance, fluid and electrolyte disorders, and acid-base disorders are summarized in multiple reviews (Table 145-5).^{34,40,47,48,65,74,92-104}

PN-associated hepatic dysfunction, as evidenced by elevations in serum liver function measurements such as total bilirubin, aspartate aminotransferase, alanine aminotransferase, and alkaline phosphatase, is well documented.⁹³⁻⁹⁵ No single etiology has been identified, although several risk factors have been reported. Risk factors for children include degree of prematurity, sepsis, hypoxia, lack of enteral nutrition, small bowel bacterial overgrowth, GI conditions requiring surgical intervention, duration of PN therapy, and long-term administration of excessive calories.^{40,94,95} PN-associated hepatic dysfunction in infants is characterized clinically by a serum direct bilirubin concentration greater than 2 mg/dL.⁹⁵ Taurine deficiency has been

TABLE 145-5 Metabolic Abnormalities Associated with PN Macronutrients

Abnormality	Possible Etiologies
Hyperglycemia	Metabolic stress, infection, corticosteroids, pancreatitis, diabetes mellitus, peritoneal dialysis, excessive dextrose administration
Hypoglycemia	Abrupt dextrose withdrawal, excessive insulin
Excess carbon dioxide production	Excess dextrose administration
Hypertriglyceridemia	Metabolic stress, familial hyperlipidemia, pancreatitis, excess IVFE dose; rapid IVFE infusion rate
Abnormal liver function tests (elevated ALT, AST, Alk Phos, Bili)	Metabolic stress, infection, excess carbohydrate intake, excess caloric intake, EFAD; long-term PN therapy

ALT, alanine aminotransferase (SGPT); AST, aspartate aminotransferase (SGOT); Alk Phos, alkaline phosphatase; Bili, bilirubin; EFAD, essential fatty acid deficiency; EN, enteral nutrition; IVFE, intravenous fat emulsion; PN, parenteral nutrition.

proposed as an etiology of cholestasis in preterm infants and neonates.⁹⁵ Taurine is a conditionally essential amino acid that is not present in standard CAA solutions but which is important in neonatal and infant bile metabolism. However, the effectiveness of PN regimens with CAA solutions containing supplemental taurine is unclear.^{94,95} Risk factors for PN-associated hepatic dysfunction in adults include preexisting liver diseases, sepsis, preexisting malnutrition, extensive bowel resection, duration of PN therapy, lack of enteral intake, nutrient deficiencies such as choline deficiency, and long-term administration of excessive calories.^{93,94} PN-associated hepatic dysfunction in adults typically presents as steatosis and steatohepatitis on biopsy.^{93,94} Clinically, PN-associated hepatic dysfunction is characterized by mild elevations in serum liver enzymes, usually less than three times the upper limit of normal, with peak enzyme levels usually occurring between 1 and 4 weeks after initiating PN.^{93,94} In many cases, the liver abnormalities improve or resolve with manipulation of substrate intake or discontinuation of PN therapy. However, in severe cases, liver dysfunction may progress to overt failure and death.⁹⁴ Intestinal transplant with or without liver transplantation has become a treatment option for those PN-dependent patients who have failed available therapies for reversing progression of severe PN-associated liver dysfunction.⁹⁴

Hypertriglyceridemia, defined as serum triglyceride concentrations of 400 to 500 mg/dL in adults and 150 to 200 mg/dL in preterm infants, neonates, and older pediatric patients, may occur in patients receiving IVFE-based PN. Risk factors include preexisting liver or pancreatic dysfunction, sepsis, multiple-organ failure, degree of prematurity, IVFE infusion rate, and dose.^{37,45,46}

IVFE-associated hypertriglyceridemia generally is thought to be caused by defective lipid clearance.⁴⁵ Premature infants and neonates have relatively slower lipid clearance than do adults because of immature metabolic pathways, including decreased lipoprotein lipase activity.^{37,45,46} Reducing the IVFE infusion rate or dose or withholding IVFE therapy should be considered when patients present with hypertriglyceridemia or lipemic serum.^{45,46} Use of low-dose heparin to stimulate lipoprotein lipase activity has been suggested as a potential therapeutic intervention to treat IVFE-associated hypertriglyceridemia.^{16,45} The role of carnitine for treatment of IVFE-associated hypertriglyceridemia is not clear.^{16,45,46}

Severe and rapid declines in serum phosphate, potassium and magnesium concentrations, fluid retention, and other micronutrient deficiencies are common features of the refeeding syndrome.^{96,97} Individuals at risk for refeeding syndrome include those who are severely malnourished with significant weight loss who receive aggressive nutritional supplementation. Other examples of patients receiving PN therapy who may be at risk for developing refeeding syndrome abnormalities include those who are unfed for 7 to 10 days with evidence of stress or nutritional depletion, those with chronic diseases causing undernutrition such as cancer, cardiac cachexia, chronic obstructive pulmonary disease or cirrhosis, and those with previous morbid obesity and massive weight loss.⁹⁷ The mechanism of the electrolyte abnormalities appears to be related to acute provision of macronutrient substrates that promote anabolism in an environment of depleted total body stores of phosphorus, potassium, and magnesium. Recommendations for initiating PN in adults at risk for refeeding syndrome include providing 25% to 50% of the calculated nonprotein caloric requirements initially. The dextrose dose should be initiated at approximately 100 to 200 g/day. Calories should be advanced over 3 to 4 days to the desired goal. Because the metabolic abnormalities described with refeeding syndrome appear to be related primarily to acute provision of large dextrose amounts, the goal protein dose may be provided with the initial PN infusion.⁹⁶ Pediatric PN regimens are usually advanced over several days as a general practice for all pediatric patients. However, additional recommendations for minimizing the risk of refeeding syndrome in pediatric

patients includes provision of additional phosphorus and potassium above standard nutrient requirements at the time PN is initiated.⁴⁰

Other nutritional complications of PN therapy may develop over a prolonged course of therapy (weeks to months) as a result of inappropriate intake of a particular nutrient. Certain conditions, such as metabolic stress in a previously malnourished patient, may elicit symptoms of deficiency much earlier if a nutrient is not appropriately provided. For example, lactic acidosis and other life-threatening complications associated with severe thiamine deficiency have been reported in patients who received PN solutions without multivitamin supplementation.⁹⁸ At least maintenance doses of vitamins, trace elements, and essential fatty acids should be provided to all patients with normal age-related organ function receiving PN.

Patients receiving PN regimens without IVFEs for extended periods (weeks to months) are at risk for development of EFAD. Clinical signs of EFAD include hair loss, desquamative dermatitis, thrombocytopenia, and malabsorption and diarrhea resulting from changes in intestinal mucosa.^{34,47,48} EFAD also may be diagnosed by evaluating plasma fatty acid profiles. A triene-to-tetraene ratio more than 0.4 is biochemical evidence for EFAD. Although the time in which EFAD may develop is dependent on the patient's nutrition status, disease state, and age, these manifestations may occur 2 to 4 weeks after initiation of fat-free PN in adults and within 72 hours in premature infants.^{37,47}

Metabolic bone disease is a complication usually reported in adults and children receiving long-term home PN.^{93,99} This disorder in adults is characterized by osteomalacia with or without osteoporosis that may present without associated clinical, radiologic, or biochemical abnormalities. The diagnosis may not be made in premature infants until after the development of bone fractures or overt rickets. The etiology is poorly understood and likely multifactorial. Treatment options include pharmacologic intervention, calcium and vitamin D supplementation, and exercise. Others have recommended removal of vitamin D from the PN in patients with low serum parathyroid hormone and 1,25-hydroxyvitamin D concentrations.⁹⁹

Clinical symptoms of trace element deficiencies, although rare, have been reported in patients receiving PN. More commonly, decreased serum trace element concentrations have been reported in a variety of patient populations. However, the clinical significance of decreased concentrations of many trace elements is not known because serum concentrations often do not correlate with total body stores.^{62,63} Clinical signs and symptoms of trace element deficiencies are reviewed elsewhere.^{62,63}

Occasionally, patients may develop nutrient-induced toxicities, most commonly as a result of the accumulation of fat-soluble vitamins or trace elements as a result of either excessive intake or decreased excretion. Certain disease states (e.g., severe renal or hepatic failure) may necessitate reduction in vitamin and trace element intake.

Many trace elements are present in PN components as contaminants.^{54,100,101} The content varies among components and manufacturers. Some investigations of patients with normal organ function who were receiving PN have reported concern with elevated serum concentrations of particular trace elements such as chromium and manganese.^{67,100,101} Aluminum is a common contaminant of many sterile IV solutions, including those used for compounding PN. Calcium and phosphorus solutions are among those components with higher levels of aluminum contamination.^{102,103} Aluminum accumulation may occur during long-term PN therapy, especially in patients with renal insufficiency, and is associated with abnormal neurologic and hematologic function and metabolic bone disease in adults and premature infants.^{99,102,103} Preterm infants are at higher risk of aluminum toxicities because they receive larger doses (micrograms per kilogram) from PN solutions than adults.^{99,102,103} Preterm infants are also more likely to retain aluminum because of

immature renal function. Although the maximum safe level of IV aluminum intake is unknown, the FDA has defined parenteral doses of 4 to 5 mcg/kg per day as amounts associated with central nervous system and bone toxicity in patients with impaired renal function, including premature neonates.^{103,104} Even lesser amounts may result in tissue accumulation but no documented toxicity.

Recent data suggest that the aluminum content of sterile solutions used for compounding PN has declined as a result of awareness of toxicity and improvements in industrial PN component preparation.¹⁰³ However, in 2004 the FDA implemented a restriction of aluminum content in large-volume PN stock solutions (CAA, dextrose, sterile water for injection, IVFE) to a maximum of 25 mcg/L and a requirement for manufacturers to indicate the maximum aluminum concentration at expiration for both large and small volume parenteral products used for PN.^{103,104}

HOME PARENTERAL NUTRITION

Advances in technology for the delivery of IV solutions have allowed medically stable patients who require extended PN therapy to be maintained indefinitely on IV nutrition. An increasing concern for cost containment of healthcare services has fostered use of sophisticated infusion devices to provide PN at home. Numerous programs are now available outside the traditional healthcare setting to support patients with various long-term or permanent medical conditions. Standards have been developed to promote safe and effective care.⁶ Home PN services may be coordinated and administered through a hospital, or by a commercially operated corporation.

Many factors are considered in selecting candidates for home PN therapy. Significant benefit must be expected from placing a patient into the program. Additionally, the patient and the patient's caregiver must be willing to complete training successfully and assume numerous other responsibilities that are important for managing a new daily routine in the home. Other logistics such as funding, procurement of solutions and supplies, and clinical management and followup must be evaluated, resolved, and implemented for each patient in order to achieve the desired outcomes.⁶

Patients with Crohn's disease, ischemic bowel disease, severe GI motility disorders, extensive intestinal obstruction, and congenital bowel dysfunction have been maintained successfully with home PN.¹⁰⁵

Patients commonly receive premixed PN solutions from the hospital or a commercial vendor. Intravenous vitamins or other additives may be added daily by the patient or caregiver, depending on the arrangement with the PN provider. The solution generally is administered through the night by infusion pump over 10 to 12 hours.⁷⁴ A cycled regimen allows the patient time away from the pump during daylight hours and provides many patients with the freedom to have a reasonably normal daily routine. Clinical management and followup are performed periodically according to the needs of the patient and the protocol of the care provider. A coordinated effort among several healthcare professionals, including physicians, pharmacists, nurses, social workers, and the patient and the patient's caregiver, as well as the suppliers, is paramount to providing safe and effective management. Home PN affords some patients the potential for an ambulatory lifestyle while maintaining an IV feeding regimen that was previously only available in the hospital setting. For others, home PN may contribute to a better quality of life in the comfort of their home.¹⁰⁵

PHARMACOECONOMIC CONSIDERATIONS

⁹ Because numerous variables have an impact on the provision of PN support and the response to therapy, determining the true cost of PN is difficult.^{105–108} In general, PN is an expensive intervention,

and cost varies depending on the underlying indication for treatment and whether PN is provided at home or in an acute care setting.^{105–108} Expenses associated with PN therapy may be categorized as direct and indirect costs.^{107,108} Direct costs may be further categorized as fixed or variable costs. Fixed costs do not depend on the volume of patients receiving therapy. For example, an automatic compounder and the tubing sets required to transfer volumes of stock solutions to the administration bag would be considered fixed costs in many practice settings. These costs per patient tend to be highest in low-volume environments. Variable costs such as PN administration bags depend directly on the number of patients receiving PN. Other direct costs include ancillary services required by patients receiving PN and costs related to the management of nutritionally associated complications.

Benefits and other clinical effects of PN (i.e., length of stay and frequency of complications) in specific patient populations have been evaluated.^{15–18} Few investigations have reported an economic assessment of the therapy. However, economic data from many of these reports would not necessarily reflect current costs. Indeed, the direct cost of PN solution components generally has declined over the past decade. Attempting to measure the cost or cost savings associated with reported benefits of PN therapy and other clinical effects based on results of controlled clinical trials is difficult.^{106,107} Clinical outcomes measurements and hence economic outcomes are influenced by multiple factors, including experimental design, sample size, and specific health system practices. Several investigations used for determining costs and benefits of PN therapy have been criticized for such biases.¹⁰⁸

Although the results of economic analyses of PN remain controversial, similarities among several reports provide a basis for methods of limiting the costs of PN therapy. These similarities include the following:

1. Use PN only for the most appropriate patients as described by institution-specific criteria based on current consensus statements.¹¹⁰ The costs and complications associated with enteral nutrition are demonstrated to be less than those associated with PN.¹¹¹
2. Reassess the need for routine laboratory measurements used for monitoring PN therapy. In general, the level of laboratory monitoring should decrease as a patient's clinical condition stabilizes.
3. Minimize the direct cost of PN by using efficient purchasing practices for PN solutions and compounding supplies through contract purchasing, streamlined compounding procedures, standardized administration times, and 24-hour hang times to reduce waste, single-bag PN solutions, and optimized monitoring plans.

CONCLUSIONS

Appropriate patient selection, assessment, and monitoring are key to successful PN therapy and the prevention of unnecessary complications. Because pharmacists are actively involved in the provision of PN at many levels, including direct patient care, education, and research, nutrition support is recognized as a pharmacy practice specialty.¹¹² In addition, as the interdisciplinary approach to specialized nutrition support has evolved, standards of practice have been defined for pharmacists, as well as for other healthcare professionals who provide nutrition support care.^{4,8–10} Standardized order forms and monitoring protocols are useful tools to ensure appropriate administration and monitoring of PN therapy. The future of PN therapy and the role of the nutrition-support clinician will be affected primarily by new insights from clinical research and economic challenges in the healthcare environment.

ABBREVIATIONS

CAA: crystalline amino acid
 CPN: central parenteral nutrition
 EFAD: essential fatty acid deficiency
 FDA: Food and Drug Administration
 GI: gastrointestinal
 IVFE: intravenous fat emulsion
 IV: intravenous
 LCT: long-chain triglyceride
 MCT: medium-chain triglyceride
 NAG-AMA: Nutrition Advisory Group of the American Medical Association
 PN: parenteral nutrition
 PPN: peripheral parenteral nutrition
 PUFA: polyunsaturated fatty acid
 TNA: total nutrient admixture

VANESSA J. KUMPF AND KATHERINE HAMMOND CHESSMAN

KEY CONCEPTS

- 1 The gastrointestinal (GI) tract defends the host from toxins and antigens by both immunologic and nonimmunologic mechanisms, collectively referred to as the gut barrier function. Whenever possible, enteral nutrition (EN) is preferred over parenteral nutrition (PN) because it is as effective, may reduce metabolic and infectious complications, and is less expensive.
- 2 Candidates for EN are those who cannot or will not eat, those who exhibit a sufficiently functioning GI tract to allow adequate nutrient absorption, and in whom enteral access can be safely obtained.
- 3 The most common route for both short-term and long-term EN access is directly into the stomach. The method of delivery may be either continuously via an infusion pump, intermittently via a pump or gravity drip, or by bolus administration.
- 4 Patients unable to tolerate feeding directly into the stomach because of impaired gastric motility and for those at high risk of aspiration, feeding tube tip placement into the duodenum or jejunum may be indicated. When feeding into the small bowel, the continuous method of delivery via an infusion pump is required in order to enhance tolerance.
- 5 Selection of the enteral feeding formulation depends on nutritional requirements, the patient's primary disease state and related complications, and nutrient digestibility and absorption. A standard polymeric formulation will meet the needs of the majority of adult patients and children older than 10 years of age.
- 6 Measurement of gastric residual volumes can be used to monitor GI tolerance in patients receiving gastric feeding. Although not always reliable, excessive residual volumes may be associated with nausea, abdominal distension, and increased risk for aspiration.
- 7 Management of diarrhea in patients receiving EN should focus on identification and correction of the most likely cause(s). Tube feeding-related causes include too rapid delivery or advancement of formula, intolerance to the formula composition, and occasionally formula contamination.
- 8 Prior to administering medications through a feeding tube, the feeding tube tip location should be verified (stomach or small

bowel) and the most suitable dosage form selected. Medications that should not be crushed and administered through a tube include enteric-coated or sustained-release capsules or tablets and sublingual or buccal tablets.

- 9 The coadministration of medications with EN can result in alterations in bioavailability and/or changes in the desired pharmacologic effects of several medications, including phenytoin, warfarin, selected antibiotics, antacids, and omeprazole.

Enteral nutrition (EN) is defined as the delivery of nutrients by tube or by mouth into the GI tract. This chapter focuses on nutrient delivery through a feeding tube rather than the oral ingestion of food. The terms EN and tube feeding are thus used interchangeably in this context. The goal of EN is to provide calories, macronutrients, and micronutrients to those patients who are unable to achieve these requirements from an oral diet. Over the past 20 to 30 years, EN has replaced parenteral nutrition (PN) as the preferred method of specialized nutrition support in many patients who are at risk of malnutrition. Improvements in enteral access techniques and feeding formulations, and the recognition of methods to prevent and manage complications have resulted in an increased use of EN across all healthcare settings.

In this chapter, the principles and practices related to the successful use of EN support are described. Digestive and absorptive physiology is reviewed and the beneficial effects of EN are presented. The indications for EN, and descriptions of various enteral access and administration methods are also summarized. Characteristics of commercially available enteral feeding formulations are presented, as well as initiation and monitoring guidelines to prevent and manage complications. Clinical therapeutic controversies are highlighted and discussed. In addition, issues of drug compatibility, drug–nutrient interactions, and drug administration via enteral feeding tubes are discussed. Finally, the effectiveness and pharmacoeconomics of EN in enhancing nutrition and disease outcome goals are reviewed.

GASTROINTESTINAL TRACT PHYSIOLOGY

DIGESTION AND ABSORPTION

Digestion and absorption are GI processes that generate the body's usable fuels.^{1–3} Digestion consists of the stepwise conversion of a complex chemical and physical nutrient into a molecular form which is absorbable by the intestinal mucosa. Absorption from the GI tract is a multistep process that includes the transfer of a nutrient across the intestinal cell membrane. The nutrient ultimately reaches the systemic circulation through the portal venous or splanchnic lymphatic systems, provided the GI or biliary tract does not excrete

TABLE 146-1 Gastrointestinal Enzymes and Hormones

Enzyme/Hormone	Site of Secretion	Main Actions
Amylase	Salivary glands, pancreas	Converts carbohydrates, starch, and glycogen to simple disaccharides
Cholecystokinin (CCK)	Duodenum, jejunum	Stimulates pancreatic enzyme secretion and gallbladder contraction
Chymotrypsinogen	Pancreas	Breaks down proteins into proteases and peptides
Enteroglucagon	Duodenum, small intestine	Inhibits pancreatic enzyme secretion and bowel motility
Gastric inhibitory peptide (GIP)	Small intestine	Decreases gastric motility and stimulates insulin secretion
Gastrin	Stomach, duodenum	Stimulates gastric acid secretion and mucosal growth
Glucagon	Pancreas	Stimulates hepatic glycogenolysis and inhibits motility
Lipase	Pancreas	Hydrolyzes short-chain and medium-chain triglycerides, involved in fat absorption
Pancreatic polypeptide	Pancreas	Inhibits gallbladder contraction and pancreatic and biliary secretion
Pepsinogen	Stomach	Converts large proteins into polypeptides
Secretin	Small intestine	Stimulates hepatic and pancreatic water and bicarbonate release
Trypsinogen	Pancreas	Breaks down proteins into proteases and peptides
Vasoactive inhibitory peptide (VIP)	Small intestine, pancreas	Vasodilator; stimulates water and bicarbonate secretion, release of insulin and glucagon, and production of small intestinal juice

it. Ingested nutrients are primarily large polymers that cannot be absorbed by the intestinal cell membrane unless they are transformed into an absorbable molecular form. In addition, a coordinated interplay of GI motility and neurohormonal secretion is required to facilitate adequate digestion and absorption.

Nutrient digestion involves the complex coordination of multiple mechanical, enzymatic, and physicochemical processes.¹⁻³ Mechanical dissolution of food occurs by chewing, mixing, and grinding of the stomach contents. Food stimulates the secretion of numerous neurohormones and enzymes from the salivary glands, stomach, liver and biliary system, pancreas, and intestines (Table 146-1). As food passes along the gut lumen, these neurohormones modulate GI motility and the secretions from subsequent organs of the digestive system. Nutrient digestion occurs within the gut lumen and is a specific function of the intestinal cell membrane, which is comprised of finger-like projections called villi. Each individual villus is made up of epithelial cells called enterocytes. The enterocyte surface contains special luminal projections called microvilli, which provide an increased surface area that is referred to as the brush-border membrane.

Figure 146-1 illustrates the digestion and absorption of carbohydrate, fat, and protein within the small intestine. Carbohydrates are presented to the small intestine as either a digestible or nondigestible form. Polysaccharides (starches) and oligosaccharides (sucrose and lactose) undergo enzymatic digestion within the small intestine to

produce simple sugars. The simple sugars are absorbed via active and passive transport mechanisms and are eventually released into the portal vein. Polysaccharides such as cellulose complexes and other fiber components pass undigested to the colon, where they are digested by bacteria and enzymes to short-chain fatty acids.⁴ Absorption of short-chain fatty acids by the colon stimulates sodium and water reabsorption, serves as an energy source, and provides nourishment to the colonic mucosa cells.

Fat is presented to the small intestine as long-chain triglycerides.⁵ Its digestion requires pancreatic enzyme release and formation of mixed bile salt micelles, which then facilitate absorption across the intestinal enterocyte. Within the enterocyte, triglycerides are reesterified and packaged into chylomicrons for release into the lymphatic system. Medium-chain triglycerides (MCTs) can be absorbed intact by the mucosal membrane and are acted on by intracellular lipase within the enterocyte to release free fatty acids that pass directly into the portal vein.

Protein is presented to the small intestine primarily as large polypeptides and to a small extent as free amino acids because of the denaturation of protein within the stomach. Luminal polypeptide digestion generates oligopeptides, which are further hydrolyzed to dipeptides and tripeptides. Absorption of peptides occurs via a peptide transport system, while free amino acids are carried via specific amino acid transport systems. The carriers for the peptides are very efficient, whereas absorption of free amino acids appears to be more

FIGURE 146-1. Schematic of carbohydrate, fat, and protein digestion.

limited and less efficient.³ Understanding the mechanisms of digestive and absorptive physiology can greatly enhance the rational use of EN during conditions of normal or altered GI anatomy and/or function. Several circumstances may alter the efficacy of nutrient digestion and absorption. For example, the functional immaturity of the neonatal gut may lead to clinical problems associated with inadequate digestion and absorption of EN. These factors, as they relate to successful EN practice, are discussed in detail throughout this chapter.

GUT HOST DEFENSE MECHANISMS

1 Besides digesting and absorbing nutrients to maintain nutritional health, the GI tract is actively involved in defending the host from toxins and antigens by means of nonimmunologic and immunologic mechanisms.⁶ These gut host defense mechanisms are also collectively referred to as the gut barrier function. The gut barrier acts to prevent the spread of intraluminal bacteria and endotoxin to systemic organs and tissues. Hydrochloric acid secreted by the stomach kills the majority of the bacteria ingested with food. Under normal circumstances, a mucus gel layer coats the intestinal epithelium and thereby alters the adherence of bacteria to the cells of the GI tract and provides a favorable environment for anaerobic bacteria. Anaerobic bacteria, which normally colonize the mucus layer, aid in preventing tissue colonization by potential pathogens. Small-bowel peristalsis further prevents bacterial stasis and overgrowth. The gut barrier function is also maintained by the intestinal immune system, known as the gut-associated lymphoid tissue. This gut-associated lymphoid tissue regulates the local immune response to antigens within the GI tract. Specific immunoglobulins are secreted to kill remaining organisms and neutralize any toxins they produce. The hepatic Kupffer cells help to maintain gut barrier function by clearing the portal blood of gut-derived bacteria and endotoxins. The integrity of gut barrier function may be affected by numerous pathogenic insults such as physiologic stress and ischemia, and a variety of drugs, including chemotherapeutic agents. The nutritional aspects that influence the maintenance of the gut barrier are addressed in the Benefits of Enteral Nutrition and Enteral Feeding Formulation Selection sections of this chapter.

INDICATIONS FOR ENTERAL NUTRITION

2 The decision to initiate EN is based on a variety of factors. Suitable candidates are those who cannot or will not eat a sufficient amount to meet nutritional requirements, those who exhibit a sufficient functioning GI tract to allow the absorption of nutrients, and those in whom a method of enteral access can be safely obtained.⁷⁻⁹ Enteral nutrition may be indicated in a variety of conditions or disease states (Table 146-2). For example, patients who have neurologic disorders, such as a cerebrovascular accident, and have difficulty swallowing often require EN. Patients unable to eat because of conditions such as facial or jaw injuries, lesions of the oral cavity or esophagus, esophageal stricture, or head and neck cancer may also be candidates for EN delivered distal to the affected site. Extreme prematurity necessitates tube feeding because the suck-swallow mechanism has not yet developed sufficiently to allow safe oral intake.

Critically ill patients who are endotracheally intubated for mechanical ventilation represent a large percentage of patients requiring EN. Many of these patients may have reduced gastric motility and emptying caused by sepsis, GI surgery, anesthetic agents, opioid analgesics, and underlying pathology such as diabetic gastroparesis. However, successful EN can often be achieved by bypassing the stomach and placing the tip of the feeding tube beyond the pylorus into the duodenum, or preferably into the jejunum.

The use of EN during acute pancreatitis has increased. Concerns that feeding may exacerbate the disease process by stimulating

TABLE 146-2 Potential Indications for Enteral Nutrition

Neoplastic disease	Gastrointestinal disease
Chemotherapy	Inflammatory bowel disease
Radiation therapy	Short bowel syndrome
Upper gastrointestinal tumors	Esophageal motility disorder
Cancer cachexia	Pancreatitis
Organ failure	Fistulas
Hepatic	Gastroesophageal reflux disease
Renal	Esophageal or intestinal atresia
Cardiac cachexia	Neurologic impairment
Pulmonary	Comatose state
Bronchopulmonary dysplasia	Cerebrovascular accident
Congenital heart disease	Demyelinating disease
Hypermetabolic states	Severe depression
Closed head injury	Failure to thrive
Burns	Cerebral palsy
Trauma	Other indications
Postoperative major surgery	Acquired immune deficiency syndrome
Sepsis	Anorexia nervosa
	Complications during pregnancy
	Geriatric patients with multiple chronic diseases
	Organ transplantation
	Inborn errors of metabolism
	Cystic fibrosis
	Extreme prematurity

exocrine pancreatic secretion historically led to the widespread use of PN and bowel rest in these patients. However, EN has been associated with a significant reduction in infectious complications compared to PN in patients with acute pancreatitis.¹⁰ The degree of pancreatic stimulation depends on the location of the tip of the feeding tube and the composition of the feeding formulation.¹¹ The more distally the feeding is delivered, the less pancreatic stimulation occurs. When patients with pancreatitis require specialized nutrition support, EN should be attempted prior to initiating PN.⁷

The only absolute contraindications for EN are mechanical obstruction⁸ and necrotizing enterocolitis.¹² However, conditions such as severe diarrhea, protracted vomiting, enteric fistulae, severe GI hemorrhage, and intestinal dysmotility may result in significant challenges to the successful use of EN.

BENEFITS OF ENTERAL NUTRITION

The importance of maintaining nutrient delivery through the GI tract in patients without a contraindication to its use is well supported. The beneficial effects of EN, specifically in the critically ill patient, is further enhanced if EN is initiated within 24 to 48 hours of admission to an intensive care unit.

ENTERAL VERSUS PARENTERAL NUTRITION

Clinical studies comparing EN to PN in the critically ill demonstrate a decrease in infectious complications and thereby improved outcomes with the use of EN.¹³⁻¹⁵ The mechanism for the apparent beneficial effects is not clear although animal evidence suggests that EN prevents bacterial translocation across the gut. Without intraluminal fuels, it has been proposed that the integrity and function of the GI tract may deteriorate, and under stress, allow for the translocation of microbes or endotoxins.¹⁶⁻¹⁸ It is further proposed that endotoxin release can activate inflammatory pathways and thereby contribute to the development of multisystem organ failure. Provision of enteral nutrients appears to help maintain intestinal mucosal structure and function, which may prevent translocation of gut bacteria to the portal or lymphatic circulation. Thus enteral nutrition appears to play a role in maintaining gut mucosal growth and development to preserve gut barrier function.

Critical reviews of available randomized controlled trials comparing EN to PN in the critically ill adult patient with an intact GI tract suggest a significant reduction in infectious complications associated with EN.^{7,13,15} Decreased infectious complications have been documented in patients with abdominal trauma, burns, or severe head injury given EN compared to PN. EN is thus preferred over PN for the feeding of critically ill patients requiring specialized nutrition support.^{7,15}

Enteral nutrition is more physiologic than PN in terms of nutrient utilization and therefore is generally associated with fewer metabolic complications, such as glucose intolerance and elevated insulin requirements to maintain normoglycemia.¹⁹ It has been proposed that better blood glucose control occurs during enteral administration because the insulin released is absorbed with the glucose via the portal vein and is then metabolized by the liver. An additional physiologic benefit of enteral feeding is that it stimulates bile flow through the biliary tract and hence reduces the risk of developing cholestasis, gallbladder sludge, and gallstones, conditions which have been associated with long-term PN and bowel rest.²⁰ Also, EN avoids the potential infectious and technical complications associated with the placement and use of a central venous access device required for PN. Finally, EN is less costly than PN when all factors are considered.

EARLY VERSUS DELAYED INITIATION

The optimal timing of initiation of EN is a controversial issue. It has been suggested that initiating EN early in the course of illness may attenuate the stress response and improve feeding tolerance. Clinical studies demonstrating a decrease in infectious complications with the use of EN compared to PN in the critically ill patient initiated feeding within 24 to 48 hours of hospital admission.^{13,15,21} The benefits of decreased infectious complications are not apparent when the initiation of EN is delayed. A review of available studies comparing early versus delayed EN in critically ill patients showed a trend toward a reduction in infectious complications with early EN.¹⁵ In addition, a trend toward reduction in mortality associated with early EN has also been noted.^{15,22}

In critically ill patients who are hemodynamically unstable, early EN may result in gut ischemia because of poor gut blood flow and increased oxygen demand. Consequently, it is recommended that initiation of EN be delayed until the patient is fluid resuscitated and

has an adequate perfusion pressure. Once this goal is achieved, often within 6 hours of hospitalization, the initiation of EN at a low infusion rate is considered appropriate, along with clinical monitoring to assure GI tolerance.^{23,24} Therefore, early EN (within 24 to 48 hours after hospital admission) is recommended in critically ill patients.¹⁵ Early initiation of EN is not warranted for the mild to moderately stressed patient who is otherwise well nourished. It is reasonable to delay the initiation of EN in these patients until oral intake is inadequate for 7 to 14 days.⁷

ENTERAL ACCESS

Recent advances in enteral access techniques have contributed to the expanded use of EN for conditions in which PN had previously been used. In particular, improved methods of achieving jejunal access for feeding have allowed for the use of EN during the early postoperative and postinjury period when gastric motility is typically delayed. As outlined in Table 146–3, various factors influence the selection of enteral access site and device, including anticipated duration of use (short-term or long-term) and whether to feed into the stomach or small bowel. Figure 146–2 illustrates the predominant enteral access options.

SHORT-TERM ACCESS

3 Short-term enteral access is generally easier to initiate, less invasive, and less costly than the establishment of long-term access.²⁵ The most frequently used routes for short-term enteral access are established by inserting a tube through the nose and passing the tip into the stomach (nasogastric [NG]), duodenum (nasoduodenal), or jejunum (nasojejunal). In general, these tubes are used in the hospitalized patient when the anticipated tube feeding duration is less than 4 to 6 weeks. The orogastric route is generally reserved for patients in whom the nasopharyngeal area is inaccessible or in young infants who are obligate nasal breathers. Because these routes do not require surgical intervention, they are the least invasive. The feeding tube is frequently held in place only by a piece of tape on the nose or face, and therefore can be inadvertently pulled out relatively easily.

TABLE 146-3 Options and Considerations in the Selection of Enteral Access

Access	Indications	Tube Placement Options	Advantages	Disadvantages
Nasogastric or orogastric	Short-term Intact gag reflex Normal gastric emptying	Manually at bedside	Ease of placement Allows for all methods of administration Inexpensive Multiple commercially available tubes and sizes	Potential tube displacement Potential increased aspiration risk
Nasoduodenal or nasojejunal	Short-term Impaired gastric motility or emptying High risk of GER or aspiration	Manually at bedside Fluoroscopically Endoscopically	Potential reduced aspiration risk Allows for early postinjury or postoperative feeding Multiple commercially available tubes and sizes	Manual transpyloric passage requires greater skill Potential tube displacement or clogging Bolus or intermittent feeding not tolerated
Gastrostomy	Long-term Normal gastric emptying	Surgically Endoscopically Radiologically Laparoscopically	Allows for all methods of administration Large-bore tubes less likely to clog Multiple commercially available tubes and sizes Low-profile buttons available	Attendant risks associated with each type of procedure Potential increased aspiration risk Requires stoma site care
Jejunostomy	Long-term Impaired gastric motility or gastric emptying High risk of GER or aspiration	Surgically Endoscopically Radiologically Laparoscopically	Allows for early postinjury or postoperative feeding Potential reduced aspiration risk Multiple commercially available tubes and sizes	Attendant risks associated with each type of procedure Bolus or intermittent feeding not tolerated Requires stoma site care

GER, gastroesophageal reflux.

FIGURE 146-2. Access sites for tube feeding.

Nasogastric tubes vary in diameter size and stiffness. The large-bore (≥ 14 French [F]) rigid NG tubes are used primarily to decompress the stomach but can also be used for feeding. There is a low incidence of clogging with these tubes, and they provide a reliable way to measure gastric residual volumes. The major disadvantage associated with the use of these tubes is patient discomfort. Small-bore nasal tubes designed solely for feeding are available in varying lengths (16 to 60 inches) and diameter sizes (4F to 12F) to accommodate both pediatric (including neonates) and adult patients. The tip of the tube can be placed into the stomach, duodenum, or jejunum. These tubes consist of a lightweight, pliable silicone or polyurethane material that is more comfortable for the patient. A disadvantage of the small-bore tubes is that they may become easily occluded, often as a result of improper medication administration or tube flushing technique. Another disadvantage to the use of these tubes is that they do not allow a reliable way to monitor gastric residual volumes, as they will collapse when aspiration of gastric contents is attempted. Therefore, when the monitoring of gastric residual volumes is important, such as in a critically ill patient, a large-bore NG tube is preferred.

4 In general, the stomach is the least expensive and the least labor-intensive access site to use for enteral feeding; however, feeding into the stomach is not as well tolerated. Patients with impaired gastric motility may be predisposed to aspiration and pneumonia when feedings are delivered into the stomach. Many critically ill, injured, and postoperative patients exhibit delayed gastric emptying, limiting their ability to tolerate gastric feeding. In addition, patients with diabetic gastroparesis or patients with severe gastroesophageal reflux disease or intractable vomiting are at a higher risk for aspiration of gastric contents resulting in pneumonia. In these patients, placing the tip of the tube into the duodenum or jejunum (also referred to as transpyloric placement) may be required to enable successful enteral feeding. However, studies have yet to prove definitively that transpyloric tube feedings actually do decrease the risk of aspiration and pneumonia. One meta-analysis of studies comparing gastric to transpyloric feeding in critically ill patients demonstrated no difference in the incidence of pneumonia,²⁶ whereas another critical review of the same patient population suggested that small-bowel feedings were associated with a reduction in gastroesophageal regurgitation and a lower rate of ventilator-associated pneumonia.²⁷ Thus, the true difference in aspiration and pneumonia risk between gastric and small-bowel feeding remains unclear. However, the

transpyloric route may be beneficial in patients who do not tolerate gastric feeding. Its use may enable the successful use of EN in patients who would have otherwise failed and required PN.

Nasoenteric feeding tubes can be inserted at the patient's bedside by trained medical personnel. However, greater skill is required to advance the tip of the feeding tube beyond the pylorus. Several techniques have been described in the literature to help facilitate bedside placement. Prokinetic agents, such as metoclopramide and erythromycin, when given prior to insertion increase GI motility and facilitate spontaneous passage of the tube from the stomach into the small intestine.^{28,29} Variable success rates have been reported with these techniques and are largely dependent on clinician experience. Alternatively, a variety of endoscopic and fluoroscopic techniques have been described to insert transpyloric tubes.²⁵ Radiographic confirmation of appropriate tip placement for feeding tubes inserted by bedside techniques should be obtained prior to use.⁷

LONG-TERM ACCESS

Feeding tubes used for short-term enteral access are usually not optimal for long-term use because of patient discomfort, long-term complications, and mechanical failures that develop over time. Long-term access should generally be considered when EN is anticipated for longer than 4 to 6 weeks. Many techniques can be used to establish long-term enteral access, including laparotomy, laparoscopy, endoscopy, and fluoroscopy. The ability to perform the various techniques will be somewhat dependent on the expertise and facilities available within each institution. Long-term enteral access options include gastrostomy, jejunostomy, esophagostomy, and pharyngostomy.

A gastrostomy is the most common type of long-term enteral access. It eliminates the nasal irritation and discomfort associated with nasoenteric feeding tubes and inadvertent removal is uncommon. In addition, because feeding gastrostomies use large-bore tubes, clogging is less of a problem. Multiple techniques for insertion of a gastrostomy tube have been described, including surgical laparotomy, endoscopy, radiography, and laparoscopy. The most common technique is the percutaneous endoscopic gastrostomy (PEG). It is minimally invasive and can be performed safely and cost-effectively in an endoscopy suite or at the bedside using conscious sedation and local anesthesia. Small children, however, will usually require general anesthesia for the procedure. Numerous kits are available for PEG

placement in both children and adults and vary in size (12F to 28F; 1- to 4.5-cm shaft lengths), material used, internal and external bolsters, and insertion techniques. There are, however, ethical implications regarding determination of appropriate candidates for PEG placement.³⁰⁻³² Because of its relative ease of placement, the PEG tube is often placed inappropriately based on unrealistic expectations of what EN can accomplish in patients who are unable to eat. PEG placement is associated with an unexpectedly high 30-day mortality rate, which suggests that the procedure is being performed in patients who have multiple coexisting morbid conditions.³⁰ Patients with a poor prognosis are not appropriate candidates for PEG placement.

Once the gastrostomy tract has matured, a low-profile skin-level gastrostomy device may be placed for patient convenience and comfort. The “gastric button” consists of a short, silicone, self-retaining conduit with either a mushroom tip or a balloon at the internal end and a one-way valve and small flange at the skin surface. Because this averts the external tube presence, it tends to be preferred in children or ambulatory adults who are receiving intermittent feedings. The exit site of all gastrostomies requires general stoma care to prevent inflammation and infection. In patients at high risk of gastroesophageal reflux disease and aspiration who require long-term enteral access, a jejunostomy may be the most appropriate option.³³ Jejunostomies may also be indicated in patients unable to tolerate gastric feeding as a result of impaired gastric motility or delayed gastric emptying. These tubes can be inserted surgically, endoscopically, radiologically, or laparoscopically. The most appropriate technique depends on the expertise and facilities available. A surgical jejunostomy may be preferred if the patient requires a laparotomy or laparoscopy for other reasons. Endoscopic placement of a jejunostomy can be done by various methods. Typically, a small-bore jejunal extension tube (6F, 8F, or 10F) is inserted through a PEG and advanced through the pylorus into the duodenum or jejunum. This procedure has been referred to as percutaneous endoscopic jejunostomy, but this is misleading. The percutaneous endoscopic jejunostomy designation implies a direct opening from the skin into the jejunum. The more appropriate name is percutaneous endoscopic gastrojejunostomy or PEG with a jejunal extension tube. Also described in the literature are laparoscopically and radiologically placed jejunostomies.³³ Because jejunostomies use smaller-bore tubes, occlusion occurs more commonly than with gastrostomy tubes.

Pharyngostomies and esophagostomies are invasive because the tube is located in the neck and passes through the skin into the pharynx or esophagus, respectively. Historically, they have been used in patients with head and neck malignancies, and in patients with impaired swallowing caused by neuromuscular disorders. However, better long-term enteral access techniques have replaced the need for the pharyngostomy and esophagotomy routes. They are rarely performed today because of the high complication rate and extreme difficulty associated with their care.³⁰

ADMINISTRATION METHODS

Enteral nutrition may be administered by continuous, cyclic (i.e., a continuous rate over a portion of the day), or bolus methods and may be accomplished by syringe, gravity, or infusion pump-controlled techniques. The method of delivery depends on the location of the tip of the feeding tube, the clinical condition and intestinal function of the patient, the environment in which the patient resides, and the patient's tolerance to the tube feeding.

CONTINUOUS

In the hospitalized patient, the continuous administration of EN is most commonly used for initiation, and is generally the preferred method in critically ill patients.^{34,35} When initiating feeding into the

stomach, the continuous method of delivery is less likely to result in abdominal distension, vomiting, and diarrhea than the intermittent bolus method. Once tolerance is established, a conversion to intermittent bolus administration may be warranted. When EN is delivered into the small intestine, the continuous method is preferred because it is associated with enhanced tolerance. The rapid delivery of feeding into the small intestine, especially hyperosmotic formulations, may contribute to abdominal distension, cramps, hyperperistalsis, and diarrhea. Therefore conversion to intermittent bolus administration is not recommended for those who have an access placed into the duodenum or jejunum. Continuous feeding may also be preferred in patients who have limited absorptive capacity due to rapid GI transit or severely impaired digestion. Slow continuous administration in such patients allows greater time for digestion and absorption of nutrients as they pass through the intestine.

The delivery system for a continuous infusion generally includes a feeding reservoir or bag attached to an extension set that is connected to an infusion pump. The delivery system is then attached to the patient's enteral access tube. Continuous infusion may increase nursing time because routine checks of the enteral infusion are needed, but this disadvantage is offset by the improved tolerance. For adults, EN infusion rates generally range from 50 to 125 mL/h, although higher infusion rates have been used without complications. In children, EN infusion rates of 1 to 2 mL/kg per hour can be started with advancements every 4 to 8 hours until the goal rate needed to meet caloric needs is achieved with good GI tolerance. The primary disadvantage to this method of administration is the cost and inconvenience associated with the pump and administration sets. In the home care setting, battery-operated ambulatory enteral pumps are available to allow the patient greater mobility.

CYCLIC

A patient who is not eating well during the day because of complaints of fullness and lack of appetite may benefit from a trial of cyclic EN wherein the enteral feeding is held during the day and infused only at night. In addition, the infusion of EN only at night will free the patient from the pump during the day and allow for greater mobility. This increased mobility may be particularly useful for the home patient or patient requiring rehabilitation. Because a pump controls the rate of infusion, this method of administration may be used in patients with either gastric or small bowel access.

BOLUS

The bolus administration of EN is most commonly used for patients in long-term care settings who have a gastrostomy. This administration technique involves the delivery of the enteral feeding formulation, usually over 5 to 10 minutes. Essentially the only equipment needed is a syringe to instill the feeding solution into the tube. Depending on the patient's nutritional requirements, an instillation volume of 240 to 500 mL is generally used and repeated four to six times per day. From a convenience standpoint, it is generally preferable to adjust the bolus volume in increments of the feeding formulation can size (usually 240 mL). The volume given in children is usually 20 to 25 mL/kg per feeding until their caloric requirements or adult volumes are reached. Although many patients tolerate this approach, the bolus technique may result in cramping, nausea, vomiting, aspiration, and diarrhea, especially in those who have duodenal or jejunal access. Its use should be avoided in patients with delayed gastric emptying and in patients who are at high risk of aspiration.

INTERMITTENT

If a patient is experiencing intolerance to bolus administration over 5 to 10 minutes, it may be helpful to administer the prescribed

volume over a longer time period, generally 20 to 60 minutes. For this method, the desired volume of feeding formulation is emptied into a reservoir bag or container and infused by an infusion pump or gravity drip using a roller clamp. The bolus method of administration is more consistent physiologically with normal eating patterns than the continuous method. One study in infants demonstrated that normal gallbladder emptying did not occur with continuous infusion feedings, but was present in those infants receiving bolus feedings.³⁶ Thus those patients who need long-term EN and PN, especially children, may benefit when this approach is used because it minimizes the development of cholestatic liver disease.

ENTERAL FEEDING FORMULATION SELECTION

Historically, enteral formulas were created to provide essential nutrients. Over the years, enhancements have been made to meet specific patient needs and improve tolerance. For example, enteral formulas have been modified in nutrient composition by changing the content of the amino acids (such as glutamine and arginine), changing the omega-3 polyunsaturated fatty acid content, and adding ribonucleic acid to enhance immune function and improve disease outcome. These specific nutrients have been called nutraceuticals or pharmacognutrients because of the intent to use them to modify the disease process and improve clinical outcome. Currently, enteral feeding formulations are categorized by the U.S. Food and Drug Administration (FDA) as medical foods. They are considered components of supportive care and are simply regulated to ensure sanitary manufacture. Unfortunately, they are not subject to rules governing health claims, and the issue of the promotion of medical foods for therapeutic intent is currently not regulated by the FDA.^{37,38}

The macronutrient content of enteral formulas (namely, protein, carbohydrate, and fat) varies in nutrient complexity (Table 146-4). Nutrient complexity refers to the amount of hydrolysis and digestion a substrate source requires prior to intestinal absorption. Polymeric or intact substrates are of similar molecular form as the food we eat. Enteral formulas that contain partially hydrolyzed or elemental substrates are characterized as elemental, or defined-formula diets. The caloric contribution of each of the macronutrients is as follows: carbohydrates, 4 kcal/g; protein, 4 kcal/g; and fat,

9 kcal/g. Micronutrients, including electrolytes, vitamins, trace elements, and water, do not contribute to caloric content.

PROTEIN COMPOSITION

The essential amino acid content of the protein source determines the quality of the protein, and most commercially available enteral feeding formulations contain proteins of high quality. The molecular form of the protein source in enteral formulas will determine the amount of digestion that is required for absorption within the small bowel. Polymeric or intact protein sources require digestion to smaller peptides and free amino acids before they are absorbed from the GI tract. Therefore enteral formulation protein sources such as meat, milk, eggs, and caseinates require digestion by hydrochloric acid, specific protein enzymes, and pancreatic enzymes. Enteral formulations may also contain protein sources that are partially hydrolyzed as peptides or L-amino acids. As the molecular form of protein is reduced in size, the osmotic load within the enteral formula is increased. Many commercially available enteral feeding formulations contain combinations of intact and partially hydrolyzed protein sources.

CONDITIONALLY ESSENTIAL AMINO ACIDS

Glutamine and arginine are generally considered nonessential amino acids. However, during periods of high physiologic stress, patients may become deficient; consequently, these amino acids are characterized as conditionally essential. Because they are usually present in low amounts in most enteral feeding formulations, those formulations targeted for the critically ill may be supplemented with glutamine and/or arginine.

Glutamine serves as a key fuel for rapidly dividing cells, including enterocytes, endothelial cells, lymphocytes, and fibroblasts. The primary site of glutamine production is skeletal muscle. During critical illness, the catabolism of skeletal muscle provides an increased supply of glutamine, but this may not be enough to meet the high rate of glutamine use by cells of the immune system and other cells involved in recovery and repair. Glutamine depletion may result, particularly during prolonged periods of metabolic stress. However, it is unclear whether glutamine supplementation in enteral formulations plays a role in preserving normal intestinal morphology and function or preserving immune function.^{39,40} Further research and investigation are required to determine the potential benefits and harm associated with glutamine-enriched enteral feeding formulations.

Arginine has been added to selected enteral formulations in concentrations that range from 4.5 to 14 g/L. However, the supplementation of arginine remains controversial, especially in patients with sepsis.^{13,15,41,42} Many of the physiologic effects of arginine are mediated by its conversion to nitric oxide, which, in turn, modulates immune function, inflammation, and response to sepsis. Some of the effects may be potentially harmful in the patient with sepsis, especially when higher arginine intakes are used. Unfortunately, human studies evaluating arginine alone are limited. There is currently no consensus on whether arginine-supplemented enteral formulations should be used in septic patients.^{13,15,41,42}

CARBOHYDRATE COMPOSITION

The carbohydrate component of enteral feeding formulations usually provides the major source of calories. Polymeric or intact enteral formulations contain starches and numerous types of glucose polymers, which require digestion to monosaccharide moieties prior to intestinal absorption (see Fig. 146-1). As the hydrolysis of carbohydrate increases within an enteral formulation, the osmolality of the

TABLE 146-4 Enteral Formula Nutrient Complexity

Nutrient	Polymeric or Intact	Partially Hydrolyzed or Elemental
Carbohydrate	Starches	Oligosaccharides
	Fruit, vegetable, cereal solids	Maltodextrins
	Glucose polymers	Disaccharides
	Corn syrup solids	Maltose, sucrose, lactose
	Polysaccharides	Monosaccharides
Fat		Glucose
		Galactose
	Long-chain triglycerides	Medium-chain triglycerides
	Polyunsaturated fatty acids	Coconut oil
	Corn oil	Palm kernel oil
	Safflower oil	Free fatty acids
	Soybean oil	Linoleic
	Butterfat	
Protein	Menhaden oil	
	Fish oils	
	Whole	Oligopeptides
	Egg, milk, wheat, whey	Dipeptides
	Isolates	Tripeptides
	Caseinate salts	L-Amino acids
	Lactalbumin	

formulation increases. Elemental carbohydrates such as glucose and galactose contribute significantly to the osmolality of enteral formulations, which is associated with feeding intolerance. Consequently, polymeric entities, rather than elemental sugars, are preferred in enteral formulas. Glucose polymers provide a useful carbohydrate source that is tolerated by most individuals (see Table 146–4). The polymers are large chains that provide minimal osmotic load, yet are absorbed easily in the intestine. The one shortcoming of glucose polymers and oligosaccharides is that they are not as sweet as simple glucose and thus may decrease the palatability of orally consumed products. Finally, almost all commercially available enteral feeding formulations used in adults and older children are lactose-free because some ethnic populations are lactase deficient and disaccharidase production within the gut lumen is reduced during illness or bowel rest. Infant formulas are available with or without lactose.

FAT AND FATTY ACID COMPOSITION

Fat is an important constituent in the diet because it provides a concentrated calorie source and serves as a carrier for fat-soluble vitamins. Sufficient linoleic acid is required to prevent essential fatty acid deficiency and should approximate 1% to 3% of total daily calories. The most common sources of fat in enteral feeding formulations are vegetable oils (soy or corn) rich in polyunsaturated fatty acids. The concentration of fat varies between less than 2% to 45% of total calories. High fat content of the diet is associated with delayed gastric emptying. Enteral feeding formulations can also contain fat in the form of MCTs, derived from palm kernel or coconut oils. Because MCTs do not contain linoleic acid, most enteral formulations that contain MCTs will also contain a source of long-chain triglycerides to provide essential fatty acids. Potential advantages of MCTs compared to long-chain triglycerides are that they are more water soluble, undergo rapid hydrolysis, require little to no pancreatic lipase or bile salt for absorption, and do not require carnitine for transport into the mitochondria where they are converted to energy. They also do not require chylomicron formation for small-bowel enterocyte absorption.

The source of long-chain fat within some enteral formulations has been modified from omega-6 to omega-3 fatty acids in an effort to modulate the inflammatory response to metabolic stress.⁴³ The omega-6 fatty acids serve as precursors to certain cytokines that are potent inflammatory mediators and also decrease cell-mediated immune response. The omega-6 fatty acids are high in linoleic acid and are derived from vegetable oil, whereas the omega-3 fatty acids, derived from cold water fish oils, are high in linolenic acid. It has been proposed that if the dietary proportion of omega-3 fatty acids is increased and omega-6 fatty acids is decreased, less inflammation and immunosuppression may occur during metabolic stress.

Docosahexaenoic acid (DHA) and arachidonic acid (ARA) are two fatty acids abundant in human milk, but until recently, were not contained in commercial infant formulas. Although the role of ARA supplementation is unclear, DHA is known to be important in both brain and eye development. In some studies, DHA and ARA supplementation provided benefits to a child's visual function and/or cognitive and behavioral development.^{44–47} Other studies showed no difference with DHA and ARA supplementation.⁴⁸ The FDA has classified the plant-based fatty acid blends of DHA and ARA (DHASCO and ARASCO; Martek Biosciences Corporation, Columbia, MD) as generally recognized as safe in infant formulas, and most infant formulas are now routinely supplemented with these fatty acids.

FIBER CONTENT

Fiber, in the form of soy polysaccharides, has been added to several enteral feeding formulations intended for use in both children and

adults in amounts ranging from 5.9 g/L to 24 g/L of dietary fiber. Infant formulas do not contain fiber, with the exception of one formula intended for use in infants with diarrhea (Similac Isomil DF, Abbott Nutrition, Columbus, OH). Fiber supplementation is common in clinical practice, primarily because fiber-free enteral formulations are implicated as a contributing factor to both diarrhea and constipation. Ingested fiber undergoes bacterial degradation within the colon to produce short-chain fatty acids. Potential benefits of fiber are the trophic effects on the colonic mucosa as well as promotion of sodium and water absorption within the colon.⁴ It may help regulate bowel function in both normal individuals and in those with altered colonic motility. In addition, the resulting short-chain fatty acids are an excellent energy source. Although beneficial effects of fiber supplementation have not been clearly proven in clinical studies, there is experimental evidence that fiber may play an integral role in normal human nutrition and risk is generally minimal.^{49,50} Fiber supplementation may be beneficial when long-term EN is required or in patients who experience diarrhea or constipation while receiving a fiber-free enteral formulation. In intensive care units, however, drugs and metabolic stress seem to be more powerful determinants of bowel function than the presence or absence of fiber.

OSMOLALITY AND RENAL SOLUTE LOAD

The osmolality and the renal solute load can affect tolerance to enteral feeding formulations. The osmolality of a given enteral formulation is a function of the size and quantity of ionic and molecular particles, primarily related to the protein, carbohydrate, electrolyte, and mineral content within a given volume. The unit of measure of osmolality is milliosmoles per kilogram (mOsm/kg). Iso-osmolar is considered to be approximately 300 mOsm/kg. Enteral formulations with greater amounts of partially hydrolyzed or elemental substrates have a higher osmolality than formulations containing polymeric or intact substrate forms. Therefore formulations that contain sucrose or glucose, dipeptides and tripeptides, and amino acids are generally hyperosmolar. Increased caloric density also increases the osmolality of an enteral formulation. In general, the osmolality of commercially available enteral feeding formulations ranges from 300 to 900 mOsm/kg. The American Academy of Pediatrics recommends that enteral formulations for use in infants have an osmolality of approximately 450 mOsm/kg or less. An extensive tabulation of the osmolality of formulas and medications commonly used in neonatal intensive care units was published over a decade ago and an update is long overdue.⁵¹

Symptoms of gastric retention, diarrhea, abdominal distension, nausea, and vomiting have been attributed to enteral formulations having high osmolality based on the assumption that a higher osmolality will draw water into the gut lumen. However, clinical evidence to support the relationship between osmolality and GI tolerance is lacking.⁵¹ The practice of diluting hyperosmolar formulations has not been shown to enhance tolerance and should be discouraged unless dilution is done to increase fluid intake.³⁵ Factors such as concurrent antibiotic therapy, method of enteral feeding administration, and the formulation's composition are likely to play a greater role in GI tolerance than the osmolality.

The renal solute load is determined by the protein, sodium, potassium, and chloride content of the enteral formulation. Formulations that contain a greater solute load increase the obligatory water loss via the kidney. It is estimated that 40 to 60 mL of water is the minimal amount necessary to excrete 1 g of nitrogen.⁵⁶ Those receiving high-protein enteral formulations unable to ingest more water, such as a geriatric patient or a patient with altered mental status, may be at risk for significant dehydration.

TABLE 146-5 Adult Enteral Feeding Formulation Classification System

Category	Features	Indications
Standard polymeric	Isotonic 1–1.2 kcal/mL NPC:N 125:1 to 150:1 May contain fiber	Designed to meet the needs of the majority of patients. Patients with functional GI tract. Not suitable for oral use.
High protein	NPC:N <125:1	Patients with protein requirements >1.5 g/kg/day, such as trauma, burns, pressure sores, or wounds. Patients receiving propofol.
High caloric density	May contain fiber 1.5–2 kcal/mL Lower electrolyte content per calorie Hypertonic	Patients requiring fluid and/or electrolyte restriction, such as renal insufficiency.
Elemental	High proportion of free amino acids Low in fat	Patients who require low fat. Use has generally been replaced by peptide-based formulations.
Peptide-based	Contains dipeptides and tripeptides Contains MCTs	Indications/benefits not clearly established. Trial may be warranted in patients who do not tolerate intact protein due to malabsorption.
Disease-specific		
Renal	Caloric dense Protein content varies Low electrolyte content	Alternative to high caloric density formulations, but generally more expensive.
Hepatic	Increased branched-chain and decreased aromatic amino acids	Patients with hepatic encephalopathy.
Pulmonary	High fat, low carbohydrate	Patients with compromised pulmonary function.
Diabetic	High fat, low carbohydrate	Alternative to standard, fiber-containing formulation in patients with uncontrolled hyperglycemia.
Immunomodulating	Supplemented with glutamine, arginine, nucleotides, and/or omega-3 fatty acids	Indications not clearly established.
Oral supplement	Sweetened for taste Hypertonic	Select nutrients may be beneficial or harmful in subgroups of critically ill patients. Patients who require supplementation to an oral diet.

MCT, medium-chain triglyceride; NPC:N, nonprotein calorie-to-nitrogen ratio.

CLASSIFICATION OF ENTERAL FEEDING FORMULATIONS

5 Although the majority of patients' needs can probably be met using three or four different formulations, certain disease states or clinical conditions may warrant the use of a specialty feeding formulation. Development of an effective formulary system should avoid the duplication of enteral feeding formulations and use only those specialty formulations with an established role. Categorizing enteral feeding formulations according to therapeutic class is necessary in developing a formulary system for adults (Table 146–5) and children (Table 146–6).

STANDARD POLYMERIC

A large number of commercially available enteral feeding formulations fall within the category of a standard polymeric formulation. These formulations are approximately isotonic (300 mOsm/L), provide about 1 kcal/mL, and are composed of intact nutrients in a well-proportioned mix of carbohydrate, fat, and protein. They are provided with or without dietary fiber. The nutrient requirements of the majority of adult patients and children older than 10 years of age receiving EN can generally be met using feeding formulations in this category. The nonprotein calorie-to-nitrogen ratio of these products is approximately 125:1 to 150:1. This ratio is a useful parameter for assessing protein density in relation to calories provided. Certain feeding formulations in this category may be promoted as high nitrogen, but fall within standard protein amounts. To maintain their isotonicity, products within this category are not sweetened, making them not very palatable and generally only suited for tube feeding and not oral supplementation; however, flavored products are available.

HIGH PROTEIN

Enteral feeding formulations with a nonprotein calorie-to-nitrogen ratio less than 125:1 can be categorized as high protein. The lower the ratio, the higher the protein density in relation to calories provided. In patients with high protein requirements, it is generally unacceptable to use a feeding formulation with standard protein amounts because the volume necessary to meet protein requirements will often result in excessive calorie intake. Patients who may be candidates for a high-protein feeding formulation are those with trauma, burns, pressure sores, surgical wounds, high fistula output, and other critically ill patients. In general, adult patients with estimated protein requirements exceeding 1.5 g/kg per day may benefit from a high-protein formulation. High-protein formulations may also be beneficial in mechanically ventilated patients who are receiving propofol for sedation. The vehicle for propofol is a soybean fat emulsion that contains 1.1 kcal/mL. At therapeutic dosages, the use of propofol can significantly contribute to caloric intake and a high protein formulation may be beneficial in allowing for the provision of protein requirements while minimizing the risk of overfeeding.

HIGH CALORIC DENSITY

High caloric density formulations are concentrated to provide less fluid and electrolyte intake in comparison to a standard polymeric formulation. They provide approximately 2 kcal/mL and will achieve similar calorie and protein intake to a standard polymeric formulation, using half the volume. High caloric density formulations are often necessary for patients who require fluid and/or electrolyte restriction, such as those with renal insufficiency or congestive heart failure. Although specialty enteral formulations targeted for acute and chronic renal failure are also available, many patients with renal failure can be managed using a product in this category (see Chap. 147).

TABLE 146-6 Pediatric Enteral Feeding Formulation Classification System

Formula Type	Features	Indications
Infants		
Cow's milk-based	Isotonic Standard energy density for feeding: 20–24 kcal/oz, but also available in concentrate (40 kcal/oz) and powder forms Standard formulation contains lactose, but also available as lactose-free Most contain ARA and DHA	Normal, healthy infant
Soy protein-based	Hypotonic Standard energy density for feeding: 20 kcal/oz, but also available in concentrate (40 kcal/oz) and powder forms Lactose-free Most contain added soy fiber	Lactase deficiency or intolerance, galactosemia
Prematurity	Isotonic Standard energy density for feeding: 24 kcal/oz, but also available in 20 kcal/oz form Provide increased protein, mineral, electrolytes, and vitamins compared to term infant formulations	Preterm infants weighing less than 2–3 kg
Transition	Hypotonic Standard energy density for feeding: 22 kcal/oz Provide higher calcium and phosphorus content compared to term infant formulations	Preterm infants weighing less than 3 kg ready for discharge
Semielemental	Typically hypertonic Standard energy density for feeding: 20 kcal/oz Hydrolyzed protein and free amino acids May contain ARA and DHA Lactose-free Typically contain MCTs ranging from 5%–86% of fat content	Malabsorption, cow's milk protein allergy, chylothorax, cystic fibrosis, biliary atresia, short-bowel syndrome
Special diets	Low electrolyte/mineral content	Renal disease
Children ages 1–10 years		
Standard	Isotonic Standard energy density for feeding: 30 kcal/oz (1 kcal/mL) Intact protein; 30–38 g/L May contain added fiber	Functioning GI tract requiring tube feedings
Elemental	Typically hypertonic Standard energy density for feeding: 20–30 kcal/oz Hydrolyzed protein and free amino acids Lactose-free MCTs range from 25%–60% of fat content	Malabsorption, cow's milk protein allergy, chylothorax, cystic fibrosis, biliary atresia

ARA, arachidonic acid; DHA, docosahexaenoic acid; MCT, medium-chain triglycerides.

ELEMENTAL/PEPTIDE BASED

Formulations in this category contain protein and/or fat components that are hydrolyzed into smaller, predigested forms. Traditionally, enteral formulations in this category were referred to as elemental and contained a high proportion of protein in the form of free amino acids and a low amount of fat. Although still commercially available, many of these formulations have been replaced in clinical practice with formulations containing a portion of the protein in the form of dipeptides and tripeptides and less free amino

acids. These formulations are referred to as peptide based. The alteration in protein composition was made in an effort to optimize protein absorption in patients with impaired digestive or absorptive capacity. Results from human and animal intestinal perfusion studies indicate that the partially hydrolyzed sources of protein provide an absorptive advantage over formulas that contain free amino acids.⁵³ Peptide-based formulations are generally higher in fat than the older, elemental formulations, and use MCTs in varying proportions as the fat source.

Indications for use of peptide-based formulations are not clearly established. Unfortunately, there are few controlled data on the nutritional efficacy of the peptide-based or free amino acid formulations. The routine use of peptide-based or free amino acid formulations is generally not recommended. Patients who do not tolerate standard, intact nutrient formulations as a result of malabsorption might be candidates for a trial of a peptide-based formulation. In addition, elemental or peptide-based products that have higher percentages of MCTs and small amounts of long-chain triglycerides may be beneficial for patients with severe pancreatic insufficiency such as chronic pancreatitis and cystic fibrosis, severe abnormalities of the intestinal mucosa such as untreated celiac disease, biliary tract disease such as biliary atresia or severe cholestasis, or chylothorax.

DISEASE SPECIFIC

Newer enteral feeding formulations have been designed to meet specific nutrient requirements and manage metabolic abnormalities associated with specific disease states. Conditions for which specialized enteral feeding formulations exist include renal and hepatic failure, pulmonary disease including acute respiratory distress syndrome, diabetes mellitus, wound healing, and metabolic stress. Chapter 147 discusses specific nutrient concerns during organ failure. Unfortunately, scientific and clinical research supporting the efficacy of specialized enteral feeding formulations is minimal.

Specialized enteral formulations designed to modulate the inflammatory response in patients with severe metabolic stress have been referred to as immune-enhancing formulations or immunonutrition. These specialized formulations are supplemented with nutrients such as glutamine, arginine, branched-chain amino acids, nucleotides, and omega-3 polyunsaturated fatty acids, as a result of their potential role in regulating immune function; guidelines for their use in critically ill patients have been published.^{15,54–58} In some surgical and critically ill patients, the use of immune-enhancing formulations were associated with a reduced infection rate and length of hospital stay. However, the results of these trials are conflicting and controversial. Positive results have been demonstrated in patients undergoing elective GI surgery, major cancer surgery of the head and neck, and patients with severe trauma. However, immune-enhancing formulations are associated with increased mortality in patients with preexisting severe sepsis. There may be subgroups of critically ill patients who do not benefit and are actually harmed by immune-enhancing formulations. More study is warranted to determine the benefit-to-risk ratio associated with the use of these formulations and to identify which, if any, of the supplemented immune-enhancing nutrients are contributing to improved clinical outcome.

CLINICAL CONTROVERSY

The role of immune-enhancing enteral formulations in critically ill patients is controversial. Although some clinicians recommend their use in subgroups of critically ill patients, others await more evidence to support safety. When immune-enhancing enteral formulations are used, the optimal duration of therapy is unclear, although some studies suggest a minimum duration of 5 days.

In patients with acute respiratory distress syndrome, improved outcomes from using a low carbohydrate formulation supplemented with specific fatty acids (eicosapentaenoic acid and γ -linolenic acid) and antioxidants have been documented.⁵⁹ When compared with a high fat formulation, the specialized diet was associated with fewer days of ventilatory support, fewer intensive care unit days, and fewer new organ failures. Consequently, it is recommended that this specialized formulation be considered for patients with acute respiratory distress syndrome.^{15,56,58}

There are no disease-specific enteral products currently marketed for use in infants or children from 1 to 10 years of age. The use of modular supplements is often necessary in children with special nutrition needs (see Modular Products below).

ORAL SUPPLEMENTS

In general, oral supplements are not intended for tube feeding, but to enhance an oral diet. They are sweetened to improve taste and therefore are hypertonic (about 450 to 700 mOsm/kg). Osmolality is generally not a problem in the patient with a functioning GI tract. However, in the tube-fed patient, a sweetened product is unnecessary and may contribute to GI intolerance, particularly diarrhea. Powder supplements that are mixed with milk should be avoided in lactose-intolerant patients. In addition to liquid supplements, puddings, gelatins, bars, and milkshake-like supplements are available.

MODULAR PRODUCTS

A module is a powder or liquid form of nutrients (i.e., protein, carbohydrate, or fat) that is used to supplement a commercially available enteral formulation. Addition of a modular product may be necessary, especially in children, to achieve a nutrient mix not supplied by a single commercially available product.⁶⁰ Alternatively, formulations available in powder or concentrate can be mixed with less water than needed for the standard dilution to deliver more nutrients in less volume. Infant formulas generally are concentrated beyond their standard concentration in this way. The mixing process required for modular components increases the potential for bacterial contamination and incorrect preparation. Contamination is a particular concern with the use of blenders and reconstitution of powders.^{61,62} Human milk fortifiers are available for supplementation of human milk so that it meets the needs of a premature infant. Human milk fortifiers add additional calories, protein, and minerals and have been shown to improve nutritional outcomes in human milk-fed premature infants.^{63–65}

REHYDRATION

Oral rehydration formulations are useful in maintaining hydration or treating dehydration in adult and pediatric patients with high GI output. Such formulations are available commercially in powder or liquid form or can be extemporaneously compounded.⁶⁶ They can be administered orally or given via a feeding tube. The glucose content of oral rehydration solutions is important because it stimulates active transport systems, which, in turn, stimulates passive sodium and water uptake simultaneously with the glucose. Therefore oral or enteral administration of rehydration solutions may decrease fecal water loss and generate a positive electrolyte balance.

FORMULARY AND DELIVERY SYSTEM CONSIDERATIONS

The selection of product should be based on the patient's nutritional requirements. In general, no more than one product is necessary per category of enteral feeding formulation and it may be

possible to omit certain categories based on the specific patient population within a given institution. Additional selection criteria include container size and type, liquid or powder form, shelf life, ease of use, and cost.

The majority of enteral products are available as ready-to-use, prepackaged liquids, a few are available in the powdered state and require reconstitution prior to use. Advantages of ready-to-use liquid formulations are convenience and lower susceptibility to microbiologic contamination. One disadvantage is that more storage space is required. The ease or convenience of a ready-to-use liquid is especially important for self-care patients, the disabled, and those who have difficulty reading or following printed instructions. Ready-to-use liquid enteral formulations are generally available in rigid containers, cans, or closed, ready-to-hang bags. Bolus administration of EN is usually achieved using formulas available in cans. However, when formula from a can is used for continuous or cyclic administration, it must first be poured into a bag or bottle to allow for infusion via a pump. This "open system" differs from the closed, ready-to-hang containers from the standpoint of microbial contamination risk. The use of a powder formula is also considered an open system of delivery.

Contaminated enteral feeding formulations are a potential source of infectious complications.^{61,62,67,68} The GI tract may serve as a portal of entry for bacteria into the systemic circulation, especially in patients who are receiving multiple antibiotics, have undergone a surgical procedure, or have GI tract stasis from a variety of causes. The contamination of enteral feeding formulations is associated with a lack of attention to proper handling techniques, inability to disinfect preparation equipment, and nonsterile or contaminated tube feeding additives. Unlike liquid formulations, powdered products are not guaranteed to be sterile by the manufacturer because of the inability to properly sterilize the powder without destruction of some of its components. Contamination of one infant formula with *Enterobacter sakazakii* at the manufacturing site was implicated in the death of an infant in a neonatal intensive care unit, prompting FDA warnings regarding the use of powdered formulations in premature neonates and other immunocompromised infants. Because powder formulations require reconstitution, often in a blender that is difficult to sterilize, they are also more susceptible to contamination at the time of preparation. Stringent handling procedures are recommended during all aspects of enteral feeding preparation and delivery to minimize contamination risk. The closed-system containers supply a ready-to-hang, prefilled, sterile supply of formula in volumes of 1 to 1.5 L. Numerous, but not all, enteral formulations intended for use in adults are available in the closed-administration system. The closed-administration system also offers the advantage of not requiring refrigeration and allowing hang times beyond 24 to 36 hours, whereas the conventional open-delivery system necessitates hang times of generally 4 to 8 hours.

INITIATION AND ADVANCEMENT PROTOCOL

Guidelines for the initiation and advancement of enteral feeding formulations vary greatly and scientific support for any of the guidelines is weak or nonexistent. The typical recommendation for continuous administration of EN for adults is to start at 20 to 50 mL/h and advance by 10 to 25 mL/h every 4 to 8 hours until the desired goal is achieved. For intermittent administration, the typical recommendation is to start at 120 mL every 4 hours and advance by 30 to 60 mL every 8 to 12 hours.³⁵ In children, the recommendation for continuous administration is initiation of 1 to 2 mL/kg per hour or 20 to 25 mL/kg per bolus with advancement by 2 mL/kg per hour every 4 to 12 hours. In premature infants, feedings are initiated at lower rates usually 10 to 20 mL/kg per day. Schedules for progression of tube feeding from initial to target rates are important and may influence tolerance. If the protocol is too conservative, it may take an

excessively long period of time to reach nutrient goals. As previously discussed, the practice of diluting enteral feeding formulations is not routinely recommended unless necessary to increase fluid intake.³⁵ The development of an EN protocol within an institution that outlines initiation and advancement criteria may be a useful strategy to optimize achievement of nutrient goals.¹⁵ Such a protocol should allow nursing to advance the rate (i.e., 25 mL/h every 4 hours until goal rate achieved) based on GI tolerance. Clinical signs of intolerance include abdominal distension, abdominal cramping, high gastric residual volumes, aspiration, and diarrhea.

COMPLICATIONS AND MONITORING

The majority of complications associated with EN are metabolic, GI, and mechanical. The early detection and management of potential complications is necessary to allow for the successful use of EN. In addition, measures to avoid complications should be incorporated into the management of all patients receiving EN and require close monitoring (Table 146–7).

METABOLIC COMPLICATIONS

Metabolic complications associated with EN are similar to those associated with PN, but the incidence tends to be lower. EN is frequently administered at lower rates than PN, resulting in less risk of metabolic complications associated with overfeeding. In addition, EN is associated with the achievement of lower blood glucose concentrations than PN.⁶⁹ Complications related to hydration and electrolyte imbalance and altered glucose control are observed more

frequently in critically ill patients, especially those with underlying organ dysfunction. The micronutrient and water content within enteral feeding formulations are in fixed amounts intended to meet recommended dietary allowances for the average patient. Consequently, the frequency of clinical and laboratory assessment to monitor hydration, electrolyte, organ function, and glucose control adequately for a patient who is critically ill is greater than for a stable patient residing in a rehabilitation unit or at home. Patients receiving long-term EN at home may only require laboratory monitoring every 2 to 3 months, depending on their clinical status. In addition to macronutrient content, it is important to evaluate the actual content of water and micronutrients provided by the enteral formulations, especially in critically ill patients at high risk for metabolic complications. Supplemental fluid and electrolytes may be required in some patients. Conversely, for patients who have fluid retention or increased serum electrolytes, the enteral formulation may need to be changed to one that is more concentrated or provides less of a particular nutrient.

GASTROINTESTINAL COMPLICATIONS

6 The GI complications associated with tube feeding include nausea, vomiting, abdominal distension, cramping, aspiration, diarrhea, and constipation. A gastric residual volume refers to the volume of contents in the stomach and is measured by using a syringe and aspirating from a large-bore NG or gastrostomy tube. For patients receiving tube feeding into the stomach, gastric residual volumes are widely used as an indicator of tolerance. It is believed, although not well documented, that patients with high gastric residual volumes are at higher risk of vomiting and/or aspiration. The frequency of measuring gastric residual volumes generally varies between 4 and 8 hours, and most institutions follow a protocol that directs nursing to the frequency of monitoring and when to hold tube feeding.⁷⁰

TABLE 146-7 Suggested Monitoring for Patients on Enteral Nutrition (EN)

Parameter	During Initiation of EN Therapy	During Stable EN Therapy
Vital signs	Every 4–6 hours	As needed with suspected change (i.e., fever)
Clinical assessment		
Weight	Daily	Weekly
Length/height (children)	Weekly–monthly	Monthly
Head circumference (<3 y of age)	Weekly–monthly	Monthly
Total intake/output	Daily	As needed with suspected change in intake/output
Tube feeding intake	Daily	Daily
Enterostomy tube site assessment	Daily	Daily
GI tolerance		
Stool frequency/volume	Daily	Daily
Abdomen assessment	Daily	Daily
Nausea or vomiting	Daily	Daily
Gastric residual volumes	Every 4–8 hours (varies)	As needed when delayed gastric emptying suspected
Tube placement	Prior to starting, then ongoing	Ongoing
Laboratory		
Electrolytes, blood urea nitrogen/serum creatinine, glucose	Daily	Every 1–3 months
Calcium, magnesium, phosphorus	3–7 times/week	Every 1–3 months
Liver function tests	Weekly	Every 1–3 months
Trace elements, vitamins	If deficiency/toxicity suspected	If deficiency/toxicity suspected

CLINICAL CONTROVERSY

Clinicians argue about what constitutes an excessive gastric residual volume. In adults, the definition of a high residual volume ranges from greater than 200 mL to greater than 500 mL. In children, residual volumes greater than twice the bolus volume or twice the hourly infusion rate for continuous gastric feedings are considered excessive.

If high gastric residuals occur, the response is often to withhold the next scheduled tube feeding. However, frequent interruptions in the delivery of EN can adversely impact the attainment of nutrient goals. Because gastric residual volumes are unreliable, symptoms such as abdominal distension, fullness, bloating, and discomfort should also be assessed and they are generally more reliable indicators of EN intolerance. A trend in elevated gastric residual volumes is generally more important than an isolated high measurement. If symptoms are present and residual volumes are elevated, a decrease in tube feeding rate may be warranted. In general, abruptly stopping tube feeding should be reserved for patients with overt regurgitation or aspiration.⁷¹ Gastric residual volumes should generally be returned to the patient unless they are excessive (greater than 500 mL in adults).^{34,71} It may be beneficial to initiate a prokinetic agent such as metoclopramide to increase gastric emptying rate and decrease residual volume, thereby enhancing tolerance.^{34,72,73} If high gastric residual volumes persist, a transpyloric feeding tube may be considered for feeding into the small bowel. Other interventions may include a trial of a proton pump inhibitor or histamine₂-receptor antagonist to decrease the volume of gastric secretions, and minimizing the use of narcotics, sedatives, or other agents that may delay gastric emptying.^{34,35}

Aspiration pneumonia is considered the most serious complication associated with tube feeding and is potentially life-threatening. Although aspiration is a fairly common event for critically ill patients receiving tube feeding, progression to aspiration pneumonia is difficult to predict. Risk factors for aspiration include a previous aspiration episode, decreased level of consciousness, neuromuscular disease, structural airway or GI tract abnormalities, endotracheal intubation, vomiting, persistently high gastric residual volumes, and prolonged presence in the supine position.³⁴ Identification of these risk factors, along with close monitoring of gastric residual volumes, is recommended for the management of critically ill patients receiving tube feeding. Traditionally, blue food coloring had been added to enteral formulations in an attempt to detect aspiration. However, because of its low sensitivity for detection and association with several serious adverse events, including death, the addition of blue food dye to enteral formulations should no longer be used.^{34,74} An alternative to blue dye is to test the tracheobronchial secretions for glucose (the glucose oxidase strip method). This method assumes that the glucose concentration of these secretions is normally less than 5 mg/dL and that higher concentrations are consistent with aspiration of a feeding formulation. Unfortunately, false positives can occur using this technique as a result of blood in the specimen or when formulas containing low glucose concentrations (i.e., <200 mg/dL) are used.⁷⁵

Strategies to decrease aspiration risk include keeping the patient's head of the bed elevated to a 30° to 45° angle during feeding and for 30 to 60 minutes after intermittent boluses in addition to those mentioned above. This positioning makes it more difficult for the EN formulation to migrate up the esophagus against gravity. Changing from bolus or intermittent to continuous administration may also reduce the risk. Aspiration may also occur with improper feeding tube placement or displacement. Therefore regular assessment of tube position is recommended.³⁴

The reported incidence of diarrhea in patients receiving EN ranges from 20% to 70% because of the lack of a standard definition and the number of contributing factors.^{35,76,77} When monitoring for diarrhea, stool frequency, consistency, and volume should be evaluated and previous bowel habits should be considered. One commonly accepted definition of diarrhea is more than three to five liquid stools per day or more than 250 to 500 mL/day (10 mL/kg per day in children) stool output for at least 2 consecutive days.⁷⁶ A single loose stool does not constitute diarrhea or require intervention.

7 Diarrhea in patients receiving tube feeding may be caused by a number of factors and management should be directed at identifying and correcting the most likely cause(s). Tube feeding-related factors that may contribute to diarrhea include too rapid delivery or advancement of formula, intolerance to the formula composition, administering large volumes of feeding into the small bowel, and formula contamination. Measures to prevent or manage the development of diarrhea related directly to the tube feeding should address these potential causes.⁷⁷ If diarrhea occurs when using a fiber-free formulation, consider switching to a fiber-containing formulation. If using a high-fat formulation, it may be beneficial to switch to a formulation lower in fat or having a proportion of the fat supplied as MCTs. If protein malabsorption is suspected, switching from an intact protein to a peptide-based source may be beneficial. Avoid lactose-containing enteral formulations, although the majority of products designed for tube feeding are lactose-free. Finally, assess the risk of bacterial contamination of the formula and take steps to minimize any potential risk factors. Once infectious etiologies have been excluded, pharmacologic intervention may be required to control severe diarrhea, including the use of opiates, diphenoxylate, and loperamide.

A common cause of diarrhea that is unrelated to the tube feeding is drug therapy, particularly the use of broad-spectrum antibiotics. Another drug-related cause is the sorbitol contained in many liquid medication formulations. Sorbitol is used as a sweetening agent to

enhance palatability, but acts as an osmotic laxative. In addition, many drugs available in a liquid form are hyperosmolar, which may also contribute to diarrhea. Because many patients receiving tube feeding also receive medications in a liquid form, all medications should be evaluated for their potential contribution. Infectious causes of diarrhea, such as antibiotic-induced bacterial overgrowth by *Clostridium difficile* or other intestinal flora, need to be considered when diarrhea develops. Diarrhea also may occur as a result of malabsorption, secondary to the underlying disease state or condition.

MECHANICAL COMPLICATIONS

Mechanical complications of EN are those associated with the feeding tube, including tube occlusion or malposition, and nasopulmonary intubation. Feeding tube occlusion is usually a result of the improper administration of medications and/or flushing technique. Kinking of the tube also may cause occlusion. The tube should be flushed with at least 30 mL of water before and after administering any medication. The recommended volume used in children is generally less than 30 mL and depends on the size of the tube. The frequency of flushing should be at least every 8 hours during continuous feeding and before and after each intermittent feeding. If tube occlusion occurs, an attempt to irrigate the tube with warm water should be made. Other fluids such as colas and cranberry juice have been used to irrigate occluded tubes but have not been shown to be any better than warm water. Some success in reestablishing patency also has been shown with the use of pancreatic enzymes mixed in sodium bicarbonate.⁷⁸ In addition, declogging devices that are specifically designed to unclog feeding tubes are available. They have been designed to either mechanically break through or remove the occlusion or provide an applicator and syringe prefilled with pancreatic enzymes and various powders targeted to restore patency.

Inadvertent tube removal or displacement has been reported to occur in more than 50% of patients receiving enteral tube feeding.⁷⁹ An agitated or confused patient may pull at the feeding tube and cause its removal or malposition. Measures to decrease agitation and confusion should be attempted. Various manipulations done to the patient throughout the day may also cause malposition. Securing the tube with tape may be helpful, as well as marking the tube with permanent ink at the exit site to assess for change in position.

When a feeding tube is inserted nasally or orally, there is a risk that the tube may inadvertently enter the tracheobronchial tree. The risk may be higher in patients who have an impaired cough or gag reflex and when a stylet is used for tube insertion. Proper positioning of the tube should always be confirmed by radiography prior to feeding initiation to avoid inadvertent administration of enteral formula into the lung.

OTHER COMPLICATIONS

A unique complication of tube feedings in children, especially in the first year of life, is the development of feeding disorders as a consequence of oral hypersensitivity, poor oral/motor skills, and food aversion. In these children, transitioning from tube to oral nutrition is often difficult and protracted. The involvement of an occupational or speech therapist, behavioral psychologist, or other trained individual, as well as perseverance by the family, often is necessary to improve oral intake. Avoidance of a strict nothing by mouth (NPO) status, if possible, and oral stimulation programs for those children who must remain NPO are recommended to avoid this complication.⁸⁰

DRUG DELIVERY VIA FEEDING TUBE

Using enteral feeding tubes to deliver drugs is a common practice and offers an alternative for patients unable to take drugs by the oral

route. However, in addition to complications of tube occlusion, effects on drug bioavailability and other potential interactions need to be considered when using this route. Medications have been given as a concomitant bolus administration via the feeding tube or admixed with the enteral feeding formulation.

CONCOMITANT DRUG ADMINISTRATION

8 Concomitant administration of medications with enteral feedings requires awareness of certain limitations. Medications delivered directly into the stomach allow for the normal process of drug dissolution. Medications delivered into the small bowel may result in alterations of drug dissolution because the stomach is bypassed. In addition, therapeutic effect designed to occur within the stomach, such as with antacids and sucralfate, may be influenced by feeding tube route. Because many drugs are best absorbed in the fasted state, they should be administered on an empty stomach as much as possible. Patients receiving bolus gastric feedings may receive medications appropriately spaced between the feedings, but patients receiving continuous feeding will require interruption for drug administration.

Selecting the proper medication dosage form for coadministration with the tube feeding is another important consideration. Medications in sublingual form, sustained-released capsules or tablets, and enteric-coated tablets should not be crushed and therefore should not be administered via enteral feeding tubes. An extensive list of oral dosage forms that should not be crushed is available in the literature.^{81,82} Solid dosage forms that are appropriate to crush should be prepared as a very fine powder and mixed with 15 to 30 mL of water or other appropriate solvent before administering through the tube. In addition, the content of many capsules may be opened and administered in the same manner. Pellets contained inside microencapsulated dosage forms should generally not be crushed. It may be acceptable to administer intact pellets through the feeding tube, provided that the pellets are small enough and drug absorption is not compromised.^{83–85} To avoid the need to crush a solid dosage form and mix with water, liquid dosage preparations have been used for administration through the feeding tube. However, the risk of GI intolerance should be considered because of the hyperosmolality of the liquid formulation and possible sorbitol content.^{83,84} Although the use of a liquid dosage preparation may be more convenient than a solid dosage form, it may not be the best choice if GI intolerance is an issue.

As previously mentioned, adherence to proper flushing technique is necessary to prevent occlusion when administering medication

through a feeding tube. At least 30 mL of water in adults and usually 10 to 15 mL in children should be given before and after medication administration to clear the drug through the tube and help get the drug into the stomach. If more than one medication is scheduled for a given time, each should be administered separately and the tube should be flushed with at least 5 mL water between them.^{82,83,85}

ADMIXTURE OF DRUGS WITH ENTERAL FEEDING

Mixing liquid medications with certain enteral feeding formulations is associated with several types of physical incompatibilities, including granulation, gel formation, separation, and precipitation.^{82,83} Not only can these physical incompatibilities inhibit drug absorption, gel formation potentially may clog small-bore enteral feeding tubes. Physical incompatibility with medications is more common in formulations that contain intact protein than in those with hydrolyzed protein. Also, medication and enteral formula incompatibilities are more common with the use of acidic pharmaceutical syrups. The most prudent recommendation is to avoid the routine admixture whenever possible, especially for nonaqueous preparations and syrups. In the clinical setting, exceptions do exist, such as adding electrolyte injections of potassium or sodium to enteral formulas to assist in maintaining or replenishing electrolytes.

DRUG–NUTRIENT INTERACTIONS

9 The most significant drug and nutrient interactions that can occur during continuous enteral feeding are those in which the bioavailability of the drug is reduced and the desired pharmacologic effect is not achieved (Table 146–8). Unfortunately, limited clinical studies are available to document the extent of this problem with enteral feeding. Most of the observations are anecdotal case reports involving few patients. One of the most studied interactions has been the interaction between phenytoin and enteral feeding that results in decreased phenytoin bioavailability. The interaction was first reported in 1982,⁸⁶ yet the precise mechanism for the interaction remains unclear. Phenytoin serum concentrations may decrease by as much as 50% to 75% when phenytoin is given concomitantly with EN, possibly as a result of the binding of phenytoin to calcium caseinates or protein hydrolysates in the enteral formulation. Patients typically require higher than normal phenytoin doses while receiving EN.^{83,84,87} The patient’s clinical response and phenytoin serum concentrations should be monitored closely if phenytoin is given enterally during continuous enteral feeding and after its discontinuation.

TABLE 146-8 Medications with Special Considerations for Enteral Feeding Tube Administration

Drug	Interaction	Comments
Phenytoin	Reduced bioavailability in the presence of enteral nutrition Possible binding of phenytoin to calcium caseinates or protein hydrolysates in enteral feeding	A suggestion to minimize interaction is to hold tube feeding 1–2 hours before and after phenytoin, but this has no proven benefit Adjust tube feeding rate to account for time held for phenytoin administration Monitor phenytoin serum concentrations and clinical response closely Consider switching to IV phenytoin route if unable to reach therapeutic serum concentration Consider holding tube feeding before and after administration Avoid jejunal administration of ciprofloxacin Monitor clinical response
Fluoroquinolones Tetracycline	Potential for reduced bioavailability because of complexation of drug with divalent and trivalent cations found in enteral feeding	Adjust warfarin dose based on international normalized ratio Anticipate need to increase warfarin dose when enteral feedings are started and decrease dose when enteral feedings are stopped
Warfarin	Decreased absorption of warfarin because of enteral feeding; therapeutic effect antagonized by vitamin K in enteral formulations	Granules become sticky when moistened with water and may occlude small-bore tubes Suggested that granules be mixed with acidic liquid when given via a gastric feeding tube An oral liquid suspension can be extemporaneously prepared for administration via a feeding tube ^a
Omeprazole Lansoprazole	Administration via feeding tube complicated by acid-labile medication within delayed-release, base-labile granules	

^aFrom references 89 and 90.

CLINICAL CONTROVERSY

A number of methods to minimize the interaction between phenytoin and continuous enteral feeding have been suggested, but no consensus exists. Some clinicians choose to hold the feeding for 1 to 2 hours before and after phenytoin administration to minimize the interaction. But because this has not been proven effective and may result in suboptimal nutrition, others choose not to interrupt the feeding. Regardless of the method used, serum concentration monitoring is imperative.

Decreased bioavailability of certain antibiotics, particularly quinolones, has been documented when coadministered with enteral feeding.^{83–85,88} Although the practice of holding tube feeding for 30 minutes before and 30 minutes after quinolone administration has been recommended, it has not been shown to ultimately improve drug absorption. There is evidence to suggest that ciprofloxacin absorption is significantly decreased when given via a jejunostomy tube, so this practice should be avoided.⁸⁸ Warfarin resistance has been documented during enteral feeding, possibly as a consequence of decreased absorption or the antagonist effects of vitamin K. Prior to 1980, it was thought that the content of vitamin K (up to 1,330 mcg/1,000 kcal of enteral feeding formula) was contributing to the pharmacologic interaction with warfarin. Subsequently, the vitamin K content within formulas intended for use in adults was reformulated to less than 200 mcg/1,000 kcal. However, warfarin resistance continues to be reported and a warfarin dosage increase may be required in patients receiving EN.^{83,84} The patient's international normalized ratio should be closely monitored in patients receiving both warfarin and enteral feedings. Conversely, when EN is discontinued, a reduction in warfarin dose may be required.

NUTRITION OUTCOME GOALS

Nutrition outcome goals of EN are to promote an adequate nutritional state in adults and promote growth and development of infants and children. Assessing the outcome of EN includes monitoring objective measures of body composition, protein and energy balance, and subjective outcome for physiologic muscle function and wound healing. Besides an improvement in nutrition outcome, another goal of EN is to reduce disease-related morbidity and mortality. Measures of disease-related morbidity include length of hospital stay, infectious complications, and the patient's sense of well-being. Such clinical outcome goals are extremely difficult to document with the use of EN, in part because other factors such as age, underlying comorbidities, extent of injury, immunocompetence, and end-organ complications also affect disease outcome. However, no disease process improves significantly with prolonged starvation. Ultimately, the successful use of EN can avoid the need for PN in patients unable to meet nutrient requirements with an oral diet.

PHARMACOECONOMIC CONSIDERATIONS

EN has consistently been shown to be less expensive than PN. The pharmacoeconomic comparison between EN and PN should include an evaluation of therapeutic outcome relative to the cumulative cost associated with providing the therapy. Therapy costs should include costs related to placement and maintenance of enteral or parenteral access; costs of nutrients and related supplies; the time spent by professional staff in ordering, compounding, delivering, administering, and managing therapy; costs of laboratory monitoring; and costs of managing complications that result from therapy. However, it is very difficult to capture all of these costs and separate cost from charge-based estimates. None of the existing pharmacoeconomic

analyses incorporate all costs related to EN and PN therapy, but selected cost comparisons derived from clinical research trials in institutional settings have been published.^{91–93} The cost of EN has been reported to be approximately 25% to 50% that of PN. Incorporating the cost of managing complications related to therapy greatly increases the overall cost of PN compared with EN.⁹³ In situations in which improved outcome has not been demonstrated with PN, EN appears preferable on a cost basis.⁷

ABBREVIATIONS

ARA: arachidonic acid
DHA: docosahexaenoic acid
EN: enteral nutrition
FDA: Food and Drug Administration
MCT: medium-chain triglyceride
NG: nasogastric
NPO: nothing by mouth
PEG: percutaneous endoscopic gastrostomy

Nutritional Considerations in Major Organ Failure

BRIAN M. HODGES AND MARK DELEGGE

KEY CONCEPTS

- 1 Carbohydrate calories absorbed and protein lost via renal replacement therapy must be accounted for when designing a parenteral or enteral nutrition regimen for patients with renal failure.
- 2 Administration of renally excreted or regulated electrolytes, such as potassium, magnesium, and phosphorus, should be limited in patients with renal failure unless refeeding syndrome is present or continuous renal replacement therapies are used.
- 3 Hyperglycemia is common in cirrhosis. Patients with fulminant hepatitis are, however, instead prone to hypoglycemia.
- 4 Folic acid and thiamine supplementation is important in patients with liver disease for the prevention of anemia and Wernicke's encephalopathy, respectively.
- 5 In short-bowel syndrome, parenteral nutrition should be used to meet nutritional needs in the immediate postoperative period after intestinal resection.
- 6 Increased fluid and electrolyte replacement is often necessary in short-bowel syndrome patients to replace gastrointestinal losses. Patients may need increased calcium, magnesium, zinc, and other trace elements because of decreased absorption and/or excessive gastrointestinal losses.
- 7 Patients with ileal resection commonly develop vitamin B₁₂ deficiency, necessitating therapy with parenteral cyanocobalamin.
- 8 As small-bowel adaptation occurs, some short-bowel syndrome patients receiving parenteral nutrition can be transitioned successfully to enteral nutrition. Early initiation of enteral intake affects adaptation because intraluminal nutrients are a stimulus for this process.
- 9 Care should be taken to avoid overfeeding of patients with respiratory failure, as excessive carbon dioxide production may limit the patients' ability to have mechanical ventilation discontinued.
- 10 Excessive fluid administration should be avoided in patients with pulmonary disease because it may worsen already compromised pulmonary function.

Because organ failure may alter absorption, use, and excretion of nutrients, administration of standard nutrients to patients with organ dysfunction may be inappropriate. Individualization of a nutritional regimen for these patients often requires a planned, disease-specific approach. Different laboratory testing or more frequent monitoring of traditional markers may be necessary to ensure that the desired therapeutic goals are achieved. For example, it is impossible to collect a 24-hour urine specimen to measure urea nitrogen and nitrogen balance in an anuric patient. In this situation, an alternative method of calculating urea nitrogen appearance is required.

Patients with acute organ failure requiring nutrition support often are hospitalized in intensive care units (ICUs). With advances in treating chronic organ failure, increasing numbers of older, chronically ill patients will require nutritional support on a long-term basis. It therefore will become increasingly common for nutrition support to be provided in community and ambulatory settings. Regardless of the setting, the clinician needs a firm pathophysiologic foundation on which to build a pharmaceutical care plan to ensure appropriate outcomes for patients requiring nutritional support.

This chapter discusses the nutritional needs of patients with renal, hepatic, gastrointestinal, and pulmonary failure. The predominant approaches to ensure delivery of safe and efficacious nutrients to patients with these disorders are critically reviewed.

RENAL FAILURE

Major differences exist between the metabolic, fluid, and electrolyte management of patients with acute renal failure (ARF) versus those with stable chronic kidney disease (CKD) and those with an ARF episode that complicates preexisting CKD. For example, positive nitrogen balance is more difficult to achieve in patients with ARF because of the increased rate of protein catabolism. Additionally, patients with ARF are more likely to develop hyperglycemia during nutritional support and frequently are dialyzed by modalities that are not used commonly for the patient with end-stage kidney disease. Because of these differences, the nutritional management of patients with ARF is discussed separately.

ACUTE RENAL FAILURE

Epidemiology

ARF, as defined in Chap. 45, is a decrease in glomerular filtration rate occurring over hours to weeks that is associated with an increase in the serum concentrations of waste products, such as urea and creatinine. ARF has been observed in as many as 5% of hospitalized patients, and in up to 50% of patients receiving care in an ICU.¹ The mortality rate of ARF patients who require renal replacement therapy ranges from 40% to as high as 70%. A recent study in Austria demonstrated that despite the recent advancements made in renal

Learning objectives, review questions,
and other resources can be found at
www.pharmacotherapyonline.com.

replacement therapies and ICU care, the mortality rate of patients was still 62.8%.² Severe malnutrition has been documented in 42% of patients with ARF and is an independent predictor of in-hospital mortality and increased morbidity from sepsis, shock, dysrhythmias, and acute respiratory failure.³ Because malnutrition is an important apparently independent contributor to mortality in patients with ARF, nutrition support remains a cornerstone in the treatment of these patients, despite a lack of evidence demonstrating improvement in patient survival.^{1,4}

Pathophysiology

Energy Requirements ARF does not itself change patient energy requirements. Energy requirements in ARF are greatly influenced by comorbid critical illness and the types of renal replacement therapies used.^{4,5} Energy requirements in this patient population ideally should be measured by indirect calorimetry (see Chap. 143) because energy expenditures of patients with ARF are highly variable. Energy expenditure is close to normal in patients with uncomplicated ARF, but resting energy expenditure (REE) increases of up to 30% have been reported in the presence of sepsis and ARF.⁶ Typically, ARF patients without underlying hypermetabolic conditions should receive 20 to 30 kcal/kg per day. Those with underlying hypermetabolic conditions, such as thermal injury or head injury, usually need even greater caloric intake, up to 35 kcal/kg per day, unless indirect calorimetry indicates otherwise.⁷ Patients with stage 4 or 5 chronic kidney disease and acute metabolic illness or injury should receive similar energy provisions.⁵ Increasing energy provision beyond this to 40 kcal/kg/day is not associated with better nutritional outcomes and has been associated with more frequent metabolic complications.⁸

Carbohydrate Hyperglycemia and peripheral insulin resistance are common in ARF. These patients usually have a superimposed illness that exacerbates glucose intolerance. The etiology of glucose intolerance in ARF is thought to be a result of increased levels of glucagon, growth hormone, and catecholamines—all known antagonists of insulin. Other proposed mechanisms include an elevated glucagon-to-insulin ratio secondary to impaired degradation of these hormones and elevated secretion of inflammatory cytokines.

Fat Intolerance to intravenous lipid emulsion (IVLE), evidenced by increased serum triglyceride concentrations, is common in ARF. Hypertriglyceridemia is thought to be caused by decreased catabolism of triglycerides and increased triglyceride synthesis from free fatty acids.¹ Hepatic triglyceride lipase and peripheral lipoprotein lipase activity may be reduced significantly in ARF patients.⁶ Insulin resistance and metabolic acidosis may contribute to this process by inhibiting lipoprotein lipase.⁹ Triglyceride concentrations therefore should be measured before administering IVLE to patients with ARF.

Protein ARF is associated with marked protein catabolism and urea accumulation. Most patients with ARF have a primary stressful illness that results in ureagenesis, and thus protein breakdown is accelerated. Protein catabolism in ARF may be stimulated as the result of insulin resistance, metabolic acidosis, circulating proteases and inflammatory mediators, and the effects of uremic toxins.¹ The mechanism may be direct, via modulation of protein synthesis, or indirect, by inhibiting the action of anabolic hormones. Unlike healthy patients or those with CKD, protein catabolism in the presence of ARF is not significantly attenuated by the administration of exogenous nutrition support.⁴

Significant amounts of protein and amino acids are also removed by dialysis. Amino acid losses of 5.2 g per conventional hemodialysis (HD) treatment, 7.3 g per high-flux HD session, and up to 13 to 16 g/day during continuous renal replacement therapy (CRRT) have been reported.¹⁰ In one study, CRRT removed urea nitrogen to the same degree as functionally normal kidneys.¹¹ The clearance of histidine and tryptophan are enhanced, whereas the clearance of

phenylalanine and valine are reduced in nondialyzed patients with ARF.¹² In patients undergoing CRRT, glutamine represents roughly one-third of all amino acid dialysate losses. Serum glutamine concentrations decrease significantly early during CRRT, but may return to baseline subsequently, suggesting altered glutamine metabolism early in the course of CRRT.¹³

Fluid, Electrolyte, and Acid–Base Disorders The volume status of patients with ARF depends primarily on residual urine output and the type of dialysis received, if any. The patient with oliguric ARF will have impaired excretion of sodium and water. In nonoliguric ARF, considerable sodium may be lost in the urine, necessitating replacement to maintain sodium balance. This also applies to the patient who is losing considerable gastric fluids. Patients on CRRT will lose sodium via hemofiltration or dialysis and should be given sodium as part of their CRRT replacement fluid regimen. To maintain sodium balance, most replacement fluids contain between 140 and 154 mEq sodium/L. The rate of administration of these fluids varies based on the type of CRRT, the rate of ultrafiltration, and the patient's clinical condition.¹⁴

Hyperkalemia is observed frequently in ARF secondary to protein catabolism and intracellular potassium release, as discussed in Chap. 54. Hyperkalemia also results from the impaired secretion and excretion of potassium by the kidney and the endogenous release secondary to tissue breakdown. If this is severe, emergent dialysis may be indicated. Patients on CRRT, however, usually require potassium replacement to avoid hypokalemia as a consequence of the significant dialytic potassium losses.

Because phosphorus is excreted renally, hyperphosphatemia is common in ARF. Like potassium, large amounts of phosphorus are released into the circulation secondary to tissue breakdown during ARF. Control of hyperphosphatemia is important because as the calcium-phosphorus product (serum calcium in milligrams per deciliter multiplied by serum phosphorus in milligrams per deciliter) exceeds 55, the risk of developing metastatic calcification increases (see Chap. 53). Conversely, with initiation of dialysis, particularly CRRT, patients must be monitored for dialysis-induced hypophosphatemia. Hypophosphatemia may also be observed in patients with acute or chronic renal failure who continue to receive oral phosphate binders despite decreased oral phosphorus intake.

The net removal of calcium during the continuous dialysis modalities depends on the calcium concentration of the dialysate fluid. Severe hypocalcemia has been reported when regional citrate anticoagulation has been used for CRRT in ARF and hepatic failure patients.¹⁴

Hypermagnesemia is less common than other electrolyte abnormalities, but can occur in ARF secondary to impaired excretion and endogenous release from tissue breakdown. Both magnesium and calcium losses via CRRT have been quantified recently: average daily losses were 24 mmol and 70 mmol of magnesium and calcium, respectively.¹¹

Patients with ARF usually have metabolic acidosis because of impaired excretion of organic acids. If potassium and sodium are needed in the parenteral nutrition (PN) regimen, they should be added as acetate salts, which are converted to bicarbonate in the liver. This increase in bicarbonate partially compensates their metabolic acidosis. Intermittent and continuous dialytic therapies also may help improve the metabolic acidosis accompanying ARF by increasing the removal of these endogenously generated acids, as well as by increasing serum bicarbonate levels as the result of diffusion from the dialysate into the blood. Correction of acidosis was greatest when lactate buffers (lactate > bicarbonate > acetate) were used in one study employing continuous venovenous hemofiltration.¹⁵

Trace Elements The requirements for trace elements during nutritional support of ARF patients are not well established because trace element accumulation or losses during ARF have not been character-

ized. Additionally, many of the trace element alterations in ARF may represent an “acute-phase reaction.”⁹⁷ Zinc and chromium are excreted by the kidney and theoretically can accumulate because of reduced excretion and increased intake secondary to impurities in dialysate or intravenous fluids. In ARF patients undergoing CRRT, zinc intake via nutrition support exceeds patient losses.¹¹ Selenium concentrations are reduced in ARF patients and may result in a decrease in thyroxine concentrations.^{16,17} Because manganese and copper are excreted in bile and zinc and copper are removed by peritoneal dialysis (PD) and HD, most ARF patients receiving PN should receive trace element supplementation; in addition, some recommend that additional selenium supplementation may be necessary.^{4,17} Doses of 50 to 70 mcg/day may be necessary to maintain selenium balance.⁷

Vitamins Little information is available concerning alterations in vitamin requirements in ARF, and the known changes require monitoring but not routine changes to patient treatment.¹⁸ Losses of vitamins via dialysis also must be considered. Traditional HD clears several water-soluble vitamins such as folic acid, vitamins C and B₁₂, and pyridoxine, but not the highly protein-bound vitamins A and D.¹⁹ Significant reductions in the plasma concentrations of water soluble vitamins have also been observed in patients receiving CRRT.^{13,17} Currently, it seems prudent to administer vitamins at least daily in doses recommended by the Nutrition Advisory Group of the American Medical Association for patients receiving PN (see Chap. 145).⁷ Administration of ascorbic acid should be restricted to 50 to 100 mg/day to offset losses caused by renal replacement therapies, but to avoid secondary oxalosis which may worsen renal function.^{5,20} If the enteral route is used for nutritional support, vitamin administration should at least meet the recommended daily allowances.

TREATMENT

Acute Renal Failure

■ DESIRED OUTCOME

The maintenance of lean muscle mass and prevention of disorders of macro- and micronutrient excess or deficiency are the primary goals in the nutritional management of the patient with ARF. Although it has yet to be proven that nutrition support is associated with a reduction in mortality of patients with ARF, the secondary goals of nutrition therapy are to optimize immunocompetence and

promote wound healing. Additionally, the attenuation of the inflammatory state, metabolic derangements, and alterations of the patient's antioxidant capacity should also be considered in the design of specialized nutrition support for patients with ARF.⁴

■ GENERALIZED APPROACH TO TREATMENT

Enteral nutrition (EN) is the preferred route of nutrient delivery in patients with ARF.^{4,5} The products used frequently during EN are the calorically dense, electrolyte-free or electrolyte-reduced formulas.²¹ These formulas are useful in patients with fluid overload, hyperkalemia, hypermagnesemia, and hyperphosphatemia. EN is well tolerated by many patients with ARF,²² and is associated with improved maintenance of gastrointestinal tract function and survival in nonrandomized studies of patients with ARF.^{2,23} It is recommended that EN be used, even if PN must be used as a supplement to meet the patient's nutritional needs. Unfortunately, because of the high incidence of gastrointestinal complications, many patients may not tolerate EN and thus require PN support.²

■ PHARMACOLOGIC THERAPIES

Drug Treatments of First Choice

Patients with ARF and comorbid hypermetabolism typically require 25 to 35 kcal/kg per day.²⁴ Increasing energy provision beyond this does not improve nutritional outcomes and is associated with increasing metabolic complications and a greater net fluid imbalance.⁸ A relatively conservative initial estimate of patient energy needs is appropriate since the result of slightly underfeeding the patient are far less serious than those associated with overfeeding.^{4,25}

① In the absence of dialysis, the nutritional formula should be concentrated in a small volume and contain minimal sodium (Table 147-1). In the oliguric patient who is receiving renal replacement therapy, these restrictions may be less rigorous, but the formula generally will need to be concentrated.⁵ When using these high-dextrose-concentration formulas, careful monitoring of glucose homeostasis (every 6 hours) is important because the maintenance of euglycemia has been associated with improved clinical outcomes of critically ill adults.²⁵ Additionally, CRRT, which is increasingly popular in the treatment of ARF (see Chap. 45), contributes significant calories to a nutritional regimen. This is a direct result of the absorption of glucose from the dialysate or ultrafiltrate replacement fluids: net uptakes of up to 355 g/day have been reported.¹³ Total glucose intake should range from 3 to 7 g/kg/day.⁵

TABLE 147-1 Empiric Parenteral Nutrition Formulas for Patients with Organ Failure

	Acute Renal Failure	Chronic Renal Failure	Hepatic Failure	Short Bowel	Pulmonary Failure
Dextrose (%) ^a	40	30	25	20	20
Crystalline amino acids (%) ^a	Variable	4	5 ^b	5	5
Lipids (%) ^a	1	2	2	2	3
NaCl (mEq/L)	0	0	0	80 ^c	10
Na acetate (mEq/L)	0	30	0	0	0
Na phosphate (mEq/L)	0 ^d	7.5	15	7.5	30
K acetate (mEq/L)	0 ^d	0	50	60	20
K chloride (mEq/L)	0	10	0	0	20
Ca gluconate (mEq/L)	5 ^d	5	5	10	5
Magnesium sulfate (mEq/L)	0 ^d	6	16	10	5
Multivitamins (mL/day)	10	10	10	10	10
Zinc (mg/day)	3	3–6	8	10	3
Copper (mg/day)	1.2	1.2	<1.2	1.2	1.2
Manganese (mcg/day)	300	300	<300	≤300	300
Chromium (mcg/day)	12	12	<12	20	12
Selenium (mcg/day)	—	40	40	60	40

^aFinal concentrations after admixture.

^bHepatamine 4% when criteria for use are met.

^cDoes not include 0.45% sodium chloride injection or lipid.

^dThe continuous renal replacement therapies frequently require variable additions of electrolytes.

ARF is not a contraindication to IVLE use, despite the changes in lipid metabolism. When the serum triglyceride concentration is less than 300 mg/dL, IVLE is recommended to prevent essential fatty acid deficiency and to provide a balanced caloric intake. Typically, doses of less than 1 g fat/kg per day will not significantly worsen triglyceride concentrations.⁷ Current recommendations call for patients to receive between 0.8 and 1.2 g/kg/day, but no more than 1.5 g/kg/day.⁵

Although individual patient assessment for presence of hypercatabolism and dialytic losses is necessary, it is not uncommon for patients to require 2.5 g/kg per day of protein or more to achieve a positive nitrogen balance.²⁶ Protein restriction, to reduce the urea nitrogen appearance rate from exogenous protein intake, should not be used unless the ARF is thought to be temporary (e.g., expected to resolve in 7 to 10 days) and hypercatabolism is not present.^{5,7,24} Once dialysis therapy is instituted, protein intake should be liberalized to 1 to 1.5 g/kg per day for noncatabolic patients and at least 1.5 g/kg per day for hypercatabolic patients.²⁴ Patients undergoing CRRT with hypermetabolism may need to receive 1.5 to 1.8 g/kg/day²⁴ or more (up to 2.5 g/kg/day) to achieve positive nitrogen balance.²³ The safety and efficacy of this aggressive strategy remains to be confirmed before it can be routinely recommended.^{5,27}

CLINICAL CONTROVERSY

There is debate as to the most appropriate protein provision for patients with ARF who are receiving CRRT. Although initial data has shown an association between higher protein intake (up to 2.5 g/kg/day) and improved survival, many express concern about the effectiveness and safety of this practice.

② Several electrolytes (i.e., phosphorus, magnesium, and potassium) warrant special attention in patients with ARF.⁵ During early ARF, PN solutions should not contain potassium unless the patient is hypokalemic or undergoing CRRT. After several days, the serum potassium concentrations tend to decrease, often necessitating cautious addition of potassium to the PN solution. If the enteral route is used, formulas with minimal potassium may be needed. Serum potassium concentrations may decrease more rapidly in patients receiving CRRT. Potassium losses during CRRT are proportional to the potassium gradient between blood and dialysate. Therefore cautious additions of potassium may be considered early in the course of ARF for those patients treated with CRRT. Serum magnesium concentrations do not decrease as quickly as potassium concentrations in patients receiving electrolyte-free nutrition regimens. As serum concentrations decrease toward normal and/or renal function returns, magnesium should be added to the PN solution in small amounts (4 to 6 mEq/L).

Phosphorus can be omitted from the nutritional formula of patients receiving PN until the phosphorus level approaches normal (<5 mg/dL). It is prudent to monitor phosphorus concentrations daily and to add phosphorus in small doses once the serum concentration is below 4 mg/dL. Failure to do so can lead to severe hypophosphatemia (see Chap. 53) despite continued renal failure, especially in the patient who is treated with CRRT. Patients with persistently high serum phosphorus concentrations who have a functional gastrointestinal tract can be prescribed phosphate-binding therapy (see Chap. 47) and enteral feedings low in phosphorus to minimize the absorption of exogenous phosphorus.

Alternative Drug Treatments

Standard mixed amino acids rather than essential amino acid solutions should be used.^{5,24} Improved survival and return of renal function were observed decades ago when essential amino acids plus

glucose were compared with glucose alone in patients with ARF. This led to the marketing of parenteral amino acids containing predominantly or solely essential amino acids. These products were formulated on the hypothesis that significant nitrogen reuse (urea recycling) occurs during ARF to synthesize nonessential amino acids. Subsequently, several prospective, double-blind studies have indicated no significant reduction in mortality when the essential amino acid formulations were used.^{1,5,24}

■ PHARMACOECONOMIC CONSIDERATIONS

While analyses of total costs of ARF care have been published,²⁸ no specific research has yet been published assessing the cost-effectiveness of nutrition support in patients with ARF. Some authors, however, extrapolate the results of critical care nutrition studies²⁹ indicating that EN results in significant cost savings compared to PN to strengthen their recommendation that EN should be preferred over PN.^{1,4,22}

■ EVALUATION OF THERAPEUTIC OUTCOMES

Although the clinical and quality-of-life (QOL) outcomes for patients with ARF have been reported, data specifically analyzing the effects of nutrition support are limited.²⁸ To date, there is no clear consensus regarding the degree of benefit, if any, of nutrition support on the outcome parameters of renal recovery or mortality. Data suggest that malnourished ARF patients experience significantly higher mortality rates (odds ratio of in-hospital mortality of 7.21) than ARF patients without malnutrition.³ In one retrospective analysis EN was associated with a survival benefit, even when controlling for severity of illness.² No prospective studies to date show a survival benefit from aggressive nutritional support in patients with ARF. When nutrition support is used, the evaluation tools used in monitoring ARF patients are similar to those used for other patients receiving PN and EN (see Chaps. 145 and 146).

CHRONIC KIDNEY DISEASE

CKD is defined by either structural or functional damage to the kidneys that is present for at least 3 months (see Chap. 46). Malnutrition secondary to reduced oral nutrient intake frequently is evident when the glomerular filtration rate drops below 20 to 25 mL/min. Stage 5 CKD has been associated with inflammatory and metabolic changes that increase the likelihood of malnutrition and increased nutrient losses have been documented in those receiving hemodialysis and peritoneal dialysis. Because of its chronicity, malnutrition in these patients is treated most frequently in the ambulatory setting with oral nutritional supplements and EN.

Epidemiology

Protein-energy malnutrition is very common in patients with CKD and is a significant predictor of morbidity and mortality. Significant malnutrition has been noted in 28% to 48% of predialysis patients, in 9% to 72% of patients undergoing HD, and in up to 45% of patients commencing PD.^{30,31} In one of the larger studies to date (n = 1,397), mean dietary calorie and protein intake in those 50 years of age and older was 22 kcal/kg per day and 0.9 g/kg per day, respectively.³² Both these values are lower than published recommendations for patients with CKD.³³ Protein-energy malnutrition and wasting at initiation of dialysis is a significant predictor of morbidity and mortality in most studies of patients with stage 5 CKD.³⁰ However, there appears to be a gender difference in nutritional status in stage 5 CKD patients: women tend to have a higher prevalence of malnutrition³¹ and poorer nutritional outcomes, yet a lower mortality rate.³⁴

Pathophysiology

Carbohydrate In general, stage 5 CKD patients are not as nutritionally stressed as patients with ARF; however, more than one-half of stage 5 CKD patients have insulin resistance and hyperglycemia. This is attributed to the increased glucagon-to-insulin ratio, resulting in protein breakdown and gluconeogenesis. In patients with normal peritoneal transport on peritoneal dialysis, roughly 60% of glucose in the dialysate is absorbed. One method of estimating the quantity of glucose absorbed is as follows: glucose absorbed (g/day) = $0.89x$ (g/day) – 43, where x is the total amount of dialysate glucose instilled daily. This dialysate glucose absorption can worsen existing hyperglycemia and contribute significantly to the patient's energy intake, making kwashiorkor-type malnutrition common. Although glucose control is not problematic unless the patient is diabetic, infected, or subjected to operative stress, insulin can be added to chronic ambulatory peritoneal dialysis bags to control hyperglycemia (see Chap. 48).

Fat Hypertriglyceridemia is common in stage 5 CKD patients. This is mainly a result of decreased catabolism of triglycerides secondary to decreased hepatic lipoprotein lipase activity.³⁵ Most stage 5 CKD patients receiving HD also receive heparin, which activates lipoprotein lipase and converts triglycerides to free fatty acids and glycerol. Carnitine, an amino acid necessary for the transport of long-chain fatty acids across mitochondria where oxidation results in energy production, is removed by HD and PD, and therefore serum carnitine concentrations typically are reduced in stage 5 CKD.³⁶

Current guidelines do not advocate carnitine administration for the treatment of hypertriglyceridemia.³⁷ Studies of carnitine for this indication have varied widely in duration and have used both oral and intravenous administration in varying doses (1 mg/kg to 2 g/day intravenously, 10 mg/kg per day to 3 g/day orally).

Leptin, which is produced and secreted by fat cells, regulates satiety and energy balance (see Chap. 148). Leptin concentrations often are elevated in stage 5 CKD patients, particularly those undergoing PD probably as the result of decreased renal degradation of leptin and increased production as the result of chronic inflammation. Hyperleptinemia in CKD is associated with decreased protein intake and weight loss. Further study is required to better define the relationship between leptin concentrations and nutrition status in patients with CKD.^{38,39}

Protein Secondary analysis of the Modification of Diet in Renal Disease Study indicated that in nondiabetics, a reduction of dietary protein intake may slow the rate of renal disease progression and ultimately delay the onset of dialysis (see Chap. 46).⁴⁰ The recent National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF K/DOQI) guidelines for nutrition in patients with CKD recommend a diet providing 0.6 g/kg of protein per day for those with a glomerular filtration rate of less than 25 mL/min.³⁷ Although the safety of low-protein diets has been questioned, it has been suggested that for carefully selected and monitored patients, protein intakes of as low as 0.3 g/kg per day supplemented with essential amino acids can be used safely.^{5,24}

Stage 5 CKD patients receiving PD require special attention as a consequence of protein losses across the peritoneal membrane. Peritoneal protein losses typically range from 5 to 15 g/day in PD patients.³⁷ PD protein losses, however, do not predict risk for malnutrition (as measured by serum albumin concentration) in all patients.³⁷ The American Society for Parenteral and Enteral Nutrition (ASPEN) and K/DOQI guidelines suggest that dietary protein intake of at least 1.2 to 1.3 g/kg per day (at least 50% of high biologic value) is needed to consistently achieve neutral or positive nitrogen balance in nonacutely ill peritoneal dialysis patients and clinically stable HD patients.³⁷ Dialysate protein losses also must be considered for the stage 5 CKD patient undergoing HD. The amount of protein

lost via HD depends on the dialysis membrane used and whether the dialyzer is being reused. Typical losses are 10 to 12 g per dialysis session, but this may be increased by up to 50% with dialyzer reuse.³⁷

Fluid and Electrolytes Hyponatremia, often due to overhydration, is common in CKD patients (see Chap. 52). Regular dialysis is the principal means for control of body water and serum sodium concentration in the stage 5 CKD patient. Patients with CKD who develop hyperkalemia generally have ingested excessive potassium relative to the potassium-removing capacity of the failing kidney (and dialysis, in the case of stage 5 CKD patients). The undernourished CKD patient receiving PN, however, may require considerable potassium as new body cell mass is synthesized.

Patients with CKD often are treated for hyperphosphatemia with phosphorus-restricted diets and phosphate binding agents (see Chaps. 46 and 47). When these patients receive aggressive nutritional support, the combination of refeeding (cellular uptake of phosphorus for synthesis of body cell mass) and vigorous phosphate-binding therapy can result in hypophosphatemia.

Metabolic acidosis, a common complication of stage 5 CKD, is associated with increased protein degradation and decreased synthesis of albumin.³⁷ Correction of acidosis in stage 5 CKD patients may be associated with increases in serum albumin, body weight, and midarm muscle circumference, and fewer hospitalizations.⁴¹ Stabilization of serum bicarbonate concentrations (>22 mEq/L) via alteration of the dialysate bicarbonate concentration or administration of oral bicarbonate salts is a prudent nutritional intervention in these patients (see Chaps. 47 and 55).

Trace Elements There are considerable data regarding trace element requirements in patients with stage 5 CKD.¹⁹ Decreased zinc concentrations have been linked to taste disturbances and sexual dysfunction. Zinc supplementation, however, does not universally reverse these anomalies. Although serum concentrations of this trace element are decreased, total body stores of zinc in stage 5 CKD often are increased. This suggests a redistribution of zinc or increased need to maintain normal enzymatic function in stage 5 CKD patients.

Serum chromium concentrations are elevated in chronic HD and peritoneal dialysis patients, perhaps because the needles used during HD and the peritoneal and hemodialysate fluids are sources of chromium. Both HD and peritoneal dialysis patients have decreased selenium concentrations that can be increased with oral selenium supplements of 135 to 140 mcg/day in HD patients.⁴² It appears that for patients undergoing HD, significant selenium losses occur during dialysis.¹⁹

Vitamins Vitamin status is better defined in CKD patients than those with ARF. CKD patients are prone to develop water-soluble vitamin deficiencies because of decreased dietary intake secondary to anorexia and restriction of many foods because of their protein, potassium, or phosphorus content. Additionally, in the stage 5 CKD patient, HD losses of ascorbic acid, folic acid, and pyridoxine are common. Plasma ascorbic acid concentrations are usually normal in PD patients. This decrease was recently associated with increased cardiovascular morbidity and mortality.⁴³ The highly protein-bound vitamins (A, D, and B₁₂) are not removed significantly by HD.¹⁹ Vitamin D deficiency is correlated with decreased serum albumin concentrations, and supplementation of vitamin D has increased serum albumin concentrations significantly in deficient patients.⁴⁴ Vitamin A concentrations often are elevated in CKD and can lead to hypervitaminosis A and its cirrhosis-like syndrome. Conversely, vitamin E supplementation may have a distinct benefit to patients with stage 5 CKD. Increased oxidative stress in Stage 5 CKD patients may contribute to the accelerated atherosclerosis. Vitamin E in doses of 800 international units per day decreases low-density lipoprotein oxidation in patients with stage 5 CKD, especially in patients under-

going peritoneal dialysis.⁴⁵ Thiamine concentrations decrease during dialysis; supplementation within the daily recommended intake recommendations is sufficient to keep concentrations in the normal range. Hyperhomocysteinemia is common in patients with stage 5 CKD. Folate doses from 2.5 mg three times weekly to 60 mg/day have lowered homocysteine concentrations in stage 5 CKD patients, but have not completely reduced concentrations to normal. In patients with stage 3 to 4 CKD, elevated homocysteine concentrations are associated with increased cardiovascular risk. In patients with stage 5 CKD, lower homocysteine concentrations are associated with an increased risk of cardiovascular events. It is thought that in these patients, ongoing malnutrition and inflammation suppress homocysteine concentrations while continuing to accelerate atherosclerosis.⁴⁶

TREATMENT

Chronic Kidney Disease

DESIRED OUTCOMES

Goals of nutrition support in CKD are similar to those in other patient populations, with only a few additional considerations because of the metabolic derangements that are commonly observed. Prevention of undernutrition and maintenance of lean body mass are of primary importance. Other goals include correction and prevention of metabolic disorders, maintenance of electrolyte homeostasis, minimization of CKD progression, and preservation of optimal gastrointestinal structure and function.⁵ The ultimate goal of nutritional interventions, considering the strong relationship between malnutrition and morbidity and mortality in CKD is to optimize patient survival.³⁰

GENERAL APPROACH TO TREATMENT

Nutrition support for CKD patients can usually be managed with oral supplementation or EN. These patients rarely need PN because their gastrointestinal tract is usually functional. Guidelines for nutrition support have been developed by NKF K/DOQI, ASPEN, and the European Society for Parenteral and Enteral Nutrition (ESPEN) (Fig. 147-1).^{5,24,37} The calorically dense low-electrolyte (potassium, phosphorus, magnesium) enteral formulas are particularly useful. Even though stage 5 CKD patients receive regular dialysis, many are anuric between dialysis sessions, so excess fluid intake is a potential problem. Nepro, Magnacal Renal, Nutren Renal, and Re/Gen are marketed specifically (because of their high caloric density and low electrolyte content) for the stage 5 CKD patient who receives HD or PD.²¹ Suplena and Renalcal Diet, which are lower in protein, should be used for protein-restricted CKD patients who are not yet undergoing dialysis. If there is superimposed illness that precludes EN, balanced amino acid products should be used as the protein component of PN formulations. There is no data supporting the use of essential amino acid parenteral formulations.

NONPHARMACOLOGIC THERAPIES

Nutritional interviews, diaries, and counseling are essential parts of the nutrition support plan for CKD patients. The NKF K/DOQI guidelines stress the importance of renal dietetic interventions, and recommend that patients maintain 3-day dietary diaries intermittently and discuss the results with their dietary care provider. These interventions are conducted to optimize the quantity and quality of patient energy and protein intake. In other populations, such interventions with frequent nutritional counseling have resulted in increased adherence to the recommended dietary intake.³⁷

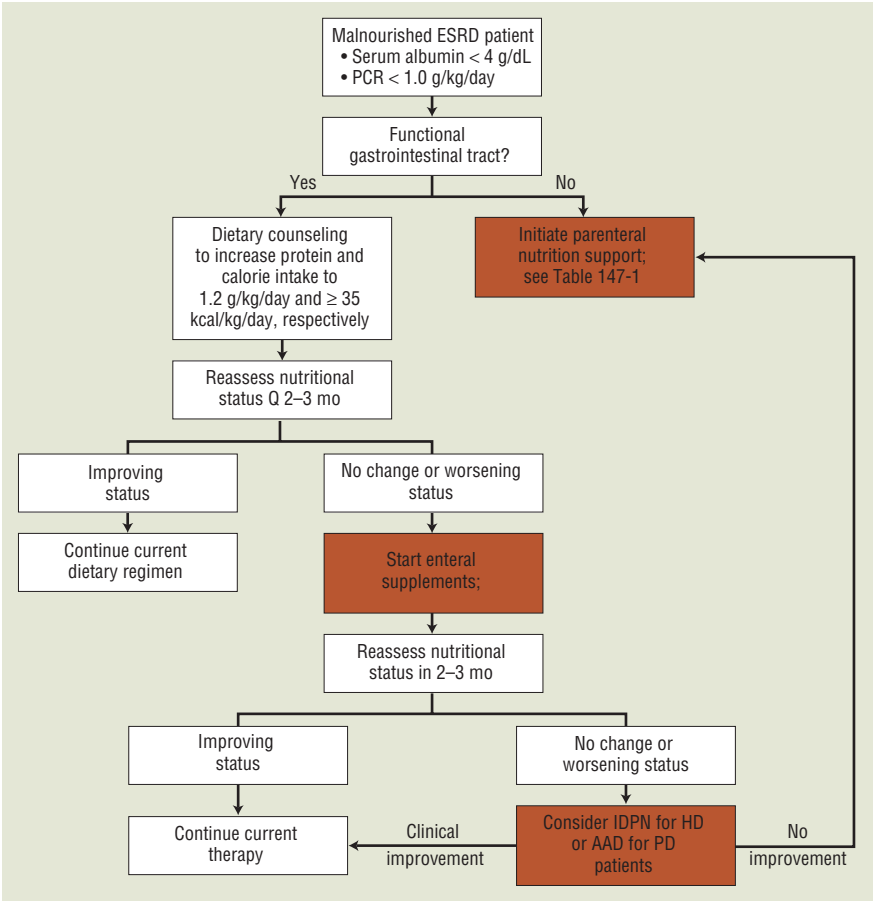

FIGURE 147-1. An algorithmic approach to nutritional support in the patient with end-stage renal disease. (AAD, amino acid dialysate; CAPD, continuous ambulatory peritoneal dialysis; ESRD, end-stage renal disease; IDPN, intradialytic parenteral nutrition; HD, hemodialysis; PCR, protein catabolic rate.)

■ PHARMACOLOGIC THERAPIES

Drug Treatments of First Choice

Current recommendations from NKF K/DOQI that factor in concurrent illnesses and the likelihood of preexisting malnutrition advocate 35 kcal/kg per day and 1.2 g/kg per day of protein for chronic HD patients <65 years of age and 1.2 to 1.3 g/kg per day of protein for chronic peritoneal dialysis patients.³⁷ This is higher than the spontaneous dietary intake in most dialysis patients. This emphasizes the importance of dietary counseling to encourage compliance with current dietary recommendations especially for patients with concurrent hypercatabolic illnesses.

In patients who cannot achieve recommended dietary intake goals, several studies have examined the effect of oral or enteral nutritional supplementation on nutritional outcomes. A systematic review of these studies reveals that oral supplementation or EN is associated with significant increases in energy and protein intake and serum albumin concentration.³⁰ No significant increase in metabolic or electrolyte imbalances were noted. However, no significant differences in CKD patient morbidity or survival were noted.

Several electrolytes warrant special attention for the CKD patient. Generally, sodium should be administered to CKD patients during nutritional support only to replace losses in order to avoid overhydration. Examples of initial daily supplementation can be found in Tables 147-1 and 147-2, and may be adjusted based on the patient's serum sodium concentration and fluid balance. Although these patients also are predisposed to hyperkalemia, once anabolism is attained, potassium requirements may be as high as 40 to 80 mEq/day. This dose needs to be given carefully and requires serum potassium concentration monitoring. Clinically significant hypermagnesemia is less common in patients with CKD than with ARF. It is usually added to the PN solution in reduced doses (4 mEq/L).

Patients with ESRD or stage 5 CKD often are treated for hyperphosphatemia. With aggressive nutritional support, the combination of refeeding and phosphate-binding therapy can result in hypophosphatemia. Decreasing or temporarily discontinuing the phosphate-binding therapy is appropriate if this occurs. Thereafter conservative amounts of phosphorus may need to be administered.

Some practitioners advocate withholding trace elements from CKD patients receiving PN. Others recommend the administration of standard dietary intake of trace elements, because serum concentrations in stage 5 CKD patients of certain trace elements are normal (e.g., manganese) and others are decreased (e.g., zinc and selenium).¹⁹ Additional zinc and selenium supplementation may be considered in documented cases of deficiency.⁵

During PN, avoidance of vitamin A is recommended. Dialytic losses of ascorbic acid, folic acid, and pyridoxine are common. Thus stage 5 CKD patients should receive ascorbic acid 50 to 100 mg/day, pyridoxine 5 to 10 mg/day, and at least 1 mg/day folic acid in addition to the other essential vitamins.¹⁹ Typical PN and EN prescriptions for a patient with stage 5 CKD are presented in Tables 147-1 and 147-2, respectively.³³ Figure 147-1 is an algorithmic approach to improve nutritional status and ensure optimal outcomes integrating recommendations from NKF K/DOQI, ASPEN, and ESPEN.^{5,24,37}

Alternative Drug Treatments

Poor nutritional intake due to anorexia and impaired gastrointestinal motility have led to research assessing the impact of appetite stimulants and prokinetic agents on nutritional outcomes in patients with CKD. The use of the appetite stimulant megestrol acetate and prokinetic agent metoclopramide are associated with increases in serum albumin in patients with CKD.⁴¹ Further research is needed to better define the effect and optimal dosing if their use is to be applied more widely for nutritional intervention in CKD.

The association of poor nutritional status and increased morbidity and mortality in stage 5 CKD has led to the development of alternative nutritional delivery systems for the Stage 5 CKD patient. One such approach is intradialytic parenteral nutrition (IDPN), or the provision of glucose-amino acid-lipid admixture during HD. IDPN typically allows for the infusion of 650 to 1,100 kcal per session (250 mL of 50% to 70% dextrose and 250 mL of 10% to 20% lipids) and 50 to 90 g of protein (500 mL of 10% to 15% amino acids).⁴⁷ An evidence-based evaluation of 24 studies employing IDPN found that the use of IDPN was associated with decreased mortality, but only 3 of the 24 studies were randomized. Because of the limitations of presently available data, IDPN should be reserved for malnourished patients who have serum albumin <3.4 g/dL, weight loss >10% of ideal body weight, dietary history of intake of <25 kcal/kg per day, and who failed attempts at oral supplements and enteral tube feedings or who are not appropriate for such attempts.^{24,48}

Amino acid dialysate is the IDPN counterpart for the PD patient. This technique entails using a 1.1% amino acid solution in place of one or two of the dextrose-containing PD exchanges per day. Improvements in serum transferrin and total protein concentrations have been observed in malnourished PD patients; however, no beneficial effect has been noted on patient mortality. Adverse effects of this therapy have included exacerbations of uremic symptoms (because of increases in blood urea nitrogen) and metabolic acidosis. In the longest study to date, amino acid dialysate was associated with improved maintenance of albumin and cholesterol concentrations, but no significant difference in morbidity or mortality.⁴⁹ In summary, amino acid dialysate may be useful in the treatment of malnourished PD patients, but better-designed studies are needed.

Recombinant human growth hormone (rhGH) in doses of 0.2 international unit/kg per day subcutaneously has been used experimentally in adults with stage 5 CKD to enhance anabolism; weight gain and increased transferrin concentrations have been reported after 4 weeks.⁵⁰ Despite these gains, rhGH associate sodium and water retention, and the fact that its effects may be lessened by catabolic illness or decreased dietary intake limit its utility. In the future there may be a role for rhGH or other anabolic agents in the treatment of stage 5 CKD patients who have inadequate oral intake despite appropriate dietary counseling and oral supplements.⁴¹

■ PHARMACOECONOMIC CONSIDERATIONS

There is no data demonstrating the economic value of nutrition support in patients with CKD. The lone published report indicates that a very-low-protein diet supplemented with essential amino acids may result in cost savings compared to a low-protein diet, as a

TABLE 147-2 Initial Enteral Nutrition Prescription for Patients with End-Stage Renal Disease

Nutrient	Recommendation
Nonprotein calories	35 kcal/kg per day for HD 35 kcal/kg per day PD (including calories from glucose absorption from dialysate)
Protein	1.2 g/kg IBW for HD 1.2–1.3 g/kg IBW for PD
Sodium	2–3 g/day for HD ^a 2 g/day for PD ^a
Potassium	2,000–2,500 mg/day ^a
Phosphorus	800–1,000 mg/day ^a
Calcium	<2,500 mg/day total intake ^a
Fluid	1,000 mL + daily urine output for HD To maintain appropriate fluid balance for PD

CAPD, continuous ambulatory peritoneal dialysis; HD, hemodialysis; IBW, ideal body weight.

^aIndividualized based on patient's laboratory values.

Data from references 5 and 38.

TABLE 147-3 Routine Nutritional Monitoring in Patients with End-Stage Renal Disease

Parameter	Frequency
Predialysis serum albumin	Monthly
Percentage of usual postdialysis or postdrain body weight	Monthly
Subjective global assessment	Every 6 months
Protein equivalent of total nitrogen appearance (PNA) ^a	Monthly for HD, every 3–4 months for PD
Dietary interview and/or diary	Every 6 months
Predialysis prealbumin	As needed
Anthropometry	As needed
Dual-energy x-ray absorptiometry	As needed

BUN, blood urea nitrogen; PD, peritoneal dialysis; HD, hemodialysis.
^aBeginning of week PNA = $Co/[36.3 + (5.48)(spKt/V) + (53.5/spKt/V)] = 0.168$, where Co is predialysis BUN and spKt/V, the single-pool index of hemodialysis adequacy = $\ln(R - 0.08 \times t) + [4 - (3.5 \times R)] \times UF/W$ (R is postdialysis:predialysis BUN ratio, t is dialysis session in hours, UF is ultrafiltration in liters, and W is postdialysis weight in kilograms). (See Chap. 48.)

result of a significant decrease in erythropoietin requirements in the very-low-protein group.⁵¹

EVALUATION OF THERAPEUTIC OUTCOMES

The short- and long-term monitoring plan for the stage 5 CKD patient receiving PN or EN needs to be carefully tailored. Special attention should be paid to maintenance of fluid and electrolyte homeostasis. This can be achieved via frequent (daily) monitoring of serum electrolyte concentrations (e.g., sodium, potassium, phosphorus, magnesium, and calcium) and fluid balance. Serum glucose concentrations should be followed frequently (four times daily) in those who develop persistent hyperglycemia.

Because protein-energy malnutrition is a significant predictor of morbidity and mortality in stage 5 CKD patients, monitoring to ensure the effectiveness of the long-term nutritional plan becomes critical. Increased serum albumin concentrations are correlated with increased survival and thus monitoring of serum albumin concentrations is recommended for all HD and PD patients (Table 147–3).

HEPATIC FAILURE

The liver is the primary organ involved in the digestion, metabolism, and storage of nutrients. When functional capacity is depressed, profound nutrient intolerance (hyper- or hypoglycemia, hypertriglyceridemia, and hepatic encephalopathy) may result. Other sequelae that accompany the failing liver are fluid and electrolyte imbalances, vitamin deficiencies, and malnutrition. It is estimated that 65% to 90% of patients with advanced liver disease and almost 100% of patients awaiting liver transplantation have some degree of malnutrition, which increases morbidity and mortality. Nutritional support is an important component of the overall care of the patient with liver disease that may decrease complications and extend survival.⁵²

EPIDEMIOLOGY

It is estimated that 30% of cirrhotic patients have protein-energy malnutrition, 40% have protein malnutrition, and 10% have energy malnutrition.⁵³ Changes in body composition such as decreases in body cell mass may be seen in early phases of the disease, and become more severe as cirrhosis progresses. In general, there is no significant difference in the incidence of malnutrition between

those with cirrhosis caused by alcoholism and those with postviral cirrhosis. One study, however, found that abstinent patients with alcoholic cirrhosis had lower average measures of nutritional adequacy than those with cirrhosis caused by chronic hepatitis C.⁵⁴

PATHOPHYSIOLOGY

Energy

A decrease in spontaneous oral intake is quite common in patients with cirrhosis and appears to be multifactorial in nature. Potential causes of decreased oral intake include altered taste, early satiety as a result of ascites and/or hyperleptinemia, impaired motility and bacterial overgrowth in the small intestine, malabsorption as a consequence of gastrointestinal dysfunction and treatment with neomycin or lactulose, nausea, and chronic encephalopathy.^{24,52}

Resting energy requirements in stable cirrhotics can appear to be normal, but approximately one-third are hypometabolic and one-third are hypermetabolic when energy expenditure is corrected for alterations in lean body mass.⁵² The Harris-Benedict equation for estimating caloric needs usually underestimates their needs by 15% to 20%.⁵⁵ The marked variability in energy expenditure underscores the need for patient-specific regimen design and monitoring, and may suggest the need for indirect calorimetry testing.⁵² An initial energy provision of 35 to 40 kcal/kg per day is recommended by ESPEN for patients with alcoholic steatohepatitis and liver cirrhosis.⁵⁶

Carbohydrate

3 In healthy adults, approximately 60% of absorbed glucose is taken up by the liver and used for glycogen synthesis, triglyceride synthesis, and glycolysis. In general, glycogen synthesis and glycolysis are enhanced by insulin, whereas gluconeogenesis and glycogen breakdown are controlled by glucagon. Hyperglycemia is common in cirrhosis as a result of peripheral insulin resistance, which is mediated by a decreased binding to insulin receptors and defective postreceptor signal handling in peripheral tissues. Plasma concentrations of insulin are elevated with or without a glucose stimulus. This makes administration of large doses of glucose problematic because administration of insulin to control hyperglycemia may not improve its utilization substantially.

Patients with fulminant hepatitis are prone to hypoglycemia because hepatic glucose production is depressed secondary to decreased glycogen stores, diminished gluconeogenesis, and impaired degradation of insulin. A continuous intravenous infusion of 5% dextrose usually prevents hypoglycemia in acute hepatitis, but concentrations greater than 10% dextrose may be needed in more severe cases.

Fat

The liver is responsible for synthesis of cholesterol, high-density lipoproteins, and very-low-density lipoproteins. The enzymes lipoprotein lipase and lecithin-cholesterol acyltransferase are synthesized in the liver. Increased serum triglyceride and free fatty acid concentrations are thus encountered in patients with hepatic failure, primarily as a result of the increased lipolysis. The significant insulin resistance that can be seen in cirrhosis causes a shift to lipids as a primary fuel source.⁵² Whereas only 35% of total calories are derived from fat in normal patients after an overnight fast, this can increase to 75% in patients with cirrhosis.⁵⁵ Incorporation of late-evening snacks in patients with liver cirrhosis may correct abnormal substrate metabolism, increase carbohydrate metabolism, and decrease fat oxidation rates.^{57,58}

Patients with severe liver failure may be at increased risk for essential fatty acid deficiency; the ratio of nonessential to essential fatty acids was found to be increased in patients with acute and

chronic liver failure. Poor oral intake of fat and dietary fat malabsorption in patients with cirrhosis both contribute to essential fatty acid deficiency.⁵⁹ The concentrations of linoleic acid can be increased with administration of an average of 33 g/day of IVLE supplementation.⁶⁰ Despite concerns of impaired clearance of long-chain triglycerides in IVLE as a consequence of impaired synthesis of apoprotein CII in cirrhotic patients, IVLE solutions have been given safely to patients with fulminant hepatic failure.⁶¹

Diarrhea and steatorrhea are common in patients with hepatic cholestasis because of intestinal malabsorption (partly as a result of mucosal edema from hypoalbuminemia), inadequate bile acid delivery to the duodenum, and pancreatic dysfunction with decreased secretion of lipase.⁵⁵ Because the micelle formation is impeded, the long-chain fatty acids pass through the colon, resulting in a foul-smelling, soapy diarrhea.

Protein

Nitrogen requirements for the patient with liver failure are similar to those of normal subjects, but intolerance to protein may limit the achievement of this goal. Thus some have advocated restriction of dietary protein intake. Recent research indicates, however, that protein restriction is not beneficial for patients with cirrhosis even in the midst of episodic hepatic encephalopathy.⁶²

CLINICAL CONTROVERSY

The need for protein restriction in patients with hepatic encephalopathy has been questioned. While it has been a standard practice in the past, newer data has revealed that reducing protein intake to <1.2 g/kg/day in medically optimized patients with episodic encephalopathy may be unwarranted.

Because the liver metabolizes the aromatic amino acids (i.e., phenylalanine, tyrosine, and tryptophan), methionine, and glutamine, the plasma concentrations of these amino acids are elevated in cirrhotic patients. Plasma concentrations of the branched-chain amino acids (i.e., valine, leucine, and isoleucine) often are depressed because these amino acids are metabolized by skeletal muscle. This altered plasma aminogram most likely contributes to the development of hepatic encephalopathy.

Fluid and Electrolytes

Patients with severe cirrhosis often have ascites and peripheral edema. The excess of total body sodium in the presence of an even greater excess of total body water results in hyponatremia. Salt and fluid restrictions are required to avoid exacerbating this overhydrated state (see Chap. 52).

Hypokalemia is common in patients with liver failure who have normal renal function. Poor nutritional intake and vomiting may initiate this disorder. Severe vomiting may also lead to volume contraction metabolic alkalosis, with increased renal excretion of potassium (see Chap. 55). Secondary hyperaldosteronism, a common finding in liver failure patients with intravascular volume depletion, also increases renal excretion of potassium. Loop diuretic therapy causes increased renal excretion of potassium, whereas diarrhea from lactulose therapy increases fecal excretion of potassium. All these conditions can lead to profound hypokalemia. Therefore, potassium requirements in liver failure patients receiving specialized nutritional support may be substantially larger than those in otherwise healthy adults.

Poor nutritional intake secondary to alcohol abuse and increased excretion of magnesium secondary to diuretic therapy contribute to hypomagnesemia. Even in cirrhotic patients with normal serum magnesium concentrations, muscle magnesium is depleted and inde-

pendently associated with hepatic encephalopathy.⁶³ During nutrition support, requirements for phosphorus are also substantially elevated because synthesis of body cell mass occurs, placing this population at risk for developing hypophosphatemia during refeeding.

Trace Elements

Many patients with liver failure have a malabsorption syndrome and chronic diarrhea. Chronic diarrhea causes zinc deficiency. Cytokines, such as tumor necrosis factor, interleukin-1, and interleukin-6, may stimulate metallothionein, an intestinal zinc-binding protein, thereby further inhibiting zinc absorption. Thus patients with chronic diarrhea should be suspected of having zinc deficiency; measurement of serum concentrations, however, are rarely used to confirm such deficiencies. Patients receiving a protein-restricted diet may be at additional risk because substantial amounts of zinc are found in red meat.

Because copper and manganese are excreted in the bile, it has been recommended that these two trace elements not be administered or be administered in reduced doses to patients with serious cholestasis. Direct measurements of manganese in the globus pallidus of cirrhotic patients who died in hepatic coma were two- to sevenfold higher than expected. These findings suggest that reduced quantities of manganese should be provided in the nutritional formulation to avoid exacerbating encephalopathy in the patient with chronic liver disease. There are no prospective evaluations, however, demonstrating benefits of low copper or manganese diets.

An association between alcoholism and low serum selenium concentrations has been reported. Because selenium is important in maintaining the enzyme glutathione peroxidase, a deficiency of this trace element has been implicated as a cause of hepatic injury in the alcoholic patient. However, because human serum contains at least three fractions of selenium, the use of serum selenium concentrations as a marker for selenium deficiency is controversial. At this time, maintaining a daily selenium intake of 40 mcg is the most appropriate approach in patients with chronic liver disease.

Vitamins

④ Folic acid deficiency may lead to megaloblastic anemia, whereas thiamine deficiency may result in Wernicke's encephalopathy after rehydration with intravenous glucose. Depletion of hepatic stores of vitamin A, pyridoxine, folic acid, riboflavin, pantothenic acid, vitamin B₁₂, and thiamine have been reported in patients with hepatic failure. Poor intake and malabsorption are the principal causes of vitamin deficiencies in patients with chronic liver disease.

Because vitamin D is metabolized to 25-hydroxyvitamin D in the liver, low concentrations of this vitamin are seen in patients with biliary cirrhosis. Impaired absorption of dietary vitamin D as a consequence of decreased bile production may also contribute to these low serum concentrations and the resultant osteoporosis. The most appropriate approach at this time is to provide the daily recommended intake of these vitamins and consider additional supplementation when a deficiency is documented.

TREATMENT

Hepatic Failure

■ DESIRED OUTCOMES

The primary objective of nutrition support in patients with cirrhosis is the provision of the recommended amounts of energy and protein. Adequate nutrition support may slow disease progression, prevent morbidity, enhance the structure and function of the gastrointestinal tract, and decrease mortality.^{52,56}

FIGURE 147-2. An algorithmic approach to nutritional support for the patient with hepatic failure.

■ GENERAL APPROACH TO TREATMENT

Enteral nutrition is preferred in patients with cirrhosis when the gastrointestinal tract is functional and accessible (Fig. 147-2). The recommendations in this figure are based on guidelines from ASPEN and ESPEN.^{24,56} The indications for PN in the patient with liver failure are similar to those for general hospitalized patients. Because EN can contribute to hyperammonemia in cirrhotic patients with transjugular intrahepatic portosystemic shunts,⁶⁴ the use of PN in such patients might be preferable. In most cases, PN in the patient with liver failure can be accomplished via the administration of standard mixed amino acids (Fig. 147-2).

■ NONPHARMACOLOGIC THERAPIES

Dietary counseling makes patients aware of the risks that malnutrition poses for the progression of their disease and can provide strategies for patients to attain goal intakes, while being mindful of dietary restrictions. Many patients will have a higher likelihood of maintaining normal substrate utilization if they eat four or five small meals a day and a snack at bedtime. At least one study has found that intensive counseling is equivalent to providing oral nutritional supplements in increasing patient intake.⁵² Cirrhotic patients may also derive up to a 26% increase in energy intake and a significant increase in lean body mass by receiving a transjugular intrahepatic portosystemic shunt.⁶⁵

There is considerable interest in the use of vegetable-protein diets in the chronic management of patients with cirrhosis and hepatic encephalopathy. Enthusiasm for this therapy is based on the reduced amounts of aromatic amino acids and methionine in vegetable protein and a decrease in nitrogen absorption as the result of a decreased gastrointestinal transit time and an increase in fecal nitrogen excretion by colonic bacterial flora. However, compliance is more difficult to achieve with vegetable-based than animal-based protein diets. ASPEN recommends that a diet with vegetable-based protein be considered for those patients who do not tolerate at least 1 g/kg/day of protein from their normal diet.²⁴

■ PHARMACOLOGIC THERAPIES

Drug Treatments of First Choice

In patients with liver disease who are unable to meet their nutritional needs despite dietary counseling, ESPEN guidelines recommend that EN be initiated with a goal of providing 35 to 40 kcal/kg/

day and protein intake of 1.2 to 1.5 g/kg/day.⁵⁶ Indirect calorimetry quantification may be preferred to empiric estimates of caloric requirements in this setting. Excessive calorie provision actually may promote liver dysfunction and increased production of carbon dioxide with an associated increased work of breathing. Standard whole-protein formulas are recommended, but more concentrated formulations are appropriate to avoid excessive fluid overload in patients with ascites.⁵⁶

When dextrose-based PN is started in those who cannot tolerate EN, additional thiamine may be needed to prevent Wernicke's encephalopathy. Standard mixed amino acids are appropriate for most patients. IVLE should be used in patients with liver failure only to prevent essential fatty acid deficiency when initial serum triglyceride concentrations exceed 300 mg/dL. If serum triglyceride concentrations are low or normal, IVLE may be used as a calorie source. Monitoring serum triglyceride concentration and free fatty acid oxidation (not available in all facilities) to ensure that lipid is both cleared and oxidized appropriately has been suggested. Oral medium-chain triglycerides have been used occasionally with success because they do not require pancreatic enzymes or micelle formation before absorption. However, these products do not provide essential fatty acids.

The electrolytes that warrant the most careful monitoring in liver disease include sodium, potassium, phosphorus, and magnesium. During fluid and salt restriction, patients (especially those receiving concurrent lactulose therapy for encephalopathy) should be observed for symptoms of volume depletion (e.g., increased pulse rate, decreased blood pressure, or dry mucous membranes). Magnesium concentrations as high as 24 mEq/L in the PN solution, which is two to three times the standard daily dose, may be required to maintain concentrations in the normal range.

Trace elements that warrant individual attention include zinc, copper, and manganese. For patients receiving PN, withholding copper from the solution until a copper serum concentration in the normal range is documented or the cholestasis resolves may be appropriate. Patients who have chronic cholestasis may require copper in reduced doses (e.g., 0.6 mg/day); however, they should have serum copper concentrations checked regularly (once per month in the acute care setting and every 6 months in the ambulatory setting). Manganese restriction also may be required in these patients. Table 147-4 lists the nutritional requirements of patients with liver failure secondary to cirrhosis and Table 147-1 presents an empiric PN formula for the patient with hepatic failure.^{55,61}

TABLE 147-4 Nutrition Recommendations for Patients with Liver Disease

Patient Type	Calorie Energy (kcal/kg/day)	Protein (g/kg/day)	Comments
Compensated cirrhosis	25–35	1–1.2	Use a bedtime snack and frequent small meals
Decompensated cirrhosis ^a	25–35	0.5–1.5 for mild; 0.5 for severe	Use branched-chain amino acids for refractory cases of encephalopathy unresponsive to protein restriction
Decompensated cirrhosis ^a with malnutrition	35–40	1.5	May have to temporarily decrease protein for encephalopathy worsening

^aDecompensated cirrhosis: cirrhosis accompanied by significant ascites or encephalopathy.

Alternative Drug Treatments

The major controversy in nutritional support of the patient with liver failure has centered on the use of protein products. Modified amino acid solutions for PN (e.g., HepatAmine) are marketed for patients with liver failure and hepatic encephalopathy. They are enriched with branched-chain amino acids and have reduced amounts of aromatic amino acids and methionine. These products are formulated on the basis of the false neurotransmitter hypothesis, which postulates that hepatic encephalopathy may be a result of increased aromatic amino acid concentrations in the central nervous system.

NutriHep, a supplement for patients with hepatic encephalopathy, meets vitamin and mineral requirements, contains a high percentage of medium-chain triglycerides, and is supplemented with carnitine. Clinical trials using this and other branched-chain amino acid products have yielded promising outcomes, including decreases in morbidity and mortality. These results, however, have not been consistent. Enteral products with branched-chain amino acids also result in significant nonadherence because of poor taste.⁵² This, coupled with the increased cost of these products, has led ASPEN and ESPEN to recommend reserving these products for patients with severe encephalopathy who decompensate on standard protein formulations despite continued lactulose-neomycin therapy.^{24,56}

■ PHARMACOECONOMIC CONSIDERATIONS

Nutritional supplementation in patients with alcoholic cirrhosis reduces the frequency of hospitalizations.⁶⁶ Intuitively, this should be a cost-saving intervention, but without formal analysis the degree of benefit cannot be proven or quantified.

■ EVALUATION OF THERAPEUTIC OUTCOMES

Weight, albumin concentration, and prealbumin concentration are commonly used markers of nutrition status that may not be as reliable in patients with hepatic failure. Ascites, edema, and impaired hepatic protein synthesis make nutritional evaluation difficult in this patient population. Indeed, many of the commonly used markers of nutritional status correlate poorly with body cell mass in those with end-stage liver disease. Subjective global assessment, prognostic nutritional index, bioelectrical impedance, midarm muscle circumference, and handgrip strength have been tested as predictors of body cell mass.⁵² Handgrip strength best correlates with malnutrition and is a better predictor of major complications in patients with cirrhosis.⁶⁷

SHORT-BOWEL SYNDROME

Short-bowel syndrome (SBS) is generally a consequence of significant surgical resection of the small bowel that results in the malabsorption of nutrients and fluids. Morbidity and mortality caused by gastrointestinal failure in SBS patients has been improved with the provision of PN and EN. The goal of nutritional support with EN and PN is to maintain nutritional status, prevent or correct nutritional deficiencies, and enhance quality of life.⁶⁸

EPIDEMIOLOGY

There are at least 10,000 patients who have SBS in the United States.⁶⁹ The most common etiologies in adults are surgical resections because of Crohn's disease, mesenteric vascular disease, and cancer. In infants, necrotizing enterocolitis, midgut volvulus, and intestinal atresia are the most common etiologies for resection leading to SBS.⁶⁹ SBS occurs more commonly in women than in men, most likely as a consequence of women having less small intestine length at baseline. This condition also may be functional as opposed to anatomic and occur in individuals who have not had resections, but who have a decreased small bowel absorptive capacity as a result of etiologies such as radiation enteritis or severe inflammatory bowel disease.⁶⁸ Symptoms of SBS generally include diarrhea, dehydration, electrolyte disturbances, and progressive malnutrition.⁶⁹

PATHOPHYSIOLOGY

The average length of the small intestine, where the majority of nutrients are absorbed, in adults is 400 to 600 cm. The American Gastroenterological Association considers a patient to have SBS when the patient has 200 cm or less of functional small intestine.⁷⁰ Losing this absorptive capacity leads to deficiencies in multiple nutrients, requiring the initiation of interventional nutrition.

5 PN must be used at least immediately following resection of the small intestine while the gastrointestinal tract is healing and adapting. Enteral nutrition may be used later during the transition to oral feedings, as the gastrointestinal tract is able to adapt with time, by increasing absorptive capacity, in approximately 50% of patients with SBS.⁶⁹ The length and type of nutritional support a patient may require is based on such factors as the length of remaining small intestine and the presence or absence of a functional colon. Adult patients have the highest likelihood of transitioning off of PN if the residual jejunum-ileum length is greater than 100 cm for individuals without a colon, or greater than 60 cm if a portion of the colon is in continuity with the remaining small intestine.⁷¹ Factors that are predictive of a poor outcome include older age, disease in the residual bowel, and removal of the ileocecal valve, the physiologic sphincter that controls the rate of passage of intestinal contents from small to large bowel and prevents small bowel bacterial overgrowth.⁷²

Intestinal Adaptation

The adaptation process of the residual small intestine to compensate for the loss of the resected area begins 24 to 48 hours after bowel resection and may continue to occur for 1 to 2 years.⁷³ Several factors act as stimuli for adaptation including enteral nutrients, pancreatic-biliary secretions, and intestinal hormones.²⁴ The ability of the remaining intestine to adjust after resection is also influenced by the area of bowel loss. The jejunum is the primary site for absorption of most nutrients, but if it is removed the ileum usually can accommodate and take on the structural characteristics and functional roles. Even with this compensation, patients with less than 50 to 60 cm of jejunum typically need indefinite PN. With ileal resection, the jejunum has a decreased capacity to adapt and perform the functions of the ileum.⁷³

Energy Requirements

Caloric intake and energy needs of SBS patients are variable. Individuals who have lost more than 50% of their small intestine typically require 25 to 30 kcal per kg of ideal body weight, and when receiving enteral feedings, may need to ingest twice that number of calories to compensate for malabsorption.^{70,74} This process is referred to as *adaptive hyperphagia*.⁷⁵ The average recommendation for patients with SBS who are receiving PN is also 25 to 30 kcal/kg of ideal body weight per day.⁷⁰

Carbohydrate

Carbohydrate malabsorption plays a major role in diarrhea associated with SBS. Unabsorbed carbohydrates, especially simple carbohydrates, represent a substantial osmotic load in patients with SBS and are associated with an increased output. In patients with an intact colon, however, soluble fiber and complex carbohydrates are broken down by colonic bacteria to short-chain fatty acids, hydrogen, and methane. This fermentation causes flatulence; however, the colon is able to use the short-chain fatty acids as a source of energy. Thus, complex carbohydrates may provide a significant caloric source for patients with a massive resection and a preserved colon.⁷¹

Fat

Fat malabsorption also is common in SBS. The pathophysiology of this problem is complex and related to alterations in pancreatic enzyme secretion and bile salt absorption. The ileum is the major site of the latter process, and with its removal, bile salt malabsorption is common. Eventually, the total bile salt pool may be depleted, resulting in increased fat malabsorption and steatorrhea.⁶⁹ There has been much debate regarding the restriction of oral fats, which may decrease steatorrhea, number of stools, and stool weight in some patients. Fats have the highest number of kilocalories per gram, make the diet more palatable, and patients with SBS without a colon should not be restricted in the amount of fats they take in. For small-bowel patients with a healthy colon a diet higher in complex carbohydrates and lower in fat may result in lower stool volume and electrolyte loss, so this type diet may be more beneficial.⁷¹ Medium-chain triglycerides have also been suggested for patients with SBS and an intact colon, as MCTs are better absorbed than long-chain triglycerides. MCTs may be especially useful in decreasing steatorrhea in patients with bile acid or pancreatic insufficiency. Care must be taken, however, because medium-chain triglycerides do not contain essential fatty acids.^{69,71}

Protein

Protein is typically well tolerated as a caloric source in SBS patients. The optimal form for the delivery of protein to patients with SBS is the subject of much study and debate.⁷¹ In the past, EN was often initiated with elemental formulas that contain free amino acids as the protein source because the efficiency of protein uptake was perceived to be better. However, total protein absorption is faster and more complete with dipeptide and tripeptide formulations. Absorption of free amino acids by the enteral route is a saturable process, whereas the absorption of small peptides is not. These more complex protein sources also may stimulate intestinal adaptation.⁷³ The American Gastroenterological Association now recommends that standard enteral formulas be used preferentially in SBS.⁷⁰

Fluid, Electrolyte, and Acid–Base Disorders

6 After substantial resections of the small bowel, the postoperative course is complicated by fluid and electrolyte imbalances that typically last 1 to 3 months.⁷³ Patients may have high-volume gastric fluid loss from nasogastric tubes and small intestine fluid loss from

ostomies. Sodium content usually is elevated in these secretions, with concentrations reaching 80 to 100 mEq/L.⁶⁹ Acute gastric hypersecretion may occur after massive resection and contribute significantly to these deficits.⁷³ Secretory diarrhea (see Chap. 38) also results in fluid and electrolyte losses that may be difficult to quantify.

Patients with end jejunostomies or proximal ileostomies (surgically created openings into the jejunum and ileum, respectively, that divert the intestinal contents externally through a stoma) can have recurrent dehydration and electrolyte deficiencies. A high jejunostomy can produce fluid output of 3 to 4 L/day, with sodium loss of 90 mEq/L. To overcome the net secretion of sodium and water into the jejunum, the sodium content of fluids ingested by the patient needs to be approximately 90 mEq/L. In patients who have small intestine in continuity with the colon, the malabsorbed bile and fatty acids stimulate sodium and water excretion into the large bowel, but in general, these patients are at less risk for sodium and water depletion.⁶⁹

Patients with a jejunostomy and individuals with long-term sodium depletion, magnesium deficiency, or excessive loss from diarrhea are at risk for hypokalemia.⁶⁸ Metabolic alkalosis, which may occur when a patient becomes dehydrated, accelerates the renal excretion of potassium, as all hydrogen ions are conserved in an attempt to correct the acid–base disorder. As bicarbonate ions are excreted renally, potassium is taken with them to maintain osmotic balance.

The unusually large amount of unabsorbed fatty acids within the remaining small intestine and colon of the patient with SBS will cause increased binding to calcium, resulting in a deficiency. This also may result in hyperoxaluria because dietary oxalate usually complexes with the intraluminal calcium and is excreted in the stool. As a result of decreased calcium available for binding, more oxalate is absorbed and available for renal excretion and thereby the risk of calcium oxalate renal stone formation is increased.⁷¹ Vitamin D deficiency results in insufficient calcium absorption; thus SBS patients requiring long-term PN are at risk for metabolic bone disease. Magnesium deficiency is common in SBS patients with large ostomy or diarrheal losses. This deficiency should be corrected aggressively because of the correlation between low magnesium and potassium concentrations with the development of calcium oxalate stones. Serum concentrations are commonly monitored, but urinary magnesium concentrations may decrease earlier with deficiency, and may be a better estimate of total body stores than serum levels. Oral supplementation may be difficult because it can contribute to increased diarrhea or ostomy output. However, repletion is necessary to prevent complications and to effectively correct potassium deficits.⁶⁸

SBS patients can lose substantial amounts of chloride (60 to 140 mEq/L) in addition to sodium from ostomy output. These individuals have a high risk of developing hypochloremic metabolic alkalosis. Patients who have SBS complicated by a pancreatic fistula and severe diarrhea lose considerable potassium and bicarbonate and may develop metabolic acidosis. Patients with severe diarrhea who have an intact colon will conserve sodium and chloride, resulting in considerable loss of potassium and bicarbonate and the development of metabolic acidosis. Quantifying fluid losses with particular attention to the sources of loss will aid in the acid–base management of these patients (see Chap. 55).

Lactic acidosis can occur in patients with SBS who have an intact colon and may result in symptoms of ataxia and delirium.⁷³ D-Lactic acid is produced by the fermentation of malabsorbed carbohydrates by colonic bacteria, and increased concentrations are associated with small bowel bacterial overgrowth. The diagnosis of D-lactic acidosis should be considered in patients with a functional colon who have an unexplained metabolic acidosis and an elevated anion gap.⁷³

Trace Elements

Patients with SBS are particularly prone to zinc deficiency as a result of excessive losses from stool, ostomy outputs, and fistula drainage.

Although serum zinc concentrations are not always reflective of body zinc status, a low serum zinc concentration requires an adjustment in the replacement amount.⁶⁹ Significant bowel resection, GI losses, and impaired intestinal absorption also contribute to imbalances of other trace elements, such as copper, selenium, and manganese. Because trace element deficiencies are common, the need for supplementation of these micronutrients is essential for SBS patients, including those receiving PN, EN, or an adequate diet.⁷³

Vitamins

7 Patients with ileal resection commonly develop vitamin B₁₂ deficiency, necessitating therapy with parenteral or intranasal cyanocobalamin. Most other water-soluble vitamins are absorbed in the proximal jejunum, and deficits of these vitamins are less common. There are reports, however, of SBS patients with symptomatic thiamine, folate, and biotin deficiencies.⁶⁹ Small bowel bacterial overgrowth can contribute to diminished vitamin B₁₂ because bacteria may metabolize the nutrient within the intestine, decreasing its availability for absorption. SBS patients with fat malabsorption can acquire deficiencies in vitamins A, D, E, and K.⁶⁹

TREATMENT

Short-Bowel Syndrome

■ DESIRED OUTCOMES

The desired outcomes of the nutritional management of patients with SBS are to provide effective energy, protein, micronutrients, and fluids in amounts adequate to maintain patient health and normal growth, avoid complications of SBS or the nutrition support regimen, and to optimize quality-of-life.⁶⁸ Finally, one wants to

maximize the use of the gastrointestinal tract for nutrient provision to maintain gastrointestinal tract function.

■ GENERAL APPROACH TO TREATMENT

After intestinal resection, the clinical course and nutritional management of SBS patients may be described in three stages, or phases (Fig. 147–3). This algorithm is based on recommendations from the American Gastroenterological Association and a recent consensus conference on the management of patients with SBS.^{70,72} The first stage, or acute phase, occurs during the initial postoperative period. This phase lasts at least 1 week, and may continue from 3 weeks to 3 months. It is complicated by major fluid and electrolyte losses (up to 5 L/day). The parenteral route should be used to supply nutritional needs.

8 The second stage lasts from a few months to longer than a year, and institution of enteral or oral intake early during this stage is important because intraluminal nutrients are essential stimuli for intestinal adaptation. The amount of enteral/oral nutrition can be advanced as the patient tolerates; concomitantly, the duration and or rate of PN may be decreased. In the third and final stage, adaptation is maximized and many patients can be maintained with full enteral or oral nutrition. However, PN may not be required on a daily basis. If a PN regimen is to be reduced or discontinued, it should be done slowly; initially 1 to 2 nights of PN may be eliminated each week. Eventually, some patients may be able to tolerate administration on an every-other-night or every-third-night basis.^{72,73} During the different phases of management, PN is administered through a peripherally inserted central catheter or surgically placed indwelling central venous catheter (see Chap. 145).

■ NONPHARMACOLOGIC THERAPY

Initially surgical management focuses on preventing GI resections and then preserving as much gastrointestinal tract as possible. Intestinal

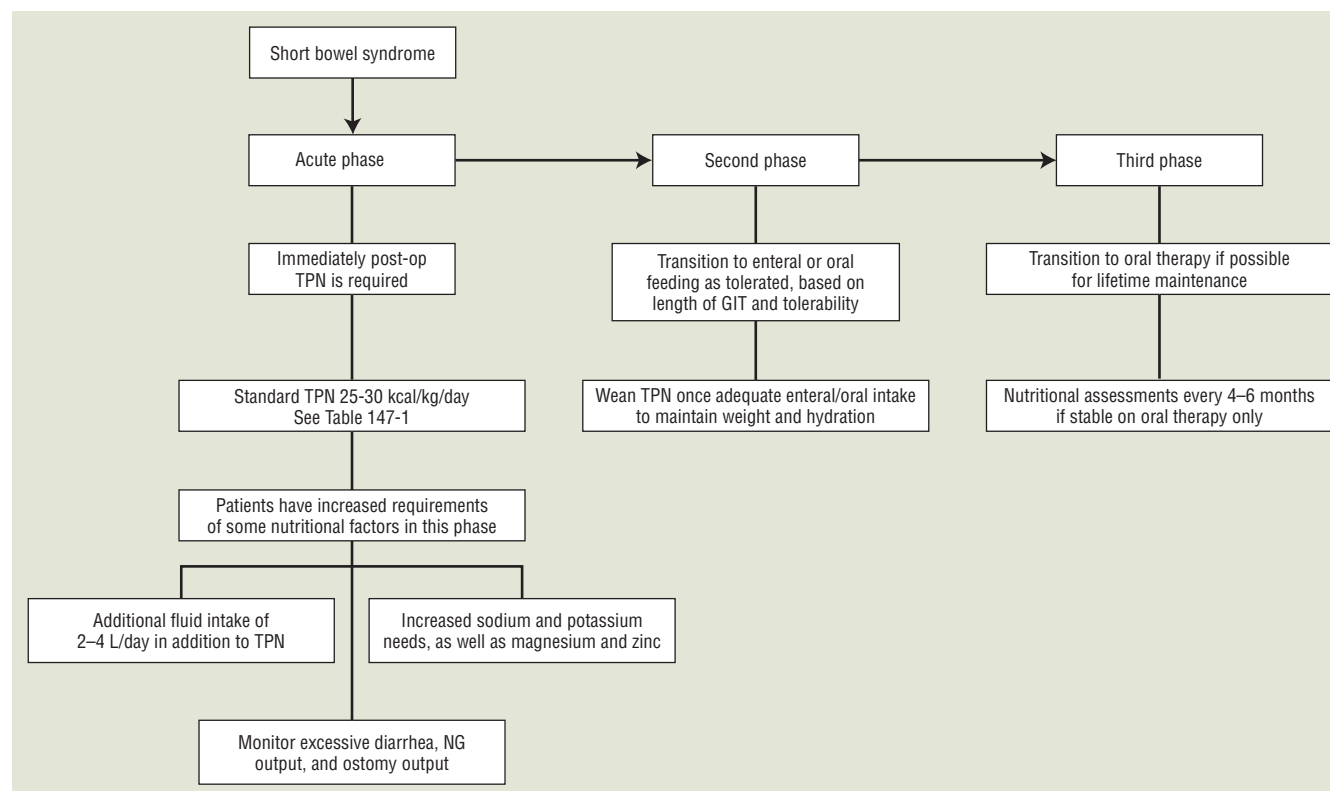

FIGURE 147-3. An algorithmic approach to nutritional support for the patient with short-bowel syndrome. (GIT, gastrointestinal tract; NG, nasogastric; TPN, total parenteral nutrition.)

transplantation is a surgical treatment option for patients with SBS, and approximately 1,200 such procedures have been performed.⁶⁸ With refinement of patient selection and surgical techniques, the 1-year survival rate after small-bowel transplantation is similar to that of those receiving home PN. Five-year survival, however, is still poorer than that reported in patients receiving home PN.⁷⁶ After transplantation, the majority of survivors are able to completely discontinue PN.⁶⁸ Consideration for small-bowel transplantation is currently reserved for those patients with SBS who fail therapy with PN because of recurrent line sepsis, loss of vascular access, PN-induced liver failure, or frequent severe dehydration.⁷⁰ As patient selection and immunosuppressive regimens continue to evolve, the indications for surgical treatment of SBS will likely expand.

■ PHARMACOLOGIC THERAPY

Drug Treatments of First Choice

The early phase of SBS is associated with large day-to-day variations in fluid and electrolyte losses. Strict output records should be assessed, as well as all intake, including intravenous medications. Initially, it is recommended to start a standard PN solution that meets the patient's maintenance metabolic, fluid, and electrolyte needs, and a separate intravenous replacement solution is typically necessary to keep the patient euvoletic based on actual fluid losses. Insensible losses should be estimated between 300 and 800 mL/day above measured output, and daily urine output should be kept at least 0.5 mL/kg/h. As fluid and electrolyte losses stabilize over time, it becomes possible to incorporate these replacement requirements into the PN solution. The American Gastroenterological Association recommends that the PN solution typically be composed of standard crystalline amino acids, glucose, and intravenous lipids. Energy provision of 25 to 30 kcal/kg ideal body weight per day is recommended, and may be administered as 1.0 to 1.5 g/kg of protein per day, approximately 20% to 30% of calories from intravenous lipids, and the remainder of calories from carbohydrates.⁷⁰ Table 147-1 gives an example of a PN formula for the patient with SBS.

The amounts of chloride versus acetate salt forms chosen for cation delivery should be based on assessment of the acid-base balance of the patient and sources of GI losses. More proximal GI losses generally are associated with increased chloride needs and more distal outputs with increased bicarbonate (i.e., acetate) requirements. Sodium losses may be extreme in SBS patients as already mentioned, requiring supplementation above what a typical PN patient requires. In addition, supplementation of potassium, calcium, magnesium, zinc, or other micronutrients over their maintenance amounts may be necessary to meet replacement needs.⁷³

The transition from PN to enteral feedings is desirable because it is a stimulus for adaptation, and should be instituted as the patient progresses throughout the postoperative period.⁶⁹ Enteral nutrition, given as a continuous infusion through a nasogastric or gastric feeding tube, may be advantageous over bolus feedings because it can maximize absorptive capacity, and may decrease recovery time and minimize diarrhea.⁷³ Although specialized and elemental formulas have been studied, standard EN formulations are preferred in SBS.⁷⁰ Avoiding lactose-containing foods and enteral formulations is also appropriate in patients who have extensive jejunal resection or who demonstrate lactose intolerance.⁶⁹

Small volumes (600 to 1,000 mL/day) of oral electrolyte solutions such as low-carbohydrate sports drinks and sugar- and caffeine-free beverages are optimal for patients with a colon, and oral rehydration solutions (with approximately 90 mEq/L sodium) for those without a colon. Frequent, small amounts of solid food composed primarily of complex carbohydrates and proteins (600 to 1,000 kcal/day) have been recommended, with avoidance of concentrated sweets and dairy products.⁷¹ When a patient is able to maintain

hydration and weight via EN and/or eating, PN may be tapered.⁷² Many factors must be considered once a patient begins to transition off interventional nutrition when determining the content of a long-term oral diet for an SBS patient. Factors such as the site and length of remaining intestine, tolerance, and patient acceptance must be considered. Fat generally is not restricted in patients without a colon. However, patients with a colon may experience more diarrhea with a high-fat diet and may benefit from oral intake that has more calories from carbohydrates and less fat content.⁷¹ The oral diet for patients with remaining functional colon also must account for oxalate content, and patients should avoid foods with high amounts of oxalate (e.g., spinach, parsley, rhubarb, cocoa, and tea) to decrease formation of calcium oxalate renal stones.⁷¹ Finally, oral diets in SBS patients often need to be supplemented to maintain electrolyte, mineral, vitamin, and trace element balance.

The delivery of medications to patients with SBS may present many challenges, not the least of which is the questionable absorption of oral therapies. Oral products that contain sorbitol or mannitol should be avoided to minimize medication-related diarrhea. Loperamide and octreotide may be used to control diarrhea (see Chap. 38), and proton pump inhibitors and H₂-receptor antagonists are frequently required to reduce gastric hypersecretion (see Chap. 35). Because of erratic absorption, the dose of oral or enteral medications may need to be greater than recommended for patients with an intact gastrointestinal tract.

Alternative Drug Treatments

The use of specialized nutrients and growth factors to enhance small-bowel adaptation is a focus of intensive research. The amino acid glutamine is a fuel for intestinal cells, and may be necessary for maintaining intestinal structure in normal and physiologically stressed states. Initial uncontrolled research findings suggested that those who received glutamine in combination with rhGH and a high-carbohydrate/low-fat diet, may have a reduced PN dependence and increased nutrient absorption.⁷⁷ Recombinant growth hormone was added to the regimen because of its stimulant properties on bowel adaptation. Subsequent double-blind, placebo-controlled crossover studies, which were done in small numbers of patients were unable to duplicate the beneficial results of glutamine and rhGH.⁷⁸

However, the most recent double-blind, placebo-controlled trial showed that glutamine, rhGH, and a high-carbohydrate/low-fat diet (optimized for 2 weeks prior to the treatment phase) resulted in a significant reduction in PN volume and caloric requirements.⁷⁴ Patients in the group receiving glutamine and rhGH were able to maintain their nutritional status while decreasing their average PN requirements from 5 to 6 days per week down to 2 days per week.⁷⁴ In the wake of this study, the FDA approved one form of rhGH for use in patients with SBS who are receiving specialized nutrition support.

CLINICAL CONTROVERSY

While there is some data indicating that rhGH in combination with dietary optimization and glutamine may decrease PN dependence in patients with SBS, the role of these therapies are still not well defined. There are conflicting data as to whether this therapy enhances nutrient absorption. The timing of therapy and identification of appropriate patient populations are also still areas of active research.

A consensus panel convened by a manufacturer of rhGH recommended the FDA-labeled dose of 0.1 mg/kg subcutaneously daily for 4 weeks be considered a reasonable therapeutic intervention. The panel suggested that appropriate patients are PN-dependent patients who are nutritionally stable and on an optimized diet and medication

regimen, and that treatment be given 6 to 24 months after bowel resection.⁷⁸ This treatment, however, is not recommended by the American Gastroenterological Association.⁷⁰ Other experts question the benefit of rhGH and suggested that before incorporating it into SBS treatment, it should be studied during the adaptive phase of SBS.⁶⁹ The safety of prolonged use of rhGH is also unknown.

■ PHARMACOECONOMIC CONSIDERATIONS

Nutritional management of SBS is quite costly, especially in patients who require home PN. One year of home PN therapy is estimated to cost approximately \$100,000.⁷⁶ This figure does not include home nursing, equipment, and the costs of intermittent hospitalizations. Significant savings may be realized in patients who are able to transition from PN, but this is unlikely to occur in patients who are still PN dependent after 2 years. No analyses have yet been published that describe the economic consequences of the potential PN-reducing effect of rhGH.⁷⁸ It has been reported that intestinal transplantation is a cost-effective intervention relative to the cost of home parenteral nutrition in patients who survive for 2 years postoperatively.⁷⁹

■ EVALUATION OF THERAPEUTIC OUTCOMES

Therapeutic monitoring of SBS patients who are receiving PN for metabolic complications should follow the guidelines outlined in Chap. 145. This patient population differs in that serum electrolytes should be obtained daily until the patient has stabilized postoperatively. Special consideration should also be given to the fluid status of SBS patients, especially in the period immediately following surgery, when fluid losses are extreme. Monitoring of stool output is such a large factor that it must be taken into consideration for all SBS patients. Because many patients with SBS remain on PN for extended periods of time, clinicians must be careful to monitor for elevations in liver enzymes, and cycling PN for 12 to 14 hours daily should be considered in those patients to minimize these complications. Obtaining a serum fatty acid profile may be judicious in those patients on long-term PN without oral intake to ensure they do not have essential fatty acid deficiency.⁸⁰

The most comprehensive and thorough analysis of the clinical outcomes of patients receiving home PN or EN comes from Medicare and the North American Home Parenteral and Enteral Patient Registry.⁸¹ It was estimated that 40,000 and 152,000 patients in the United States were receiving home PN and EN support, respectively. Patients with GI failure, which included those with Crohn's disease, ischemic bowel disease, motility disorders, and congenital bowel defects, had relatively good clinical outcomes, especially when compared with the groups with cancer or acquired immune deficiency syndrome. The patients with GI failure had an 87% annual survival rate and a 50% to 75% likelihood of complete rehabilitation. Sepsis, metabolic disorders, and mechanical problems with catheters resulted in one to two hospitalizations per year for all patients.⁸¹

■ QUALITY-OF-LIFE ISSUES

Initially those patients on extended PN therapy have a significant gain in QOL when transitioning from the hospital to their home setting. This is often followed by the reality of restrictions in daily living, dehydration and malnutrition despite PN, and complications such as sepsis and liver dysfunction. Patients with SBS on home PN have reported that their QOL is significantly reduced in comparison to those with anatomic or functional SBS not on home PN.⁷⁸ There are currently no data assessing the effect of treatment with growth factors such as rhGH on QOL, although one might expect to see an improvement. Valid comparisons of home PN and intestinal transplantation are not available, as a consequence of the limited indica-

tions for transplantation.⁷⁹ Preparing patients and their caregivers for the possible stresses associated with this therapy (e.g., financial challenges, fatigue, depression, complications, and social or emotional problems) through education and referral to support groups, such as the Oley Foundation, may help to increase QOL.⁸²

PULMONARY FAILURE

Nutrition support is an important aspect of preventing and treating both acute and chronic pulmonary failure. Malnourished patients are at increased risk of acute respiratory distress syndrome (ARDS), and malnutrition in patients with chronic obstructive pulmonary disease (COPD) is well documented. There is also a correlation between the outcomes of patients with alterations in nutritional status and concurrent pulmonary diseases.⁸³ Loss of lean muscle mass is detrimental because the depletion of diaphragm and intercostal muscles make the effort of breathing harder, and progression of weight loss leads to muscle fatigue and respiratory failure. The ventilatory drive, as well as compensation to hypoxia, is depressed in COPD patients who are malnourished, and nutritional support plays a key role in optimizing respiratory muscle function in patients with pulmonary disease.⁸⁴

EPIDEMIOLOGY

More than 10% of the U.S. population older than 45 years of age suffers from COPD, resulting in significant cost to the healthcare system.⁸⁴ Weight loss and protein-calorie malnutrition may occur in up to one-half of those patients suffering from COPD, and weight loss often coincides with disease progression.^{24,84} In those patients suffering from acute respiratory failure, nutritional abnormalities have been reported in up to 70%.⁸³ Engelen et al. studied body composition in patients with COPD, specifically emphysema and chronic bronchitis. They found a higher incidence of lean mass depletion in patients with emphysema than in those with chronic bronchitis. Body weight and body mass index were also lower in the group with emphysema.⁸⁵ In a further evaluation of these patients, the same investigators reported that skeletal muscle weakness was associated with wasting of extremity fat-free mass that was independent of COPD subtype.⁸⁶ Malnutrition is associated with an increased mortality rate in COPD patients with decreasing body mass index.⁸⁷

PATHOPHYSIOLOGY

Energy Requirements

⑨ Patients with COPD have highly variable REE, and commonly used predictive measures may underestimate their energy needs.⁸⁸ Those who are losing weight tend to have significantly higher REE adjusted for fat-free mass compared with weight-stable patients. Total daily energy expenditure also was found to be elevated in clinically stable COPD patients with both normal and increased REE. The cause of elevated total daily energy expenditure despite a normal REE is still unknown, although the oxygen cost of breathing, acute or chronic systemic inflammation, and medications may contribute.⁸³ Although the optimal approach to energy needs in COPD has not been identified, it is evident that there is no advantage to providing $1.7 \times \text{REE}$ compared to $1.3 \times \text{REE}$.⁸⁹ Hypermetabolism likely contributes to the decreased body weight and fat-free mass, although it has been shown that in this patient population intake may be suboptimal. During meals hypoxic patients tend to experience decreases in oxygen saturation and increased dyspnea. Gastric filling may also be impaired because of diaphragmatic expansion and a false feeling of fullness.⁸³ These problems, combined with increased daily requirements, may result in the negative energy balance seen in many COPD patients. Several specialized equations have been devel-

oped to estimate energy requirements in this patient population, and indirect calorimetry may be used, but clinical benefit is questionable. Patients with acute respiratory failure also may have alterations in energy expenditure, but the situation is similar in that predictive formulas for energy needs exist, and indirect calorimetry may be used. Providing excess calories to the acutely ill patient in respiratory failure should be avoided because this may increase carbon dioxide production and the associated work of breathing.^{24,84}

Carbohydrate

Malnutrition in patients with pulmonary disease has been consistently identified in the literature, and nutrition support should be considered as part of the overall treatment plan. However, increasing nutritional intake can be complicated because it may elevate the respiratory quotient, which may lead to a corresponding increase in work of breathing and resulting hypercapnia. The respiratory quotient is the ratio of the amount of CO₂ produced divided by the amount of O₂ consumed. When a subject is overfed, the amount of CO₂ produced markedly exceeds the amount of O₂ consumed, which can result in increased ventilatory demand.⁹⁰ Ventilatory drive may be improved in some patients with moderate infusions of carbohydrates; however, administration of glucose formulas at a rate greater than 5 mg/kg per minute has been shown to increase production of CO₂, and is associated with the inability to wean from mechanical ventilation.⁸⁴

Fat

Fats have the lowest respiratory quotient, but administration of intravenous fat emulsions to mechanically ventilated patients has the potential to adversely affect pulmonary gas exchange in some clinical conditions.⁹¹

CLINICAL CONTROVERSY

There are conflicting data on the safety of administration of lipid emulsions to patients with ARDS. Discrepancies in trial data may be due to the use of differing lipid infusion rates and duration, as well as pre-existing lung function.

The administration of lipid emulsions to patients with ARDS may possibly decrease oxygenation. A recent trial assessing both long-chain triglyceride and combination long-chain triglyceride/medium-chain triglyceride administration showed that there was no deleterious effect on oxygenation. Discrepancies in trial data may be a result of differing lipid infusion rates and duration, and preexisting lung status.⁹² Rapid administration of intravenous lipids should be avoided; a rate of 3 mg/kg per minute increases pulmonary vascular resistance in patients with ARDS.⁹² A review of nutritional intervention in ambulatory COPD patients revealed that diets high in fat placed a lower demand on the respiratory system in comparison to diets with a higher carbohydrate content. In addition to an improvement in forced expiratory volume, the number of breaths needed per minute decreased within 3 weeks in COPD patients who switched to a high-fat/low-carbohydrate diet.⁹⁰ Although these effects are important, the most critical element in managing patients with pulmonary compromise is to avoid overfeeding.²⁴

Protein

Undernourished patients demonstrate a blunted response to hypercapnia that improves after as little as 1 week of adequate nutritional support. This response is thought to result from protein administration, as evidenced by decreased partial CO₂ pressure, increased minute ventilation, and improved breathing patterns after the start of PN. Protein administration also may influence ventilatory demand by

increasing ventilatory response to hypoxia and hypercapnia. This stimulation may be altered by the amino acid composition of the protein source, with increased amounts of branched-chain amino acids having a greater effect compared with standard amino acids. Although this protein effect is potentially beneficial in some patients, excessive protein administration could theoretically lead to increased work of breathing and fatigue.⁸⁴

Fluid, Electrolyte, and Acid-Base Disorders

10 In patients with ARDS or pulmonary edema, excessive fluid intake should be avoided, and fluid accumulation is associated with a poor outcome. Patients in the ICU often receive substantial fluid loads from medication administration, and when possible it is important to limit intake by concentrating these sources.^{24,84}

Alteration of micronutrient requirements in respiratory failure is commonly focused on phosphorus replacement. Phosphorus has an essential role in the synthesis of adenosine triphosphate and 2,3-diphosphoglycerate (2,3-DPG). Inadequate stores of adenosine triphosphate can lead to respiratory muscle weakness, and normal contractility of the diaphragm muscles is dependent on phosphate.⁸⁴ Finally, a significant percentage of critically ill patients experience hypophosphatemia from refeeding. Most patients with moderate to severe hypophosphatemia and respiratory failure should be treated with intravenous sodium or potassium phosphate (see Chap. 53). Correction of hypophosphatemia in ICU patients receiving nutritional support with a graduated weight-based dosing scheme of phosphorus replacement has been reported.⁹³

Ventilator-dependent patients and those with stable COPD often have respiratory acidosis. A balanced mixture of chloride and acetate salts often is appropriate in these patients. The acid-base status of the ICU patient with pulmonary compromise should be monitored daily, whereas every 2 to 3 days may be adequate for the stable hospitalized COPD patient.

Vitamins and Trace Elements

Patients with pulmonary disease usually do not have significant alterations in vitamin and trace element requirements, and they can receive standard doses of these micronutrients. There are some data that support the additional supplementation of antioxidants vitamin C, vitamin E, and β -carotene because of a correlation with moderately improved pulmonary function. COPD patients may have an increased burden of oxidants from cigarette smoke or release of oxygen free radicals from inflammatory leukocytes in the lungs, and deficiencies of antioxidants may contribute to oxidant/antioxidant imbalances in these individuals.⁹⁴

TREATMENT

Pulmonary Failure

■ DESIRED OUTCOMES

In patients with pulmonary failure, nutritional support should be given to meet energy and protein requirements and to limit wasting of respiratory muscles. In stable COPD patients, this may be done in addition to exercise rehabilitation programs to optimize weight and fat-free body mass. To date, nutrition support has not been shown to affect long-term survival in these patients.⁹⁵

■ GENERAL APPROACH TO TREATMENT

When oral feedings are inadequate, ASPEN recommends that the enteral route be used in those who have a functional gut and can meet their needs through this route.²⁴ In acute respiratory failure, PN is

often recommended when the GI tract is not usable, or as a supplement to EN if sufficient energy intake is otherwise not possible.^{24,84}

Most general EN formulas contain an equal balance of nonprotein energy between carbohydrate and fat. Elemental or chemically defined products are the exception because they are intended to be high-carbohydrate, low-fat formulas to enhance absorption and digestion. In pulmonary patients administration of a high-carbohydrate formula may result in a significant increase in minute ventilation, heat production, and CO₂ production when compared with a high-fat formula. Because most general formulas contain balanced nonprotein calories, moderate doses of these products may be appropriate in most patients with pulmonary disease.⁸⁷ Patients who are fluid restricted should be given a higher energy formulation so as to maintain an appropriate fluid balance.²⁴

■ NONPHARMACOLOGIC THERAPY

Patient education and nutritional counseling are essential to maximizing the health of patients with COPD. Education about appropriate energy and caloric intake and the proper use of oral nutritional supplements may enhance patient adherence to these practices. Ambulatory COPD patients may also benefit from a pulmonary rehabilitation program that integrates, diet, supplements, and exercise.⁸⁷

■ PHARMACOLOGIC THERAPY

Drug Treatment of First Choice

Moderate doses of carbohydrate, fat, and protein given enterally are appropriate in most conditions. Total calorie provision 30% above basal energy expenditure does not have any untoward effects on pulmonary status. However, patients who are overfed, i.e. those who are receiving twice the basal energy expenditure, often produce excessive CO₂. Critically ill patients with respiratory failure can be fed 25 to 30 kcal/kg/day as they recover.^{24,96} In patients with borderline ventilatory status the nutritional regimen should be monitored closely to

prevent excessive CO₂ production, and increasing the proportion of nonprotein calories as fat relative to the amount of carbohydrates may be beneficial.⁸⁴ In general, patients with ARDS who need PN may receive nonprotein calories administered within the following ranges: 60% to 70% carbohydrate and 30% to 40% lipid. A reasonable protein dose is 1 to 1.5 g/kg per day for the patient with stable COPD. Patients who are mechanically ventilated with superimposed illness may require higher doses of protein (1.5 to 2.5 g/kg per day). Figure 147-4 illustrates an approach to the patient with acute respiratory failure requiring PN or EN support based on recommendations from ASPEN and ESPEN.^{24,96} Table 147-1 includes an empirical PN formula for the patient with respiratory failure.

Alternative Drug Therapies

Enteral formulas (e.g., Pulmocare, NutriVent, and Respilor) marketed for use specifically in patients with pulmonary disease are commercially available. These products contain a higher percentage of nonprotein calories as fat (>50%). Several studies evaluated the use of these high-fat/low-carbohydrate products in patients with COPD and acute respiratory failure, and generally the outcomes were favorable.⁹⁰ These specialized pulmonary EN products are calorically dense (1.5 kcal/mL), which may be helpful for patients with severe ARDS or pulmonary edema, as well as others who may require fluid restriction. There are no data, however, indicating that these formulas result in improved clinical outcomes in patients with pulmonary failure. Non-specialty formulations, and high concentration formulations for those requiring fluid restriction, are still preferred for routine use.^{24,87}

An additional concentrated formula (Oxepa) has been marketed specifically for critically ill patients on mechanical ventilation, and studied in patients with acute lung injury and ARDS. The macronutrient composition of Oxepa is similar to that of the other specialized pulmonary enteral formulas, with 55% of the nonprotein caloric content being from fat. However, the lipid blend in the formula was altered with the goal being to decrease the production of proinflammatory cytokines by including eicosapentaenoic acid from fish oil and

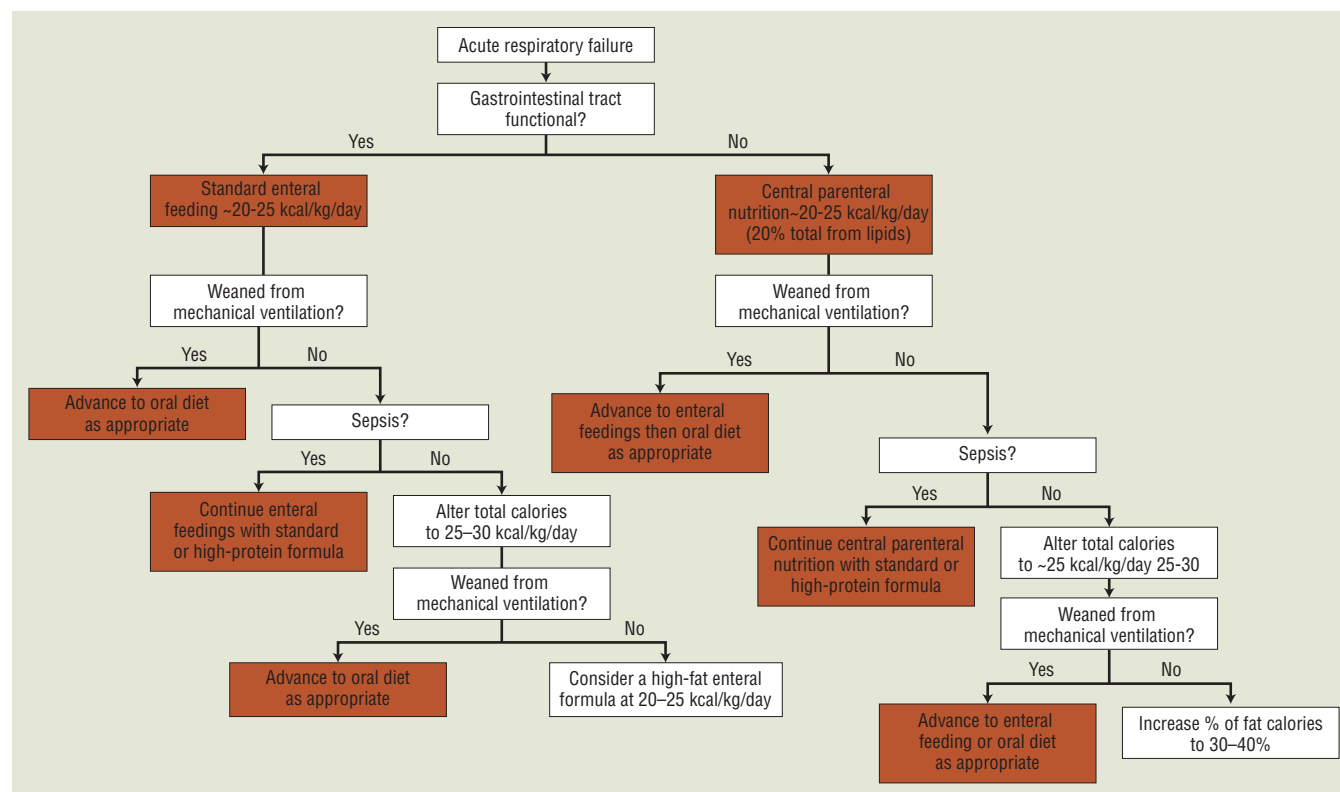

FIGURE 147-4. An algorithmic approach to nutritional support for the patient with acute respiratory failure.

γ -linolenic acid from borage oil. Nutrients with antioxidant properties (i.e., vitamin C, vitamin E, and β -carotene) also are supplemented in the product.^{97,98} This formulation is associated with improved respiratory mechanics, decreased ventilatory dependence, and an attenuation of the inflammatory state in acute lung injury/ARDS. Although ASPEN and ESPEN recommend the use of this product, it has not yet been shown to improve survival in critically ill patients.^{24,96}

rhGH is known to induce general muscle growth, lipolysis, and protein anabolism. When used as adjunctive therapy to EN support, COPD patients have shown improvements in lean body mass, maximal inspiratory pressure, and exercise capacity. The benefit of rhGH is debatable, with trials having differing results, but body mass and fat-free mass typically increase in patients after use of this product. The benefit in pulmonary patients as shown by improvements in respiratory muscle function and pulmonary function testing is questionable. The effects of anabolic steroids also have been evaluated for use in COPD as an adjunct to nutritional intervention. Patients on anabolic steroids tend to have larger increases in fat-free mass and more favorable distributions in weight gain in comparison to interventional nutrition alone.⁹⁹ More studies are needed to characterize the benefits of rhGH, as well as anabolic steroids, and to determine the risk to benefit ratio.

■ PHARMACOECONOMIC CONSIDERATIONS

There is no data available that establishes the pharmacoeconomic value of nutrition support in patients with respiratory failure.

■ EVALUATION OF THERAPEUTIC OUTCOMES

Because pulmonary patients are at extreme risk of malnutrition, monitoring the progression of the patient on interventional nutrition is extremely important. Therapeutic monitoring of pulmonary patients on PN for metabolic complications should follow the guidelines presented in Chap. 145. Patients on EN should be monitored as described in Chap. 146. Pulmonary status must be assessed for any changes, especially with the initiation of higher carbohydrate formulas of PN or EN. Weights should be charted frequently, and it is important that prealbumin concentrations are assessed weekly for hospitalized patients. It is important to remember that patients with ARDS in critical care units are prone to fluid overload from medication administration, so careful monitoring of intake and output is necessary to avoid pulmonary edema. Nutritional status should be monitored every 4 to 6 months for those patients with stable pulmonary disease and COPD.

■ QUALITY-OF-LIFE ISSUES

Patients with COPD who have fat-free mass depletion experience decreased energy and disease-specific QOL when compared to control patients who are not underweight.¹⁰⁰ Decreased activity and exercise capacity is associated with low fat-free mass, which appears to be related to decreasing patient satisfaction.⁸³ Dyspnea also has been shown to be correlated strongly with health-related QOL in patients with decreased fat-free mass, and may be the strongest predictor of patient satisfaction in correlation with malnutrition. Nutrition support supplementation has not been shown to definitively improve QOL in COPD. In one study, however, patients who maintained a diet of $1.3 \times$ REE showed an improved feeling of control over their COPD, whereas those fed $1.7 \times$ REE did not report any improvement in QOL.⁸⁹

JOHN V. ST. PETER AND CHARLES J. BILLINGTON

KEY CONCEPTS

- 1 Two clinical measures of excess body fat, regardless of sex, are the body mass index (BMI) and the waist circumference (WC). BMI and WC provide a better assessment of total body fat than weight alone and are independent predictors of obesity-related disease risk.
- 2 Excessive central adiposity increases risk for development of type 2 diabetes, hypertension, and dyslipidemia.
- 3 Weight loss of as little as 5% of total body weight can significantly improve blood pressure, lipid levels, and glucose tolerance in overweight and obese patients.
- 4 It is appropriate to consider medication therapy if 6 months of diet, exercise, and behavioral modification fail to stimulate weight loss.
- 5 A sufficient degree of obesity (BMI = 30 kg/m² and/or WC = 40 inches for males or 35 inches for females, or BMI of 27 to 30 kg/m² with concurrent risk factors) should be present before pharmacotherapy-facilitated weight loss is considered.
- 6 There is a high probability of weight regain when obesity pharmacotherapy is discontinued.
- 7 The FDA does not regulate labeling of herbal and food supplement diet agents, and content is not guaranteed.

It is now estimated that more than 95 million adults are overweight or obese in the United States.¹ Additionally, the number of adolescents who are overweight or obese has been increasing at an alarming rate during the last 30 years.^{1,2} The presence of obesity and overweight is associated with a significantly increased risk for the development of many diseases (Table 148–1), poorer outcomes of comorbid disease states, and increased healthcare costs. Observational epidemiologic studies show that overall mortality parallels body weight increases above an optimal level.^{3,4} This evidence is strongest for adults between the ages of 30 and 44 years. In older age groups, excess body weight increases the risk of death, but the degree of impact diminishes with age.⁵ Annually, up to 35% of Americans have actively resolved to lose weight, spending between \$30 and \$50 billion on such attempts.⁶ As of 2003, it is estimated

that overweight and obesity account for 5% to 7% of total medical expenditures in the United States and the sum of direct and indirect costs is approaching \$150 billion annually.⁶ The recent report of the Surgeon General and the inclusion of several aggressive Healthy People 2010 goals have helped to stimulate national initiatives to reverse the rising rate of obesity through implementation of prevention strategies, consensus guidelines, and best practices.^{7–10} This chapter reviews the epidemiology, pathophysiology, and therapeutic approaches for the management of obesity. Although nonpharmacologic treatment modalities are discussed, the pharmacotherapy of obesity is highlighted, and the role of pharmacotherapy relative to the other therapeutic options is critically reviewed.^{11–14}

EPIDEMIOLOGY

Obesity is increasing in prevalence in the United States. The National Health and Nutrition Examination Survey (NHANES) II data (1976–1980) estimated a prevalence of overweight persons in the United States at 25.4% of adults, representing 34 million individuals. During NHANES III (1988–1991), the prevalence had increased to 33.3%, representing 55 million American adults,^{6,15} making the prevention of obesity a public health priority.⁸ This is further emphasized by the continued pursuit of safe and effective long-term therapy for obesity. Individuals who were “fat” as children tend to remain overweight as adults.^{1,16} In contrast to body weight, adult body mass index (BMI) was not well predicted from childhood weight. The fattest children had the highest risks of adult obesity. However, most obese adults had not been fat at earlier ages: Only 17% and 18% of obese 33-year-old men and women, respectively, had been fat at age 7 years. In contrast, early adulthood may be an important time for intervention to prevent future obesity; obesity increased in prevalence from 2% to 11% in men and from 3% to 12% in women during the 10-year period between ages 23 and 33 years.¹⁶ The prevalence of overweight varies between races within the United States.^{6,17–19} Mexican American women and black women had the highest prevalence, 48.1% and 49.1%, respectively. The prevalence of obesity also increases with age, reaching a maximum by the sixth decade in women and the seventh decade for men. Beyond this age, the prevalence progressively falls for both genders. Socioeconomic status also affects the prevalence of obesity in those between the ages of 25 and 54 years. The prevalence of overweight in nonpregnant women for each respective decade of life—25 to 34 years, 35 to 44 years, and 45 to 54 years—is 30.8%, 49.1%, and 54.1% of women with incomes below the poverty line versus 18.4%, 23.7%, and 30.3% of those above the poverty line.¹⁶ Educational achievement, which is linked to socioeconomic status, is also correlated with the fraction of people who are overweight; prevalence of overweight is greatest in those with less than a high school education versus those with some college education.

TABLE 148-1 Conditions More Prevalent in Obese Populations

Cardiovascular	Musculoskeletal
Hypertension	Degenerative joint disease
Left ventricular hypertrophy	Skin
Congestive heart failure	Acanthosis nigricans
Coronary artery disease	Stretch marks
Stroke	Hirsutism
Pulmonary	Skin tags
Obstructive airway disease	Gastrointestinal
Sleep apnea	Cholelithiasis
Pulmonary hypertension	Esophageal reflux
Metabolic	Hiatus hernia
Hypercholesterolemia	Psychological
Hypertriglyceridemia	Eating disorders
Low serum high-density lipoprotein	Depression
Diabetes mellitus and glucose intolerance	Affective disorders
Hyperinsulinemia	Social stigma
Polycystic ovary syndrome	Neoplasm
Increased serum urate	Breast cancer
	Colon cancer

ETIOLOGY

The etiology of obesity in the vast majority of individuals can rarely be established. Obesity is a complex trait, and as such the etiology is multifactorial in origin, with genetic, environmental, and physiologic factors contributing to various degrees in different individuals. However, studies in twins confirm the presence of genetic contributions,²⁰ while the rapid increase in obesity prevalence in the last 30 years indicates a strong environmental contribution. In a small minority of individuals, diagnosis of an underlying medical condition contributing to the weight excess can be made. Even then, the diagnosed condition may or may not be treatable. One of the current areas of investigation is the extent that genetic traits influence the risk of developing obesity, as well as how these genetic traits interact with environmental factors to cause obesity.²¹

GENETIC PREDISPOSITION

Family studies show a clear correlation of body weight between parents and children. The correlation between siblings is even higher. In monozygotic twins, BMI is almost always identical, and there is a strong correlation in the accumulation of visceral fat. These twin studies demonstrate the strong role of genetics in determining both obesity and distribution of body fat. The incidence of obesity in adopted individuals relative to their adopted parents provides insight into the role of genetics versus family environment. A clear correlation between the BMI of adult adoptees and their biologic parents exists, but not between an adoptee and

the adoptee’s adoptive parent. These observations further support the notion that genes are primarily responsible for determining adult body weight. The relative impact of genetic versus environmental factors varies between persons. In some individuals, genetic factors are the primary determinants of obesity, whereas in others, the obesity may be caused primarily by environmental factors. The actual variance in body fat between individuals determined by genes is unknown. Estimates for this variance range from 20% to a high of almost 80%. A number of single-gene mutations producing obesity have been identified, but so far such mutations are rare and account for an extremely small number of the total cases of obesity.²² The total number and identity of contributing genes is still being determined, as is the means by which the many potential “obesity” genes interact with each other, and with the environment, to produce the obesity phenotype. Clearly, without positive calorie balance, obesity cannot occur. The environment, now largely created by humans, interacts with underlying genetic traits for obesity, with the modern urban American environment apparently being an ideal one for obesity expression.

Syndromes in which obesity is a major component are extremely rare. Prader-Willi, Simpson-Goabi-Behmel, Cohen, Bardet-Biedl, Carpenter, Börjeson, and Wilson-Turner syndromes are all associated with obesity. Of these, Prader-Willi syndrome is the most common, with a frequency of 1 in 20,000 live births. Other phenotypic features include changes in stature, mental retardation, and developmental abnormalities (e.g., hypogonadism). Because the incidence of these syndromes is rare, even collectively they contribute very little to the incidence of obesity. The clinician evaluating a patient for obesity needs to be aware of their existence, and the physical examination of obese patients always should include an assessment for secondary causes of obesity, including genetic syndromes.

ENVIRONMENTAL FACTORS

Economic development is associated with lifestyle changes.² Many of these societal changes may contribute to the observed rise in the prevalence of obesity throughout the world. Those that are most probably related to obesity include reduced physical activity or work (sedentary lifestyle), abundant and readily available food supply, increased fat intake, increased consumption of refined simple sugars, increased consumption of pre-prepared and processed foods, and decreased ingestion of vegetables and fruits. These changes in our environment likely contribute to a state of positive energy balance in many individuals (Fig. 148-1).²³ Observations from public health studies support this concept. For example, the prevalence of obesity in Copenhagen remained stable during the period between 1925 and 1942 at approximately 0.1%. However, since the end of World War II, there has been a steady increase in the prevalence of obesity.²³ These observational data suggest an environmental role for the development of obesity.

FIGURE 148-1. Net energy stores are determined by various inputs and outputs. Simply stated, obesity occurs when imbalance occurs between energy intake and expenditure.

NUTRITION

The appropriate diet that leads to long-term weight loss in ambulatory self-sufficient individuals is unknown. Weight regain is common, primarily because people return to their prediet food-intake patterns. It is clear that caloric intake in excess of habitual energy expenditure is a prerequisite to weight gain and obesity, but not all individuals with high caloric intake gain weight. The primary consideration is total calorie intake but macronutrient composition of the diet (i.e., percentage of calories as carbohydrates, protein, or fat) that is most favorable for maintaining healthy weight is still debatable. Of the three macronutrients, dietary fat has received the most attention. Both animals and humans prefer and often will seek out foods high in fat. High-fat foods have a desirable texture and sensory characteristics in the mouth. Although fat is itself tasteless, fats enhance the flavor of other foods. Clearly, one way that fatty foods promote weight gain is by increased energy intake because fat is more energy dense than other macronutrients. Furthermore, fats are stored with greater efficiency than protein or carbohydrates. Nutritional management of obesity as discussed in this chapter is based on reducing calorie intake. Because the Western diet is high in fat, and because fat contains more than twice the calories per gram of carbohydrate and protein, in most diets the total fat content is reduced by necessity.²⁴

APPETITE

Appetite is a complex behavioral phenotype that results from processing of many inputs and values within a distributed brain network involving principally the hypothalamus, limbic system, brainstem, hippocampus, and elements of the cortex. Within this neural network, many neurotransmitters and neuropeptides have been identified that can stimulate or depress the brain's appetite network and thereby impact total caloric intake.

Biogenic Amines

The first receptor systems found to either stimulate or decrease food intake in animals and humans were the biogenic amines, and these neurotransmitters remain the basis for the most robust pharmacologic interventions for obesity. Serotonin, also known as 5-hydroxytryptamine (5-HT), and cells known to respond to 5-HT are found throughout the central nervous system and the periphery. At least seven distinct subfamilies of 5-HT receptors have been cloned to date, with each of these seven exhibiting one or more subtypes. Currently, two major noradrenergic receptor subtypes are recognized (α and β), each with multiple subtypes. Histamine and dopamine also demonstrate multiple receptor subtypes, but their role in regulation of human eating behaviors and food intake is less-well documented. Direct stimulation of 5-HT_{1A} and noradrenergic α_2 -receptors will increase food intake, whereas the opposite occurs with 5-HT_{2C} and noradrenergic α_1 - or β_2 -receptor activation. In animal models, stimulating histamine receptor subtypes 1 or 3 and dopamine receptor subtypes 1 or 2 results in lowering of food intake. Table 148–2 summarizes the major effects of direct receptor stimulation, inhibition, or changes in synaptic cleft amine concentrations on food intake.

Neuropeptides

The hypothalamus is a crucial site within the brain's appetite network, and many neuropeptides, which influence appetite, have their main effects within the hypothalamus. Attention in the last several years has focused on the neural projection between parts of the hypothalamus, the arcuate nucleus sending signals to the paraventricular nucleus. The key peptides in this projection are currently thought to be neuropeptide Y and α -melanocyte-stimulating hormone, which engages melanocortin receptors in the paraventricular

TABLE 148-2 Effects of Various Neurotransmitters, Receptors, and Peptides on Food Intake

Brain Site	Increased Eating	Decreased Eating
Arcuate Nucleus of Hypothalamus (ARC)	Ghrelin	Leptin Glucagon Like Peptide-1 (GLP-1) Peptide YY (PYY)
Paraventricular Nucleus of Hypothalamus (PVN)	Neuropeptide Y (NPY) Agouti Related Protein (AgRP) Opioids (especially μ) Galanin	Melanocyte Stimulating Hormone (MSH, Melanocortin) Corticotropin Releasing Hormone (CRH) Cholecystokinin (CCK)
Lateral Hypothalamus (LH)	Orexin Melanocyte Concentration Hormone (MCH)	
Hypothalamus	Norepinephrine α_2 Serotonin 5-HT _{1A}	Norepinephrine α_1 and β_2 Serotonin 5-HT _{1B} and 5-HT _{2C} Histamine H ₁ and H ₃
Nucleus Accumbens Amygdala Brainstem (Hindbrain)	Dopamine Opioids (especially μ) Neuropeptide Y (NPY) Agouti Related Protein (AgRP) Opioids (especially μ)	Leptin Melanocyte Stimulating Hormone (MSH, Melanocortin) Cholecystokinin (CCK)
Vagus Nerve	Ghrelin	Leptin Cholecystokinin (CCK) Glucagon Like Peptide-1 (GLP-1) Peptide YY (PYY)
Various or Undetermined	Cannabinoid CB ₁	Dopamine D ₁ and D ₂

nucleus.²⁵ Neuropeptide Y is the most potent known stimulator of eating when it is active in arcuate to paraventricular projection,^{26,27} while action at the melanocortin receptor is one of the crucial inhibitors of eating.²⁵ Melanocortin action to suppress eating is thought to be especially important in humans because melanocortin pathway genes are among those found to influence body weight.²²

The lateral hypothalamus has been historically known as the hunger center within the brain, and peptides that potentially convey the hunger message have been identified in the lateral hypothalamus.²⁵ The most prominent of these lateral hypothalamic peptides, orexin, increases food intake stimuli within the lateral hypothalamus and from lateral to paraventricular hypothalamus.²⁷ Another peptidergic stimulator of eating that principally originates in the lateral hypothalamus is melanocyte-concentrating hormone. Neurons in the lateral hypothalamus use orexin and melanocyte-concentrating hormone to communicate with other neurons throughout the brain, affecting a number of functions beyond appetite.

Hunger and satiety, in the sense that these relate to the energy state of the body, are functions thought to be sited especially in the hypothalamus. Long-term energy state and body fat content are particularly important in the sensing and integrative functions of the hypothalamus. However, humans eat in response to a broader set of stimuli and values than energy need and fat mass. Reward, pleasure, learning, and memory are among the other important values processed within the brain that contribute to the decision to eat.

Many of the hedonic aspects of eating are handled within the broad category of brain sites referred to as the limbic system, and a different set of neurotransmitters and neuropeptides are thought to be important in the function of this system. Dopamine in the nucleus accumbens is the best known of these hedonic and eating-related neural peptides. It has also been implicated in the neural pathways underlying other behaviors, such as the use of drugs of

abuse.²⁵ In the amygdala, other emotional aspects of eating are processed, and in part are influenced by endogenous opiates which mainly initiate their effect by altering mu opioid receptor-based signaling.²⁸ Also thought to be involved in the hedonics of eating are the endocannabinoids, although the brain site most important for this function is not yet clearly defined.²⁹

Peripheral Appetite Related Signals to the Brain

Since the 1950s, it has been conjectured that body fat content must be sensed in some way at the level of the hypothalamus.³⁰ The protein product of the mouse obese gene (*ob*) called *leptin* (after *leptos*, the Greek word for “thin”), appears to be the signaling mechanism between fat and hypothalamic feeding centers.³⁰ The *ob/ob* genetically obese mouse does not produce leptin, and this animal’s marked obesity and hyperphagia subsides with leptin supplementation. The human leptin homologue has been cloned, and unlike the leptin-deficient *ob/ob* mouse, obese human serum leptin levels increase as fat cell mass increases. In fact there is a direct relationship between serum leptin concentrations and various markers of obesity such as percentage of body fat, BMI, and serum insulin concentrations. Figure 148–2 shows the peripheral link that leptin appears to provide in signaling the central nervous system about the status of fat cell mass. Unlike endocrine feedback systems, leptin blood levels in humans mainly matter when they are low, and higher serum levels of leptin and even supplementary leptin do not have much affect on the brain appetite network function. Thus, it is not surprising that recent studies of leptin supplementation in humans have not significantly decreased obesity.³¹ However, there is increasing evidence of the complicated nature of leptin effects both within and outside the central nervous system.^{30,32,33}

Other peripheral signals important to the brain’s processing of appetite include those from the gastrointestinal tract.³⁴ Several gut hormones are of current interest, notably those released by the intestine in response to passage of digesting food such as glucagon-related peptide-1, oxyntomodulin, and peptide YY. Each of these hormonal signals suppress eating in animals and humans. Glucagon-related peptide-1 also has other effects, most importantly as an incretin, which facilitates release of insulin by pancreatic β -cells in response to meal-related glucose. Interestingly, there is also a gut

hormone, ghrelin, which is released from the distal stomach and duodenum when they are empty, and stimulates appetite.

An understanding of the relationships between the brain, its many neurotransmitters and neuropeptides, environmental stimulation of brain activities, and other hormones, such as insulin and glucocorticoids, is still evolving.^{25,27} Exogenous manipulation of neural signals and associated peripheral hormones may provide future pharmacotherapeutic approaches to obesity management.²⁷

ACTIVITY

It is generally accepted that increased physical activity is important in the management of obesity.^{6,35} Similarly, a sedentary lifestyle predisposes to weight gain and obesity. Studies tend to show that obesity is associated with lower levels of physical activity, but it is unclear whether lower activity in the obese is a cause or consequence of the excess weight. It is clear that excess weight increases the physical cost of activity, and may offset, to some degree, the lower levels of activity with respect to energy balance. It is also clear that the obese can be physically active and there is evidence that increased fitness can protect the obese from some of the harm associated with their excess weight. Physical activity includes voluntary work, recreational activity, and spontaneous physical activity including involuntary movements. Some authors suggest that obese individuals have reduced levels of spontaneous physical activity leading to lower daily energy expenditure. However, results from studies designed to measure total daily energy expenditure remain controversial. A recent literature review found only a modest beneficial effect of exercise in preventing weight gain, with or without previous weight reduction.³⁶

WEIGHT GAIN SECONDARY TO MEDICAL CONDITIONS

Occasionally patients present with obesity secondary to an identifiable acquired medical condition. Weight gain is often associated with hypothyroidism, although the majority of patients presenting with hypothyroidism are not overweight (see Chap. 78). Some of these patients lose weight within weeks of thyroxine-replacement therapy. However, many patients will not achieve a normal or ideal body

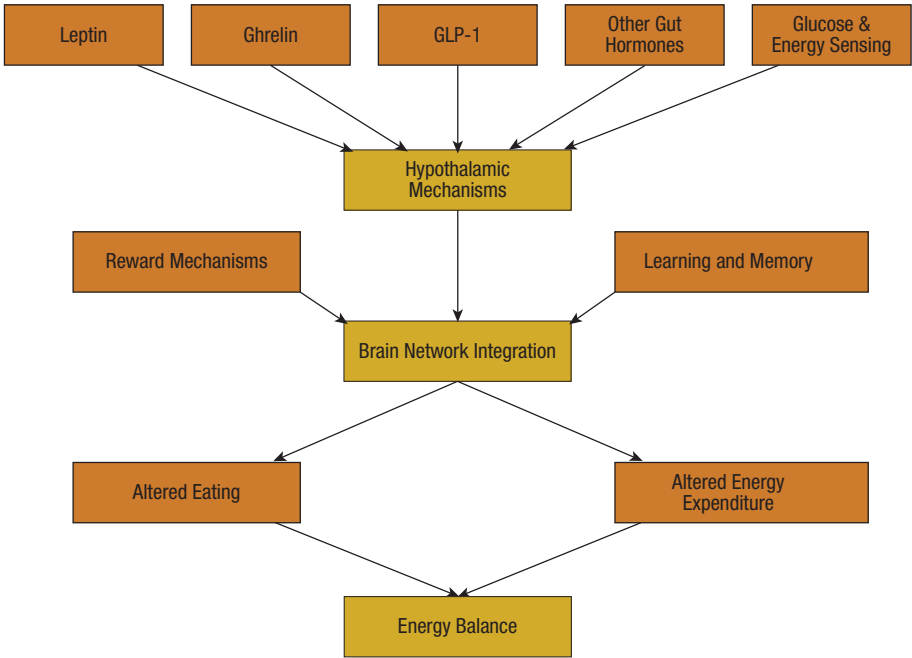

FIGURE 148-2. Intrinsic hypothalamic hunger and satiety mechanisms are modified by input from fat tissue via leptin; from gut via ghrelin, GLP-1 and other hormones; and by direct sensing of prevailing glucose and other energy signals. The hypothalamus generates signals that are integrated within brain networks, which are also receiving signals and food hedonics, learning and memory, and other motivations. The brain network affects change in energy balance by modifying food intake and energy expenditure.

weight despite adequate thyroid hormone replacement. Indeed, it is not uncommon for patients to request higher than physiologic replacement doses of thyroxine to artificially suppress their weight. It is important to remember that excess thyroid therapy can be associated with complications, including osteoporosis and cardiac disorders. Cushing's syndrome, another cause of obesity, is seen most commonly in patients receiving exogenous glucocorticoid therapy. These agents often are prescribed for a chronic condition such as chronic obstructive pulmonary disease, organ transplantation, and arthritis. Idiopathic Cushing's disease caused by excess endogenous steroid secretion is, in contrast, very rare. In both iatrogenic and idiopathic Cushing's disease, the weight gain is partly a result of fluid retention, as well as of increased adiposity. The adiposity associated with glucocorticoid excess has a particular body distribution in that it is central with relative loss of body muscle mass and thinning of the skin, leading to the characteristic purple skin striae and a buffalo hump behind the neck.

An increasing number of medications are associated with weight gain.³⁷ Most prominent among these are several of the treatments for diabetes, notably insulin, sulfonylureas, and thiazolidinediones. Some of the weight gain associated with diabetic treatments is thought to be caused by appetite-stimulated transient hypoglycemia, but it is likely that other mechanisms are also involved. More recently, weight gain was associated with a number of psychiatric medicines used for treatment of psychosis, mood disorders, and depression, and with several anticonvulsants. The most prominent weight gain problems have been seen with atypical antipsychotics, but it now seems clear that older antipsychotic agents are also sometimes implicated in weight gain. The pharmacologic mechanism responsible for the weight gain in patients who are receiving atypical and other antipsychotics, as well as most anticonvulsants has not been determined, but does not appear to be related to dopamine blockade. Interestingly, one anticonvulsant, topiramate, can cause weight loss, sometimes substantial weight loss.³⁸

Occasionally patients can present with lesions of the hypothalamus that lead to hyperphagia and obesity. This disorder is rare and should not be confused with behavioral disorders of eating that are associated with psychopathology. These include binge eating disorders, which may respond to psychotherapy, and in some cases, to pharmacotherapy (see Chap. 66). Obesity is itself associated with a higher prevalence of affective disorders, which if untreated may impair the success of any weight-loss program. The clinician managing obesity must be aware of the presence of psychosocial disorders, both as a cause and as an effect of obesity. Counseling strategies need to be incorporated into the management of selected obese individuals.¹² Furthermore, medications used to manage affective disorders, such as the selective serotonin reuptake inhibitors, have not been studied extensively with regard to combination use with appetite suppressant agents.

PATHOPHYSIOLOGY

ENERGY BALANCE

The net balance of energy ingested relative to energy expended by an individual over time determines the degree of obesity. Figure 148–1 represents the interplay between energy intake and expenditure. Energy stores will increase if there is imbalance between intake and expenditure. An individual's metabolic rate is the single largest determinant of energy expenditure. It is important to determine metabolic rate under standardized conditions, giving rise to terms such as resting energy expenditure (REE) and basal metabolic rate (BMR). REE is defined as the energy expended by a person at rest under conditions of thermal neutrality. BMR is defined as the REE measured soon after awakening in the morning, at least 12 hours

after the last meal. Metabolic rate increases after eating, based on the size and composition of the meal. It reaches a maximum approximately 1 hour after the meal is consumed and is essentially back to basal levels 4 hours after the meal. This increase in metabolic rate is known as the *thermogenic effect of food*. The REE may include the residual thermic effect of a previous meal and may be lower than BMR during quiet sleep. In practice, BMR and REE differ by less than 10%, and the terms frequently are used interchangeably. Physical activity is the other major portion of total energy expenditure, and is the most variable component. Even “sedentary” people expend some additional energy each day through their physical activity, but that amount is quite small relative to marathoners.

PERIPHERAL STORAGE AND THERMOGENESIS

Adipose tissue generally is divided into two major types, white and brown. The primary function of white adipose tissue is lipid manufacture, storage, and release. Lipid storage occurs in response to insulin with lipid release occurring during periods of calorie restriction, when insulin levels are suppressed. Brown-type tissue is notable for its ability to dissipate energy via a process of uncoupled mitochondrial respiration.³⁹ Currently, the exact roles of each of these tissue subtypes are better defined in animal models than in humans. Adipose tissue is highly innervated by the sympathetic nervous system, and adrenergic stimulation is known to activate lipolysis in fat cells as well as increase energy expenditure in adipose tissue and skeletal muscle. These properties provide a potential pharmacologic avenue for altering energy balance and changing weight status. A major focus of research in obesity pharmacotherapy has centered on the activity of adrenergic receptors and their effect on adipose tissue with respect to energy storage and expenditure or thermogenesis.⁴⁰ All three subtypes of β -adrenergic receptors (β_1 , β_2 , and β_3) appear to be active in fat cell function. The β_3 -receptor appears to be less responsive than β_1 and β_2 with respect to activation via norepinephrine. This has led to the development of specific β_3 -adrenoceptor agonists. However, apparent differences in selectivity and responsiveness between animal and human β_3 -receptors have complicated the drug development process. In vivo studies in humans suggest that the β_3 -receptor may be largely responsible for adipose tissue adrenergic-mediated increases in thermogenesis.⁴¹ Genetic polymorphisms have been identified in both the β_2 - and β_3 -receptor systems that are associated with obesity or excess weight gain.⁴² Thus genetic susceptibility for excess weight status may in part be related to adrenergic dysfunction. The development of effective pharmacotherapies involving these receptor systems may be delayed pending definitive identification of receptor subtype contributions.

CLINICAL PRESENTATION

1 A consistent and reproducible description of weight status is essential in the diagnosis and management of obesity. Evidence-based guidelines issued by many groups, notably the World Health Organization and the National Institutes of Health, have established a stratification of weight excess based on associated medical risk.⁴³ The first increment of excess weight is termed *overweight*, with the term *obesity* reserved for the higher levels of weight excess. For use in the clinic, these levels of excess weight are defined on the basis of BMI, a measure of total body weight relative to height. Those with a BMI of 18.5 to 25 are considered to have “normal” weight; overweight, obese, and severely obese are reserved for those with a BMI of 25 to 30, 30 to 40, and over 40, respectively. Using metric units, BMI (kg/m^2) is defined as weight in kilograms divided by height in meters squared (kg/m^2). Using pounds and inches, BMI (lbs/in^2) is estimated as: weight [pounds]/height [inches]² \times 703. Because the BMI may over-

estimate the degree of excess body fat in some clinical situations (e.g., edematous states, extreme muscularity, muscle wasting, short-stature), the final decision is often based on clinical judgment.

BMI is an acceptable measure of obesity and is the practical method of defining obesity in the clinic and epidemiologic studies; however, it does not always correspond to excess fat. Ideally, obesity refers to a state of excess body fat as determined by measures of skinfold thickness, body density using underwater body weight, bioelectric impedance and conductivity, dual-energy x-ray absorptiometry, computed tomography, or magnetic resonance imaging. These measurement techniques that determine body fat directly are currently too expensive and time-consuming to be used in population studies or for application in the clinical setting.

Furthermore, all fat is not equal in its danger to health. Central obesity reflects high levels of intraabdominal or visceral fat, and this pattern of obesity is associated with an increased propensity for the development of hypertension, dyslipidemia, type 2 diabetes, and cardiovascular disease (sometimes referred to as the “metabolic syndrome”). Intraabdominal fat is best estimated by imaging techniques such as computed tomography and magnetic resonance imaging. The other broadly defined type of fat is subcutaneous fat, which may be heterogeneous in its metabolic effects. Superficial subcutaneous fat has a weak association with metabolic markers of insulin production, release, and resistance, whereas deep subcutaneous fat demonstrates a strong relationship with insulin resistance.³⁹ Thus, in addition to the absolute excess fat mass, the distribution of this fat regionally in the body has an important effect on the mortality of obese individuals.

Waist circumference (WC) is the most practical method of characterizing central or visceral adiposity. Clinically, WC is the narrowest circumference measured in the area between the last rib and the top of the iliac crest.²⁴ The current definition for high-risk WC is greater than 40 inches in males and greater than 35 inches in females.²⁴ Notably, epidemiologic studies demonstrate that WC adds little in terms of risk prediction once a patient’s BMI reaches 35 kg/m². Thus, routine collection of WC should be implemented in those with BMIs between 25 and 35 kg/m². Although BMI and WC are related, each measure independently predicts disease risk. Both measurements should be taken at initial assessment and during routine followup of therapy for obesity.

The importance and clinical applicability of these measurements continue to evolve as there are probably racial and ethnic differences in the relationship between BMI, WC, and risk for development of disease and enhanced comorbidity.^{17–19,44} Table 148–3 outlines the current classification of overweight and obesity using BMI and WC. The table identifies risk for development of type 2 diabetes, hypertension, or cardiovascular disease at various stages of BMI or WC. Note that increased WC confers increased risk even in normal-weight individuals.

COMORBIDITIES

2 Obesity is associated with serious health risks and increased mortality. Several disease states and/or conditions are more prevalent in obese patients (see Table 148–1). Increased body fat, increased total body weight, and a central distribution of body fat are all associated with an increased incidence of mortality, primarily as a result of cardiovascular disease. Hypertension, hyperlipidemia, insulin resistance, and glucose intolerance are all known cardiac risk factors that tend to cluster in obese individuals. Therefore, the obese individual is exposed to multiple risk factors. Some of the earliest studies from Framingham have confirmed the relationship between obesity and increased risk of stroke and coronary heart disease in both men and women.⁴⁵ Increased mortality is seen even with modest excess body weight. Blood pressure frequently is elevated in obese individuals and may in part explain the increased incidence of

TABLE 148-3 Classification of Overweight and Obesity by Body Mass Index (BMI), Waist Circumference, and Associated Disease Risk

	BMI (kg/m ²)	Obesity Class	Disease Risk ^a (Relative to Normal Weight and Waist Circumference)	
			Men ≤40 in Women ≤35 in	>40 in >35 in
Underweight	<18.5		—	—
Normal ^b	18.5–24.9		—	—
Overweight	25.0–29.9		Increased	High
Obesity	30.0–34.9	I	High	Very high
	35.0–39.9	II	Very high	Very high
Extreme obesity	≥40	III	Extremely high	Extremely high

^aDisease risk for type 2 diabetes, hypertension, and cardiovascular disease.
^bIncreased waist circumference can also be a marker for increased risk even in persons of normal weight.

stroke and cardiovascular disease observed with obesity. Hypertension in lean individuals is associated with concentric cardiac hypertrophy as a consequence of an increased afterload, which increases the risk of cardiac ischemia. In contrast with obesity, eccentric dilation is observed, leading to an increased volume load. This dilated cardiomyopathy is associated with a reduction in ventricular ejection fraction and a high-output cardiac state. The combination of obesity and hypertension is associated with thickening of the ventricular wall, ischemia, and increased heart volume. This leads more rapidly to heart failure an association that has been recognized for more than two decades.^{46,47} Alterations in pulmonary function are common in patients with obesity. Sleep apnea is a significant and costly condition in terms of morbidity and mortality that is associated with obesity.^{46,47} This disorder is more common in men. The exact mechanism by which obesity leads to sleep apnea is unknown, but weight loss often results in significant and sometimes dramatic improvements in sleep apnea.

Diabetes mellitus and impaired glucose tolerance are associated with insulin resistance and obesity. The cellular mechanism by which obesity causes insulin resistance is unknown. Proposed mechanisms include downregulation of insulin receptors, abnormal postreceptor signals, circulating antagonists to insulin such as fatty acids or cytokines, and impaired gene transcription in insulin-responsive cells. Regardless of the mechanism of the insulin resistance, as insulin response becomes impaired, the pancreatic β -cells respond by increasing insulin production and release, resulting in a state of relative hyperinsulinemia. Although hyperinsulinemia is known to be associated with an increased risk of cardiovascular disease, it is not known whether the increased insulin levels contribute directly to cardiac disease or if they are just a marker for the underlying defect of insulin resistance and glucose intolerance. Insulin resistance, in turn, also frequently leads to impaired lipid metabolism (increased cholesterol, increased triglycerides, and low circulating high-density lipoprotein) and hypertension. As with cardiovascular disease, fat distribution is an important factor in determining the risk of developing type 2 diabetes. Central obesity increases the risk of diabetes. Intentional weight loss reduces mortality substantially in obese individuals with diabetes.⁴⁸

Osteoarthritis in weight-bearing joints, such as the knees, may be related directly to the mechanical effects of excess body weight and the resulting forces exerted on these joint surfaces. The increase of osteoarthritis in non-weight-bearing joints, however, suggests that obesity may lead to altered cartilage, collagen, and even bone metabolism. Osteoarthritis and its symptoms, such as pain, are a significant barrier to physical activity and a key impediment to sustained weight loss.

Obesity affects the human reproductive system in a number of ways. Obesity is associated with earlier menarche in girls and hyperandrogenism, hirsutism, and anovulatory menstrual cycles in women. In some women this disorder manifests as overt polycystic ovary syndrome.⁴⁹ Insulin resistance is common in these women. Weight loss, and more recently, therapy with insulin-sensitizing drugs such as the thiazolidinediones and biguanides, have been shown to restore normal ovulation in some women.⁴⁹ These observations suggest that insulin resistance plays a part in the causation of polycystic ovary syndrome-associated with obesity.

TREATMENT

Obesity

■ DESIRED OUTCOME

3 Weight management is commonly considered successful when a predefined amount of weight has been lost such that a final goal is achieved. However, desired outcomes are fully dependent on the clinical situation. Success may also include end points of decreasing the rate of weight gain or maintaining a weight-neutral status. A significant number of web-based resources for supporting both patient and practitioner weight management activities are available.^{8,10,24,50–52}

■ GENERAL APPROACH TO TREATMENT

The success of obesity therapy has been measured most often as weight loss over study periods of up to 12 months. Successful obesity treatment plans have incorporated diet, exercise, behavior modification (with or without pharmacologic therapy), and/or surgical intervention. Specific weight goals should be established that are consistent with medical needs and patient personal desire. For most obese patients, a weight loss goal of 5% to 10% to no more than 30% of initial weight is reasonable. An average rate of weight loss after the first month of therapy is around 1 lb per week. Patients should not be allowed to attain weight less than their estimated ideal weight.

Patients seeking help for obesity do so for many reasons, including improvement in their quality of life, a reduction in associated morbidity, and to prolong their life. Yet numerous individuals seek therapy for obesity primarily for cosmetic purposes and often have unreasonable goals and expectations. Aggressive marketing of weight-loss programs, therapies, and diets—parallel to the fashion industry's standards of desirable body profiles—has led many individuals to set impossible goals and expectations. In some cases, these persons will go to extreme measures to achieve weight loss. Consequently, clinicians must be careful to fully discuss risks of therapies and to clearly define achievable benefits and magnitude of weight loss. Criteria for weight loss vary from the most aggressive goal of trying to achieve an “ideal weight” to the more reasonable goals of modest (e.g., loss of 5% of body weight) but sustained weight loss. In practice, the goal has to be set based on many factors, including initial body weight, patient motivation and desire, presence of comorbid conditions, and age. For example, in patients with diabetes, even modest weight loss can improve glucose control and reduce mortality significantly,^{48,49} yet in individuals with osteoarthritis, significantly more weight reduction may be required to improve symptoms. Indeed, dietary modification and exercise have been shown to ameliorate hyperglycemia, hyperlipidemia, and hypertension with weight loss of less than 5% of initial body weight. These data emphasize the importance of defining end points and measures of success in any weight-loss plan.

Weight-loss interventions must be founded on lifestyle changes such as a modification in eating practices, complemented by drug therapy if indicated, and in some cases surgery (Fig. 148–3). Prior to recommending any therapy, the clinician must evaluate the patient for the

presence of secondary causes of obesity. If a secondary cause is suspected, then a more complete diagnostic workup and appropriate therapy are paramount. The next step in the patient evaluation is to determine the presence and severity of other medical conditions either directly associated with obesity (e.g., diabetes) or that have an impact on therapeutic decision making (e.g., history of liver disease or cardiac arrhythmia). Appropriate laboratory tests to exclude and/or quantify the degree of specific conditions such as diabetes, liver dysfunction, and nephropathy should be done as indicated by the history and physical examination. Based on the outcome of this medical evaluation, the patient then should be counseled on treatment options, benefits, and risks. The ultimate goals of treatment must be defined clearly. These goals may be absolute weight loss if obesity is present without other comorbid conditions. If improvement in blood glucose, blood cholesterol, and hypertension are primary goals, then these must be defined appropriately, and may include setting target levels for low-density-lipoprotein cholesterol, glycosylated hemoglobin, or blood pressure. For these patients, weight loss goals may be as little as 5% of starting weight. In contrast, if obesity is causing physical problems such as impaired mobility, osteoarthritis, or sleep apnea, then a weight loss goal of 10% to 20% of starting weight may be a more appropriate target. All too often patients expect to lose weight overnight, only to be disappointed. Thus it is important to set a time course for the plan. A reasonable rate of weight loss is typically about 0.5 kg per week.

■ NONPHARMACOLOGIC THERAPY

Behavioral Modification

4 Behavior modification is common to almost all weight-loss interventions. The primary aim is to help patients choose lifestyles that are conducive to safe and sustained weight loss. Behavioral therapy is based on principles of human learning and thus attempts to substitute learned undesirable habits with desirable behaviors using a combination of stimulus control and reinforcement. Most such programs use self-monitoring of diet and exercise both to increase patient awareness of behavior, and as a tool for the clinician to determine patient compliance as well as patient motivation.^{53,54} Behavior is reinforced by techniques including behavioral contracting, social support, relapse prevention, and in some cases booster treatments. Behavioral contracts are written agreements jointly developed by the patient and clinician. Components of these agreements include goals of therapy, methods to achieve these goals, and rewards for achieving these goals successfully. Social support requires the active participation of a close friend or relative who is involved in monitoring compliance and reinforcing behavior. Relapse prevention is geared to identifying high-risk situations for relapse such as social events, and training the individual to avoid these circumstances. Eventually, the patient is trained to deal with these situations actively, such as refusing high-fat foods assertively rather than avoiding such social events.

Diet

Numerous diet or nutrition plans exist to aid in weight loss.^{54,55} The lay press is replete with many diet routines that fall into and out of favor.

CLINICAL CONTROVERSY

Because of the popularity of diets such as Atkin's New Diet Revolution (high fat, low carbohydrate, high protein) and The New Pritikin Program (low fat, high carbohydrate, medium protein), there is extensive discussion in the lay media and academic circles regarding the risks, benefits, and outcomes related to diets that preferentially employ macronutrient extremes (i.e., high protein vs. high carbohydrate vs. low fat). Ultimately, overall energy balance will determine the rate and extent of weight change.

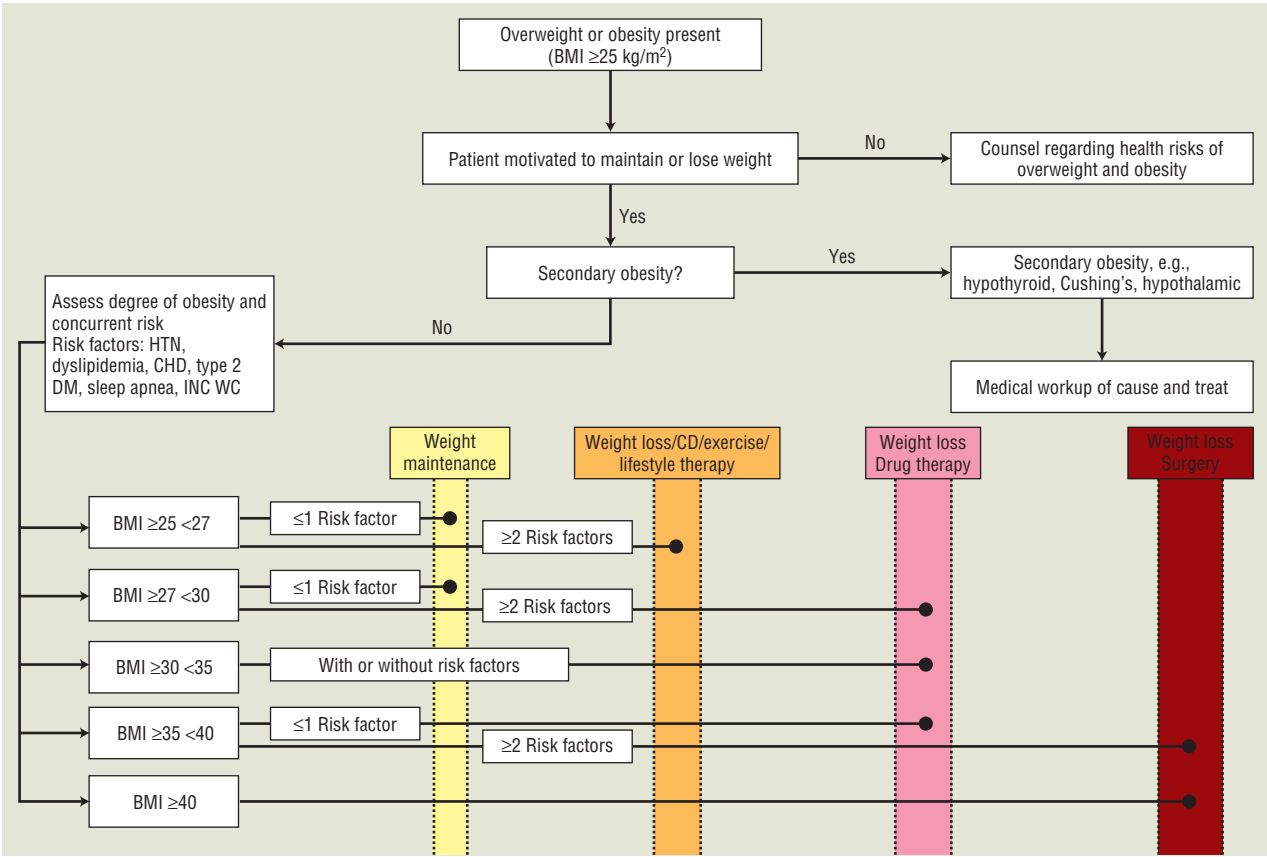

FIGURE 148-3. Pharmacotherapy treatment algorithm. A select population of individuals, based on BMI and WC together with concurrent risk factors, may benefit from medication therapy as an adjunct to a program of weight loss that includes diet, exercise, and behavioral modification. (WC, waist circumference; INC WC, >40 inches for males and >35 inches for females; BMI, body mass index; CHD, coronary heart disease; DM, diabetes mellitus; HTN, hypertension; LCD, low-calorie diet.)

Few, if any, of the popular “fad” diets have been objectively studied in a randomized, controlled fashion, with sufficient power to clearly determine their acute and chronic effects. Current data suggests that low carbohydrate diets achieve better weight loss than low protein diets for the first 6 months of treatment, but that the diets are equal in their effects at 1 year. Additionally, the relative efficiency of these diets for weight loss and chronic weight maintenance remain ill defined. However, recent efforts to better understand the acute and chronic effects of these extremes in macronutrient intake are being reported.^{56,57} Whichever diet program is selected, it is clear that energy consumption must be less than energy expenditure to achieve weight loss (see Fig. 148–1). The challenge has been to develop a diet plan that leads to consistent adherence by the patient and therefore sustained weight loss and/or maintenance. Two broad categories of diet have been used in clinical practice: low calorie and very low calorie. The low-calorie diet or Step 1 Diet, is recommended as part of the recent National Heart, Lung, and Blood Institute’s Obesity Education Initiative. This low-calorie diet recommends from 1,000 to 1,200 kcal/day for women and 1,200 to 1,600 kcal/day for men, based on estimated needs and weight maintenance or reduction goals. Very-low-calorie diets generally contain less than 800 kcal/day. These highly restrictive diets often result in early weight loss, but have been disappointing in the long-term, in part because it is difficult for individuals to maintain compliance. Additionally, very-low-calorie diets require intensive medical monitoring, and are possibly less effective, for long-term weight reduction than low-calorie diets. Other investigators have proposed total or modified fasts. The obvious problem with total fasts is that both fat and lean body mass are lost. In addition, because of diuresis, significant mineral losses

occur. Because of the problem with total fasting, alternate regimens called protein-supplemented modified fasts, became popular. With a protein-supplemented modified fast, the protein is given in the form of either formula or natural foods such as fish or lean meat. The consensus is that it is dangerous to allow these diets to be continued for longer than 16 weeks at a time. Patients may lose 1.5 to 2.3 kg per week on these diets. When these types of severe calorie-restricted diets are employed individuals will need vitamin and mineral supplementation.^{24,51}

A more reasonable goal for individuals is weight reduction of about 0.5 to 1 kg per week achieved by a negative calorie balance of approximately 500 to 1,000 kcal/day. This translates into a diet of approximately 20 kcal/kg of desirable body weight for most adults. The dietary regimen should be well balanced in fat, carbohydrates, and proteins, as well as in micronutrients. Generally 0.8 g of protein per kilogram of desirable body weight is recommended, with at most 30% of calories from fat.

Surgery

Surgery remains the most effective intervention for the treatment of obesity. However, because of its related morbidity and mortality, this intervention is reserved for those with BMI greater than 40 kg/m² or 35 kg/m² and significant comorbidity.^{58–60} Surgical procedures mainly reduce stomach volume, complemented in some cases by a reduction of the absorptive surface of the alimentary tract, and often are associated with some degree of malabsorption. Currently, the three major types of procedures are stapled gastroplasty, adjustable gastric banding, and conventional Roux-en-Y gastric bypass.⁶¹

CLINICAL CONTROVERSY

The superiority of conventional Roux-en-Y bypass versus adjustable gastric banding in terms of efficacy, morbidity, and mortality is actively debated. However, given the nature of bariatric surgery and available alternatives, the probability that randomized controlled trials will be completed to answer these questions is low.

Gastroplasty and adjustable gastric banding are designed to reduce the volume of the stomach and thus restrict the rate of nutrient intake. Conventional bypass combines a restrictive approach with a degree of malabsorption induced by excluding 90% to 95% of the stomach, the entire duodenum, and a portion of the proximal jejunum. Conventional Roux-en-Y bypass yields greater and more long-lasting weight loss than the other two methods. Ultimately, reductions in total body weight of approximately 35% can be achieved. Less optimal weight loss, late weight gain, the need for surgical revision in 15% to 20% for outlet stenosis or severe reflux, and long-term failure rates of up to 80% have dampened interest in gastroplasty.⁶¹ Similarly, gastric banding is plagued by frequent reoperation for stenosis and erosion or both of the band. Improvements in the peri- and postoperative care of gastric surgery patients has reduced morbidity and mortality with conventional bypass to approximately 10% and 1%, respectively.⁶¹ Some of the most common early complications of conventional gastric bypass are deep venous thrombosis, anastomotic leaks, and wound infections. Approximately one-third of patients develop significant vitamin B₁₂ and iron deficiency, with a large proportion demonstrating microcytic anemia. Dumping syndrome, characterized by colic, nausea, diarrhea, and bloating, does occur in a small number of patients and can complicate provision of drug therapy in some cases. Classically, Roux-en-Y gastric bypass was only performed as an open surgical procedure. However, recent developments in surgical technique have allowed this procedure to be performed via laparoscope.⁶⁰ Long-term results comparing the outcomes of open versus laparoscopic meth-

ods are not yet available. After experiencing weight loss, many gastric surgery patients are able to discontinue pharmacotherapy for glucose lowering, dyslipidemia, and hypertension. Frequently however, hypertension medications must be restarted at various time periods postsurgery, in spite of the fact that weight regain has not or has only minimally occurred. The reasons and mechanisms for this are unclear, but reiterate the need for intensive followup by all clinical specialties involved in the care of these patients.

Selection of the appropriate patients for surgery and subsequently identifying the most appropriate procedure for each patient is critical. The input of an experienced surgeon working with a multidisciplinary team is invaluable.

CLINICAL CONTROVERSY

The debate regarding the appropriateness of obesity pharmacotherapy remains heated, fueled by the recognized national need to treat a growing epidemic. Controversy about the standards by which to judge long-term outcomes studies, and the medical and litigious fallout from the failed use of fen-phen (fenfluramine-phentermine) and dexfenfluramine (Redux) have fueled the debate.

■ PHARMACOLOGIC THERAPY

5 The debate regarding the appropriateness of obesity pharmacotherapy remains heated, fueled by the recognized national need to treat a growing epidemic and the medical and litigious fallout from the failed use of fen-phen (fenfluramine-phentermine) and dexfenfluramine (Redux).^{62,63} Strategies for the pharmacologic management of obesity have been focused on modulating central and/or peripheral sites that regulate human energy balance. Figure 148-4 depicts sites of action of these therapies within the energy intake, storage, and expenditure cycle. Table 148-4 lists the status of the most common classes of agents currently in use. Since the 1970s, numerous studies of the effects of central appetite suppressant agents on weight status have been completed.⁶⁴ The National Task

FIGURE 148-4. Sites of action for obesity treatments are represented by circled X. Most appetite suppressants act on hunger and satiety mechanisms, but the endocannabinoid antagonist rimonabant is an example of intervention that appears to affect hedonic properties of eating. Traditional diets act by limiting food intake, as does bariatric surgery. Orlistat interferes with fat absorption in the gut, while gastric bypass surgery interferes with absorption more generally.

TABLE 148-4 Pharmacotherapeutic Agents for Weight Loss

Class	Availability	Status	Daily Dosages (mg)
Gastrointestinal lipase inhibitor			
Orlistat (Xenical)	Rx	Long-term use	360
Noradrenergic/serotonergic agent			
Sibutramine (Meridia)	Rx	Long-term use	5–15
Noradrenergic agents			
Phendimetrazine (Prelu-2, Bontril, Plegine, X-Trazine)	Rx	Short-term use	70–105
Phentermine (Fastin, Oby-trim, Adipex-P, Ionamin)	Rx	Short-term use	15–37.5
Diethylpropion (Tenuate, Tenuate Dospan)	Rx	Short-term use	75
Cannabinoid receptor agent			
Rimonabant (Acomplia ^a)	Rx	Approval pending in the United States	20

^aTrade name in European markets.

Force on the Prevention and Treatment of Obesity concluded that short-term anorexic agent use was difficult to justify because of the predictable weight regain that occurs on discontinuation of pharmacotherapy.⁶⁵ However, long-term pharmacotherapy may have a place in the treatment of obesity for patients who have no obvious contraindications to available drug therapy.^{24,66} Additionally, the American Association of Clinical Endocrinologists and the American College of Endocrinology have developed a guideline for multidisciplinary obesity team approach to the management of therapy.⁶⁷ More recently, the U.S. Preventive Services Task Force published an exhaustive summary of evidence related to screening and interventions for adult obesity that incorporates a graded assessment of obesity pharmacotherapy randomized controlled trials.⁵⁴ The discovery of cardiac valve disease in relation to serotonergic appetite suppressant use and its resulting multibillion dollar class action litigation affirms the task force’s call for further study of available therapies.^{62,63} A five-state survey demonstrated the relatively common concurrent use of both prescription and nonprescription weight loss medications.⁶⁸ Therefore, clinicians should maintain a high degree of sensitivity toward the potential polypharmacy practices of patients with obesity.

Lipase Inhibitors

Orlistat The percentage of dietary intake as fat is implicated as a contributing factor in the development of obesity. Fat represents an extremely dense energy source; 9 kcal/g as compared with approximately 4 kcal/g from protein or carbohydrate. In humans, most of accumulated body fat excess is derived from dietary sources because of a limited capacity to synthesize fat from carbohydrate. Gastrointestinal (gastric, pancreatic, and carboxyl ester) lipases are essential in the absorption of the long-chain triglycerides commonly found in Western diets. Additionally, lipase is known to play a role in facilitating gastric emptying and secretion of other pancreaticobiliary substances. Orlistat (Xenical, Alli) is a synthetic derivative of lipstatin, a natural lipase inhibitor produced by *Streptomyces toxytricini*. Orlistat is minimally absorbed and selectively inhibits gastrointestinal lipases. Lipase inhibition results in decreased formation of free fatty acids from dietary triglyceride. Additionally, lower luminal free fatty acid concentrations result in malabsorption of cholesterol. Orlistat induces weight loss by a persistent lowering of dietary fat absorption. Clinical studies employing orlistat as an

adjunct to diet therapy demonstrate dose-dependent reductions in fat absorption. Up to 30% reduction in fat absorption occurred with daily doses of 360 mg.^{11,14,69} No additional decreases in fat absorption occur with doses above 400 mg/day. The drug must be taken with foods that contain fat in order to exert its effect.

At least one gastrointestinal complaint (soft stools, abdominal pain/colic, flatulence, fecal urgency, or incontinence) is reported initially in up to 80% of individuals using orlistat. These complaints are most common in the first 1 to 2 months of therapy, are mild to moderate in severity, and tend to improve with continued orlistat use. Limiting dietary fat prior to initiation of orlistat therapy may be beneficial in decreasing initial gastrointestinal complaints. Orlistat-induced malabsorption of fat-soluble vitamins has been documented.^{11,14,69} Therefore, vitamin supplementation should be considered during therapy with this agent. Orlistat does not appear to change the pharmacokinetic or dynamic profiles of numerous other agents including oral contraceptives, digoxin, glyburide, phenytoin, pravastatin, warfarin, nifedipine, captopril, atenolol, furosemide, and ethanol. A notable exception is cyclosporine, wherein case reports suggest significant decreases in cyclosporine serum concentrations with concurrent orlistat use.⁶⁹

Overall, results from clinical trials demonstrate that orlistat effectively increases the amount of weight lost and decreases the amount of weight regained during medically supervised weight-loss programs.^{11,14} Significant improvements in lipid profile, glucose control, and other markers of metabolism are seen in spite of the relatively small 2- to 4-kg differences in weight lost when using orlistat in addition to diet. In patients with impaired glucose tolerance, weight loss using orlistat significantly decreased the rate of conversion to type 2 diabetes. Additionally, improved glycemic control can be attained in patients with type 2 diabetes by inducing or increasing weight loss with orlistat in addition to diet management. In some cases, dosages or the number of agents required for glucose lowering may be decreased.⁶⁹ Orlistat is the first agent for the chronic treatment of obesity with an indication for use in adolescents aged 12 to 16 years. Finally, orlistat was recently approved in the United States for over-the-counter use without a prescription (trade name Alli, GlaxoSmithKline, Moon Township, PA) when ingested at a reduced daily dose of 180 mg.

Noradrenergic–Serotonergic Agents

Sibutramine This orally active racemic mixture became available in the United States in early 1998.^{11,14,70} The parent compound and two active metabolites appear to increase synaptic concentrations of serotonin, norepinephrine (NE), and dopamine via reuptake inhibition. The active metabolites (M₁ and M₂) are more potent than the parent-compound. Reuptake inhibition appears to be greatest for NE, followed by serotonin, with dopamine the least inhibited. Sibutramine, M₁, and M₂ do not directly stimulate serotonergic (5-HT₁ or 5-HT₂), noradrenergic (α_1 , α_2 , β_1 , β_2 , and β_3), or dopamine receptors. It is thought that sibutramine induces weight loss by both decreasing appetite and maintaining or increasing thermogenesis via the combined effects on 5-HT and NE reuptake. In humans, the degree to which these effects can be attributed to central versus peripheral activity is currently unknown. Sibutramine is subject to hepatic first-pass metabolism via cytochrome P450 3A4. Moderate changes in sibutramine and/or metabolite disposition have been seen with ketoconazole coadministration. M₁ and M₂ area under the curve increased by 58% and 20%, respectively, with concurrent ketoconazole (200 mg twice daily for 7 days). Smaller changes were noted with concurrent erythromycin and cimetidine therapy. The active metabolites M₁ and M₂ exhibit elimination half-lives of 14 and 16 hours, respectively. Further metabolism of the active metabolites results in conjugates that are eliminated renally. The pharmacokinetics of sibutramine allow for once-daily oral dosing.

6 Sibutramine has been studied in clinical trials in doses from 1 to 30 mg daily and it demonstrates a relatively clear dose–response relationship. Weight loss from daily doses of 1 mg is, on average, no different than from placebo. The recommended starting dose is 10 mg daily, with a recommended dose range of 5 to 15 mg daily. Dry mouth, anorexia, insomnia, constipation, appetite increase, dizziness, and nausea were noted two- to threefold more frequently in sibutramine-treated subjects than in placebo-treated subjects. Statistically significant increases in both systolic and diastolic blood pressure, in the range of 2 mm mercury, and pulse rate have been noted with sibutramine use.⁷⁰ Baseline blood pressure should be established prior to beginning therapy, and close monitoring is required when using this agent. Sibutramine product labeling indicates that it should not be used in patients with a history of coronary artery disease, stroke, congestive heart failure, or arrhythmias. Like other centrally acting appetite suppressants, sibutramine should not be used in patients receiving monoamine oxidase (MAO) inhibitor therapies. Sibutramine is listed as a schedule IV prescription substance despite being noted as having no street value by recreational substance users. Primary pulmonary hypertension has not been reported with sibutramine use. Echocardiographic assessments of a small cohort of patients from clinical trials with approximately 6 months of exposure do not demonstrate the cardiac valve problems seen with the fenfluramine derivatives. Based on 12-month clinical trials, weight loss with sibutramine therapy appears to be most significant during the first 6 months of therapy. Twenty-nine percent of placebo-treated patients in these trials attained a 5% reduction in total body weight after 12 months whereas 56% and 65% of patients receiving 10 or 15 mg of sibutramine, respectively, achieved at least a 5% reduction in total body weight. A 10% reduction in body weight was achieved by 8% of placebo-treated patients, whereas 30% and 39% of those taking sibutramine 10 and 15 mg/day, respectively, achieved this level of weight reduction. As with other centrally active appetite suppressants, weight regain occurs with cessation of therapy.

Endocannabinoid System Agents

Rimonabant. During the last 20 years, arachidonic acid derivatives known as endocannabinoids were identified as endogenous substances that activate cannabinoid receptors.^{71,72} A complex regulatory relationship exists between the endocannabinoid system, energy regulatory hormones, and neuropeptides.⁷¹ The endocannabinoid system appears to be overactive in states of overweight and obesity. Additionally, the endocannabinoid system appears to be involved in the propagation of addictive behaviors related to ingestion of substances such as nicotine, cocaine, heroin, alcohol, and amphetamines.

Two distinct cannabinoid receptors are known and have been cloned, CB₁ and CB₂. The existence of a third, CB₃, is hypothesized.⁷² These G-protein-coupled receptors have wide and differing tissue distribution. CB₁ receptors are found in high concentrations in brain and peripheral organs including liver, gastrointestinal tract, adipocytes, skeletal and cardiac muscle.⁷¹ Central and peripheral CB₁ receptors are involved in many aspects of energy balance; regulation of food intake, glucose and lipid metabolism and body composition. CB₂ receptors are mainly expressed within immune system tissues and are not currently recognized as affecting energy balance.

Rimonabant (SR141716A) first described in 1994 as an inhibitor of brain CB₁ receptors is now recognized as having potent central and peripheral effects on feeding, nutrient metabolism, and body composition.^{14,72} An extensive series of randomized, double-blind, placebo-controlled clinical trials have been undertaken to assess rimonabant safety and efficacy for the treatment of obesity with and without comorbid diabetes and dyslipidemia. It is also being studied as an adjunct therapy for smoking cessation.

For weight-loss studies, rimonabant doses of 5 mg or 20 mg daily have been employed. Significant weight loss at 1 year over that with

placebo occurs with both doses, approximately 2 kg with the 5-mg dose and 6 kg with the 20-mg dose. Notably, almost 60% of those receiving 20 mg of rimonabant sustained weight loss of greater than or equal to 5% of total body weight. Fewer patients, approximately 30%, achieved this goal at the 5-mg dose versus approximately 19% in placebo-treated arms. Significantly, about one-third of patients receiving 20 mg rimonabant sustained and maintained weight loss of greater than or equal to 10% of total body weight.

Statistically and clinically significant improvements in lipid profile have been noted with rimonabant exposure with increases in high-density lipoprotein and decreases in triglyceride concentrations. As with weight loss, the greatest effects are noted at rimonabant doses of 20 mg daily. In patients with comorbid type 2 diabetes, marked improvements in glycemic control were seen, with more than 40% of those receiving rimonabant 20 mg daily attaining hemoglobin A_{1c} levels of less than 6.5%. Weight loss produced by rimonabant can improve many of the significant comorbidities of obesity including effects on glycemia and lipids. Although these effects are expected with any form of weight loss, there is some evidence for additional mechanisms affecting these comorbidities with the endocannabinoid blockade.⁷²

The FDA's Endocrinologic and Metabolic Drugs Advisory Committee in June 2007 agreed unanimously that rimonabant did not demonstrate a favorable enough risk-to-benefit profile to enable it to be approved for weight management in individuals with a BMI of ≥ 30 kg/m² or in individuals with a BMI of ≥ 27 kg/m² when accompanied by at least one comorbid condition.⁷³ The committee's concerns centered on what many concluded was a "clear" signal of increased risk of neurologic side effects—seizures, depression, anxiety, aggressiveness, and suicidal thoughts among patients randomized to rimonabant. Consequently, Sanofi-Aventis will have to gather more detailed safety information about rimonabant over the long-term, in larger patient numbers, before it can request further consideration for approval for marketing in the United States.

Noradrenergic Agents

Phentermine Phentermine is structurally similar to amphetamine, but it has less-severe CNS stimulation and a lower abuse potential. Its mechanism of action is related to enhanced NE and dopamine neurotransmission. Phentermine is available in both immediate-release and sustained-release formulations. However, the value of sustained-release formulations are questionable based on the reported phentermine plasma half-life of 12 to 24 hours.⁷⁴ Phentermine is an effective adjunct to diet, exercise, and behavior modification for producing weight loss in excess of that seen with placebo.⁷⁵ Intermittent phentermine therapy appears to elicit comparable weight loss when compared with continuous use. However, most individuals experience weight regains during therapy and generally always after discontinuing use.⁷⁴ A single dose of 30 mg once daily in the morning provides effective appetite suppression throughout the day. Divided doses of 8 mg immediately prior to meals, however, are common. Doses above 30 mg daily do not improve effectiveness.⁷⁵ Evening or nighttime dosing should be avoided because of insomnia. Significant increases in blood pressure, palpitations, and arrhythmias can occur with phentermine administration. Use is not advisable in hypertensive patients and those with unstable cardiovascular function. The potential for hypertensive crisis with coadministration of phentermine and MAO inhibitors is noted in product labeling because of the documented cases of this syndrome seen with coadministration of amphetamine or noradrenergic derivatives and MAO inhibitors.⁷⁶ Similar warnings have been noted regarding concomitant use of tricyclic antidepressants, but this is less-well documented. With MAO inhibitors, a minimum washout time of 14 days prior to use of any adrenergic agent is suggested to avoid excessive adrenergic stimulation syndromes. Phentermine use is

contraindicated in patients who are abusers of substances such as cocaine, phencyclidine, and methamphetamine, again because of the potential for excessive adrenergic stimulation syndromes and abuse potential. Mydriasis from adrenergic stimulation can worsen glaucoma, and patients diagnosed with glaucoma should not receive phentermine. Diabetic patients may experience altered insulin or oral hypoglycemic dosage requirements soon after beginning therapy and prior to any substantial weight loss.

Phentermine currently remains on the market as a short-term pharmacotherapy for obesity despite recognition of cardiac valvulopathy in a high percentage of patients who used phentermine in combination with fenfluramine derivatives. Phentermine remains one of the most widely prescribed weight management medications in spite of product labeling that indicates short-term, monotherapy use only.⁷⁷ This usage pattern persists in spite of the current federal recommendations that promote only long-term drug intervention when obesity pharmacotherapy is appropriate.⁵¹

Mazindol Chemically distinct from amphetamines and phentermine, mazindol's tricyclic structure resulted in amphetamine-like appetite suppression.¹¹ Despite demonstrated efficacy as a short-term therapy for weight reduction, mazindol is no longer available in the United States.

Diethylpropion Diethylpropion stimulates norepinephrine release from presynaptic storage granules. Increased adrenergic neurotransmitter concentrations activate hypothalamic centers, which result in decreased appetite and food intake. This drug undergoes extensive first-pass hepatic metabolism. Active metabolites are eliminated renally and account for approximately 70% of the administered dose. The elimination half-life of these metabolites is approximately 8 hours.⁷⁵ Less than 10% of the parent compound is recovered in urine. No specific dosing recommendations exist for use in patients with renal or hepatic insufficiency. Diethylpropion can be taken in divided daily doses, generally 25 mg three times daily before meals. An extended-release formulation is also employed by some clinicians, usually as 75 mg taken once daily in the morning or midmorning. Both dosing regimens are effective in achieving short-term weight loss in excess of placebo.¹¹ Complaints of insomnia increase if late afternoon dosing is used. Diethylpropion causes less CNS stimulation than mazindol and generally causes less insomnia than phentermine. Patients with severe hypertension or significant cardiovascular disease should not receive diethylpropion. Diabetic patients may experience decreased insulin or oral hypoglycemic dosage requirements soon after beginning therapy and prior to any substantial weight loss. More frequent blood glucose self-monitoring and medical follow-up are warranted when treating diabetic patients with diethylpropion.

Amphetamines Appetite suppressant effects of the amphetamines were well recognized in the 1930s. Amphetamines activate central noradrenergic receptor systems as well as dopaminergic pathways at higher doses, by stimulating neurotransmitter release. Increases in blood pressure and mild bronchodilation are attributed to peripheral α - and β -receptor activation. The powerful stimulant and addictive potential of the amphetamines relative to other available agents has resulted in their general avoidance for the treatment of obesity.

Serotonergic Agents

Serotonin is an important neurotransmitter involved in many human physiologic systems. Sleep–wake cycles, sensitivity to pain, blood pressure, mood, and eating behaviors have links to serotonin activity. Increasing central serotonin levels decreases the amount of food consumed and prolongs the time between food intake. Some serotonergic agents increase central serotonin concentrations via stimulating release of presynaptic stores and/or inhibition of reuptake into storage granules. Additionally, either the parent compound

or metabolites of these agents also may stimulate postsynaptic 5-HT receptors directly. Peripheral serotonin effects that have an impact on appetite, such as slowing gastric motility, also have been described. A major distinction between serotonergic and noradrenergic anorexiant is that serotonergic agents lack the central stimulant effects and thus the abuse potential seen with the noradrenergic compounds.^{11,14} Conversely, decreased wakefulness, altered sleep patterns, and changes in affect can be seen.

Antidepressants: Selective Serotonin Reuptake Inhibitors

It is interesting to note that some of the serotonergic appetite-suppressing agents were first studied as antidepressants and then noted subsequently to have effects on weight. As a class, the serotonin reuptake inhibitors generally are weight neutral as opposed to other commonly used compounds such as the tricyclic antidepressants (see Chap. 71). Patients receiving fluoxetine (60 mg/day) demonstrate initial weight loss of up to 2 to 4 kg on average, but weight regain occurs despite continued medication use such that no difference is noted between fluoxetine and placebo over periods of up to 1 year.¹⁴ A direct relationship exists between amount of weight lost and the sum of fluoxetine and norfluoxetine plasma concentrations. Higher plasma concentrations are associated with greater weight loss. The antidepressant serotonin reuptake inhibitors are not approved by the FDA as weight management agents and are not recommended currently for routine treatment of obesity. Some practitioners have prescribed these agents for the treatment of obesity “off label” either alone or in combination with phentermine. The safety and efficacy of phentermine-serotonin reuptake inhibitor combinations is unclear. A case report of adverse experiences (e.g., impaired mentation, tremor, hyperreflexia, and gastrointestinal symptoms) with unintentional concurrent use of phentermine and fluoxetine reinforces the need for caution by prescribers of unlabeled combination therapy.⁷⁸ Serious adverse effects such as primary pulmonary hypertension and cardiac valve abnormalities in excess of background prevalence have not been reported in relation to selective serotonin reuptake inhibitor use for obesity therapy.

Not Recommended but of Historical Interest

Phenylpropanolamine Although commonly classified as a noradrenergic anorexic, phenylpropanolamine (PPA) is atypical with regard to its mechanism and site of action. PPA racemates, D- and L-norephedrine, have chemical structures quite similar to amphetamine.^{11,14} PPA has been used for many years as a constituent of nonprescription appetite suppressants and various cough and cold preparations. However, because of persistent case reports of hemorrhagic stroke related to PPA exposure, the U.S. Food and Drug Administration and pharmaceutical manufacturers partnered to complete a case-control study known as the Hemorrhagic Stroke Project during the 1990s. In October 2000, the Nonprescription Drugs Advisory Committee discussed the Hemorrhagic Stroke Project report and concluded that PPA was not safe for continued use. Based on the accepted background prevalence of stroke and the odds ratios defined by the Hemorrhagic Stroke Project report, Kernan et al. estimate that 1 woman may experience PPA-related stroke for every 107,000 to 3,268,000 women exposed to PPA appetite suppressants.⁷⁹ Despite the very low risk of hemorrhagic stroke, the FDA believes that a favorable risk-to-benefit ratio no longer exists for any PPA-containing products. As such, PPA-containing products have either been reformulated without PPA or removed from the market in the United States. However, because of the voluntary nature of the request for reformulation or removal from the market, the FDA recommends that all consumers review product labels to ensure the absence of PPA from weight loss and cough or cold preparations.⁸⁰

Ephedrine Ephedrine appears to suppress appetite and increase energy expenditure via release of presynaptic norepinephrine and direct stimulation of thermogenic β -adrenergic receptors.¹⁴ The efficiency of ephedrine stimulation is somewhat blunted by physiologic feedback systems involving adenosine and various prostaglandins. This notion has stimulated research to characterize the effect of ephedrine in the presence of adenosine and prostaglandin antagonists such as caffeine and aspirin.¹⁴ Ephedrine in combination with caffeine has enhanced appetite suppression and thermogenesis as compared with placebo and other anorectics over time periods of up to 6 months. Oral doses of 20 mg ephedrine and 200 mg caffeine up to three times daily have been studied. The spectrum of side effects with ephedrine and ephedrine-caffeine combinations is similar to that seen with other noradrenergic agents. Side effects are more notable at higher doses and most commonly include tremor, agitation, nervousness, increased sweating, and insomnia; palpitations and tachycardia have also been reported. Patients with diabetes, hypertension, or cardiovascular disease (including arrhythmic conditions) should not self-medicate with ephedrine-containing products without evaluation by a qualified physician. Ephedrine is available both with and without a prescription; neither form is labeled by the FDA for use as an obesity therapy.

■ COMPLEMENTARY AND ALTERNATIVE THERAPIES

7 Many individuals choose to undertake weight-loss regimens that incorporate the ingestion of herbal, natural, or food supplement products without medical monitoring. It is important to remember that the FDA does not regulate the manufacture and labeling of these products. Some herbal and food supplement diet agents contain pharmacologically active substances that should be used with caution or avoided in obese patients with conditions such as diabetes, hypertension, and significant cardiovascular disease. Another problem with many of these marketed products is the lack of consistency in labeling versus actual product content. Table 148-5 lists some of the common constituents found in many of these products.

Chromium

The inclusion of chromium as an effective agent for weight loss is unclear. The hexavalent form of this trace element is thought to be carcinogenic, whereas the trivalent form found in human food sources is essentially nontoxic.⁸¹ Chromium is considered an essential nutrient and experimentally in animals is an insulin cofactor active in carbohydrate, protein, and lipid metabolism.⁸¹ In humans, insulin resistance has been reported in a few cases of apparent severe chromium deficiency during long-term total parenteral nutrition (see Chap. 145). Currently, there is no reliable means of assessing total

body chromium status, making diagnosis of deficiency difficult. The tryptophan metabolite, picolinic acid, forms a complex with trivalent chromium, which improves bioavailability. Food sources with highly available chromium include brewer's yeast, calf liver, American cheese, and wheat germ.⁸¹ A double-blind, placebo-controlled study of chromium picolinate as a supplement to aerobic exercise in the treatment of obesity failed to demonstrate any effectiveness.⁸²

Ephedra Alkaloids

Based on the known effects of ephedrine, dietary supplements claiming weight management effects have employed plant sources of ephedra alkaloids. Various parts of the Ephedraceae, *ma huang*, *Sida cordifolia*, and *Pinellia ternata* plants are known to produce ephedra alkaloids, including L-ephedrine, D-pseudoephedrine, L-norephedrine, D-norpseudoephedrine, L-N-methylephedrine, and D-N-methylpseudoephedrine.⁸³ Common names routinely included in dietary supplement labeling for these alkaloid sources include joint fir, popotillo, country mallow, sea grape, and yellow horse. From 1994 through July 1997, the FDA received more than 800 reports of serious adverse events, including seizures, stroke, and death, coincident with ephedrine alkaloid-containing dietary supplement use. An in-depth review of 140 reports of adverse events related to ephedrine alkaloid-containing dietary supplements demonstrated that approximately half the reports involved cardiovascular symptoms.⁸⁴ As of 2004, the FDA has determined that all sources of ephedra alkaloids must be excluded from dietary supplements because they present an unreasonable high health risk.⁸⁵

St. John's Wort

A perennial flowering plant (*Hypericum perforatum*), St. John's wort has been employed as a medicinal herb for thousands of years. Its use in weight loss and herbal supplements probably is based on the proposed effects of its constituent naphthodianthrone (hypericin and pseudohypericin). These are thought to be inhibitors of MAO and would be expected to increase synaptic concentrations of monoamines such as serotonin and NE. Consistent with these assumptions, *Hypericum* extracts appear to be more effective than placebo in the treatment of depression.⁸⁶ However, in vitro studies have not been able to substantiate direct MAO inhibition at physiologic hypericin concentrations, and recognized antidepressant effects may be due to other constituents.⁸⁷ The risks of concurrent use of *Hypericum* derivatives and other adrenergic and serotonergic compounds have not been characterized. Currently, St. John's wort has not been studied with respect to its role in obesity management and cannot be recommended for routine use in self-management of obesity.

Pyruvate

Pyruvate is a commonly listed ingredient in many herbal weight management preparations. Multiple salt forms are used, including sodium, magnesium, potassium, and calcium. Other names include α -ketopropionic acid, 2-oxopropanoic acid, and acetylformic acid. Pyruvate is a three-carbon intermediate formed during normal glucose metabolism and/or during glycolysis. It is advertised in the lay press for its ability to "increase metabolism" and thus promote weight loss. Objective data documenting these effects are lacking.^{88,89} Although most pyruvate nutritional weight management supplements contain less than 2 g per dose, large exposures (more than 20 g) are known to cause noticeable gastrointestinal side effects, including bloating and diarrhea.

Hoodia

Hoodia is a desert cactus of the Apocynaceae plant family. Natives indigenous to the Kalahari Desert are purported to consume the

TABLE 148-5 Herbal/Natural Products and Food Supplements Used for Weight Loss^a

Herbal/Natural/Food Supplements	Active Moiety	Proposed Mechanism
Chromium picolinate	Chromium	Unclear
St. John's wort	Hypericin	Serotonergic/monoamine oxidase inhibition
Hoodia	P57	Unclear
White willow bark	Salicylate	Inhibit norepinephrine breakdown
Calcium pyruvate	Pyruvate	Unclear
Guarana extract	Caffeine	Noradrenergic
Various tea extracts	Caffeine	Noradrenergic
Garcinia gambogia extract (citron)	Hydroxycitric acid	Unclear
Chitosan	Cationic polysaccharide	Block fat absorption

^aSafety and efficacy not documented.

stems and roots of this plant for their appetite suppressant effects. Other names appearing on product labels include Kalahari cactus, Hoodia cactus or extract, Hoodia gordonii cactus, and Kalahari diet. Hoodia extract, sometimes also referred to as P57, is rumored to elicit weight loss; however, no peer-reviewed reports of effectiveness are currently available.

White Willow Bark

White willow bark is a source of salicylate, a prostaglandin inhibitor. Prostaglandin inhibition may enhance adrenergic stimulation via inhibition of NE breakdown.

Guarana Extract and Various Tea Extracts

Guarana and tea are sources of caffeine that have inherent adrenergic properties and increase the effects of stimulant substances such as ephedrine or ephedra alkaloids.

Chitosan

Chitosan is a cationic polysaccharide, specifically a partially *N*-deacetylated form of chitin. This nonhydrolyzable fiber exhibits properties similar to those of cellulose. In vitro and preclinical data indicate that chitosan may be effective in blocking absorption of fat from the gut. It has been suggested that orally administered chitosan may be an effective weight-reduction agent by blocking calories ingested as fat. Chitosan is a major constituent in several heavily advertised weight-management food supplements and nonprescription preparations. However, a small number of properly randomized and blinded or open-label investigations currently demonstrate that orally administered chitosan is not an effective inhibitor of fat absorption in humans.⁸⁸ While further research may be warranted with respect to the appropriate dose in humans needed to impair fat absorption, current claims of chitosan effectiveness in humans are unsubstantiated.

■ PHARMACOECONOMIC CONSIDERATIONS

There are few data regarding economic consequences of treating obesity. One study evaluated the savings in prescription costs following a 12-week weight reduction program in 40 type 2 diabetic patients. Patients lost an average of 33.7 lb over the study period. A cost analysis was completed on 32 of 40 patients who were taking antihypertensive and/or antidiabetic medications using the out-of-pocket costs for these medications at the beginning of the study and after 1 year. The patients sustained a mean weight loss of 19.8 lb over the next year. The average cost of these prescriptions at the beginning as compared to the 1-year followup was \$63.30 versus \$32.50 per month. The estimated annual average saving in prescription costs per patient was \$443. A more objective assessment of costs related to orlistat use has been published based on data obtained from three peer-reviewed publications. In this report from the United Kingdom, the cost utility of orlistat was estimated at £46,000 (approximately \$75,000) per quality-adjusted life-year gained. Sensitivity analysis from this report demonstrated marked variability in this estimate of £14,000 to £132,000 (approximately \$23,000 to \$215,200). The authors raised questions about the potential long-term value of pharmacotherapy for obesity.⁹⁰

Finally, Martin et al. compared the costs associated with medical and surgical treatment of obesity.⁹¹ Medical therapy groups received diet therapy only (no medications), and cost included weekly clinic visits for behavioral modification. A successful outcome was defined as loss of at least one-third of excess body weight above ideal body weight. They monitored all patients for 2 years and some for as long as 7 years so that long-term weight control could be addressed. As expected, the costs of surgery were much higher than medical

therapy over the first 2 years (\$24,000 vs. \$3,000). However, when costs were extrapolated out to 6 years, the cost per pound lost for medical therapy exceeded surgical therapy (about \$313 vs. \$261 per pound lost). It is clear from the preceding data that weight loss can be expensive for the consumer. Prospectively designed cost-benefit or cost-effectiveness analyses are needed to determine if costs of weight loss therapy or surgery are balanced by lower costs of hospitalizations for other medical problems associated with obesity or the additional life years gained. Quality-of-life measures also need to be taken into consideration when evaluating these types of data.

Third-party payor and insurance reimbursement for provision of obesity treatment services continues to be inconsistent. However, these issues are under active discussion and specific information regarding reimbursement for obesity treatment from multiple different perspectives including the Centers for Medicaid and Medicare Services and the IRS are freely available via the Web.⁹²⁻⁹⁴

■ EVALUATION OF THERAPEUTIC OUTCOMES

Monitoring the Care Plan

Outcome Measures Assessment of patient progress should be documented in a healthcare setting once or twice monthly for 1 to 2 months and then monthly thereafter.^{24,67} Each encounter should document weight, WC, BMI, blood pressure, medical history, and patient assessment of obesity medication tolerability.^{24,67} Chronic use of obesity medications should be consistent with the approved product labeling. Medication therapy should be discontinued after 3 to 4 months if the patient has failed to demonstrate weight loss or maintenance of prior weight. A recent American Association of Clinical Endocrinologists/American College of Endocrinology statement on obesity provides a patient evaluation checklist, a validated survey of general well-being, and sample informed consent that could be used in screening and followup of patients receiving obesity pharmacotherapy as part of a weight loss program.⁶⁷ Additionally, numerous tools for both patient and practitioner are readily available through the Department of Human Services, NIH-NHLIB Obesity Education Initiative, and several other agencies.¹⁰ The Short Form 36 (SF-36) also has been used as a quality-of-life evaluation tool for obese patients undergoing programmatic weight loss. Quarterly assessments of well-being and quality of life using validated assessment tools can be helpful in objectively quantifying the effectiveness of therapy, as well as potential drug-induced side effects (e.g., depression).⁶⁷

Diabetic patients receiving weight loss medication require more intense medical monitoring and self-monitoring of blood glucose. Some centrally acting weight-loss agents, such as the serotonergic agents, have direct effects that immediately improve glucose tolerance, even prior to significant weight loss. Insulin therapy therefore may need to be adjusted with the start of obesity medication therapy. Peripherally active agents, such as orlistat, have also been shown to decrease oral hypoglycemic agent requirements in type 2 diabetic patients.⁶⁹ However, this effect was noted later in therapy and correlated more directly with weight loss. Some diabetic patients may require daily telephone contact with a healthcare provider to assist in adjusting their hypoglycemic therapy. Weekly patient visits to a healthcare setting may be necessary for 1 to 2 months until the effects of diet, exercise, and weight loss medication become more predictable. As frequent as quarterly assessment of hemoglobin A_{1c} may be appropriate in type 2 diabetics who lose weight to aid in adjustment of hypoglycemic therapy. Lipid profiles can normalize or improve with weight loss. Lipid status should be assessed semiannually or annually in patients with hyperlipidemia to determine need for continued hyperlipidemia therapies. Weight loss also can result in normalization of blood pressure in hypertensive obese patients.

Assessment of appropriateness of antihypertensive therapy should occur with each followup visit.

An expert committee of the National Heart, Lung, and Blood Institute of the National Institutes of Health has completed an extensive summary of clinical guidelines for the assessment and treatment of obesity.⁵¹ This report provides guidance with evidence-based, graded assessment and treatment recommendations from an extensive meta-analysis of the available obesity literature. The evaluation and management of a patient with obesity requires careful clinical, biochemical, and if necessary, psychological evaluation. The evaluation must include an assessment of current medical conditions and medications the patient uses. Clearly, a multidisciplinary team including, but not limited to, a physician, nutritionist, psychologist, and pharmacist best achieves this. The algorithm in Figure 148–3 shows an approach to determining appropriate types of treatment for the overweight individual. The decision to treat any overweight/obese patient depends on the degree and distribution of obesity present, the motivation of the patient to lose weight, and the potential benefits and risks of weight loss. The initial step in this process should be to verify the presence of clinically significant excess body weight. In the clinical setting, this is done most often by measuring height, weight, and WC of the individual and calculating BMI. If the BMI is greater than 25 kg/m² and/or WC is greater than 40 inches for males or 35 inches for females, it is likely that the patient will benefit from weight maintenance or loss. The next step is to assess whether the patient actually is motivated to lose weight. No matter what the treatment options are, they all require significant effort on the part of the patient to change lifestyle and comply with the management plan. If it is clear that the patient is not yet ready to meet these expectations, then early counseling will reduce the chance of frustration for the patient, clinician, and in some cases other family members. This does not exclude the possibility of educating the patient about potential risks of obesity and the benefits of weight loss. This type of basic information in certain cases can lead to a significant change in motivation and desire to lose weight and improved compliance.

Pharmacotherapy may be appropriate for some overweight individuals (e.g., those with a BMI of 30 kg/m² or more without weight-related, immediate life-threatening medical conditions). It also should be considered for those with BMI of 27 kg/m² or more or an increased WC who have two or more risk factors. From the healthcare providers' perspective, drug therapy for obesity always should be considered as a supplement to an integrated program of diet, exercise, and behavior modification (including group support). A complete medical and medication history is essential in determining appropriate obesity drug therapy. Consideration must be given to alcohol, nicotine, caffeine, and herbal or food supplement use as well as prescription and nonprescription drugs.

CONCLUSIONS

The prevalence of obesity has increased dramatically in the last 30 years. Obesity is determined by a combination of genetic and environmental factors. Epidemiologic studies provide evidence for a causative role of environmental factors in the development of obesity in those individuals who are genetically susceptible. Furthermore, there are clear differences in racial susceptibility to obesity and its complications such as diabetes. The precise role of genetic and environmental factors in the development is unknown. It is clear, though, that obesity is a lifelong condition. Currently, orlistat and sibutramine are available in the United States and are indicated for the long-term treatment of overweight and obesity. However, clinicians should keep in mind that long-term results over periods of 3 or more years regarding these therapies will require further research. Weight regain challenges many individuals regardless of the therapeutic modalities used, especially when treatment is

stopped. Nevertheless, in recent years, increasingly effective treatments have been developed, and there has been recognition that long term therapy, including long-term drug therapy, should be the standard in treatment of this chronic disease. These pharmaceutical agents have augmented the role of lifestyle changes and diet and therefore serve a useful role as adjunct therapies for obesity.

Every patient seeking help for the management of obesity should be evaluated for secondary causes of obesity. Although a secondary cause is rare, it is important to identify and manage. Treatment of obesity needs to be individualized. It is important to consider factors such as patient desires, age, degree and duration of obesity, and the presence or absence of medical conditions both directly related to obesity and those which may have an impact on the therapeutic decisions. Whatever combinations of therapeutic modalities are used, it is clear that management is a lifelong process requiring patient support and careful monitoring for safety and efficacy.

GLOSSARY

2,3-Bisphosphoglycerate: An intermediate in the Rapoport-Luebering shunt, formed between 1,3-bisphosphoglycerate and 3-phospho-glycerate; an important regulator of the affinity of hemoglobin for oxygen.

5- α -reductase: Enzyme responsible for conversion of testosterone to its active metabolite dihydrotestosterone. Two types of this enzyme exist. Type 2 is predominant in prostate cells.

α -Amino-3-hydroxy-5-methylisoxazole-4-propionate: See *AMPA*.

α -Hydroxy acids: Exfoliating products such as lactic, glycolic, malic, mandelic, and tartaric acid used in cosmetics.

β -Hydroxy acid: Salicylic acid.

γ -Aminobutyric acid (GABA): The major inhibitory neurotransmitter in the central nervous system.

γ -Aminobutyric acid (GABA_A) receptors: Postsynaptic ionotropic receptors that bind to GABA and result in Cl⁻ influx and neuronal hyperpolarization. GABA is the main inhibitory neurotransmitter in the brain, and GABA_A receptors mediate fast CNS inhibitory neurotransmission.

Abscess: A purulent collection of fluid separated from surrounding tissue by a wall comprised of inflammatory cells and adjacent organs. It usually contains necrotic debris, bacteria, and inflammatory cells.

Abstinence: Refraining from the indulgence in something, as sexual intercourse or substances, by one's own choice. The absence of genital contact that could permit a pregnancy (i.e., penile penetration into the vagina).

Acanthosis: Increased thickness of the prickle cell layer of the skin.

Acetabular: Relating to the acetabulum, the hollow, cuplike portion of the pelvis into which the head of the thigh bone (femur) fits.

Achalasia: Problem that occurs when a ring of muscle fibers, such as a sphincter of the esophagus, fail to relax.

Acne: Inflammatory eruption of the sebaceous gland.

Acnegenicity: Product effect that causes irritation of follicles resulting in papules and pustules.

Acquired resistance: See *Secondary resistance*.

Acromegaly: A pathologic condition characterized by excessive production of growth hormone.

Activities of daily living: Dressing, bathing, getting around inside the home, feeding, toileting, and grooming. See also *Instrumental activities of daily living*.

Acute coronary syndrome (ACS): Ischemic chest discomfort at rest most often accompanied by ST-segment elevation, ST-segment depression, or T-wave inversion on the 12-lead electrocardiogram

and caused by plaque rupture and partial or complete occlusion of the coronary artery by thrombus. Acute coronary syndromes include infarction and unstable angina. Former terms used to describe types of ACS include *Q-wave myocardial infarction*, *non-Q-wave myocardial infarction*, and *unstable angina*.

Acute pain: Can be a useful physiologic process warning individuals of disease states and potentially harmful situations. Severe, unremitting, undertreated, acute pain, when it outlives its biologic usefulness, can produce many deleterious effects (e.g., psychological problems). It usually subsides when the healing process decreases the pain-producing stimuli.

Acute pancreatitis: Acute inflammation of the pancreas that can be mild with minimal or no organ dysfunction or severe with organ failure and local complications.

Acute stress disorder: A disorder characterized by anxiety, dissociative, and other symptoms that occurs within 1 month after exposure to an extreme traumatic stressor.

Acute tubular necrosis: Acute renal failure as the result of renal tubular epithelial cell damage, which can be caused by either direct toxic or ischemic effects of drugs.

Adaptive functioning: Individual effectiveness coping with everyday stressors compared to a peer with similar background, and socioeconomic and psychosocial opportunities.

Adaptive inflammation: Inflammatory pain that promotes the shifting from prevention of tissue damage to promotion of healing.

Addiction: A primary, chronic, neurobiologic disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following five Cs: chronicity, impaired control over drug use, compulsive use, continued use despite harm, and craving.

Adjuvant analgesics: Agents that are useful in the treatment of pain but are usually not classified as analgesics.

Administrative burden: The demands placed on those who administer an instrument.

Adolescents: Pediatric patients who are 12 to 16 years of age.

Adoptive immunotherapy: Administration of immune cells for the purpose of cancer treatment.

Adrenergic: Neuronal or neurologic activity caused by neurotransmitters such as epinephrine, norepinephrine, and dopamine.

Adrenocorticotrophic hormone (ACTH): A polypeptide hormone secreted by the anterior pituitary that controls secretion of cortisol from the adrenal glands.

Adverse drug events: Injuries resulting from administration of a drug or other circumstances surrounding use of the drug but not necessarily caused by the drug itself. See also *Adverse drug reaction*.

Adverse drug reaction: Any noxious, unintended, and undesired effect of a drug that occurs at doses used in humans for prophylaxis, diagnosis, or therapy.

Affect: Pattern of behaviors that a clinician can observe that expresses a person's current state of emotion.

Afterload: The pressure or the *load* the heart must generate to eject blood into the systemic circulation. Although approximated by the systemic vascular resistance, it is a complex measure that includes blood viscosity, aortic impedance, and ventricular wall thickness. Along with preload, it is an important determinant of cardiac output.

Aganglionosis: The state of being without ganglia.

Agnosia: Cardinal symptom of Alzheimer's disease; inability to recognize or identify a familiar object in the absence of impaired sensory function.

Agoraphobia: Anxiety about, or avoidance of, places or situations from which escape might be difficult (or embarrassing) or in which help might not be available in the event of having a panic attack or panic-like symptoms.

Akathisia: The sensation of inner restlessness resulting in the need to make movements such as pacing or moving the legs. Akathisia has subjective and objective components.

Albumin: The major protein in plasma, with a molecular weight of 65 kDa.

Albuminuria: A condition where a large amount of albumin (>300 mg/day) is present in the urine, often indicating glomerular damage in the kidney.

Alcohol ablation: Alcohol ablation of the septum is a nonsurgical procedure to improve outflow tract obstruction. It is a percutaneous catheter-based method to decrease septal thickness by therapeutic myocardial infarction.

Alcoholism: A chronic, progressive, and potentially fatal biogenic and psychosocial disease characterized by tolerance and physical dependence and manifested by a total loss of control, as well as diverse personality changes and social consequences.

Algorithm (treatment algorithm): Identifies and specifies sequences for treatment alternatives, with specific options and tactics for care. Based on scientific data and on expert consensus in areas where there is little scientific data, algorithms are divided into stages so that the simplest, most efficacious, and best-tolerated treatments available are tried first. If results are not optimal, treatment advances to the next stage. Unless a patient's illness fails to improve sufficiently with early stage treatments, he or she is spared treatments that are more complex, that might be less well tolerated, or that have more potential for drug interactions or serious side effects. Algorithms recommend key decision points in treatment decision making.

Allergic interstitial nephritis: Inflammation of the interstitial region of the kidney often associated with acute onset of renal insufficiency.

Allergic salute: Constant upward rubbing of the nose as a result of allergies.

Allergic shiners: Dark circles under the eyes as a result of nasal congestion leading to venous pooling.

Allodynia: Painful response to normally non-noxious stimuli.

Allogeneic transplantation: Transfer of cells between different individuals.

Allograft: An organ or tissue transplant from one human to another.

Alloimmunization: Rapid consumption of transfused platelets through an immune-mediated reaction.

Alternate forms: All modes of administration other than the mode for which the instrument was originally developed.

Amenorrhea: Lack of menstruation or the abnormal ending of the female menstrual cycle.

American Urological Association (AUA) Symptom Index: A validated questionnaire of seven questions that can be used by patients to assess the bothersomeness of their voiding symptoms. The total score range is 0 to 35. Higher scores are consistent with severely bothersome symptoms.

Amnesia: A pathologic impairment of memory.

AMPA/kainate receptors: Two of three types of ionotropic postsynaptic glutamate receptors. These receptors are similar and are often considered together. On binding glutamate, these receptors permit the influx of sodium ions (Na⁺) and results in brain excitation. These are one of the two primary receptors for excitatory neurotransmission in the brain.

Amygdala: A small almond-shaped temporal lobe structure that plays a role in emotions and fear control.

Anaphylactoid: Anaphylaxis-like reactions that do not involve immunoglobulin E (IgE)-mediated mechanisms.

Anaphylaxis: Acute, life-threatening allergic reaction involving multiple organ systems.

Anastomosis: The surgical connection of two tubular structures, such as blood vessels, in a transplanted organ.

Andropause: Refers to a number of symptoms associated with decreased testosterone production by the testes in aging men. The symptoms include decreased libido, increased body fat, depressed mood, and osteoporosis. The symptoms of andropause generally worsen as the patient ages. Andropause in men parallels menopause in women.

Anemia of chronic disease: Mild to moderate anemia not associated with blood loss or hemolysis. Usually with normal cell size. Can be seen with chronic inflammation (e.g., rheumatoid arthritis, chronic infection) or malignancy.

Anemia of chronic kidney disease: A decrease in red blood cell production caused by a deficiency in the hormone erythropoietin normally produced by progenitor cells of the kidney. As kidney function declines, less erythropoietin is available to stimulate red blood cell production (erythropoiesis) in the bone marrow. Contributing factors include iron deficiency and a shortened, red-blood-cell life span.

Aneuploid: Deviation by a whole number in the total number of chromosomes in a cell compared to normal (46 in humans).

Angioedema: An allergic reaction characterized by edema of a tissue such as the lips, eyes, mouth, joints, or other structures because of leak of fluid from blood vessels.

Anhedonia: A lack of pleasure or interest in usual activities.

Anisocytosis: Considerable variation in the size of cells that are normally uniform, especially with reference to red blood cells.

Ankylosis: Bony fusion resulting from chronic joint inflammation.

Anomia: Cardinal symptom of Alzheimer's disease; inability to name objects or to recognize names.

Anorexia nervosa: A psychiatric disorder in which patients present with a fear of being obese. These patients often express a dislike or lack of interest in food; it is most common in young females and can disrupt normal menstrual cycles. It is associated with poor medication treatment response and can result in fatal medical complications.

Antenatal: Time between conception and birth; same as prenatal.

Anterograde amnesia: Inability to remember events or actions that occur after taking a sedative hypnotic medication.

Antibiogram: A summary of antimicrobial susceptibilities.

Anticipatory anxiety: The fear of having an anxiety attack, which is often a trigger by itself; “fear of fear.”

Anticoagulant: Any substance that inhibits, suppresses, or delays the formation of blood clots. These substances occur naturally and regulate the clotting cascade. Several anticoagulants have been identified in a variety of animal tissues and have been commercially developed for medicinal use.

Antigenic drift: The creation of antigenic variants by point mutations in the surface antigens, hemagglutinin and/or neuraminidase, of a particular subtype of influenza.

Antigenic shift: Occurs when an influenza virus acquires a new hemagglutinin and/or neuraminidase.

Antimicrobial cycling: A predetermined change in an antimicrobial recommendation for empiric therapy of a specific infection at a predetermined time.

Antimycotic: Inhibiting fungal growth.

Antithrombotic: A pharmacologic agent that prevents thrombus/clot formation. This category includes both antiplatelet agents and anticoagulants.

Anuria: Production of less than 50 mL of urine/day.

Anxiety: A state of apprehension, uncertainty, and fear resulting from the anticipation of a realistic or fantasized threatening event or situation that often impairs physical and psychological functioning.

Aortic stenosis: Aortic stenosis is the obstruction of blood flow across the aortic valve. This disorder has several etiologies: congenital unicuspid or bicuspid valve, rheumatic fever, and degenerative calcific changes of the valve.

Aphasia: Cardinal symptom of Alzheimer’s disease; inability to generate or comprehend spoken language.

Aphthous ulcer: A small superficial area of ulceration within the gastrointestinal mucosa, typically found in the oral cavity.

Apical pulse: Point at the apex (bottom portion) of the heart impacts the chest wall.

Apoptosis: Programmed cell death.

Appendageal: Referring to hair, sweat glands, and nails.

Apraxia: Cardinal symptom of Alzheimer’s disease; inability to carry out a motor task in the absence of impaired motor function.

Arteriovenous (AV) fistula: In hemodialysis, a vascular access surgically created by connection of an artery directly to a vein, usually in the forearm.

Arteriovenous (AV) graft: In hemodialysis, a vascular access surgically created using a synthetic tube to connect an artery to a vein.

Arteriovenous malformations: A tangle of blood vessels, both arterial and venous, that can rupture and cause hemorrhage in the brain.

Arthrodesis: The surgical immobilization of a joint (i.e., joint fusion).

Arthropathy: Disease of the joints.

Ascites: Accumulation of serous fluid in the peritoneal cavity.

Asherman’s syndrome: A cause for menstrual flow obstruction; often resulting from infection or surgery affecting the endometrium.

Asperger’s disorder: A type of pervasive developmental disorder characterized by severe and sustained impairment in social interaction, restricted and repetitive patterns of behavioral/interested activities—similar to autism but without clinically significant delays in language and cognitive development or age-appropriate self-help skills.

Aspiration pneumonitis: The inflammation of lung tissue caused by the aspiration of fluids and gastric contents that often leads to dyspnea, pulmonary edema, secondary infections, and adult respiratory distress syndrome. Hydrocarbon pneumonitis is caused by the pulmonary aspiration of hydrocarbons such as kerosene and gasoline.

Assertive community treatment: A treatment program for the care of individuals with schizophrenia in which teams provide comprehensive wraparound services for the patient, including going to the home to provide support for daily living skills, housing, and supported employment. Team members are available 24 hours daily if needed to meet the patient’s comprehensive care needs.

Asystole: The presence of a flat line on the electrocardiogram monitor.

Ataxia: Loss of the ability to coordinate muscular movement.

Atelectasis: Pulmonary parenchymal collapse caused by alveolar or bronchial obstruction.

Atopic dermatitis: Skin inflammation that causes itching, scales, and erythema.

Atopy: An allergic syndrome characterized by asthma, hay fever, and urticaria or eczema.

Atrial fibrillation: Rapid beating of the atria that results in variable ventricular rates.

Atropinism: Symptoms of poisoning by atropine or belladonna.

Aura: Sensory or somatosensory alteration without loss of consciousness.

Augmentation: Addition of a medication not usually used as monotherapy for a disorder to a core medication for a disorder in an attempt to enhance the patient’s clinical response.

Auscultation: Listening to the heart or other organs with a stethoscope.

Autism/Autistic disorder: A type of pervasive developmental disorder with a neurobiologic etiology, characterized by impaired reciprocal social interaction, impaired communication skills, and a limited range of activities and interests; frequently associated with mental retardation; sometimes referred to as early infantile autism, childhood autism, or Kanner autism.

Autologous transplantation: Readministration of the same person’s cells that were previously collected.

Autosomal: Pertaining to a chromosome.

Axonal transaction: Destroying or severing the axon so that electrical impulses are impeded along the nerve sheath or across the nerve

synapse. Axonal damage is not reversible and leads to long-term disability and the formation of black holes.

Azotemia: Term referring to elevated levels of urea in the serum or blood.

Azotorrhea: An excessive loss of protein in the feces.

Bacteremia: Presence of viable bacteria (fungi) in the bloodstream.

Bacterial prostatitis: An inflammation of the prostate gland and surrounding tissue as a result of infection.

Bacteriuria: The presence of bacteria in the urine.

Barrett esophagus: Inflammatory changes in the esophagus resulting in replacement of epithelial lining by columnar-type cells that can lead to stricture or adenocarcinoma.

Basal ganglia and striatum: Parts of the brain regulating movements.

Behavioral phenotype: The actions or reactions of a person to internal or external environmental influences.

Benign prostatic hyperplasia: Nonmalignant enlargement of the prostate gland in elderly men.

Bilateral salpingo-oophorectomy: Surgical excision (removal) of both ovaries.

Biliverdin: A green bile pigment formed from the oxidation of heme.

Binge eating: Excessive intake of calorie-laden food over a short period of time.

Bioavailability: The fraction of drug absorbed into the systemic circulation after extravascular administration.

Biochemical markers: Intracellular macromolecules released into the peripheral circulation from necrotic myocytes as a result of myocardial cell death (infarction). These laboratory tests are used in the diagnosis of myocardial infarction. Examples include troponin I, troponin T, creatinine kinase myocardial band (MB), and myoglobin.

Biofilm: A population or community of microorganisms adhering to a surface by a secreted coating. This coating also reduces microorganism vulnerability to antibiotics.

Biopsy: A procedure in which a tiny piece of a body part, such as the kidney or bladder, is removed for examination under a microscope.

Bioterrorism agents: Organisms or toxins that can cause disease and death in humans, animals, or plants for the purpose of eliciting terror.

Bipolar I disorder: Characterized by one or more manic or mixed episodes, and is usually accompanied by major depressive episodes.

Bipolar II disorder: Characterized by one or more major depressive episodes and accompanied by at least one hypomanic episode.

Bleeding diathesis: A condition in which there is an unusual susceptibility or predisposition to bleeding.

Blood urea nitrogen (BUN): A waste product in the blood that comes from the breakdown of food protein. The kidneys filter blood to remove urea and thus maintain homeostasis. As kidney function decreases, the BUN level increases.

Blood-brain barrier: The relative lack of permeability of large molecules (and those molecules lacking lipid solubility) into the central nervous system because of the nonfenestrated capillary beds of the cerebral vasculature.

Borborygmi: Rumbling or gurgling noises produced by movement of gas, fluid, or both in the alimentary canal and audible at a distance.

Brachytherapy: A procedure in which radioactive material sealed in needles, seeds, wires, or catheters is placed directly into or near a tumor. Also called internal radiation, implant radiation, or interstitial radiation therapy.

Bradykinesia: Delay or slowness in initiating and performing purposeful, voluntary movement as seen in Parkinsonism.

Breakthrough bleeding: The unpredictable and irregular bleeding associated with hormone therapy.

Bronchiectasis: Dilation of a bronchus or bronchi, usually related to excessive secretions.

Bronchioles: A subdivision of bronchi; smaller in diameter and without cartilage.

Bronchiolitis: Inflammation of the bronchioles.

Bronchoalveolar lavage: Instilling and then removing a lavage fluid to reveal the secretory and/or cellular contents from deep in the lung.

Bronchorrhea: Excessive bronchial secretions that can impair pulmonary ventilation.

Bruit: An abnormal and often harsh sound heard over a blood vessel, usually an artery, on examination with a stethoscope caused by turbulent blood flow.

B-type natriuretic peptide: B-type natriuretic peptide is a 32-amino-acid polypeptide secreted by the ventricles in response to excessive myocyte stretching. Elevated levels are typically seen in patients with left ventricular dysfunction and can correlate with both the heart failure severity and the prognosis.

Bulimia nervosa: A psychiatric disorder manifested by episodes of consuming a large caloric load over a short period of time (binge eating), with subsequent self-induced vomiting, use of cathartics or diuretics, fasting, or excessive exercise to prevent weight gain.

BUN (blood urea nitrogen): A waste product in the blood that comes from the breakdown of food protein. The kidneys filter blood to remove urea. As kidney function decreases, the BUN level increases.

Bursitis: Inflammation of the bursa, a fluid-filled soft tissue structure that usually results in pain and swelling.

Caffeinism: A clinical syndrome produced by acute or chronic overuse of caffeine characterized by anxiety, psychomotor alterations, sleep disturbances, mood changes, and psychophysiologic complaints.

Calcimimetic: A class of agents that stimulate calcium-sensing receptors on the parathyroid gland and *mimic* the effects of extracellular calcium. They suppress parathyroid hormone (PTH) release and increase the sensitivity of the receptor to extracellular calcium.

Calcium-sensing receptor: The calcium receptor on the chief cells of the parathyroid gland, activation of which leads to suppression of PTH release.

Candidiasis: Fungal infection involving *Candida* species.

Carcinoid: A carcinoid is a slow-growing tumor usually located in the gastrointestinal system and sometimes in the lungs or other sites. Carcinoids can spread to the liver and can secrete serotonin or prostaglandins.

Cardiac index: Cardiac output standardized for body surface area. Mathematically, cardiac index = cardiac output/body surface area.

Cardiac output: The volume of blood pumped by the heart per unit of time. Cardiac output is the product of heart rate and stroke volume.

Cardioembolic stroke: An ischemic stroke thought to be caused by an embolism arising from the heart. Cardioembolic stroke can be assumed in patients with significant cardiovascular disease including atrial fibrillation, dilated cardiomyopathy, prosthetic valves, recent myocardial infarction (MI), and patent foramen ovale.

Cardiopulmonary arrest: The abrupt cessation of spontaneous and effective ventilation and circulation following a cardiac or respiratory event.

Cardiopulmonary bypass: The use of extracorporeal devices to pump blood and oxygenate the blood while the heart or lungs are not functional. Extracorporeal membrane oxygenation (ECMO) is a form of long-term cardiopulmonary bypass that is typically used for days to weeks.

Cardiopulmonary resuscitation: The provision of artificial ventilation and circulation until it is possible to provide advanced cardiac life support and reestablish spontaneous circulation.

Carotid Doppler: A technique that provides information about the presence and severity of atherosclerosis of the carotid artery using noninvasive sound wave technology.

Carotid endarterectomy: Removal of the atherosclerotic plaque from the inside of a stenotic carotid artery by a surgical technique. The vessel is surgically opened and sewn and/or patched after removal of the plaque.

Case-control study: An observational study of persons with the disease of interest (cases) and a suitable control group of persons without the disease to establish the extent of association between exposure(s) of interest and disease.

Catalepsy: Sudden loss of muscle control with retention of clear consciousness that follows a strong emotional stimulus (as elation, surprise, or anger) and is a characteristic symptom of narcolepsy.

Cellulitis: An acute, infectious process that initially affects the epidermis and dermis and can subsequently spread within the superficial fascia.

Centrilobular: Affecting the central portion of the lobe.

Cerebral autoregulation: The process by which cerebral blood flow is maintained in a tight range over a wide range of peripheral blood pressures. It is accomplished by reactive dilation and constriction of cerebral arteries.

Cerebral blood flow (CBF): The volume of blood perfusing a given brain mass as a function of time.

Cerebral blood volume (CBV): The total volume of blood within the cerebral vasculature at a given point in time.

Cerebral microdialysis: A sampling method that allows continuous acquisition of a small volume of cerebral extracellular fluid specimens using a microdialysis probe inserted into the brain.

Cerebral oxygen consumption (CMRO₂): The cerebral metabolic rate for oxygen consumption calculated as the mean hemispheric CBF and the arteriovenous oxygen content difference (AVDO₂).

Cerebral oxygen delivery (CDO₂): The product of CBF and arterial oxygen content.

Cerebral perfusion pressure: A critical monitoring parameter in traumatic brain injury patients defined as the difference between the mean arterial pressure and the intracranial pressure.

Cerebrospinal fluid: The clear, colorless fluid that bathes and cushions the brain and spinal cord.

Cervical cap: A thimble-shaped latex rubber device that is held on the cervix by suction, thus acting as a barrier to reduce the risk of pregnancy.

Cervical effacement: During the first stage of labor, as the cervix is opening, it is also thinning. The thinning of the cervix is termed effacement.

Cervical ripening: Prior to inducing labor, the cervix must be favorable, approximately 2 cm dilated and 80% thinned out. If this is not the case, an agent must be used to induce histochemical changes to make the cervix more favorable.

Cervical stenosis: A cause for menstrual flow obstruction; often caused by surgical interventions for cervical dysplasia.

Cervicitis: Inflammation of the cervix.

Chancere: A sore or ulcer, the dermal lesion of primary syphilis.

Chancroid: A venereal dermal lesion caused by agents other than syphilis.

Children: Pediatric patients who are 1 to 11 years of age.

Cholestatic hepatitis: Rare form of hepatitis marked by stopped or suppressed flow of bile; characterized by pruritus, dark urine, light-colored stools, elevated alkaline phosphatase, and conjugated bilirubin.

Cholinesterase inhibitors: Class of medication that inhibits enzymatic activity of acetylcholinesterase, butyrylcholinesterase, or both to prevent the degradation of acetylcholine.

Chronic condition: An illness or impairment that cannot be cured.

Chronic kidney disease (CKD): Slow and progressive loss of kidney function that takes several years, often resulting in permanent kidney failure requiring dialysis or transplantation.

Chronic pain/persistent pain: Pain persisting for months to years.

Chronic pancreatitis: Chronic inflammation of the pancreas caused by the many sequelae of long-standing pancreatic injury leading to irreversible pancreatic damage.

Chvostek's sign: A facial twitch produced by tapping on the cheek over the branches of the facial nerve.

Circumstantial speech: Speech pattern whereby the expressed ideas are characterized by unnecessary detail. The speaker ultimately makes their point, but in a very roundabout manner.

Clearance: The volume of blood per unit time (e.g., L/h, mL/min) completely cleared of a drug.

Clinical inertia: A clinical situation in which no therapeutic move was made to treat a medical condition in a patient who is not considered adequately treated, or at his or her treatment goal.

Clinical outcomes: Medical events that occur as a result of the condition or its treatment.

Clinical pharmacokinetics: Discipline that describes the absorption, distribution, metabolism, and elimination of drugs in patients.

Clinical proteinuria: Total protein in the urine in amounts greater than 300 mg/day.

Clinical resistance: Refers to failure of an antifungal agent in the treatment of a fungal infection that arises from factors other than microbial resistance, such as failure of the antifungal agent to reach the site of infection, or inability of a patient's immune system to eradicate a fungus whose growth is retarded by an antifungal agent.

Clinically isolated syndrome: The first attack of multiple sclerosis characterized by a neurologic syndrome such as optic neuritis and generally seen with silent or asymptomatic white matter lesions (seen on magnetic resonance imaging) suggestive of demyelination. Individuals that experience a clinically isolated syndrome are at high risk of developing definite multiple sclerosis.

Clotting cascade: A series of enzymatic reactions by clotting factors leading to the formation of a blood clot. The clotting cascade is initiated by several thrombogenic substances. Each reaction in the cascade is triggered by the preceding one, and the effect is amplified by positive feedback loops.

Clotting factor: Plasma proteins found in the blood that are essential to the formation of blood clots. Clotting factors circulate in inactive forms but are activated by their predecessor in the clotting cascade or a thrombogenic substance. Each clotting factor is designated by a Roman numeral (e.g., factor VII) and by the letter “a” when activated (e.g., factor VIIa).

Cluster headache: A primary headache disorder characterized by attacks of severe unilateral headache pain that occurs in series of weeks or months (cluster periods) separated by remission periods usually lasting months or years.

Cluster period: The time during which cluster-headache attacks occur regularly and at least once every other day.

Codon: A sequence of three consecutive nucleotides that specify an amino acid or amino acid chain termination.

Coelomic metaplasia: Transformation of normal cells into endometrial cells.

Cognitive behavioral therapy: A form of psychotherapy designed to replace distorted or inappropriate ways of thinking with healthy, more realistic thoughts to alter maladaptive moods and behavior. It is instructional in approach and is based on the theory that thoughts (not external influences such as people, situations, and events) cause feelings and behaviors. Patients learn to identify the thinking that causes the negative feelings and behaviors and then learn how to replace that thinking with thoughts that lead to more desirable feelings and behaviors.

Cogwheeling: A ratchet-like movement in the joints, characteristic of Parkinson disease.

Cohort study: Assembly of a group of persons without a disease(s) of interest at the onset of the study, determination of the exposure status of each person, and observation of the cohort over time to determine the development of disease in exposed and nonexposed persons.

Colectomy: Surgical removal of the colon.

Colonization resistance: Preservation of anaerobic flora by selective gut decontamination to prevent colonization by potentially pathogenic gram-negative organisms.

Colony-stimulating factors: Proteins that regulate the proliferation, maturation, and differentiation of stem cells to red blood cells, white blood cells, and platelets.

Coma: A state of unconsciousness whereby a patient is not opening his or her eyes, not obeying commands, and not uttering understandable words.

Comedo, comedones (pl.): Plug of sebum and keratinous material in a hair follicle; blackhead.

Comedogenicity: Product effect that causes follicular plugging resulting in comedones.

Comedolytic: Prevents shed keratinocytes from aggregating in follicle and clogging pores.

Comorbidity: A concomitant but unrelated pathologic or disease process.

Complex partial seizure: A seizure beginning in one hemisphere of the brain. It is manifested by automatisms, periods of memory loss, or aberrations of behavior.

Compulsion: Repetitive ritualistic behavior such as ordering or hand washing or a mental act such as repeating words silently with the intent of preventing or reducing distress or some dreaded event or situation.

Conceptual model: The rationale for and description of the concepts that a measurement instrument is intended to assess and the interrelationships of those concepts.

Condom: A sheath, usually made of thin rubber, used to cover the penis during sexual intercourse to prevent conception or infection.

Confounding: A situation in which the effects of two processes are not separated. The distortion of the apparent effect of an exposure on risk brought about by the association of other factors that can influence the outcome.

Constrictive pericarditis: Constrictive pericarditis is a disorder caused by inflammation of the pericardium with subsequent thickening, scarring, and contracture of the pericardium. The pericardium cannot stretch during contraction, thereby preventing chamber filling.

Construct validity: The strength of the relationship between measures purporting to measure or reflect the same underlying theoretical construct.

Content validity: Refers to how adequately the questions/items capture the relevant aspects of the domain or concept being measured.

Continuation therapy: The second phase in drug therapy during which the goal is to eliminate any remaining symptoms and prevent a relapse.

Continuous-combined estrogen-progestogen therapy: Daily administration of both estrogen and a progestogen.

Continuous long-cycle estrogen-progestogen therapy: Estrogen is given daily and a progestogen is given six times a year (every other month for 12 to 14 days).

Convection: The movement of solutes, or metabolic waste products, by bulk flow in association with fluid removal. Convective clearance is not dependent on concentration gradients, and the magnitude of its contribution to total clearance is directly related to the ultrafiltration (fluid removal) rate.

Convulsion: Specific seizure type where the seizure is manifested by involuntary muscle contractions.

Cor pulmonale: Right-sided heart failure caused by lung disease.

Corneocytes: Flattened, dead, keratin-filled epidermal cells.

Coronary artery bypass graft surgery (CABGS): Thoracic surgery where parts of a saphenous vein from a leg or internal mammary artery from the arm are placed as conduits to restore blood flow between the aorta and one or more coronary arteries to *bypass* the coronary artery stenosis (occlusion).

Corpus cavernosum: Two chambers on the dorsal side of the penis. Chambers composed of sinusoidal tissue, which can fill with arterial blood to produce an erection.

Corpus luteum: The small yellow endocrine structure that develops within a ruptured ovarian follicle and secretes progesterone and estrogen.

Corpus spongiosum: One chamber on the ventral side of the penis. Chamber is composed of sinusoidal tissue, which can fill with arterial blood to produce an erection. The urethra passes through the corpus spongiosum.

Cortical necrosis: Acute renal failure secondary to ischemic necrosis of the renal cortex usually caused by significantly diminished renal arterial perfusion.

Corticotropin-releasing hormone (CRH): A trophic hormone released by the hypothalamus that stimulates release of adrenocorticotrophic hormone (ACTH).

Cost-effectiveness ratio: The outcome of cost-effective analysis. The numerator of the ratio summarizes the costs and financial savings associated with the therapy, including the costs of the therapy itself, side effects, medical costs, and savings from avoided illness and disability. The denominator of the cost-effectiveness ratio reflects the health effect of the intervention. The year of life saved is probably the most commonly used measure of the health effect.

Cranial nerve palsy: Paralysis of one or more of the 12 cranial (brain) nerves.

Craniectomy (for stroke): Removal of part of the skull overlying an area of injury to relieve the pressure of cerebral edema.

C-reactive protein: An endogenous marker released by the body in response to inflammation.

Creatine kinase, creatine kinase MB: Creatine kinase (CK) enzymes are found in many isoforms, with varying concentrations depending on the type of tissue. Creatine kinase is a general term used to describe the nonspecific total release of all types of CK, including that found in skeletal muscle (MM), brain (BB), and heart (MB). Creatine kinase MB is released into the blood from necrotic myocytes in response to infarction and is a useful laboratory test for diagnosing myocardial infarction. If the total CK is elevated, then the relative index (RI), or fraction of the total that is composed of CK-MB, is calculated as follows:

$$RI = (CK-MB/CK \text{ total}) \times 100$$

A RI greater than 2 is typically diagnostic of infarction.

Creatinine (serum): A protein metabolic by-product obtained from the diet or generated from muscles of the body. Creatinine is removed from blood by the kidneys; as kidney disease progresses, the level of creatinine in the blood increases.

Creatinine clearance: A test that measures how efficiently the kidneys filter creatinine and other waste products from the blood. Low creatinine clearance (<60 mL/min) usually indicates the presence of kidney damage.

Crepitus: A crinkly, crackling, or grating feeling or sound in the joints, skin, or lungs.

Cronbach α -coefficient: Commonly used statistical measure to quantify internal consistency reliability for multi-item scales or tests.

Crossmatch: A test to determine if a recipient has antibodies against donor antigens. A positive crossmatch indicates that the recipient has antibodies against the donor, and the two are incompatible. A negative crossmatch means the recipient does not have antibodies against the donor, and the two are considered compatible.

Crust: Dried exudate, secretion, or hemorrhage; scab.

Crypt abscess: Neutrophilic infiltration of the intestinal glands (crypts of Lieberkühn); a characteristic finding in patients with ulcerative colitis.

Culture negative endocarditis: Describes a patient in whom a clinical diagnosis of infective endocarditis is likely, but blood cultures do not yield a pathogen.

Cutaneous: Pertaining to the skin.

Cutis: Skin.

Cyanopsia: A condition when a patient sees a blue halo around objects, or objects appear to be blue-colored.

Cyanosis: Bluish tint to the skin or mucous membranes because of lack of oxygen.

Cyclic estrogen-progestogen therapy: Estrogen is taken continuously, with a progestogen added cyclically the last 10 to 14 days during each 28-day cycle.

Cyst: Sac or closed cavity containing fluid, semifluid, or solid material.

Cystitis: Inflammation of the bladder, usually caused by infection.

Cytokines: Protein molecules that are released by one cell (e.g., T-lymphocytes) that can have an influence on other cells. These proteins are important in numerous cell functions, such as regulating the immune response and cell-to-cell communication.

Dactylitis: Erythema and swollen hands, feet, fingers, and toes. Also known as *hand-and-foot syndrome*.

Deep vein thrombosis: A disorder of thrombus formation causing obstruction of a deep vein in the leg, pelvis, or abdomen.

Defibrillation: The therapeutic use of electric current in an attempt to completely depolarize the myocardium and provide an opportunity for the natural pacemaker centers of the heart to resume normal activity.

Delayed cerebral ischemia: A worsening in neurologic function in a subarachnoid hemorrhage patient, occurring several days after the initial bleed, not due to another cause.

Delusion: Fixed, false beliefs that are not based in reality or consistent with the patient's religion or culture. Delusions can be classified as paranoid, somatic, or grandiose in nature. Delusions are often unshakable in spite of evidence to the contrary.

Dementia: A chronic progressive neurodegenerative syndrome characterized by a decline in memory and at least one other cognitive function.

Demyelination: Destruction of myelin in the spinal cord and brain leading to the formation of plaques that impair communication between neurons. Demyelination is classically found in the central nervous system of patients with multiple sclerosis and may be reversible.

Depersonalization: A change in an individual's self-awareness, during anxiety disorder, such that one feels detached from his or her own experiences, with the self, body, and mind seeming alien or distant. Persistent or recurrent experiences as if one is an outside observer of one's mental processes or body (e.g., feeling like one is in a dream).

Derealization: A feeling of estrangement or detachment from one's environment.

Dermatitis: Inflammation of the skin.

Dermatophyte: Fungal infection of the skin.

Dermis: The inner layer of skin between the epidermis and hypodermis.

Desensitization: Administration of increasing doses of drug to achieve patient tolerance and avoidance of hypersensitivity reactions.

Detoxification programs: A medically supervised treatment program for alcohol or drug addiction designed to purge the body of intoxicating or addictive substances. Such a program is used as a first step in overcoming physiologic or psychologic addiction.

Detumescence: Process by which an erect penis becomes flaccid.

Diagnostic overshadowing: Underestimating the significance of the emotional disturbances because of the presence of significant cognitive deficits.

Dialysate: The cleansing solution used in dialysis to remove excess fluids and waste products from the blood.

Dialysis: The process of removing toxic substances and fluid across a semipermeable membrane to maintain fluid, electrolyte, and acid-base balance.

Diaphragm: (1) A flexible ring covered with rubber or other plastic material, fitted over the cervix of the uterus to prevent pregnancy. (2) Muscular membrane separating the abdominal and thoracic cavities, used for respiration.

Diastolic blood pressure: The arterial blood pressure that occurs after cardiac contraction when the cardiac chambers are filling.

Diastolic heart failure: A condition caused by increased resistance to the filling of one or both ventricles; this leads to symptoms of congestion from the inappropriate upward shift of the diastolic pressure-volume relation.

Diffusion-weighted imaging: A type of magnetic resonance imaging (MRI) that can sensitively detect changes in water movement in tissue. It is particularly sensitive to the early changes seen during brain ischemia.

Digital clubbing: Rounded and swollen tip of finger usually associated with long-term pulmonary disease.

Dihydrotestosterone: The active androgen metabolite, which is formed inside various cells. In the case of benign prostatic hyperplasia (BPH), dihydrotestosterone is formed inside prostate cells by the action of 5- α -reductase, which converts testosterone to dihydrotestosterone. Dihydrotestosterone stimulates the glandular portion of the prostate to undergo hyperplasia.

Disinhibition: A physiologic effect that occurs during psychoactive substance use characterized by a loss of normal, executive functioning and normal behavior. An increase in behaviors with the propensity to harm the individual is common.

Dissociative amnesia: Inability to remember some important aspect of an event.

Diverticulitis: Inflammation of a diverticulum, especially of the small pockets in the wall of the colon that fill with stagnant fecal material and become inflamed; rarely, they can cause obstruction, perforation, or bleeding.

Dopamine: A monoamine neurotransmitter formed in the brain by the decarboxylation of dopa and essential to the normal functioning of the central nervous system.

Doppler imaging: With Doppler imaging, a probe generates sound waves typically at 2.5 MHz. When encountering an object, sound waves are scattered or reflected back toward the probe from the object's interface with adjacent structures; this is repeated in many times per second to build up a moving real-time image of the heart.

Drug abuse: A maladaptive pattern of substance use indicated by repeated adverse consequences related to the repeated use of the substance. Examples include failure to fulfill important obligations at work, school, or home; repeated use in situations in which it is physically dangerous, such as driving under the influence; legal problems; and social or interpersonal problems such as arguments and fights.

Drug addiction: A chronic disorder characterized by the compulsive use of a substance resulting in physical, psychologic, or social harm to the user and continued use despite that harm.

Dual diagnosis: A developmentally disabled person comorbid with a psychiatric disorder.

Dysentery: Diarrhea characterized by blood, mucus, and leukocytes in the stool with tenesmus and fever.

Dyskinesia: Choreiform abnormal involuntary movements involving usually the face, neck, trunk, and extremities.

Dysmenorrhea: Crampy pelvic pain occurring with or just prior to menses. *Primary* dysmenorrhea implies pain in the setting of normal pelvic anatomy, whereas *secondary* dysmenorrhea is secondary to underlying pelvic pathology.

Dyspareunia: Painful sexual intercourse.

Dyspepsia: Literally means "bad digestion," but refers to persistent or recurrent pain or discomfort centered in the upper abdomen. Symptoms can include epigastric pain, bloating, abdominal distention, postprandial fullness, early satiety, and nausea.

Dysphagia: Difficulty swallowing.

Dysphoria or dysphoric: A feeling of discomfort or an unpleasant mood, such as sadness, anxiety, or irritability.

Dyspnea: Dyspnea is referred to as shortness of breath or difficulty or distress in breathing.

Dystonia: Sustained muscular spasm or abnormal postures.

Early empirical therapy: The administration of systemic antifungal agents at the onset of fever and neutropenia.

Economic outcomes: The direct, indirect, and intangible costs compared with the consequences of a medical intervention.

Edema: Accumulation of fluid in tissues.

Effective renal plasma flow (ERPF): The flow of plasma through the kidneys; often measured by *p*-aminohippurate (PAH) clearance and expressed in volume per unit of time (mL/min). The ERPF is less than the true renal plasma flow (RPF) because plasma flow through renal connective and adipose tissue is not measured and the extraction of PAH, although high (>0.9), is not complete.

Ejaculatory dysfunction: This is a type of sexual dysfunction that can present as premature ejaculation (before orgasm has occurred), anejaculation (failure of emission), or retrograde ejaculation (when ejaculate moves backward into the bladder as opposed to forward and out of the body during orgasm). In some cases, ejaculatory dysfunction can decrease sexual enjoyment in the patient.

Ejection fraction: The ejection fraction is the percentage of blood ejected from the left ventricle with each heart beat.

Elation: An exaggerated feeling of well-being, euphoria, or elation.

Electroconvulsive therapy: A treatment for severe mental illness in which a precisely calculated electric stimulus is administered in a controlled medical setting to produce a generalized seizure.

Electroencephalograph (EEG): Used to evaluate brain electrical activity.

Electroencephalography: A test that measures electrical brain wave activity through the use of multiple scalp electrodes.

Electromyography: Test of muscle function because of either primary muscle disease or secondary to nerve injury.

Embolism: The sudden blockage of a vessel caused by a blood clot or foreign material that has been brought to the site by the flow of blood.

Embolization: The process by which a blood clot or foreign material dislodges from its site of origin, flows in the blood, and blocks a distant vessel.

Emergency contraception: Any method of contraception that acts after intercourse to prevent pregnancy.

Emesis: See *Vomiting*.

Empirical therapy: With systemic antifungal agents is administered to granulocytopenic patients with persistent or recurrent fever despite the administration of appropriate antimicrobial therapy.

Enanthem: Eruption on a mucous membrane (as the inside of the mouth) occurring as a symptom of a disease

Encephalitis: Inflammation of the brain tissue.

Encephalopathy: An altered brain state that can occur with altered brain structure. Many etiologies are associated with encephalopathy (toxins, cancer, metabolic disorders, CNS infections, increased cranial pressure, radiation, alcohol, psychotropic drugs, trauma, inadequate nutrition, decreased brain oxygen, and CNS injury). Consciousness is impaired with patients having a decreased/altered mental state and diffuse slowing of the EEG. Encephalopathy is often associated with seizures, loss of cognitive/memory, and personality changes, and can be associated with myoclonus and other neurologic impairments.

Endobronchitis: Inflammation of the epithelial lining of the bronchi.

Endocarditis: An infection of the endocardial surface of the heart, which can include one or more heart valves, the mural endocardium, or a septal defect.

Endometriosis: Presence of endometrial tissue outside the uterus.

Enkephalins: Pentapeptide endorphins, found in many parts of the brain, that bind to specific receptor sites, some of which can be pain-related opiate receptors.

Enteric fever: Intestinal inflammation and ulceration with high fever and abdominal complaints caused by infection.

Enterocolitis: Inflammation of the small intestine and colon.

Enterotoxin: A cholera-like disease that produces secretory diarrhea.

Enuresis: Urinary incontinence, especially at night.

Enzymuria: Presence of enzymes in the urine.

Epidermis: The outer layer of skin.

Epilepsy: Two or more unprovoked seizures; symptoms of disturbed electrical activity in the brain.

Epilepsy syndrome: The combination of seizure type with other components of the patient history such as age of onset, intellectual development, findings on neurologic examination, and results of neuroimaging.

Episodic: Recurring and remitting in a regular or irregular pattern.

Epistaxis: Nose bleed.

Epithelial cells: Cells that make up epithelium.

Epithelial tissue of the prostate: Also known as glandular tissue. This portion of the prostate is responsible for producing prostatic secretions, and this comprises only approximately 25% of the total volume of the enlarged prostate gland in patients with benign prostatic hyperplasia. Epithelial tissue is androgen dependent.

Epithelium: Layer of avascular cells covering body surfaces.

Erectile dysfunction: Also known as *impotence*. This is a failure of the penis to become rigid enough to allow for vaginal penetration of the sexual partner.

Erysipelas: Infection of the more superficial layers of the skin and cutaneous lymphatics.

Erythema: Redness.

Erythema multiforme: Symmetrical patches of raised, red skin.

Erythema nodosum: Raised, red, tender nodules on the skin that vary in size from 1 cm.

Erythroderma: Generalized redness of the skin.

Erythropoiesis: The production of erythrocytes (red blood cells) within the bone marrow.

Erythropoietic agents: Agents developed with recombinant DNA technology that have the same biologic activity as endogenous erythropoietin to stimulate red blood cell production. Available agents in the United States include epoetin alfa and darbepoetin alfa.

Erythropoietin: A hormone made by the kidneys that is required for red blood cell formation in the bone marrow. Lack of this hormone leads to anemia.

Eschar: Black, painless skin ulcer characteristic of cutaneous anthrax.

Esophageal: Involving the esophagus.

Esophageal stricture: A narrowing of the esophageal lumen because of acid reflux into the lower esophagus.

Esophagitis: Inflammation of the esophagus.

Essential or primary hypertension: Persistently elevated blood pressure that results from unknown pathophysiological etiology.

Estrogen therapy: Unopposed estrogen regimens administered to postmenopausal women following hysterectomy.

Euphoria: A mood state characterized by an exaggerated, superficial sense of well-being, characterized extreme happiness, sometimes more than is reasonable in a particular situation.

Euthymia or euthymic: A mood in a *normal* range without depression or mood elevation.

Evidence-based medicine (EBM): Evidence-based medicine emphasizes the consideration of results from clinical research as the basis for clinical decision making. Under this practice approach, unless individual patient-specific factors dictate otherwise, treatment should generally be guided by those approaches that have the best research evidence for efficacy, tolerability, and patient acceptance.

Evoked potentials: EEG-based technique involving measurement of brain-wave activity in response to stimuli, usually visual or auditory.

Exanthema: An eruption on the skin occurring as a symptom of a disease.

External beam radiotherapy: Treatment by radiation emitted from a source located at a distance from the body; also called beam therapy and external beam therapy.

Extrapyramidal: Regarding involuntary motor movement.

Extrapyramidal system: Neurotransmitter tracts in the midbrain with dopamine as the primary ascending neurotransmitter, with cell bodies in the substantia nigra and axons terminating in the basal ganglia (e.g., caudate nucleus, putamen). The extrapyramidal system is largely involved in the control of fine motor movements, and with some degree of emotional expression as well.

Fasciculations: The localized contractions of muscle groups, often visible through the skin, because of excessive neuronal discharge.

Fear: A direct, focused response to a specific event or object of which an individual is consciously aware.

Felty syndrome: Rheumatoid arthritis associated with splenomegaly and neutropenia.

Fibrin: An insoluble protein that is one of the principle ingredients of a blood clot. Fibrin strands bind to one another to form a fibrin mesh. The fibrin mesh often traps platelets and other blood cells.

Fibrosis: Formation of fibrous tissue as a reparative or reactive process.

First-generation (typical or traditional) antipsychotic: An antipsychotic medication with a mechanism of action thought to be primarily caused by the blockade of dopamine-2 (D_2) receptors. D_2 -blockade is associated with hyperprolactinemia and extrapyramidal side effects.

Fistula: A communicating tubelike passage from one organ to another, or from an organ to an external surface; often seen in severe cases of Crohn's disease.

Flight of ideas: An accelerated flow of speech with thoughts that change rapidly from one topic to another.

Focal seizures: Partial seizures.

Follicle-stimulating hormone (FSH): A polypeptide hormone secreted by the anterior pituitary gland that promotes ovarian follicle development and stimulates estradiol and progesterone.

Fragile X syndrome: A genetic disorder commonly associated with mental retardation in which the tip of the long arms of the X chromosome separates from the rest of the genetic material; most males and 30% of females with fragile X syndrome have mental retardation; males develop enlarged testicles, enlarged ears, and a prominent jaw.

Freezing: Intermittent immobility lasting a few seconds, particularly in walking, seen in Parkinsonism.

Fulminant hepatitis: Acute hepatic failure; rare complication of viral hepatitis, it can also result from hepatotoxins, or drug sensitivity and causes massive necrosis of the liver; marked by a high fatality rate.

Functional analysis: Evaluation performed by a psychologist qualified in applied behavioral analysis to determine if a behavior is caused by some environmental factor.

Functional pain: Pain because of abnormal operation of the nervous system.

Functional psychiatric disorder: A mental disorder that is primarily defined by a constellation of symptoms and behaviors and for which the pathophysiologic etiology is still largely unknown.

Fungemia: The presence of fungi in the blood.

Gastroesophageal reflux disease (GERD): Symptomatic clinical condition or histologic alteration that results from episodes of gastroesophageal reflux.

Gene: Series of codons that specify a particular protein.

Generalized anxiety disorder (GAD): Excessive anxiety and worry occurring more days than not for a period of at least 6 months.

Generalized convulsive status epilepticus (GCSE): Most common and dangerous type of status epilepticus (SE). It consists of bilateral (both brain hemispheres) electrical seizure activity that manifests as tonic and/or clonic motor activity. The convulsions and/or brain discharges can be symmetrical or asymmetrical (i.e., parts of body and brain mirroring or not mirroring each other in activity). Consciousness is not maintained during the seizure episodes. The duration is sufficient enough in length to meet the definition of SE.

Generalized seizures: Seizures occurring in both hemispheres of the brain. They can be primary or secondarily generalized.

Generic/general measures: Instruments designed to be applicable across a wide variety of conditions/diseases, medical interventions, and populations.

Genotype: Genetic makeup of an organism or group of organisms with respect to a single trait or traits. Can also refer to parent-to-offspring gene transmission.

Genu valgum: A deformity marked by lateral angulation of the leg in relation to the thigh.

Genu varum: A deformity marked by medial angulation of the leg in relation to the thigh; an outward bowing of the legs.

Gestation: Time from fertilization of egg until birth.

Gigantism: Excess secretion of growth hormone prior to epiphyseal closure in children.

Glasgow coma scale: The most widely used system to grade the arousal and functional capacity of the cerebral cortex consisting of eye opening, motor responses, and verbal responses.

Glaucoma: Any of a group of ocular disorders that lead to an optic neuropathy characterized by changes in the optic nerve head (optic disk) that is associated with loss of visual sensitivity and field. Open angle and closed angle are the two major types of glaucoma.

Glomerular filtration rate (GFR): The primary index of overall kidney function; the volume of plasma that is filtered by the glomerulus per unit of time; often reported in mL/min or mL/min/1.73 m².

Glomerulonephritis: Glomerular lesions characterized by inflammation of the capillary loops in the glomerulus caused by immunologic, vascular, and other idiopathic diseases (may be diffuse or membranoproliferative).

Glomerulosclerosis: Fibrosis of the glomeruli.

Glomerulus: A coiled capillary bed in the kidney that is responsible for filtering water and small molecular weight substances from the blood.

Gonadotropin: A sex hormone that promotes gonadal growth and functioning in both males and females.

Gonadotropin-releasing hormone (GnRH): A trophic hormone released by the hypothalamus that stimulates release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH).

Gout: A disease spectrum that includes hyperuricemia, recurrent attacks of acute arthritis associated with monosodium urate crystals in leukocytes found in synovial fluid, deposits of monosodium urate crystals in tissues (tophi), interstitial renal disease, and uric acid nephrolithiasis.

gp120: The glycoprotein structure on the surface of human immunodeficiency virus (HIV) that binds to CD4 on human cells.

Grandiosity: An inflated self-appraisal of one's status, power, or identity.

Granuloma inguinale: Granuloma lesions affecting the genital area.

Growth hormone (GH): A polypeptide hormone secreted by the anterior pituitary gland that stimulates insulinlike growth factor-1 (IGF-1) production and promotes growth of all body cells.

Growth hormone-releasing hormone (GHRH): A trophic hormone released by the hypothalamus that stimulates release of growth hormone.

Guillain-Barré's syndrome: A disorder characterized by progressive symmetrical paralysis and loss of reflexes, usually beginning in the legs. The paralysis typically involves more than one limb, is progressive, and usually proceeds from the end of an extremity toward the torso. Areflexia or hyporeflexia can occur in the limbs. It typically occurs after recovery from a viral infection.

Gumma: A granulomatous lesion found in organs or tissues as a result of syphilis.

Gynecomastia: Gynecomastia is the abnormal development of large breasts in men.

Half-life: The time required for serum concentrations to decrease by one-half after absorption and distribution are complete.

Hallucination: A sensory perception (e.g., auditory, gustatory, olfactory, somatic, tactile, visual) that occurs without external stimulation of the relevant sensory organ.

Haplotype: A set of polymorphisms that are inherited together.

Haptocorrin: A group of carrier proteins that bind with vitamin B₁₂ in the blood and aid in its transport.

Haptoglobin: A group of α_2 -globulins in human serum, so called because of their ability to combine with hemoglobin, preventing loss in the urine; levels are decreased in hemolytic disorders and increased in inflammatory conditions or with tissue damage.

Hay fever: See *Rhinitis*.

Health outcomes: The consequences or end results of a disease and/or its treatment.

Health profiles: Generic instruments that provide an array of scores representing individual dimensions or domains of health-related quality of life (HRQOL) or health status.

Health-related quality of life (HRQOL): A person's perception of how health impacts his or her physical, social, and psychological functioning and well-being.

Health state preference: The perceived relative desirability of a health state measured on a scale where 1.0 equals full health, and 0.0 equals dead.

Heart failure: A clinical syndrome that can result from any disorder that impairs the ability of the heart to fill with or eject blood. Although heart failure can be caused by numerous cardiac disorders, the primary clinical signs and symptoms of dyspnea, fatigue, and volume overload are similar regardless of the initial cause.

Heinz bodies: Intracellular inclusions usually attached to the red cell membrane composed of denatured hemoglobin.

Hemagglutinin: The major antigenic determinant of the influenza virus; a surface antigen that allows the influenza virus to enter host cells by attaching to sialic acid receptors.

Hematemesis: Vomiting up blood that can be bright red or similar to coffee grounds in appearance.

Hematochezia: Passage of visible bright red bloody stools.

Hematopoiesis: The formation and maturation of blood cells and their derivatives.

Hematopoietic growth factors: See *Colony-stimulating factors*.

Hematuria: Presence of red blood cells in the urine.

Hemochromatosis: Hemochromatosis is a disorder that interferes with iron metabolism, which results in excess iron deposition throughout the body.

Hemodialysis: A dialysis procedure during which blood is pumped outside the body through a dialyzer that acts like an artificial kidney; the dialyzer removes extra fluids and wastes from the blood and returns the clean blood to the body.

Hemolytic uremic syndrome: A condition characterized by the breakup of red blood cells (hemolysis) and kidney failure. Platelets clump together within the kidney's small blood vessels resulting in ischemia leading to kidney failure.

Hemosiderin: A golden yellow or yellow-brown insoluble protein produced by phagocytic digestion of hematin; found in most tissues, especially in the liver, spleen, and bone marrow, in the form of granules much larger than ferritin molecules (of which they are believed to be aggregates) but with a higher content, as much as 37%, of iron.

Hepatosplenic candidiasis: Clinical presentation often manifested only as fever while a patient remains neutropenic (<1,000 white blood cells/mm³). When the white blood cell (WBC) count increases to >1000 cells/mm³, imaging studies can detect the presence of abscess or microabscesses in the liver and spleen, often found with acute suppurative and granulomatous reactions. Infection can persist for months and ultimately cause the patient's death despite aggressive systemic therapy with antifungal agents. Also known as *chronic systemic candidiasis*.

Heterozygous: Presence of different (alleles) genes at one location.

Hippocampal sclerosis: A condition in which there are histopathologic changes in the hippocampus that have been associated with patients with a history of prolonged SE. There is an association with hippocampal sclerosis and temporal lobe epilepsy.

Hippocampus: A sea horse-shaped structure located within the brain that is an important part of the limbic system. The hippocampus is involved in some aspects of memory, in the control of the autonomic functions, and in emotional expression.

Hirsutism: Heavy, abnormal growth of hair on the face or body; excess body hair appearing on the lower abdomen, around the nipples, around the chin and upper lip, between the breasts, and on the lower back.

HLA (human leukocyte antigen): See *Human leukocyte antigen*.

Hollenhorst plaque: Cholesterol emboli that usually dislodge from the carotid arteries, or calcific fragments from a stenosed aortic valve that can be visualized on a retinal exam.

Homocysteine: A homolog of cysteine, produced by the demethylation of methionine, and an intermediate in the biosynthesis of 1-cysteine from 1-methionine through 1-cystathionine. Elevated levels of homocysteine have been associated with certain forms of heart disease.

Homozygous: Presence of identical genes (alleles) at one location.

Hormone therapy: Either estrogen-only therapy or combined estrogen and progestogen therapy.

Hot flashes/flushes: A sensation of warmth, frequently accompanied by skin flushing and perspiration.

Human leukocyte antigen (HLA): The *self antigens* are the histocompatibility antigens found on human leukocytes and tissues that enable the body to differentiate *self* from *foreign* cells. The HLA antigens are used in histocompatibility testing to determine the suitability of an organ for transplant.

Humanistic outcomes: Patient-reported outcomes such as patient satisfaction and health-related quality of life.

Hydrocephalus: An uncharacteristic increase in the amount of cerebrospinal fluid within the skull, causing dangerous expansion of the cerebral ventricles.

Hyperalgesia: Exaggerated painful response to normally noxious stimuli.

Hyperarousal: A state of elevated or increased alertness, awareness, or wakefulness.

Hypercapnia: Elevation of carbon dioxide gas in the blood.

Hypercoagulable state: A disorder or state of excessive or frequent thrombus formation; also known as *thrombophilia*.

Hypereosinophilic syndrome: Hypereosinophilic syndrome is a group of leukoproliferative disorders characterized by an overproduction of eosinophils resulting in organ damage.

Hyperkalemia: Serum potassium concentration above 5.5 mEq/L.

Hypermagnesemia: Serum magnesium concentration above 1.8 mEq/L or 2.3 mg/dL.

Hyperpigmentation: Excess pigment in skin causing an area of darker color than surrounding skin.

Hyperprolactinemia: A state of persistent serum prolactin elevation characterized by prolactin concentrations greater than 20 mcg/L observed on multiple occasions.

Hyperresponsiveness: In the airways, the characteristic of an exaggerated response to stimuli.

Hypertensive crises: Clinical situations where blood pressure values are very elevated, typically greater than 180/120 mm Hg; they are categorized as either a hypertensive emergency or hypertensive urgency depending on the clinical presentation.

Hypertensive emergency: A clinical situation in which a patient has extremely high blood pressure values, typically greater than 180/120 mm Hg that is also accompanied by the presence of acute and/or progressing target-organ damage. Immediate but gradual reduction in blood pressure using intravenous antihypertensive agents is needed to prevent acute morbidity and/or mortality.

Hypertensive urgency: A clinical situation in which a patient has extremely high blood pressure values, typically greater than 180/120 mm Hg that is not accompanied by acute or progressing target-organ injury. These situations require oral antihypertensive therapy to reduce blood pressure to stage 1 values over a period of several hours to several days.

Hypertrophic cardiomyopathy: Hypertrophic cardiomyopathy is a genetic disorder characterized by disproportionate hypertrophy of the left ventricle, and occasionally of the right ventricle.

Hypervigilance: An enhanced state of sensory sensitivity accompanied by an exaggerated intensity of behaviors whose purpose it is to detect threats.

Hypnagogic hallucinations: Dreamlike experiences on the threshold of sleep that intrude into wakefulness.

Hypnopompic hallucinations: Dreamlike experiences on the threshold of awakening that intrude into wakefulness.

Hypochlorhydria: Presence of an abnormally small amount of hydrochloric acid in the stomach.

Hypokalemia: Serum potassium concentration below 3.5 mEq/L.

Hypomagnesemia: Serum magnesium concentration below 1.4 mEq/L or 1.7 mg/dL.

Hypomania: An abnormally and persistently elevated, expansive, or irritable mood that lasts at least 4 days but does not cause marked impairment in functioning.

Hypomimia: Decreased facial expression often associated with decreased blink rate.

Hypophonia: Decreased volume of speech.

Hypothalamus: A small region at the base of the brain that controls the release of hormones from the anterior and posterior regions of the pituitary gland and regulates limbic functions, fluid balance, body temperature, cardiovascular function, respiratory function, and diurnal rhythms.

Hysterectomy: Surgical removal of the uterus.

Hysteresis: A situation in which concentration-effect curves do not always follow the same pattern when serum concentrations increase as they do when serum concentrations decrease. Can result from tolerance to a drug (clockwise hysteresis) or accumulation of active metabolites (counterclockwise hysteresis).

Iatrogenesis or iatrogenic disease: A disease produced as a consequence of medical or surgical treatment.

Ictal: The period during a seizure.

Icteric: Relating to or marked by jaundice.

Idiopathic: Unknown etiology.

Ileitis: Inflammation of the ileus.

Illusions: Visual perceptions that are misinterpreted but have a real sensory stimulus.

Immunocompromised host: A patient with defects in host defenses that predisposes him or her to infection (risk factors can include neutropenia, immune system defects from disease or immunosuppressive drug therapy, compromise of natural host defenses, environmental contamination, and changes in normal flora of the host).

Immunoglobulin: Structurally related glycoproteins that function as antibodies and are divided into classes on the basis of structure/biologic activity.

Impaction: An immovable packing; a lodgment of something in a strait or passage of the body; as, impaction of the fetal head in the strait of the pelvis; impaction of food or feces in the intestines of man or beast.

Impending status epilepticus (SE): Any seizure that does not stop automatically within 5 minutes has been termed *impending SE*. This is a fairly new term that was created to recognize the importance of early treatment of SE. Pharmacologic and nonpharmacologic treatment of SE should be initiated for those seizures that do not spontaneously terminate within 5 minutes.

Impetigo: A superficial skin infection that is seen most commonly in children.

Implantable cardioverter-defibrillator (ICD): The ICD is a surgically implanted electronic device that monitors, detects, and treats potentially life-threatening ventricular tachycardia with rate-responsive ventricular pacing.

Inanition: Severe weakness and wasting as occurs from lack of food, defect in assimilation, or neoplastic disease.

Incubation period: The time between exposure of a biologic (i.e., pathogen), chemical, or radiologic substance and when symptoms first start to appear (also known as latency).

Induction: Administration of a highly intense level of immunosuppression in the perioperative period or use of antibody therapy to provide enough immunosuppression to delay administration of nephrotoxic calcineurin inhibitors.

Infant mortality: Deaths occurring in those younger than the age of 1 year per 1,000 live births.

Infants: Pediatric patients who are 1 month to 1 year of age.

Infection: Inflammatory response to invasion of normally sterile host tissue by the microorganisms.

Information bias: A flaw in measuring exposure or outcome data that results in systematic differences in the quality of information gathered for study and comparison groups. See also *Selection bias*.

Instrumental activities of daily living: Housekeeping chores, shopping, going outside, medication management. See also *Activities of daily living*.

Insulin-like growth factor-1: An anabolic peptide that acts as a direct stimulator of cell proliferation and growth in all body cells.

Integumentary system: Skin, subcutaneous tissue, and skin appendages.

Interleukin: A type of cytokine, usually influencing a white blood cell.

Intermittent-combined estrogen-progestogen therapy: A regimen that combines a daily estrogen with a progestogen administered intermittently in cycles of 3 days on and 3 days off (which is then repeated without interruption).

International normalized ratio (INR): A measure of coagulation calculated from the patient's prothrombin time (PT) measurement compared to the laboratory's mean normal control measurement and takes into account the sensitivity of the thromboplastin used to perform the test.

Interpersonal psychotherapy: A psychologic intervention that focuses on interpersonal relationships and psychosocial functioning.

Interpretability: The degree to which one can assign qualitative meaning to an instrument's quantitative scores.

Intertriginous areas: Body fold areas (e.g., between buttocks, beneath breasts, between toes, under arms).

Intoxication: The development of a substance-specific syndrome after recent ingestion and presence in the body of a substance; associated with maladaptive behavior during the waking state caused by the effect of the substance on the central nervous system.

Intracavernosal injection: Injection into the corpus spongiosum.

Intracranial hypertension: Excessive pressure (greater than 20 mm Hg) within the nondistensible intracranial cavity (i.e., skull) that can develop following traumatic brain injury.

Intracranial pressure: The pressure of the cerebral spinal fluid that is essentially the same as the pressure within the brain tissue (i.e., intraparenchymal pressure).

Intraperitoneal (IP): Situated within or administered by entering the peritoneum.

Intrauterine device: A device inserted in the uterus to prevent pregnancy, either through spermicidal action (copper device) or thickening cervical mucus to inhibit sperm penetration and migration (progesterone device).

Intrinsic resistance: See *Primary resistance*.

Intussusception: Invagination of one portion of the intestine into an adjacent part of the intestines.

Inulin: A fructose polysaccharide that is filtered by the glomerulus; its clearance is often used as an index of GFR.

Iothalamate: A nonradiolabeled or radiolabeled iodinated contrast agent that is filtered by the glomerulus; its clearance is often used as an index of GFR.

Irritable: Easily annoyed and provoked to anger.

Irritative voiding symptoms: Urinary urgency and frequency. This results from detrusor muscle decompensation that results from long-standing bladder outlet obstruction.

Isolated systolic hypertension: Patients with diastolic blood pressure values that are less than or equal to 90 mm Hg and systolic blood pressure values that are greater than or equal to 140 mm Hg.

Janeway lesion: These lesions appear as flat, painless, red to bluish-red spots on the palms and soles of patients with acute bacterial endocarditis.

Jarisch-Herxheimer reaction: An increase in symptoms of spirochetal disease caused by the initiation of treatment.

J-curve phenomenon (in hypertension): A theoretical situation where lowering blood pressure provides a reduced risk of cardiovascular events, but when blood pressure is lowered too much, can paradoxically increase the risk of cardiovascular events.

Jugular venous oxygen saturation (SjvO₂): Oxygen hemoglobin saturation of blood in the jugular bulb, which is a key element in estimating CMRO₂.

K complexes: Electronegative waves followed by electropositive waves seen on the EEG during sleep.

Karyotyping: Chromosomal analysis.

Keratinization: Keratin formation.

Keratinized: Skin that has developed thicker areas of keratin in the stratum corneum.

Keratinocyte: Cell of the epidermis that produces keratin.

Keratoconjunctivitis sicca: Dry, itchy eyes that result from atrophy of the lacrimal ducts, which can be seen in inflammatory arthritis.

Keratolytic: Agent that solubilizes intracellular cement of keratin cells in the stratum corneum.

Ketogenic diet: A special antiseizure diet that is high in fat and low in carbohydrates and protein.

Kleptomania: An impulse control disorder characterized by frequent and repeated theft.

Kt/V: A measurement of how much urea is being removed from the blood during dialysis. The measurement takes into account the efficiency of the dialyzer (clearance, K), the treatment time (t), and the volume of distribution of urea (V).

Kussmaul sign: Kussmaul sign is a rise in jugular venous pressure on inspiration. Kussmaul sign is seen in conditions in which there is right ventricular filling.

Lactation: Production and secretion of breast milk.

Lanugo: Fine body hair normally found on a fetus. The hair develops in patients with anorexia nervosa when they are very underweight and malnourished.

Laparoscopic: Abdominal exploration or surgery employing a type of endoscope called laparoscope.

Laparotomy: Surgical opening of the abdominal cavity.

Laryngospasm: The spasmodic closure of the larynx because of a variety of causes such as allergic reactions, response to irritants, and pharmacologic actions.

Lavage: Washing out.

Laxative: A medication or agent used to produce a bowel movement.

Left ventricular ejection fraction: Also known simply as the ejection fraction, it is the fraction or percentage of the end diastolic blood volume ejected by the left ventricle during systole. It is a measurement of cardiac systolic function with a normal ejection being >60%. It can be determined noninvasively by an echocardiogram.

Left ventricular end diastolic volume: Left ventricular end diastolic volume refers to the volume of blood found in the left ventricle at the end of heart relaxation or diastole.

Left ventricular hypertrophy: Enlargement of the left ventricle, which is seen in heart failure and can give rise to arrhythmias.

Leptospirosis: A bacterial disease that affects humans and animals caused by the genus *Leptospira*.

Lewy bodies: Pink-staining spheres found inside neuronal cells of the substantia nigra and other brain regions, considered to be a histopathologic marker for Parkinson's disease.

Lichenification: Thickening of epidermis because of irritation.

Linear pharmacokinetics: The situation when changes in long-term daily doses of drugs result in proportional changes in steady state serum drug concentrations. Most drugs follow this pattern.

Linkage disequilibrium: Two or more polymorphisms that are inherited together more frequently than would be expected based on chance.

Lipid peroxidation: A pathophysiologic process involving the iron-catalyzed attack of lipid membranes by reactive oxygen species.

Liposomes: Spherical amphiphilic vesicles capable of sustained release of water-soluble substances.

Locus ceruleus: A small area in the brainstem containing norepinephrine neurons that is considered to be a key brain center for anxiety and fear.

Lower urinary tract symptoms: This term collectively refers to obstructive and irritative urinary voiding symptoms of benign prostatic hypertrophy (BPH).

Lumbar puncture: The procedure used to withdraw cerebrospinal fluid through a needle inserted in the lumbar region of the spinal column.

Luteinizing hormone (LH): A polypeptide hormone secreted by the anterior pituitary gland that stimulates ovulation and maintains the corpus luteum.

Luteolysis: Death of the corpus luteum.

Lymphangitis: An inflammation involving the subcutaneous lymphatic channels.

Lymphocytosis: Increased blood concentration of lymphocytes ($>4 \times 10^9$ cells/mm³) commonly observed in mononucleosis, pertussis, measles, chickenpox, or lymphoid malignancies.

Lymphogranuloma venereum: Inflammation of the lymph nodes caused by *Chlamydia trachomatis* resulting in destruction and scarring of tissue.

Macule: Flat, nonpalpable, variable-colored lesion.

Maculopapular: Skin eruption containing both macules and papules.

Magnetic resonance angiography (MRA): A noninvasive method to evaluate the patency of blood vessels using magnetic resonance imaging.

Magnetic resonance imaging (MRI): An imaging technique based on the magnetic properties of the hydrogen atom. It provides an accurate, computer-processed image that can be more sensitive than computed tomography.

Major depression: A psychiatric disorder in which the patient can present with symptoms of depressed mood, a lack of interest in usual activities or inability to experience pleasure, changes in sleep and eating habits, guilt, reduced energy, thoughts of self-harm, and a sense of helplessness or hopelessness.

Major histocompatibility complex (MHC): A set of genes responsible for most of the proteins on the surface of cells in the body that are responsible for recognition of self.

Mania: An abnormally and persistently elevated, expansive, or irritable mood that lasts at least 1 week and causes marked impairment in functioning.

Mass effect: Distortion or displacement of the brain anatomy because of an implied or apparent mass (such as stroke or tumor).

Mastalgia or mastodynia: Pain in the breast.

Mean arterial pressure: The mean arterial pressure is the product of the cardiac output and systemic vascular resistance. Because the cardiac output is pulsatile, rather than continuous, and as two-thirds of the normal cardiac cycle is spent in diastole, the mean arterial pressure is not the arithmetic mean of the systolic and diastolic blood pressures. Mean arterial pressure = diastolic blood pressure + one-third (systolic blood pressure–diastolic blood pressure).

Measurement model: An instrument's scale and subscale structure and the procedures followed to create scale and subscale scores.

Meconium ileus: Intestinal obstruction caused by meconium.

Megakaryocytes: Precursors of platelets.

Melanin: Dark pigment that is part of determining skin color.

Melena: Dark-colored stools resulting from upper gastrointestinal bleed.

Membrane stripping: When the cervix is dilated, a practitioner can use a hand to separate the amniotic membranes from the uterus. This technique has been shown to reduce the need for labor induction.

Menarche: The time of the first menstrual period or flow.

Meningitis: Inflammation, usually infectious, of the meninges, a covering of the brain.

Menopause: The permanent cessation of menses following the loss of ovarian follicular activity.

Menorrhagia: Menstrual blood loss of greater than 80 mL per cycle; a more practical definition is heavy menstrual flow associated with problems of containment of flow, unpredictably heavy flow days, or other associated symptoms.

Menses: Periodic bloody discharge from the uterus.

Mental status examination: An objective patient evaluation conducted through a direct patient interview and used to make a diagnosis, assess the course of illness, or determine treatment response.

Mesolimbic pathway: A dopaminergic pathway in the brain that connects the ventral tegmental area in the midbrain to the nucleus accumbens in the striatum and is involved in motivation and reward.

Metabolic syndrome: A constellation of metabolic and cardiovascular changes consisting of at least three of the following: obesity, low high-density lipoprotein (HDL), elevated triglycerides, hypertension, and elevated fasting blood glucose.

Metastasis: Movement or spread of disease from one organ or part to a new location not directly connected.

Methemoglobin: A form of hemoglobin that occurs when its iron is oxidized to the +3 state, which decreases oxygen binding.

Methionine: The L-isomer is a nutritionally essential amino acid and the most important natural source of *active methyl* groups in the body, hence usually involved in methylations in vivo.

Michaelis–Menten kinetics: The situation where changes in steady state serum drug concentrations of drugs are disproportional to changes in long-term daily doses because of alterations in drug metabolism.

Microalbuminuria: A condition in which a small amount of albumin (30–300 mg/day) is present in the urine; often indicates an early stage of chronic kidney disease (CKD).

Microcephalic: Abnormally small head.

Microcomedo: Microscopic lesion formed from the combination of sloughed, clumping keratinocytes reacting with sebum and fatty acids from the sebaceous gland.

Micrographia: Handwriting that is small, trails off in size, or very slow.

Midsystolic: Middle of systole.

Migraine aura: Early symptom of an attack of migraine with aura, which is the manifestation of focal cerebral dysfunction. The aura typically precedes the headache.

Mild cognitive impairment: A syndrome characterized by cognitive impairment that is not of sufficient severity to warrant a diagnosis of dementia.

Milia: Small, white cysts containing keratin.

Mixed states: Rapidly alternating mood states (mania and major depressive episodes) that last at least 1 week, and cause marked impairment in functioning.

Molds: Fungal organisms that grow as multicellular branching, thread-like filaments (hyphae) that are either *septate* (divided by transverse walls) or *coenocytic* (multinucleate without cross walls). On agar media, molds grow outward from the point of inoculation by extension of the tips of filaments, and then branch repeatedly, interweaving to form fuzzy, matted growths called *mycelium*. Germ tubes are the beginning of *hyphae*, which arise as perpendicular extensions from the yeast cell, with no constriction at their point of origin.

Molybdenum (Mo): A bioelement found in a number of proteins.

Monoamine neurotransmitters: Neurotransmitters that contain one amino group and are derived from amino acids such as tyrosine and tryptophan. Includes, among others, the catecholamines (dopamine and norepinephrine) and an indoleamine (serotonin).

Mood: A more pervasive and sustained emotional state that colors a person's perception of the world.

Morbilliform: Maculopapular lesions that become confluent on the face and body.

Mucolytic: The ability to break down mucus.

Mucositis: Inflammation of the mucosa.

Multiattribute health status classification systems: Preference-based HRQOL instruments for which health-state preferences have been derived from population studies. The instruments assess respondents' health status, and then population preferences are applied to produce the index score.

Multiparity: Condition of having given birth to multiple children.

Multiple-organ dysfunction syndrome (MODS): Presence of altered organ function requiring intervention to maintain homeostasis.

Multiple sclerosis (MS): A demyelinating disease, caused by inflammation, leading to neurologic deficits and often, disability.

Mutism: A state in which a person either has the inability or refuses to speak or vocalize sounds.

Mycotic: A fungal infection.

Myectomy: A surgical removal of the overgrown septal muscle to decrease the outflow tract obstruction.

Myocarditis: Inflammation of the cardiac muscle.

Myoclonic seizures: Brief shock-like muscular contractions of the face, trunk, and extremities. They usually begin in adolescence and are referred to as *juvenile myoclonic epilepsy* (JME).

Myoclonus: A sudden twitching of muscles or parts of muscles, without any rhythm or pattern.

Myositis: Inflammation of the muscle, characterized by pain, tenderness, and sometimes spasm in the affected area.

National Kidney Foundation (NKF): A major voluntary health organization that seeks to prevent kidney and urinary tract diseases, improve the health and well-being of individuals and families affected by these diseases, and increase the availability of all organs for transplantation.

Nausea: An unpleasant sensation associated with an awareness of the urge to vomit.

Necrosis: Local death of cells or tissue.

Necrotizing fasciitis: A rare, but very severe infection of the subcutaneous tissue that can be caused by aerobic and/or anaerobic bacteria and results in progressive destruction of the superficial fascia and subcutaneous fat.

Negative symptoms: Those symptoms of schizophrenia that are largely associated with a deficit in psychosocial functioning, emotional expression, and interpersonal interactions. Examples include blunted affect, alogia, decreased interest and involvement in social and occupational activities, and decreased grooming and hygiene.

Neonatal: Within the first 4 weeks (28 days) of life.

Neonates: Newborns who are 1 day to 1 month of age.

Nephritis: Inflammation of the kidney.

Nephrolithiasis: Presence of one or more stones in the renal pelvis, collecting system, or ureters.

Nephron: The working unit of the kidney that is comprised of a glomerulus and tubule. Each kidney is made up of approximately 1 million nephrons, which collectively remove drugs, toxins, and fluid from the blood.

Nephropathy: Refers to a pathologic alteration of the kidney.

Nephrotic range proteinuria: Proteinuria >3 g/day associated with glomerular disease and nephrotic syndrome.

Nephrotoxicity: Toxic insult to the kidney.

Nerve conduction studies: Measurement of the speed of electrical conduction through a nerve.

Neuraminidase: The second major antigenic determinant of the influenza virus; a surface antigen that allows the release of new viral particles from host cells by catalyzing the cleavage of linkages to sialic acid.

Neuritic plaques: Hallmark pathologic marker of Alzheimer's disease comprised of β -amyloid protein and masses of broken neurites.

Neurofibrillary tangles: Hallmark pathologic marker of Alzheimer's disease derived from abnormal phosphorylation of τ -protein filaments.

Neuropathic pain: Pain caused by nervous system damage.

Neutropenia: An abnormally reduced number of neutrophils circulating in peripheral blood; although exact definitions of neutropenia often vary, an absolute neutrophil count of <1000 cells/mm³ indicates a reduction sufficient to predispose patients to infection.

New York Heart Association classification: The New York Heart Association classification provides a simple way of classifying the extent of heart failure. It places patients in one of four categories based on how much they are limited during physical activity.

N-methyl-D-aspartate antagonists: Class of medications that decreases the activity of synaptic glutamate, thus decreasing the likelihood of cell death.

N-methyl-D-aspartate (NMDA) receptor: An ionotropic subtype glutamate receptor that coexists with the α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptor involved in excitatory neurotransmission; it is responsible for the slow opening and closing phase of the depolarization of the postsynaptic membrane involving sodium and calcium entry; a cellular receptor complex involved in the intracellular passage of calcium into CNS cells on stimulation by amines such as glutamate and aspartate; one of three types of ionotropic post-synaptic glutamate receptors. On binding glutamate, these receptors permit the influx of calcium ions (Ca^{+2}) and result in brain excitation. These are one of the two primary receptors for excitatory neurotransmission in the brain.

Nociceptive pain: Pain caused by physiologic processes that involve stimulation, transmission, perception, modulation, and adaptive inflammation.

Nocturia: Frequent nighttime urination (>2 micturitions per night).

Nodule: Elevated, palpable, solid, round or oval lesion more than 0.5 cm in diameter.

Nonarteritic, anterior, ischemic optic neuropathy: A disorder caused by an acute decrease of blood flow to the optic nerve, which results in sudden vision loss. If persistent, it can lead to permanent vision loss.

Nonconvulsive status epilepticus (NCSE): Believed to be less common and to have a better prognosis than GCSE. The most common two types are absence status epilepticus and complex partial status epilepticus. Both are associated with an impairment in consciousness. For the more common of the two, absence status, the patient appears in a twilight state to lethargy. For complex partial status epilepticus partial return to consciousness can occur, and it may or may not be associated with motor activity or automatisms. The duration is sufficient enough in length to meet the definition of SE.

Nonoliguria: Production of >450 mL urine/day.

Nonpolyposis: Absence of polyps.

Nonulcer dyspepsia: Ulcer-like dyspepsia that has been investigated, but endoscopic findings yield no evidence of mucosal injury (ulcer).

Norepinephrine (NE): A hormone secreted by the adrenal medulla and also released at synapses.

Nosocomial infection: An infection acquired in a healthcare facility.

NSAID: Nonsteroidal antiinflammatory drug.

N-terminal proBNP: The biologically inactive fragment of B-type natriuretic peptide (BNP). Compared to BNP, N-terminal proBNP circulates at higher plasma concentrations and has a longer half-life.

Nulliparity: Condition of not having given birth to a child.

Oblique lie: The fetus is at an angle to the cervix. The head is not the presenting part, and often the patient will need to be delivered by cesarean section.

Obsession: Recurrent and persistent thoughts, images, or impulses experienced as intrusive and distressing.

Obsessive-compulsive disorder (OCD): An anxiety disorder characterized by obsessions and/or compulsions that are time-consuming and interfere significantly with normal routine, social or occupational functioning, or relationships.

Obstructive voiding symptoms: Decreased force of the urinary stream, hesitancy, incomplete bladder emptying, urinary dribbling. This results from bladder outlet obstruction as could be caused by benign prostatic hyperplasia.

Odynophagia: Painful swallowing.

Oligoanovulation: The condition of having few to no ovulatory menstrual cycles.

Oligomenorrhea: Reduced frequency of menses with a time interval between periods greater than 40 days but less than 6 months.

Oliguria: Diminished volume of urine output (volume <400 to 500 mL/day).

Omentumectomy: Excision of the double fold of peritoneum attached to the stomach and connecting it with abdominal viscera (omentum).

Onychomycosis: Fungal infection of the nail apparatus.

Open prostatectomy: In this surgical procedure, an enlarged prostate is removed in its entirety. Access to the prostate can be achieved by cutting through the bladder and reaching down to the prostate, or by cutting through the perineum (between the legs).

Ophthalmia neonatorum: Inflammation of the conjunctiva resulting from acquisition of gonococcal infection at birth.

Opioid addiction: A behavioral pattern manifesting as loss of control over opioid use, compulsive use, and continued use despite harm.

Opioid dependence: State that occurs subsequent to extended exposure to an opioid and manifests as withdrawal symptoms after abrupt dose reduction, discontinuation, or after the administration of an opioid antagonist.

Opioid tolerance: Decreased effectiveness of opioid over time because of opioid exposure.

Opportunistic infection (OI): Infection with microorganism that occurs because of altered physiologic state of the patient.

Orchiectomy: The surgical removal of the testicles.

Organic erectile dysfunction: Term used to refer to erectile dysfunction that is caused by vascular, neurologic, and/or hormonal causes.

Orthopnea: Difficulty breathing after lying down.

Orthostatic hypotension: A significant drop in blood pressure, defined as a systolic blood pressure decrease of greater than 20 mm Hg or a diastolic blood pressure decrease of greater than 10 mm Hg, that occurs when changing from a supine to a standing position.

Osler nodes: Osler nodes are red, raised tender nodules usually 5 mm in diameter on the pulps of toes or fingers. Seen in patients with endocarditis, they are thought to be caused by the deposition of immune complexes.

Osteogenesis imperfecta: Genetic disorder characterized by low trabecular and cortical bone density.

Osteomalacia: Abnormal bone mineralization, referred to as rickets in children.

Osteopenia: Low bone density, dual-energy x-ray absorptiometry (DXA) T-score of -1 to -2.5

Osteophyte: A bony outgrowth or protuberance.

Osteoporosis: Very low bone density, DXA T-score less than -2.5, with or without a low trauma fracture. National Osteoporosis Foundation definition: "A chronic, progressive disease characterized by low bone mass, microarchitectural deterioration and decreased bone strength, bone fragility and a consequent increase in fracture risk."

Osteotomy: The surgical cutting of a bone.

Otitis media: Inflammation of the middle ear.

Ovulation: Periodic ripening and rupture of mature follicle and the discharge of ovum from the cortex of the ovary.

Oxytocin: A polypeptide hormone secreted by the posterior pituitary gland that stimulates uterine contraction.

Paget's disease: Disorder of bone remodeling in discrete sections of bone.

PAH: *p*-aminohippurate, a small molecule that is completely secreted from the tubules into urine, so that blood leaving the kidney is virtually free of PAH; a marker that is often used to measure renal plasma flow (RPF).

Pain: An unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage.

Palpation: Touching the skin to feel the outline of an organ.

Pan- or holosystolic: Throughout the end time of systole.

Pancolitis: Inflammation that involves the majority of the colon in patients with inflammatory bowel disease.

Pancreatitis: An acute or chronic inflammation of the pancreas with variable involvement of local tissues and remote organs.

Panel reactive antibody (PRA): The percentage of cells from a panel of donors with which a potential recipient's bloodstream reacts. The more antibodies in the recipient's bloodstream, the higher the PRA. The higher the PRA, the higher the risk for a positive crossmatch.

Panhypopituitarism: A condition of complete or partial loss of anterior and posterior pituitary function resulting in a complex disorder characterized by multiple pituitary-hormone deficiencies.

Panic attack: A discrete period in which there is the sudden onset of intense apprehension, fearfulness, or terror, often associated with feelings of impending doom.

Panic disorder: The presence of recurrent, unexpected panic attacks followed by at least 1 month of persistent concern about having another panic attack, worry about the possible implications or consequences of the panic attacks, or a significant behavioral change related to the attacks.

Panlobular: Affecting the entire lobe.

Papillary: Upper layer of the dermis.

Papilledema: Swelling around the optic nerve, usually caused by pressure on the nerve by a tumor or stroke.

Papule: Solid, elevated, lesion more than 0.5 cm in diameter.

Papulosquamous: Raised plaque or papule with scaling.

***p*-Aminohippurate (PAH):** A small molecule that is completely secreted from the tubules into urine, so that blood leaving the kidney is virtually free of PAH; a marker that is often used to measure renal plasma flow (RPF).

Paranoia: Ideation involving suspiciousness or the belief that one is being harassed, persecuted, or unfairly treated.

Parenchyma: Specific cells or tissue of an organ.

Paresthesia: An abnormal sensation, such as of burning, pricking, tickling, or tingling.

Parkinsonism: A constellation of symptoms with atypical features such that a diagnosis of idiopathic Parkinson disease cannot be made.

Parous: Having borne one or more children.

Paroxysmal nocturnal dyspnea: Onset of difficulty breathing after lying down for several hours.

Partial agonist: A drug with high binding affinity to a receptor and that elicits a weaker response than the endogenous neurotransmitter. At least theoretically, this causes an agonist effect in states of decreased endogenous neurotransmitter tone and an antagonist effect in the endogenous state of heightened neurotransmitter activity.

Partial seizure: A seizure that begins in one hemisphere of the brain. It can be simple, complex, or secondarily generalized.

Patch: Large macule (more than 2 cm in diameter).

Patient-reported outcomes: The consequences of the disease and/or its treatment as perceived and reported by the patient.

Pelvic inflammatory disease (PID): Infection of the lining of the uterus, the fallopian tubes, or the ovaries.

Penumbra (ischemic): The area of brain tissue around the core of the infarct that has decreased function but remains viable. It is proposed that reperfusion of this tissue will allow survival of the affected neurons and other brain cells.

Peptic ulcer: Cellular distribution of the gastrointestinal mucosa, submucosa, and muscular layer. Chronic peptic ulcers usually occur as a *single hole* and are found most often in the stomach and duodenum.

Percussion: Tapping on a structure to elicit a sound.

Percussion and postural drainage: Tapping on the thorax to physically loosen pulmonary secretions and posturing the body to facilitate expectoration.

Percutaneous coronary intervention (PCI): A minimally invasive procedure whereby access to the coronary arteries is obtained through the femoral artery up the aorta to the coronary os. Contrast media is used to visualize the coronary artery stenosis using a coronary angiogram. A guidewire is used to cross the stenosis and small balloon is inflated and/or stent is deployed to break up atherosclerotic plaque and restore coronary artery blood flow. The stent is left in place to prevent restenosis of the coronary artery.

Pericarditis: Inflammation of the pericardium, which is the fibrous sac enclosing the heart.

Perimenopause: The period immediately prior to the menopause and the first year after menopause. Reflects the transition to menopause (with irregular menstrual cycles) and includes the 3 to 5 years before and 1 year after the cessation of menstrual flow.

Perinatal: Time shortly before and after birth.

Perioral dermatitis: Rash around the mouth. In patients with anorexia nervosa or bulimia nervosa, the rash is secondary to repeated vomiting that creates skin irritation from exposure to the gastric contents.

Peripheral arterial disease (PAD): Atherosclerotic occlusive disease of the extremities, usually diagnosed by symptoms (claudication) or assessment of the blood flow to an extremity.

Peripheral blood progenitor cells: Immature blood cells, which are capable of producing white blood cells, platelets, and red blood cells.

Peritoneal dialysis (PD): A dialysis procedure performed in the peritoneal cavity in which the peritoneum acts as the semipermeable membrane.

Peritonitis: The acute, inflammatory response of the peritoneal lining to microorganisms, chemicals, irradiation, or foreign body injury.

Perseveration: Persistent repetition of the same verbal or motor response despite differing stimuli.

Pervasive developmental disorder: A group of disorders characterized by severe and pervasive impairments in the development of socialization and communication skills, as well as behavioral repertoire, with a typical diagnosis younger than age 3 years; includes autistic disorder, Rett syndrome, pervasive development disorder not otherwise specified, childhood disintegrative disorder, and Asperger disorder.

Petechiae: Pinpoint, flat, round, red spots under the skin caused by intradermal hemorrhage.

Peyronie's disease: Disease of the penis associated with fibrous tissue scarring along the inside of the penile shaft resulting in significant and abnormal curvature of the erect penis. Associated with penile pain; deformity makes sexual intercourse difficult or impossible.

P-glycoprotein: An adenosine triphosphatase (ATPase)-dependent membrane transporter efflux pump coded for by the multidrug-resistance gene 1 (MDR1 or ABCB1 or PGY1) found in the human blood-brain barrier and intestine as well as other tissues; lipophilic molecules are good substrates for the ABCB1 efflux transport system at the blood-brain barrier.

Pharmacodynamics: The study of the relationship between the concentration of a drug and the response obtained in a patient.

Pharmacoepidemiology: The study of the use of and the effects of drugs in large numbers of people with the purpose of supporting safe and effective drug therapies. This type of observational research is useful when more rigorous, experimental designs are not feasible.

Pharmacogenetics: Genetic basis for interindividual differences in drug response.

Pharmacovigilance: The science and activities relating to the detection, assessment, understanding, and prevention of adverse effects or any other drug-related problems.

Pharyngitis: An acute infection of the oropharynx or nasopharynx.

Phase I reactions: Metabolic changes by the body that generally make the drug molecule more polar and water soluble so that it is prone to elimination by the kidney, such as oxidation, hydrolysis, and reduction.

Phase II reactions: Metabolic changes by the body that generally make the drug molecule more prone to elimination by the kidney, such as conjugation to form glucuronides, acetates, or sulfates.

Phenotypes: How a gene is expressed (e.g., eye color, height, drug metabolism capacity). The expression of genetic alleles (genotype) as an observable physical or biochemical trait.

Phobia: A persistent, abnormal, and irrational fear of a specific thing or situation that compels one to avoid it, despite the awareness and reassurance that it is not dangerous.

Phonophobia: Hypersensitivity to sound, usually causing avoidance.

Photostimulation: Stimulation of the visual cortex through visual stimulation with bright and alternating light.

Photoallergy: Photosensitivity disorder of skin (light and photoallergic agent).

Photophobia: Hypersensitivity to light, usually causing avoidance.

Phototoxicity: Photosensitivity disorder of skin (light and phototoxic agent).

Physical dependence: A state of adaptation that is manifested by a drug class-specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist.

Pilonidal: Hair-containing cyst.

Pilosebaceous: Sebaceous gland and adjacent hair follicle.

Placenta previa: The placenta is located over the cervical opening. In this situation, the mother and baby can hemorrhage because the placenta will separate from the uterus before the baby is born. Women who have a placenta previa must be delivered by cesarean section.

Plaque: Raised, flat lesion (more than 2 cm in diameter).

Pneumonitis: Inflammation of lung tissue.

Poikilocytosis: The presence of irregularly shaped red blood cells in the peripheral blood.

Poikilothermia: Inability to maintain normal body temperature.

Polyarteritis nodosa: A systemic necrotizing vasculitis of small and medium-sized arteries.

Polycythemia: An increase in the number of red cells present in the blood.

Polymorphisms: Interindividual variations in the genetic code at the level of one nucleotide.

Porphyria: A group of disorders involving heme biosynthesis, characterized by excessive excretion of porphyrins or their precursors; can be inherited or can be acquired, as from the effects of certain chemical agents.

Porphyrins: Pigments widely distributed throughout nature (e.g., heme, bile pigments, cytochromes) consisting of four pyrroles joined in a ring (porphin) structure.

Positive symptoms: Those symptoms of schizophrenia, largely based on perceptual and thought disturbances, that are typically associated with psychosis. Examples are suspiciousness, paranoia, delusions, hallucinations, and disorganized thought processes.

Positron emission tomography (PET): Specialized nuclear scanning technique that allows the measurement of regional blood flow and glucose metabolism. With radiolabeled ligands, also allows for the measurement of the binding of drugs to receptors.

Posterior fossa: The cavity in the back part of the skull that contains the cerebellum, brainstem, and cranial nerves 5–12.

Postexposure prophylaxis: Dispensing or administering a medication (including a vaccine) to start immediately after exposure to a disease or organism, to prevent the disease from developing or spreading.

Postictal: The recovery period after a seizure, when a patient can be lethargic or confused. Duration can be variable.

Posttraumatic seizures: Seizure event(s) that can occur following a traumatic brain injury within the first 7 days postinjury (early) or beyond 7 days postinjury (late).

Postrenal acute renal failure (ARF): Acute renal failure with an anatomical cause that is in the urinary tract.

Posttraumatic stress disorder: An anxiety disorder in which exposure to an exceptional mental or physical stressor is followed by persistent reexperiencing of the event, avoidance of reminders of the event, and arousal symptoms.

Postvoid residual urine volume: Urine left in the bladder after the patient has been asked to completely empty urine out of the bladder. Normally the postvoid residual urine volume should be zero. A high postvoid residual urine volume is associated with recurrent urinary tract infection.

PRA (panel reactive antibody): The percentage of cells from a panel of donors with which a potential recipient's bloodstream reacts. The more antibodies in the recipient's bloodstream, the higher the PRA. The higher the PRA, the higher the risk for a positive crossmatch.

Preexposure vaccination: Administration of a protective vaccine to the public, military troops, or high-risk individuals prior to the potential exposure to an infectious disease.

Preference-based measures: Measures that provide an overall HRQOL index score based on a scale anchored by 1.0 (full health) and 0.0 (dead).

Prefrontal cortex: Part of the brain that integrates thought, emotion, and motivation.

Preload: Along with afterload, it is an important determinant of cardiac output. It is the degree of stretch of the myocardial fibers (sarcomeres) at the end of diastole. As the sarcomeres are stretched, the force of contraction increases. Preload is approximated by the left ventricular end diastolic volume or pressure.

Premature infants: Those born before 37 weeks of gestational age.

Premature ovarian failure: Amenorrhea, sex-steroid deficiency, and infertility in women younger than 40 years of age.

Premenstrual dysphoric disorder (PMDD): Severe psychiatric mood disorder with marked affective symptoms causing significant interference in work or relationships temporally associated with the luteal phase and not caused by an underlying psychiatric disturbance; a severe form of premenstrual syndrome and is listed in the appendix of the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition Revised*. The diagnostic criteria require prospective documentation of symptoms, a specific constellation of symptoms, and functional impairment.

Premenstrual molimina: Includes premenstrual symptoms such as breast tenderness, pelvic heaviness or bloating, and food cravings that are not distressing and do not interfere with daily functioning.

Premenstrual syndrome (PMS): A constellation of symptoms including mild mood disturbance and physical symptoms that occur prior to the menses and resolve with initiation of menses.

Premonitory migraine symptoms: Symptoms preceding and forewarning of a migraine attack by 2 to 48 hours, occurring before the aura in migraine with aura and before the onset of pain in migraine without aura.

Prerenal ARF: Acute renal failure caused by a reduction of renal blood flow. Often associated with volume depletion or poor cardiac function.

Presbycusis: Progressive bilateral loss of hearing that occurs in the aged.

Pressured speech: More and faster speech that is difficult or impossible to interrupt.

Preterm: Before 37 weeks of gestation.

Priapism: Painful prolonged erection.

Primary amenorrhea: Absence of menses by age 16 years in the presence of normal secondary sexual development or absence of menses by age 14 years in the absence of normal secondary sexual development.

Primary hypogonadism: Failure of the testes to produce an adequate supply of testosterone to meet physiologic needs.

Primary lesion: Basic skin lesion that appears at the beginning of skin disorder.

Primary resistance: Refers to resistance recorded prior to drug exposure in vitro or in vivo, as determined by in-vitro susceptibility testing using standardized methodology.

Proctitis: Inflammation confined to the rectum in patients with inflammatory bowel disease.

Prodrome: Early symptom indicating that disease or further symptoms are imminent.

Progestogen: A term referring to progesterone and the synthetic progestational compounds (sometimes referred to as *progestins*).

Prolactin: A polypeptide hormone secreted by the anterior pituitary gland that stimulates lactation.

Proprioception: A sense or perception, usually at a subconscious level, of the movements and position of the body and especially its limbs, independent of vision; this sense is gained primarily from input from sensory nerve terminals in muscles and tendons and the fibrous capsule of joints combined with input from the vestibular apparatus.

Prostate-specific antigen (PSA): A clinical laboratory test; PSA is a tumor marker that is used to screen for, monitor response to treatment of, and determine degree of spread of prostate cancer. Normally, PSA blood levels should be low as PSA is passed out of the body in the ejaculate.

Prostatectomy: Removal of all or part of the prostate gland. There are two main types: (1) transurethral resection of the prostate (TURP)—removes part of the tissue surrounding the urethra that can be blocking the flow of urine; and (2) radical prostatectomy, which removes all of the prostate and the seminal vesicles.

Protease: An enzyme in HIV that cleaves large precursor polypeptides into functional proteins that are necessary to produce a complete virus.

Proteinuria: A condition in which the urine contains large amounts of protein (>150 mg/day); often a sign of glomerular or tubular damage in the kidney.

Proteolytic: The ability to break down protein.

Prothrombin: A clotting factor that is converted to thrombin; also known as factor II.

Prothrombin time (PT): A measure of coagulation representing the amount of time required to form a blood clot after the addition of thromboplastin to the blood sample; also known as Quick's test.

Pruritus: Itching.

Pseudoaddiction: A behavior pattern reflective of seeking relief of pain and resembling that of addictive behavior.

Pseudoallergic: Adverse reactions that appear like allergic reactions but do not have an immunologic mechanism.

Pseudocyst: Collection of pancreatic juice and tissue debris enclosed by a wall of fibrous or granulation tissue.

Pseudohypertension: A falsely elevated blood pressure measurement that is usually because of rigid, calcified brachial arteries; this can be seen in patients who are ≥ 65 years, have long-standing diabetes, or have chronic kidney disease.

Pseudomembranous colitis: Inflammation of the colon caused by the toxin of *Clostridium difficile* and resulting in bloody diarrhea.

Pseudopolyps: An area of hypertrophied gastrointestinal mucosa that resembles a polyp and contains nonmalignant cells.

Pseudoxanthoma elasticum: Pseudoxanthoma elasticum is a chronic degenerative disease of connection tissues of the skin, eyes, and cardiovascular system resulting from fragmentation and calcification of elastic fibers.

Psychoeducation: Education geared toward patients becoming more informed about their mental illness and treatment. Additional goals include self-monitoring, efforts to improve treatment adherence, interactions between patient and clinicians, and empowerment.

Psychogenic erectile dysfunction: Erectile dysfunction because of failure of central nervous system to perceive or process sexually stimulating information.

Psychometrics: The measurement of psychological constructs, such as quality of life.

Psychomotor: Movement or muscular activity related to mental processes.

Psychomotor retardation: A slowing or limitation of motor functioning or muscular movements.

Psychosocial functioning: A person's level of functioning on a daily basis that encompasses all the domains of life experience (e.g., interpersonal relationships, work, school, recreation).

Psychosocial rehabilitation programs: Care programs oriented toward improving patient's daily adaptive functioning. Includes such interventions as basic living skills, social skills training, basic education, work programs, and supported housing.

Psychosocial stressor: Any significant life event or change that can be associated with the onset, occurrence, or exacerbation of a mental disorder.

Psychotherapy: A general term used to describe a form of treatment based on talking with a therapist. Psychotherapy aims to relieve distress by discussing and expressing feelings, to help the patient to change attitudes, behavior, and habits and to develop better ways of coping.

Pulmonary artery occlusion pressure: It is usually determined by a balloon-tipped Swan-Ganz catheter that is advanced into a distal branch of the pulmonary artery. Inflation of the balloon at the catheter tip occludes the pulmonary artery and allows measurement of the left atrial pressure that reflects the left ventricular diastolic pressure. Therefore, it is a measure of the left ventricular preload.

Pulmonary aspiration: The inhalation of fluids and gastric contents into the lungs that can cause aspiration pneumonitis.

Pulmonary embolism: A disorder of thrombus formation causing obstruction of a pulmonary artery or one of its branches and results in pulmonary infarction.

Pulsating: Throbbing or beating with a rhythm.

Pulseless electrical activity (PEA): The absence of a detectable pulse and the presence of some type of electrical activity other than ventricular fibrillation (VF) or paroxysmal ventricular tachycardia.

Purgatives: An agent used for purging the bowels.

Purpura: Discoloration of skin because of a hemorrhagic spot more than 0.5 cm in diameter.

Pustule: Small, raised lesion containing pus or exudates.

Pyelonephritis: An infection involving the kidneys and representing upper tract infection.

Pyoderma: Purulent skin disease.

Pyoderma gangrenosum: Skin ulceration with necrotic edges.

Pyuria: Presence of pus or white blood cells in the urine.

Quality-adjusted life-years (QALY): A health outcome summary measure in which quantity of life is adjusted for its quality. A year in full health is equivalent to 1.0 QALY. A year in a health state considered worse than full health, such as 0.5, would equal 0.5 QALY, which is equivalent to living half a year in full health.

Radionuclide ventriculography: Radionuclide ventriculography, also known as contrast ventriculography, provides imaging of a ventricle of the heart after the injection of a radioactive contrast medium. The technique is less invasive than cardiac catheterization and is used to assess ventricular function.

Rales: The clicking, rattling, or crackling noises heard on auscultation of the lungs during inhalation.

Rating scales: Tools used to objectively describe, assess, and measure subjective findings common in psychiatric illnesses. Rating scales are also used to diagnose specific psychiatric conditions.

Rational polytherapy: The concurrent use of two or more drugs for patients not responding to monotherapy. The combination of drugs is based on a consideration of mechanism of action, clinical pharmacokinetics, adverse reactions, and drug interactions.

Rebound insomnia: Sleep that is worsened compared to patients' baseline sleep for a few days after discontinuation of a sedative hypnotic medication.

Rebound vasodilation or congestion: See *Rhinitis medicamentosa*.

Refractory status epilepticus: SE is considered refractory when adequate doses of a benzodiazepine, hydantoin, or barbiturate have failed to terminate the seizures. That is, a patient must have failed two first-line therapies to be considered refractory.

Rejection: The response of the immune system, usually involving T- or B-lymphocytes, to the recognition of foreign antigens in transplanted tissue, which destroys the cells in the transplanted organ and ultimately leads to organ failure, if not treated successfully.

Relapse: New or old multiple sclerosis symptoms lasting 24 hours or longer often associated with demyelination or inflammation in the brain or spinal cord. Relapses are also referred to as an attack, exacerbation, or flare-up of multiple sclerosis.

Relapsing-remitting multiple sclerosis: The most common form of multiple sclerosis at the time of diagnosis. It is characterized by attacks usually with full or partial recovery and no disease progression between attacks.

Relative risk reduction: The amount of risk reduced when compared to a control. When one sees a 5% event rate in the control group and a 4% event rate in the treatment group, the relative risk reduction is 20%. The absolute risk reduction is 1%.

Reliability: The extent to which measures give consistent or accurate results.

Remote symptomatic: When the cause of the SE is from a previous neurologic injury or anatomic malformation, e.g., a patient with a prior stroke, head trauma, or brain tumor.

Renal osteodystrophy (ROD): The condition resulting from sustained metabolic changes that occur with chronic kidney disease including secondary hyperparathyroidism, hyperphosphatemia, hypocalcemia, and vitamin D deficiency. The skeletal complications associated with ROD include osteitis fibrosa cystica (high bone turnover disease), osteomalacia (low bone turnover disease), adynamic bone disease, and mixed bone disorders.

Renal replacement therapy: Any form of dialysis or hemofiltration used to support patients without adequate kidney function. Goals of renal replacement therapy are to remove excess fluid; remove waste products and toxins; and control electrolyte concentrations.

Renal: General term referring to the kidneys.

Renin-angiotensin aldosterone system: A complex endogenous humorally mediated system that is involved with most of the regulatory components involved with arterial blood pressure.

Renovascular: Pertaining to blood vessels located within the kidney, such as the afferent and efferent arterioles, and renal arteries.

Respiratory disturbance index: A summary measure that quantifies the number of apneas, hypopneas, and respiratory effort-related arousals per hour of sleep.

Respondent burden: The time, energy, and other demands placed on those to whom the instrument is administered.

Responsiveness: The ability or power of a measure to detect clinically important change when it occurs.

Resting tremor: Tremor that occurs or exacerbates when the affected body part is at rest; it decreases or disappears with active motions.

Restrictive cardiomyopathy: Restrictive cardiomyopathy is characterized by nondilated ventricles with impaired ventricular filling. Hypertrophy is typically absent, although the infiltrative and storage diseases can cause a left ventricular wall thickness elevation.

Retching: Contractions of the diaphragm, thoracic, and abdominal muscles without expulsion of gastric contents.

Retinitis: Inflammation of the retina, often caused by infection with cytomegalovirus.

Retrograde pyelography: A procedure where radiocontrast dye is injected into the ureter to produce detailed radiographs of the ureter and kidneys.

Rett's syndrome: A type of pervasive developmental disorder typically associated with severe to profound mental retardation, seen in females only, with the development of significant multiple progressively worsening deficits following a period of normal development (microcephaly, loss of purposeful hand motor skills, and acquisition of stereotyped hand movements, diminished social interests, and appearance of poorly coordinated gait or trunk movements).

Reverse transcriptase: The enzyme in HIV that synthesizes a complementary strand of DNA.

Reye's syndrome: Acute encephalopathy characterized by fever, vomiting, fatty infiltration of the liver, disorientation, and coma, occurring mainly in children and usually following a viral infection, such as chicken pox or influenza.

Rhabdomyolysis: The breakdown of muscle tissue and release of myoglobin and intracellular electrolytes into the circulation because of a variety of causes such as crush injuries, drug-induced immobilization, and status epilepticus. It often leads to acute renal failure.

Rheumatoid arthritis: A systemic, symmetric autoimmune disease with swelling, pain, and inflammation of joints as a key finding.

Rhinitis: Inflammation of the nasal mucous membrane. Can be seasonal (*hay fever*) or perennial (increasingly called *intermittent* or *persistent*).

Rhinitis medicamentosa: Nasal congestion associated with tolerance to and resulting overuse of topical decongestants. Also known as *rebound vasodilation* or *rebound congestion*.

Rickets: See *Osteomalacia*.

Rigidity: Increased resistance detectable with the passive movement of a limb.

Roth spots: A hemorrhage in the retina with a white center. Roth spots are often associated with bacterial endocarditis.

Russell sign: Callus on dorsum of the hand secondary to self-induced vomiting.

S₄ gallop: An S₄ gallop is a presystolic atrial sound that immediately precedes the first heart sound (S₁). This finding on auscultation of the heart can be indicative of myocardial disease.

Salicylism: Poisoning by salicylic acid or any of its compounds.

Salpingo-oophorectomy: Surgical removal of the ovaries and fallopian tubes.

Sarcoidosis: Sarcoidosis is a multisystem granulomatous disorder of unknown etiology characterized histologically by noncaseating epithelioid granulomas involving various organs or tissues, with symptoms dependent on the site and degree of involvement.

Scale: Flake of stratum corneum.

Scar: Fibrous tissue formed during healing of injury to skin.

Schizophrenia: A chronic disorder of thought and affect encompassing different constellations of symptoms (i.e., positive symptoms, negative symptoms, cognitive dysfunction), with the individual having a significant disturbance in interpersonal relationships and ability to function in society on a daily basis.

Scleritis: Inflammation of the white portion of the eyeball, which can be superficial (episcleritis) or involve deeper layers of the eye.

Scleroderma: Scleroderma is a diffuse connective tissue disease characterized by changes in the skin, blood vessels, skeletal muscles, and internal organs.

Sebaceous gland: Gland that secretes sebum.

Sebosuppressive: Decreasing amount of sebum produced by the sebaceous gland.

Sebum: Oil produced by the sebaceous gland.

Second-generation antipsychotic (atypical antipsychotic): An antipsychotic medication that has pharmacodynamic and clinical properties different than the first generation (typical or traditional) antipsychotics that act primarily by having high levels of binding to dopamine-2 (D₂) receptors. Although definitions of atypicality vary, all second-generation antipsychotics share the property of causing a much lower incidence of extrapyramidal side effects.

Secondary amenorrhea: Cessation of menses in a woman previously menstruating for 6 months or more.

Secondary brain injury: A complex sequence of pathophysiologic events precipitated by the initial or primary brain injury that disrupts the normal central nervous system balance between oxygen supply and demand resulting in a worsened patient outcome.

Secondary hypertension: Persistently elevated blood pressure that results from a known pathophysiologic etiology or drug-induced cause.

Secondary hypogonadism: Failure of hypothalamus or pituitary gland to produce adequate amount of luteinizing hormone-releasing hormone (LHRH) or luteinizing hormone (LH). Thus, testicular production of testosterone is reduced.

Secondary prophylaxis (or suppressive therapy): Refers to administration of systemic antifungal agents (generally prior to and throughout the period of granulocytopenia) to prevent relapse of a documented invasive fungal infection that was treated during a previous episode of granulocytopenia.

Secondary resistance: Develops on exposure to an antifungal agent and can be either reversible, because of transient adaptation, or acquired as a result of one or more genetic alterations.

Secondary-progressive multiple sclerosis: Often follows relapsing-remitting multiple sclerosis whereby attacks become continuously progressive over time. It is sometimes accompanied by acute relapses.

Seizure: Paroxysmal disorder of central nervous system, characterized by abnormal neuronal discharges with or without loss of consciousness. They vary in cause, presentation, consequences, duration, and management.

Selection bias: Systematic differences in characteristics between those selected for study and those who are not. See also *Information bias*.

Sepsis: The systemic inflammatory response syndrome (SIRS) secondary to infection. See also *Systemic inflammatory response syndrome*.

Septic shock: Sepsis with persistent hypotension despite fluid resuscitation, along with the presence of perfusion abnormalities. Patients who are on inotropic or vasopressor agents might not be hypotensive at the time perfusion abnormalities are measured.

Serotonin (5-hydroxytryptamine [5-HT]): An inhibitory neurotransmitter present in the raphe nucleus of the brainstem, platelets, carcinoid tumors, and other tissues. It is a vasoconstrictor and neurochemical involved in mood and sleep.

Serum urea nitrogen (SUN): See *Blood urea nitrogen*.

Severe sepsis: Sepsis associated with organ dysfunction, hypoperfusion, or hypotension. Hypoperfusion and perfusion abnormalities can include, but are not limited to, lactic acidosis, oliguria, or acute alteration in mental status.

Short stature: A broad term describing a condition commonly defined by a physical height that is more than two standard deviations below the population mean and lower than the third percentile for height in a specific age group.

Sickle cell disease: A group of inherited red blood cell (RBC) disorder in which sickle cell hemoglobin (HbS) is present. Hemolytic anemia and painful vasoocclusion are the main features.

Simple partial seizure: A seizure beginning in one hemisphere of the brain. It is manifested by alterations in motor functions, sensory or somatosensory symptoms without loss of consciousness. It can progress to a complex partial seizure or to a secondarily generalized seizure with loss of consciousness.

Single-nephron GFR (SNGFR): The rate of filtration through a single glomerulus of a nephron; often reported in nL/min.

Sinus ostia: The pathways that drain the sinuses.

Sinusitis: An inflammation and/or infection of the paranasal sinus mucosa.

Sjögren's syndrome: An inflammatory process affecting the mucous membranes. Can cause dry mouth with difficulty swallowing. Can occur secondary to autoimmune diseases such as rheumatoid arthritis or systemic lupus erythematosus.

Sleep latency: The amount of time it takes to fall asleep.

Sleep spindles: Brief burst of electrical activity seen on the EEG, 12 to 14 Hz.

Slipped capital femoral epiphysis (SCFE): Increased width of the femoral plate observed during GH treatment resulting in hip or knee pain.

Social anxiety disorder (SAD): A disorder characterized by clinically significant anxiety provoked by exposure to certain types of social or performance situations, often leading to avoidance behavior.

Social phobia: See *Social anxiety disorder*.

Somatic pain: Pain arising from skin, bone, joint, muscle, or connective tissue.

Specific measures: Instruments intended to provide greater detail concerning particular outcomes, in terms of functioning and well-being, uniquely associated with a condition and/or its treatment.

Specific phobia: A phobia characterized by clinically significant anxiety provoked by exposure to a specific feared object or situation, often leading to avoidance behavior.

Spermicide: A substance (nonoxonyl-9 in the United States) placed in the vagina to inhibit the activity of sperm, thus reducing the risk of pregnancy; available as vaginal creams, films, foams, gels, suppositories, sponges, and tablets.

Spirochete: The class of microorganism that is the agent of syphilis (*Treponema pallidum*).

Standard gamble: An approach to health-state preference elicitation in which the respondent is offered a choice between two alternatives: choice A—living in health state *i* (a health state between full health and death) with certainty, or choice B—taking a gamble on a new treatment for which the outcome is uncertain.

Status epilepticus: Any recurrent or continuous seizure activity lasting longer than 30 minutes in which the patient does not regain baseline mental status. The two most common types are generalized convulsive status epilepticus and nonconvulsive status epilepticus.

Steatorrhea: Excessive fat in stool.

Stereotypy: Persistent repetition of senseless acts or words.

Stevens–Johnson syndrome: A serious dermatologic reaction characterized by blistering of the mucous membranes (mouth, eyes, vagina) with patchy rashes that can cover most of the body. Patients can also experience fever, headache, and cough.

Stress-related mucosal damage: Superficial gastritis-like lesions associated with critical illness in hospitalized patients.

Striae: Linear, atrophic, pink, purple, or white lesions of skin secondary to changes in connective tissue.

Stricture: An area of narrowing or constriction in the gastrointestinal tract because of buildup of fibrotic tissue; often a result of long-standing inflammation.

Stroke: A sudden onset, focal neurologic deficit, of presumed vascular origin, lasting longer than 24 hours.

Stroke volume: The volume of blood ejected from the heart during systole.

Stromal tissue of the prostate: This portion of the prostate is composed of smooth muscle tissue, which is embedded with α -adrenergic receptors. When stimulated, the muscle contracts around the urethra. This comprises approximately 75% of the total volume of the enlarged prostate gland in patients with benign prostatic hyperplasia.

Subarachnoid hemorrhage: Accumulation of blood in the space (subarachnoid space) surrounding the brain that usually contains the cerebrospinal fluid. It is usually caused by rupture of an intracranial aneurysm or trauma. It is a type of hemorrhagic stroke and can cause focal neurologic deficits.

Substance abuse: A maladaptive pattern of substance use indicated by repeated adverse consequences related to the repeated use of the substance. Examples include failure to fulfill important obligations at work, school, or home; repeated use in situations in which it is physically dangerous, such as driving under the influence; legal problems; and social or interpersonal problems such as arguments and fights.

Substance dependence: The continued use of the substance despite adverse substance-related problems. The criteria for substance dependence are the same for each of the drugs or drug classes, varying only to fit the unique pharmacologic properties of each drug.

Substantia nigra: Area of the brain (basal ganglia) where cells produce dopamine; characterized by neuromelanin deposits.

Subtle status epilepticus: For patients with prolonged refractory SE. The electrographic seizures persist; however, the motor manifestations of the seizures might not be apparent. In such cases the patient is considered in subtle SE.

Sudden death: Also known as sudden cardiac death; an unexpected death because of cardiac causes occurring in a short time period (generally within 1 hour of symptom onset) in a person with known or unknown cardiac disease in whom no previously diagnosed fatal condition is apparent. Most cases are related to cardiac arrhythmias, particularly ventricular fibrillation.

SUN (serum urea nitrogen): See *Blood urea nitrogen*.

Suppressive therapy: See *Secondary prophylaxis*.

Surge capacity: A term that refers to a healthcare system's ability to handle a large influx of patients in the event of an epidemic or disaster.

SV2A: A presynaptic vesicle protein found in the hippocampus as well as other areas of the brain believed to be important in the mechanism of action of levetiracetam.

Swan–Ganz catheter: A catheter (tube) inserted into the heart to measure pressure and cardiac output.

Symptomatic intracerebral hemorrhage: Collection of blood in the brain, usually after an ischemic stroke, that is associated with neurologic worsening.

Symptomatic: SE occurring during the time of an acute neurological injury. This etiology is associated with a poorer prognosis.

Syncope: Fainting.

Synechiae: A *creeping* angle closure that sometimes occurs in patients between attacks of closed-angle glaucoma.

Synergism: The combination of two drugs (such as antibiotics) that produces an effect greater than the sum of the two drugs if used alone.

Synesthesias: The overflow of one sensory modality to another. For example, colors are heard, sounds are seen.

Synovitis: Inflammation of the synovial lining of the joint.

Synovium: Synovial membrane, the inner of the two layers of the articular capsule of a synovial joint, composed of loose connective tissue and having a free smooth surface that lines the joint cavity. It secretes the synovial fluid.

Systemic inflammatory response syndrome (SIRS): Systemic inflammatory response to a variety of clinical insults, which can be of infectious or noninfectious etiology.

Systemic vascular resistance (SVR): The resistance to blood flow that is primarily determined by the vascular tone of the arteriolar blood vessels.

Systolic blood pressure: The arterial blood pressure that occurs during cardiac contraction.

Systolic heart failure: Systolic heart failure is a condition characterized by a decrease in myocardial contractility, which results in a reduction in the cardiac output and left ventricular ejection fraction.

Tachy-brady syndrome: Tachy-brady syndrome, also known as sick sinus syndrome, is a condition in which the sinoatrial node is unable to perform as the pacemaker of the heart.

Tangential speech: Speech pattern whereby the connections between expressed ideas are unrelated or have little relationship to each other.

Taper: To gradually decrease the dosage of a drug over a period of time.

Tardive: A modifier used to describe movement disorders secondary to chronic antipsychotic treatment (duration of treatment must be greater than 3 months). The disorder must persist for greater than 4 weeks and exhibit masking and unmasking characteristics. Tardive dyskinesia, tardive chorea, tardive dystonia, and tardive akathisia are examples of tardive movement disorders.

Tendonitis: Inflammation of tendons.

Tenesmus: A painful spasm of the urogenital diaphragm with an urgent desire to evacuate the bowel or bladder, involuntary straining, and the passage of little fecal matter or urine.

Teratogenicity: Ability of an agent to cause a defect or malformation in a fetus.

TEWL (transepidermal water loss): The rate of water loss by evaporation from the skin.

Thalassemia: Any of a group of inherited disorders of hemoglobin metabolism in which there is impaired synthesis of one or more of the polypeptide chains of globin.

Third-spacing: The shift of fluid and protein into the peritoneal cavity and bowel wall lumen that occurs as a result of peritonitis.

Thought blocking: Interruption of a train of thought whereby the person stops speaking suddenly and without warning, even in the middle of a sentence. Person may report that the thoughts were taken out of his or her head.

Thought broadcasting: Belief that one's thoughts are audible to others.

Thrombin: The enzyme formed from prothrombin that converts fibrinogen to fibrin. It is the principle driving force in the clotting cascade.

Thrombogenesis: The process of forming a blood clot.

Thrombolysis: The process of enzymatically dissolving or breaking apart a blood clot.

Thrombolytic: An enzyme that dissolves or breaks apart blood clots.

Thromboplastin: A substance that triggers the coagulation cascade. Tissue factor is a naturally occurring thromboplastin and used in the prothrombin time (PT) test.

Thrombopoiesis: The process of platelet production from immature cells.

Thrombosis: The process of forming a thrombus.

Thrombotic thrombocytopenic purpura: A life-threatening disease involving embolism and thrombosis of the small blood vessels in the brain and kidney.

Thrombus: An aggregation of fibrin and platelets within a blood vessel. A thrombus often causes vessel obstruction, inflammation, and injury.

Thrush: Fungal infection of the oral mucosa.

Thyroid-stimulating hormone (TSH): A polypeptide hormone secreted by the anterior pituitary gland that stimulates iodine uptake and thyroid hormone synthesis.

Thyrotropin-releasing hormone (TRH): A trophic hormone released by the hypothalamus that stimulates release of thyroid-stimulating hormone (TSH).

Time trade-off: An approach to health-state preference elicitation in which the respondent is asked to trade off years of life in less than full health for a shorter number of years in full health.

Tinea barbae: Fungal infection of the hair follicles of the beard or mustache.

Tinea capitis: Fungal infection of the scalp, hair follicles, or adjacent skin.

Tinea corporis: Fungal infection of the glabrous skin of the trunk and extremities.

Tinea cruris: Fungal infection of the proximal thighs and buttocks.

Tinea manuum: Fungal infection of the palmar surface of the hands.

Tinea pedis: Fungal infection of the feet.

Tinnitus: A noise in the ears, as ringing, buzzing, roaring, clicking, etc. Such sounds can at times be heard by those other than the patient.

Tocolytic: Agent that stops labor contractions.

Tolerance: (1) A state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more of the drug's effects over time. (2) The ability of the immune system to accept a transplanted allograft as part of *self*.

Tonic-clonic seizures: Sharp tonic contraction of muscles followed by a period of rigidity and clonic movement.

Tophi: Urate deposits.

Toxic epidermal necrolysis: A syndrome similar to Stevens-Johnson syndrome characterized by blistering of skin and mucous membranes in response to administration of a drug. Large areas of skin may peel off.

Toxic megacolon: A segmental or total colonic distension of >6 cm with acute colitis and signs of systemic toxicity.

Toxic shock syndrome: Sudden onset of fever, muscle ache, vomiting and diarrhea, accompanied by a peeling rash and followed by low body temperature and shock; caused by staphylococcal endotoxin, especially from infection of the vagina associated with tampon use.

Toxoplasmosis: Clinical infection with *Toxoplasma gondii*.

Transmural: Across the wall of an organ or structure; in the case of Crohn's disease, inflammation can extend through all four layers of the intestinal wall.

Transurethral incision of the prostate: In this surgical procedure, the bladder neck opening is widened by making incisions at various locations around the bladder neck with a resectoscope, which is inserted into the penis. Excess prostate tissue is not removed.

Transurethral prostatectomy: In this surgical procedure, an enlarged prostate core is removed from the inside out. That is, a resectoscope is inserted into the penis. A cutting blade at the end shaves out excess prostate tissue.

Transverse lie: The fetus is perpendicular to the mother. Usually the shoulder is the presenting part. Fetuses in this position must be delivered by cesarean section.

Transverse myelitis: Inflammation of the full width of the spinal cord that disrupts communication to the muscles, resulting in pain, weakness, and muscle paralysis.

Traveler's diarrhea: Diarrhea caused by contaminated food or water and usually attributed to enterotoxigenic *Escherichia coli* (ETEC), *Shigella*, *Campylobacter*, *Salmonella* species, or viruses.

Troponin: A protein found predominately in cardiac, but not skeletal, muscle, which regulates calcium-mediated interaction of actin and myosin. Troponin I and T are released into the blood from the myocytes at the time of myocardial cell necrosis secondary to infarction. These biochemical markers become elevated and are used in the diagnosis of myocardial infarction. Troponin I and T are more sensitive and specific for infarction than creatinine kinase, which is found in both skeletal and myocardial cells. The exact value of troponin I or T, which is diagnostic of infarction, differs based on assay.

Trousseau's sign: A hand spasm produced by placing a blood pressure cuff over the forearm and inflating the pressure above the systolic pressure for 3 minutes.

Tubule: Section of the nephron that is responsible for secretion and reabsorption of water, electrolytes, and drugs.

Tumor: Elevated, solid lesion.

Tumor necrosis factor- α (TNF- α): A proinflammatory cytokine.

Type I reaction: An immediate, immunoglobulin E (IgE)-mediated allergic reaction.

Ulcer: Loss of epidermis and dermis caused by sloughing of necrotic tissue.

Ultradian sleep-wake rhythm: A cycle of sleep and wake that repeats in less than 24 hours. Babies have an ultradian sleep-wake rhythm with multiple sleep and wake periods in a 24-hour period.

Ultrafiltration: The process of removing water from the blood during dialysis.

Umbilication: Slight, navel-like depression, or dimpling, of the center of a rounded body.

Unilateral: On either the right or left side, not crossing the midline. When used for defining sensory or motor disturbances of migraine aura, it includes complete or partial hemi-distribution.

Upper respiratory tract infection: Otitis media, sinusitis, pharyngitis, laryngitis (croup), rhinitis, or epiglottitis.

Urea: A waste product found in the blood and caused by the normal breakdown of protein in the body.

Uremia: An array of symptoms associated with accumulation of metabolic by-products and endogenous toxins in the blood due to impaired kidney function. Symptoms include nausea, vomiting, loss of appetite, weakness, and mental confusion.

Urethritis: Inflammation of the urethra.

Urinalysis: The diagnostic analysis of urine and its components; can be microscopic or macroscopic in nature.

Urinary incontinence: Involuntary leakage of urine; can result from urethral underactivity (stress urinary incontinence), urethral overactivity (overflow incontinence), or mixed pathophysiologic mechanisms.

Urine: Fluid waste resulting from filtration of blood by the kidneys; transferred to the bladder by ureters and expelled from the body through the urethra by the act of voiding or urinating.

Urticaria: A dermatologic reaction noted by elevated, erythematous patches that are pruritic.

Vacuum erection device: Medical device used to manually induce an erection.

Vagal nerve stimulator (VNS): A medical device that is surgically implanted in patients with refractory epilepsy.

Validity: An estimation of the extent to which an instrument is measuring what it is purported to be measuring.

Valsalva maneuver: The Valsalva maneuver is the expiratory effort against a closed glottis, which increases thoracic cavity pressure, which impedes venous return to the heart. This maneuver results in blood pressure and heart rate changes and is used to diagnose treat various cardiac conditions.

Vasculitis: Inflammation of blood vessels.

Vasopressin: A posterior pituitary hormone that controls fluid balance by acting on the renal collecting ducts to prevent water loss.

Vector: Carrier (person, animal, or insect) of disease.

Vegetation: Bacterial growth on heart valves.

Ventricular remodeling: Alterations in myocardial cells and the extracellular matrix that result in changes in the size, shape, structure, and function of the heart. The remodeling process leads to reductions in myocardial systolic and/or diastolic function that, in turn, leads to further myocardial injury, perpetuating the remodeling process and the decline in ventricular dysfunction and progression of heart failure.

Vesicle: Clear blister (<0.5 cm in diameter) filled with fluid.

Visceral pain: Pain arising from internal organs such as the large intestine or pancreas.

Visual analog scale: A response scale that is a line with the end points well defined (e.g., 0 = worst imaginable health state, and 100 = best imaginable health state).

Volume of distribution: A proportionality constant that relates the amount of drug in the body to its serum concentration.

Vomiting: Contraction of the abdominal muscles, descent of the diaphragm, and opening of the gastric cardia resulting in expulsion of stomach contents from the mouth.

Vulgaris: Ordinary, common.

Wearing-off phenomena: Also known as end-of-dose wearing-off or motor fluctuations. The waning of the effects of a dose of levodopa prior to the scheduled time for the next dose, resulting in return of parkinsonian features, such as, tremor, slowness, and rigidity.

Withdrawal: The development of a substance-specific syndrome after cessation of or reduction in intake of a substance that was used regularly by the individual to induce a state of intoxication. Withdrawal causes significant distress to the individual and is associated with impairment in social, occupational, or other areas of functioning. Withdrawal is usually associated with substance dependence. Withdrawal generally is also associated with a craving to readminister the drug to relieve the symptoms.

Withdrawal bleeding: The predictable bleeding that results from cessation of a progestogen.

Withdrawal syndrome: The onset of a predictable constellation of signs and symptoms involving alerted activity of the central nervous system after the abrupt discontinuation of, or rapid decrease in, dosage of a drug.

Xerosis: Dry skin.

Xerostomia: Dry mouth caused by decreased salivary production.

Yeasts: Oval or spherically shaped unicellular forms that generally produce pasty or mucoid colonies on agar media, similar to those observed with bacterial cultures. Yeasts have rigid cell walls that reproduce by budding, a process in which daughter cells arise from pinching off a portion of the parent cell.

Zeitgeber: Environmental cue.

Zollinger–Ellison syndrome: Gastric acid hypersecretory disease caused by a gastrin-secreting tumor and leading to multiple, severe duodenal ulcers.

INDEX

 for minimizing pain from injection, 52t
- Angel dust, abuse of, 1075**
- Angina pectoris**
 chest pain resembling, episodic, differential diagnosis of, 223t
 in chronic heart failure, treatment of, 194
 classification of
 Canadian Cardiovascular Society Classification System for, 218, 218t
 specific activity scale for, 218, 218t
 clinical presentation of, 221, 222–223, 223t, 224f
 diagnosis of, 221, 223t, 223–226, 225f
 incidence of, 217–218
 outcome of, determination of, number of obstructed vessels in, 218
 Prinzmetal, treatment of, 241
 stable
 with hypertension, pharmacotherapy of, 153–154
 pain pattern in, 222
 stable exertional
 β -adrenergic blocking agents for, 228, 236–237, 236t
 coronary artery bypass grafting for, 230–231
 nitrates for, 228, 237t, 237–240
 percutaneous coronary intervention for, 230
 percutaneous transluminal coronary angioplasty for, 230, 231–236, 233–234t
 pharmacologic therapy for, 236t, 236–241, 237t
 revascularization for, 229, 230, 230t
 treatment of, 227–241
 algorithm on, 229f
 unstable, pain pattern in, 222
 variant, treatment of, 241
- Angioedema, from angiotensin II receptor blockers, 197**
- Angiogenesis, therapeutic, for stable exertional angina, 240–241**
- Angiography**
 in cardiovascular disorders, 116t, 117–118
 magnetic resonance, in neurologic illness diagnosis, 910
- Angioplasty, percutaneous transluminal, for peripheral arterial disease, 411**
- Angiotensin-converting enzyme (ACE), gene for, polymorphisms of, 37–38**
- Angiotensin-converting enzyme (ACE) inhibitors**
 for acute coronary syndromes, 259t
 adverse effects of, monitoring for, 272t
 adverse effects of, 196–197
 for chronic heart failure, 187–188
 for coronary artery disease with hypertension, 154
 cough induced by, 525–526
 for diastolic heart failure, 322
 in heart failure, information on, 195–197, 196t
 hyperkalemia induced by, 882
 for hypertension, 149, 150t, 152, 159–160
 in chronic kidney disease, 154–155, 787
 in diabetes, 154
 in diabetic kidney disease, 752, 752f, 753t, 754f, 754–755
 dosing of, 159–160
 in elderly, 156–157
 mechanism of action of, 159
 with metabolic syndrome, 157
 post-MI, 153
 side effects of, 159
 uses of, 159
 for immunoglobulin A nephropathy, 824
 interaction of aspirin with, 196
 in ischemic stroke management, 379
 kidney injury mediated by, 801f, 801–802, 802f
 for left ventricular dysfunction with hypertension, 153
 for nondiabetic kidney disease, 755–756, 756t
 for nonemergent hypervolemic hypotonic hyponatremia, 852
 pregnancy as contraindication to, 159
 in recurrent stroke prevention, 155
 for secondary prevention after myocardial infarction, 270
 for systemic sclerosis, 1440
- Angiotensin II, in heart failure, 178–179**
- Angiotensin receptor blockers (ARBs)**
 for acute coronary syndromes, 259t
 adverse effects of, monitoring for, 272t
 adverse effects of, 197
 for chronic heart failure, 190
 for diastolic heart failure, 322
 in heart failure, information on, 197
 hyperkalemia induced by, 882
 for hypertension, 149, 150t, 152, 160
 in chronic kidney disease, 154–155, 787
 in diabetes, 154
 in diabetic kidney disease, 752, 753t, 754–755
 dosing of, 160
 mechanisms of action of, 160
 with metabolic syndrome, 157
 post-MI, 153
 side effects of, 160
 kidney injury mediated by, 801–802
 for left ventricular dysfunction with hypertension, 153
 for nondiabetic kidney disease, 755–756, 756t
 pregnancy as contraindication to, 159
 in recurrent stroke prevention, 155
 for secondary prevention after myocardial infarction, 270
 in secondary stroke prevention, 379
 for systemic sclerosis, 1440
- Anidulafungin**
 in-vitro susceptibility of non-*Candida* fungal pathogens for, 1975t
 for mucosal candidiasis, 1963t
- Animal bites, 1804t, 1805t, 1814–1816**
- Anion gap, serum, in metabolic acidosis, 893**
- Ankle, rheumatoid arthritis involving, 1508**
- Ankle-brachial index (ABI), in peripheral arterial disease diagnosis, 100, 410–411**
- Ankylosing spondylitis, in inflammatory bowel disease, 592**
- Ankylosis, of joints in rheumatoid arthritis, 1506**
- Anorexia, in chronic kidney disease, 750**
- Anorexia nervosa (AN)**
 clinical presentation of, 1042–1043
 diagnostic criteria for, 1042–1044
 epidemiology of, 1041
 etiology of, 1042
 pathophysiology of, 1042
 signs and symptoms of, 1042f
 treatment of
 nonpharmacologic, 1045
 outcomes of
 desired, 1044
 evaluation of, 1048
 pharmacologic, 1045–1046
- Anorexic agents, pulmonary hypertension induced by, 531**
- Anovulatory bleeding**
 clinical presentation of, 1337
 epidemiology of, 1336
 etiology of, 1336
 pathophysiology of, 1330t, 1337
 therapeutic agents for, 1332t
 treatment of, 1337–1338
 outcome of, evaluation of, 1335t
- Anoxia, definition of, 218**
- Antacids**
 as antiulcer agents, 582
 digoxin interaction with, 199t
- Anthracene derivatives, in cancer chemotherapy, 2099**
- Anthracenediones, for acute myeloid leukemia, 2268, 2269**
- Anthracyclines**
 for acute myeloid leukemia, 2268–2269
- for breast cancer
 locally advanced, 2144
 metastatic, 2148
 in breast cancer chemotherapy, 2137
- Anthralin, topical, for psoriasis, 1608–1609**
- Anthraquinone derivatives, for constipation, 627**
- Anthrax, O59–O62**
 clinical presentation of, O60f, O60–O61
 etiology of, O59
 pathophysiology of, O59–O60
 treatment of, O61–O62
- Anthropometric measurements, in nutrition status assessment, 2351**
- Anti-IgE, for chronic asthma, 489–490**
- Antiandrogens, for prostate cancer, 2212, 2213t**
- Antiarrhythmic drugs, 283–286**
 classification of, 283–286, 284t
 in CPR, 130
 for hypertrophic cardiomyopathy, 327
 intravenous, dosing of, 288t
 long-term, for atrial fibrillation, complications of, 293–295
 oral, maintenance doses of, 288t
 pharmacokinetics of, 287t
 side effects of, 286t
 for sinus rhythm maintenance in supraventricular tachycardias, selection guidelines for, 294t
 type Ia, 283
 type Ib, 283–284
 type Ic, 284
 type II, 284t, 285
 type III, 284t, 285, 285t
 type IV, 284t, 286
 for ventricular fibrillation, 308–309
- Antibiograms, in antimicrobial selection, 1733**
- Antibiotics**
 diarrhea associated with, 1863–1864
 in *Helicobacter pylori* eradication, 577–578
 for hepatic encephalopathy, 646
 macrolide, for acne vulgaris, 1594t, 1597
 oral, for febrile neutropenic cancer patients, 2010t, 2012
 for osteomyelitis, 1938–1940
 for peritonitis complicating peritoneal dialysis, O114, O114t
 prophylactic, in acute pancreatitis, 665–666, 666t
 in pulmonary therapy for cystic fibrosis, 541–543
 bacterial resistance to, 543
- Antibody(ies)**
 antigen-specific, measurement of, indications for, 1427, 1427t
 antinuclear
 in rheumatoid arthritis, 1510
 in SLE, 1432, 1433
 antiphospholipid, in SLE diagnosis, 1432–1433
 detection of, in infection diagnosis, 1719
 to factors VIII and IX, neutralizing, in hemophilia, treatment of, 1673–1674
 monoclonal. *See* Monoclonal antibodies (MoABs).
 polyclonal, in immunosuppression, for solid-organ transplantation, 1472–1473
 production of, 2041
 in glomerular injury, 812
- Anticholinergics**
 for acute, severe asthma, 478, 481
 in diarrhea management, 623
 intranasal, for allergic rhinitis, 1568t
 long-acting, in COPD management, 506–507
 for Parkinson's disease, 981, 981t
 short-acting, in COPD management, 505–506
- Anticholinesterase insecticides, poisoning by, 77–80**
 causative agents in, 78
 clinical presentation of, 77–78
 incidence of, 78–79
 management of, 79–80, 80t
 mechanism of, 78
 monitoring in, 80

- pathogenesis of, 79f
prevention of, 80
risk assessment for, 79
- Anticipatory nausea and vomiting, 609
- Anticoagulants
contraindications to, 340t
excessive, bleeding due to, management of, 340–341
heparin as, 335–343. *See also* Heparin.
major bleeding while taking, risk factors for, 340t
for non–ST-segment elevation acute coronary syndromes, 266–267
for pulmonary hypertension, O96
for secondary prevention after myocardial infarction, 269
for ST-segment elevation acute coronary syndromes, 262–263
for thrombosis in systemic lupus erythematosus, 1439
for venous thromboembolism
in pediatric patients, 363
in pregnancy, 362, 362t
warfarin as, 347–354. *See also* Warfarin (Coumadin).
- Anticoagulation
for disseminated intravascular coagulation, 1681
excessive, from warfarin therapy, management of, 352, 353f
in nephrotic syndrome, 816
- Anticoagulation status, dietary supplements affecting, 349t
- Anticontinence devices, for urinary incontinence, 1405t
- “Anticonvulsant hypersensitivity syndrome,” 1455
- Anticonvulsants
allergic drug reactions to, 1455
for attention-deficit/hyperactivity disorder, 1034
for bipolar disorder, 1149
efficacy ratings of, 1147t
product information on, 1151–1152t
for bulimia nervosa, 1047
for generalized anxiety disorder, dosages of, 1165t
in migraine prophylaxis, 1014–1015
for social anxiety disorder, 1174
use of, in pregnancy, 1150
weight gain and, 2441
- Antidepressants
adverse effects of, 1129–1130
in alcohol dependence treatment, 1087
in Alzheimer’s disease management, 1062
for anorexia nervosa, 1045
for attention-deficit/hyperactivity disorder, 1033t, 1033–1034
for binge eating disorder, 1048
for bipolar disorder, 1149
for bulimia nervosa, 1046
dosages of, adult, 1127t
dosing of, 1136
in Down’s syndrome management, O120
drug interactions with, 1132–1134
for elderly patients, 1134
for generalized anxiety disorder, 1166–1167
dosages of, 1165t
for insomnia, 1193
for lactating patients, 1134–1135
in migraine prophylaxis, 1011t, 1014
for obesity, 2448
for obsessive-compulsive disorder, 1184, 1186–1187
for panic disorder, 1170t, 1170–1171
for pediatric patients, 1134
clinical controversy over, 50
pharmacokinetics of, 1130–1132
altered, 1131–1132
plasma concentration of
clinical response and, 1132
monitoring of, 1132
- for posttraumatic stress disorder, 1182t, 1182–1183
for pregnant patients, 1134–1135
for premenstrual dysphoric disorder, 1341
for refractory patients, 1135
for social anxiety disorder, 1173–1174, 1174t
for special populations, 1134–1135
- Antidiuretic hormone (ADH), 129. *See also* Vasopressin.
- Antidotes, in poisoning treatment, 74, 75t
- Antidromic reentrant paroxysmal supraventricular tachycardia, 296
- Antidulafungin, susceptibility and interpretive breakpoints of *Candida* species for, 1975t
- Antiemetic leg exercise, for deep vein thrombosis, 362
- Antiemetic drugs, 609–610, 610t
antacids as, 610, 610t
antihistamine-anticholinergic drugs as, 610t, 610–611
butyrophenones as, 611
cannabinoids as, 611
for chemotherapy patients, recommendations for, 612t
for children, 615
corticosteroids as, 611
H₂-receptor antagonists as, 610, 610t
metoclopramide as, 611
for migraine, 1012
phenothiazines as, 611
selective serotonin reuptake inhibitors as, 611–612
substance P/neurokinin 1 receptor antagonists as, 611
use of, during pregnancy, 614–615, 615t
- Antiepileptic drugs (AEDs)
adverse effects of, 932, 935
carbamazepine as, 939–940
divalproex sodium as, 946–947
dosing of, 939t
elimination pathways for, 937t
ethosuximide as, 940–941
gabapentin as, 941–942
interactions between, 936
lamotrigine as, 942
levetiracetam as, 942–943
mechanism of action of, 932
oxcarbazepine as, 943–944
pharmacokinetic data on, 934t
phenobarbital as, 944
phenytoin as, 944–945
pregabalin as, 945
recommendations for, evidence-based, 933t
serum concentrations of, target, 939t
side effects of, 934–935t
teratogenic effects of, 938
tiagabine as, 945–946
topiramate as, 946
valproic acid as, 946–947
when to stop, 930–931
zonisamide as, 947–948
- Antiestrogens, for metastatic breast cancer, 2145t, 2146–2147
- Antifactor Xa activity, in low-molecular-weight heparin monitoring, 342
- Antifibrinolytic drugs
for coagulopathy in liver disease, 1683
for disseminated intravascular coagulation, 1681
- Antifibrinolytic therapy, for hemophilia A, 1672
- Antifolates, in cancer chemotherapy, 2097–2098
- Antifungal agents
amphotericin B as, 1997. *See also* Amphotericin B.
azole, 1998. *See also* Azole antifungal agents.
drug interactions with, 1998–1999
echinocandins as, 1997–1998. *See also* Echinocandins.
in febrile neutropenia management, 2013–2014, 2014t
flucytosine as, 1997. *See also* Flucytosine.
- for peritonitis complicating peritoneal dialysis, O114t
- plasma concentration monitoring of, 1999, 1999t
- resistance to, 1974–1976, 1975t, 1976f
clinical, 1974
microbial, 1974–1976
for sepsis, 1950–1951
susceptibility testing of, 1974, 1975t
- Antigen(s)
complete, 1449
definition of, 2041
detection of, in infection diagnosis, 1719
incomplete, 1449
prostate-specific, in screening for prostate cancer, 2209
- Antigen-presenting cells (APCs)
functions of, 1419, 1419f
major histocompatibility complex and, 1421
- Antigen recognition, 1420
cells mediating, 1420–1421
- Antigen skin testing, 1427
- Antigen-specific antibody, measurement of, indications for, 1427, 1427t
- Antigen-specific IgE, measurement of, 1427
- Antigenic determinants, in penicillin immunogenicity, 1452, 1453f
- Antiglobulin test, 1647
- Antiglomerular basement membrane glomerulonephritis, 828
- Antiglutamatergic therapy, for Alzheimer’s disease, 1057–1058
- Antihistamines
for allergic rhinitis, 1568t, 1569–1571, 1570t
for atopic dermatitis, 1622–1631
for insomnia, 1193
- Antihypertensives, 149–166
 α_1 -blockers as, 152t, 163
aliskiren as, 163
alternative, 163–164
angiotensin-converting enzyme inhibitors as, 149, 150t, 152, 159 to 160
angiotensin receptor blockers as, 149, 150t, 152, 160
 β -blockers as, 149, 151, 151t, 152–153, 161–163
calcium channel blockers as, 149, 150–151t, 152, 160–161
central α_2 -agonists as, 152t, 163
in combination therapy, 166, 166t
direct arterial vasodilators as, 152t, 164
direct renin inhibitor as, 152t
diuretics as, 158–159
loop, 158
potassium-sparing, 158
thiazide, 149, 150t, 151–152, 158
efficacy of, 167
for hypertensive emergency, 165t, 165–166
for hypertensive urgency, 165
peripheral adrenergic antagonist as, 152t
reserpine as, 163–164
toxicity of, 167
- Antiinflammatory agents
in Alzheimer’s disease prevention, 1059
for cystic fibrosis, 541
- Antimalarial drugs, for systemic lupus erythematosus, 1436t, 1436–1437
- Antimetabolites
for atopic dermatitis, 1624
in cancer chemotherapy, 2095–2098
antifolates as, 2097–2098
cytidine analogs as, 2095–2097
fluorinated pyrimidines as, 2095
purines and purine antimetabolites as, 2097
in immunosuppression, for solid-organ transplantation, 1470–1471
pulmonary fibrosis associated with, 530
- Antimicrobial combination effect test, in antimicrobial activity testing, 1725f, 1725–1726
- Antimicrobial peptides, human, 1420

intake of, adequate, in osteoporosis prevention and treatment, 1490, 1491t
metabolism of, abnormalities of, in chronic kidney disease, 750
recommendations for, 2362t

- Calcium (*Cont.*)
 in selected foods and beverages, 1492t
 supplemental, in osteoporosis prevention and treatment, 1493, 1493t, 1495, 1495t
- Calcium acetate, for secondary hyperparathyroidism complicating chronic kidney disease, 781–783, 782t
- Calcium and zinc diethylenetriamine pentaacetic acid, for radiation exposure, O87
- Calcium antagonists, for posttraumatic seizures, 973
- Calcium carbonate, for secondary hyperparathyroidism complicating chronic kidney disease, 781–783, 782t
- Calcium channel blockers (CCBs)
 for acute coronary syndromes, 259t
 for bipolar disorder, 1149
 product information on, 1152t
 for coronary artery disease with hypertension, 153–154
 for diastolic heart failure, 321
 in hemorrhagic stroke management, 380–381
 for hypertension, 149, 150–151t, 152, 160–161
 in African Americans, 157
 in chronic kidney disease, 787
 in diabetes, 154
 in diabetic kidney disease, 755
 in elderly, 155
 mechanism of action of, 161
 for hypertrophic cardiomyopathy, 326–327
 in migraine prophylaxis, 1015
 for nondiabetic kidney disease, 756
 for non–ST-segment elevation acute coronary syndromes, 268
 poisoning by, 80–83
 causative agents in, 81
 clinical presentation of, 80
 incidence of, 81
 management of, 82
 mechanism of, 81
 monitoring in, 82
 pathophysiologic changes in, 81f
 prevention of, 82–83
 risk assessment for, 81–82
 for pulmonary hypertension, O97
 for secondary prevention after myocardial infarction, 269
 for stable exertional angina, 228–229, 239–240
 for ST-segment elevation acute coronary syndromes, 263–264
 for systemic sclerosis, 1440
- Calcium chloride
 for hyperkalemia, 883, 884t
 for hypocalcemia, 868
- Calcium-containing phosphate-binders, for secondary hyperparathyroidism complicating chronic kidney disease, 781–783, 782t
- Calcium gluconate, for hypocalcemia, 868
- Calcium homeostasis, disruption of, in drug-induced liver disease, 654
- Calcium salts, for hyperphosphatemia, 871
- Caliciviruses, 1868–1869, 1869t
- Camptothecin derivatives, in cancer chemotherapy, 2098–2099
- Campylobacteriosis, 1866–1867
- Canada, pharmacist-directed documentation initiatives in, O38
- Canadian Cardiovascular Society Classification System, in grading of angina, 218, 218t
- Cancer
 breast, 2121–2156. *See also* Breast, cancer of.
 colon, risk of, reduction of, postmenopausal hormone therapy in, 1360
 colorectal, 2175–2206. *See also* Colorectal cancer.
 deaths from, 2086f
 diagnosis of, 2091
 endometrial, postmenopausal hormone therapy and, 1361
 etiology of, 2087f, 2087t, 2087–2089, 2088t
 follicular, thyrotoxicosis from, 1249
 incidences of, 2086f
 lung, 2157–2173. *See also* Lung(s), cancer of.
 nausea and vomiting in, nonchemotherapy etiologies of, 609t
 ovarian, 2245–2258. *See also* Ovary(ies), cancer of.

 prostate, 2207–2218. *See also* Prostate gland, cancer of.
 screening for, 2090–2091, 2091t
 skin, 1584–1586, 1587f to 1588f, 2311–2329. *See also* Skin, cancer of.
 staging of, 2091–2092
 thrombosis and, 332–333
 thyroid, recombinant thyroid stimulating hormone in, 1259
 treatment of, 2085–2119. *See also* Cancer chemotherapy; Chemotherapeutic agents.
 adoptive immunotherapy in, 1635
 modalities of, 2092
 principles of, 2092–2116
 warning signs of, 2091t
 workup of, 2091–2092
- Cancer chemotherapy
 for acute myeloid leukemia, in elderly, 2272
 adjuvant
 for operable colon cancer, 2189–2191
 for operable rectal cancer, 2191–2192
 administration of, 2111–2112
 alopecia in, management of, 2116
 anemia in, management of, 2112–2113
 biologic therapies in, 2108
 for breast cancer, adjuvant, 2137–2141, 2138–2139t
 cellular basis for, 2092–2093
 combination, 2111
 for Hodgkin's lymphoma, 2223
 consolidation
 for acute lymphoblastic leukemia, 2265
 for ovarian cancer, 2253
 cutaneous reactions in, management of, 2116
 cytotoxic. *See* Cytotoxic agents.
 extravasation in, management of, 2116
 for follicular lymphomas, 2234, 2234t
 immune therapies in, 2108–2109
 infertility in, management of, 2116
 intraperitoneal, for ovarian cancer, 2252, 2252t
 for lung cancer
 non-small cell
 stages I and II, 2162t, 2162–2163
 stages IIB and III, 2163–2164
 stages IIIB and IV, unresectable, 2164–2166, 2165t
 small cell, 2169–2170
 for metastatic colorectal cancer, 2192–2198, 2193t, 2194t
 hepatic artery infusion of, 2197–2198
 second-line, 2198–2199
 molecular basis for, 2092–2093
 molecular biology and, 2094, 2095f
 mucositis in, management of, 2115–2116
 myelosuppression in, management of, 2112–2115
 neutropenia in, management of, 2113–2115, 2114f
 for ovarian cancer, 2250–2253
 consolidation, 2253
 first-line treatment in, 2250–2253
 in recurrent disease, 2253–2255
 postremission, in acute myeloid leukemia, 2269–2270
 for prostate cancer, 2214–2215, 2215t
 purposes of, 2092
 response criteria for, 2109–2111
 role of, in cancer treatment, 2093t
 salvage
 for metastatic colorectal cancer, 2200
 for multiple myeloma, 2304
 for refractory diffuse large B-cell lymphomas, 2239
 secondary malignancies in, management of, 2116
 supportive care issues in, 2112–2116
 thrombocytopenia in, management of, 2115
 tumor growth principles and, 2092–2093, 2093f
 tumor proliferation and, 2093–2094
- Cancer chemotherapy agents. *See* Chemotherapeutic agents.
- Cancer pain, 991
 management of, special considerations in, 1000, 1001f
- Candesartan
 for chronic heart failure, 190t, 190–191
 for diastolic heart failure, 322

 esophageal, 1960–1967. *See also* Esophageal candidiasis.
 oropharyngeal, 1960–1967. *See also* Oropharyngeal candidiasis (OPC).
 sepsis from, therapy for, 1950
 vulvovaginal, 1957–1959, 1958t
- Candiduria, 1993
- Cannabinoids, as antiemetics, 610t, 611
- Capecitabine (Xeloda)
 adjuvant, for colorectal cancer, 2189, 2190t, 2191
 for breast cancer
 early, 2138t, 2139t
 metastatic, 2148
 dose modification of, in renal impairment, 2097t
 for metastatic colorectal cancer, 2193t, 2196–2197
 for refractory ovarian cancer, 2254t
- Capoten. *See* Captopril (Capoten).
- Capreomycin, for tuberculosis, dosages of, 1848t, 1849t
- Capsaicin, topical, for osteoarthritis, 1531
- Capsule endoscopy, in GI disorder diagnosis, 553
- Captopril (Capoten). *See also* Angiotensin-converting enzyme (ACE) inhibitors.
 for diastolic heart failure, 322
 dosage and elimination of, 196t
 for hypertensive urgency, 165
- Carbachol, for open-angle glaucoma, 1559t
- Carbamate insecticides. *See also* Anticholinesterase insecticides.
 toxicity of, 78
- Carbamazepine (Tegretol)
 in alcohol dependence treatment, 1087t
 allergic drug reactions to, 1455
 for bipolar disorder
 efficacy ratings of, 1147t
 monitoring of, laboratory tests in, 1153t
 product information on, 1151t, 1153–1154
 clinical considerations with, 939–940
 dosing of, 939t
 drug-induced aplastic anemia from, mechanism of, 1704
 drug interactions with, 936t
 pharmacokinetic data on, 934t
 pulmonary eosinophilia induced by, 527
 in schizophrenia management, 1108
 serum concentrations of, target, 939t
 side effects of, 934t
 use of, in pregnancy, risks associated with, 1150
- Carbapenems/monobactams, for urinary tract infections, 1905t
- Carbicarb, for metabolic acidosis, 899

- Carbidopa
 motor complications of, 983, 983t
 for Parkinson's disease, 981t, 982–984
- Carbohydrate(s)
 digestion and absorption of, 2400, 2400f
 disorders of
 in acute renal failure, 2418
 in chronic renal failure, 2421
 in liver failures, 2424
 in pulmonary failure, 2432
 in short-bowel syndrome, 2428
 in enteral feeding formulas, 2405t, 2405–2406
- Carbon monoxide, diffusing capacity of lung for, 457
- Carbonic anhydrase inhibitors (CAIs)
 for closed-angle glaucoma, 1561
 hyperchloremic metabolic acidosis from, 894
 for open-angle glaucoma, 1559t
- Carboplatin
 allergic drug reactions to, 1455
 in cancer chemotherapy, 2100
 dose modification of, in renal impairment, 2097t
 for lung cancer
 non–small cell, 2162t, 2163t, 2164–2166, 2165t
 small cell, 2169
 nephrotoxicity induced by, 799–800

 gastrointestinal tract in, 536
 clinical presentation of, 538
 treatment of, 539–540
 outcomes of, evaluation of, 543–544
 hematologic system in, 537
 joints in, 538
 malnutrition in, consequences of, 2372
 organ involvement in, 536t
 pathophysiology of, 535–538
 pediatric therapy and, 51
 pulmonary system in, 536–537
 clinical presentation of, 538
 treatment of, 540–543
 antibiotic, 541–543
 antiinflammatory, 541
 antiobstructive, 540–541
 outcomes of, evaluation of, 543–544
 reproductive system in, 537
 sweat glands in, 537
 treatment of, 539–544
 general approach to, 539–543
 new directions in, 544
 outcomes of, desired, 539
- Cystic fibrosis transmembrane regulator (CFTR)
 analysis of, in cystic fibrosis diagnosis, 538
 functional, loss of, in cystic fibrosis, 535–536
 functions of, 535
- Cystitis, acute uncomplicated, treatment of, 1904, 1906t
- Cystosarcoma phyllodes of breast, 2130
- Cytadren (aminoglutethimide), for Cushing's syndrome, 1270t, 1270–1271
- Cytarabine (ara-C)
 for acute myeloid leukemia, 2268–2270, 2275
 in cancer chemotherapy, 2095–2096
 in delayed intensification therapy for acute lymphoblastic leukemia, 2265
 dose modification of, in renal impairment, 2097t
 intrathecal, in CNS prophylaxis in acute lymphoblastic leukemia, 2264
 for refractory diffuse large B-cell lymphomas, 2239
- Cytidine analogs, in cancer chemotherapy, 2095–2096
- Cytochrome P450 (CYP)
 CYP2A6, 34
 CYP3A, tacrolimus pharmacokinetics and, 699–700
 CYP3A4/5, 34
 CYP2C9, 34
 polymorphic, dosing and, 698
 CYP2C19, 34
 polymorphic, dosing and, 698
 CYP2D6
 abnormal metabolizers of, dosing and, 698–699, 699f
 polymorphisms in, 33–35, 34t
 in drug metabolism, 16–17, 17t
 changes in, in liver diseases, 695
 genetic polymorphisms for, 33–35
 metabolism of, warfarin-dietary supplement interactions involving, 348t
- Cytochrome P450 enzymes
 downregulation of, in chronic kidney disease, 835–836
 metabolic activation of, in drug-induced liver disease, 654
- Cytokine receptors
 antagonists of, in immune function evaluation, 1428
 in immune function evaluation, 1428
- Cytokines
 in allergic rhinitis, 1566
 antiinflammatory, in sepsis, 1945
 detection and measurement of, 1428
 evaluation of, 1426
 immunomodulatory, for posttransplant immunotherapy, 2339
 mediating adaptive immune response, 1423, 1424t
 in peritonitis, 1877
 proinflammatory, in heart failure, 180
 in psoriasis, 1604
 for radiation exposure, O87
- Cytomegalovirus (CMV) infections
 immunoglobulin for, 2055
 post-transplant, 1478
- Cytomegalovirus immunoglobulin, 2055–2056
- Cytoreduction, secondary, for ovarian cancer, 2249
- Cytotoxic agents
 for chronic lymphocytic leukemia, 2289–2290
 for focal segmental glomerulosclerosis, 820
 for immunoglobulin A nephropathy, 824
 intravenous, emetic risk of, 608t
 for lupus nephritis, 826
 for melanoma, 2322
 for membranoproliferative glomerulonephritis, 822
 for membranous nephropathy, 821
 for metastatic breast cancer, 2147–2149
 for minimal-change nephropathy, 818
 for systemic lupus erythematosus, 1436t, 1437–1438
- Cytotoxicity
 cellular, antibody-dependent, 1449
 mechanisms of, 1421–1422
- D**
- D-Penicillamine
 for rheumatoid arthritis, 1511t
 for systemic sclerosis, 1440
- DA. *See* Dopamine (DA).
- Dabigatran, for venous thromboembolism, 344t, 345f, 345t, 346
- Dacarbazine
 in cancer chemotherapy, 2100
 for Hodgkin's lymphoma, 2223, 2225t
 for melanoma, 2322, 2323t
- Dacrylitis, in sickle cell disease, 1688
- Dalmane (flurazepam), for insomnia, 1194t
- Dalteparin
 doses for, 341t
 indications for, 341t
- Danazol, for endometriosis, 1348t, 1349
- Dapsone
 for acne vulgaris, 1599
 topical, for acne vulgaris, 1597
- Daptomycin
 for pneumococcal meningitis, 1750
 for sepsis, 1949t
- Darbepoetin, for myelodysplastic syndromes, O139
- Darbepoetin alfa
 for anemia in cancer chemotherapy, 2113
 for anemia of chronic kidney disease, 775f, 777–780. *See also* Erythropoiesis-stimulating agents (ESAs), for anemia of chronic kidney disease.
- Darifenacin, for urge urinary incontinence, 1407t, 1408
- Dartmouth regimen, for melanoma, 2323, 2323t
- Darunavir (DRV), for HIV infection, 2072, 2073t
- Darusentan, for hypertension, 164
- Darvon. *See* Propoxyphene (Darvon).
- Dasatinib (Sprycel)
 in cancer chemotherapy, 2107
 for chronic myelogenous leukemia, 2286
- Daunorubicin
 for acute lymphoblastic leukemia, 2264
 for acute myeloid leukemia, 2268, 2269
 in elderly, 2272
 in cancer chemotherapy, 2099
 dose modification of, in hepatic dysfunction, 2097t
- DAWN (Drug Abuse Warning Network), 1068
- DCA (dichloroacetate), for metabolic acidosis, 899
- DCC. *See* Direct-current cardioversion (DCC).
- DCC gene, mutations of, in colorectal cancer, 2182
- DD. *See* Developmental disability (DD).
- de Gramont regimen, for colorectal cancer, 2190t
- Death
 in older adults, leading causes of, 58, 58f
 sudden, from venous thromboembolism, 331
 sudden cardiac. *See* Sudden cardiac death (SCD).
- Decitabine (5-aza-2'-deoxyditydine)
 in cancer chemotherapy, 2096–2097
 for myelodysplastic syndromes, O140t, O140–O141
 in sickle cell disease management, 1693
- Decongestants, for allergic rhinitis, 1568t, 1571t, 1571–1572
- Decontamination, gastric, in poisoning treatment, perspectives on, 73–74
- Decubitus ulcers, 1812t, 1812–1814, 1813f
- Deep-brain stimulation, for Parkinson's disease, 986
- Deep vein thrombosis (DVT), 331
 clinical assessment models for, 337t
 clinical presentation of, 337t
 outpatient therapy for
 patient education for, 360t
 protocol for, 358–359t
 prophylaxis for, in sepsis, 1948t, 1953
 prophylaxis in, heparin for, 379
- Defective splicing, 33
- Deferoxamine, for iron toxicity, 84–85
- Defibrillation, for ventricular fibrillation, 125–126, 128, 308
- Defibrillator, cardiac, implantable, for chronic heart failure, 185
- Dehydration
 in children, clinical assessment of, by body weight loss, 1858
 in hypovolemic shock, 442
 volume depletion versus, 442
- Dehydroepiandrosterone (DHEA), for Addison's disease in women, 1275
- Delavirdine (DLV), for HIV infection, 2071, 2073t
- Delayed hypersensitivity reactions, to drugs, 1449
- Delayed hypersensitivity skin test, for lymphocyte function, 1426
- Delivery
 group B *Streptococcus* infection at, 1307
 hemorrhage after, 1308
- Demecarium, for closed-angle glaucoma, 1562
- Demeclocycline, for nonemergent euvoletic hypotonic hyponatremia, 852

- Dementia
 Alzheimer's, 1051–1065. *See also* Alzheimer's disease (AD).
 in elderly, types of, 1051t
 prevention of, postmenopausal hormone therapy in, 1362
- Demerol. *See* Meperidine (Demerol).
- Demyelinating polyneuropathy, chronic inflammatory, immunoglobulin for, 2055
- Dendritic cells, in immune system, 1419
- Denileukin diftitox, in cancer chemotherapy, 2109
- Denosumab, in osteoporosis prevention and treatment, 1498
- Dental procedures, infective endocarditis prophylaxis for, 1835, 1835t
- Depakene. *See* Valproic acid (Depakene).
- Depakote. *See* Divalproex sodium (Depakote).
- Dependence
 alcohol
 pharmacologic management of, 1087–1088
 pharmacotherapy for, 1087t
 caffeine, 1095
 nicotine, treatment of, 1089–1094. *See also* Smoking, cessation of.
 on opioids, 996–997
 physical, definition of, 1068
 on sedative-hypnotics, 1071t
 substance, 1080
- Depressants, CNS
 abuse of, 1069–1072
 withdrawal of, treatment of, 1078–1080
- Depression
 asthma and, 471
 CNS, in metabolic acidosis, 896
 postpartum, 1309
- Depression rating scales, 1027t
- Depressive disorders, 1123–1139
 5-HT/NE link hypothesis of, 1124
 biogenic amine hypothesis of, 1124
 biologic markers of, 1124
 clinical presentation of, 1125t, 1125–1126
 dopamine in, 1124
 in Down's syndrome, O120
 dysregulation hypothesis of, 1124
 emotional symptoms of, 1125–1126
 epidemiology of, 1123
 etiology of, 1124
 intellectual/cognitive symptoms of, 1126
 pathophysiology of, 1124
 physical symptoms of, 1126
 in pregnancy, management of, 1305
 psychomotor disturbances in, 1126
 suicide risk evaluation and management in, 1126
 theories of postsynaptic changes in receptor sensitivity in, 1124
 treatment of, 1126–1137

 clinical manifestations of, 1451, 1451t
 hormonal status and, 1578
 lesion assessment in, 1578–1579, 1579f, 1580f, 1581f, 1582f
 patient assessment in, 1578–1579
 in pregnancy, management of, 1304
 psoriasis as, 1603–1617. *See also* Psoriasis.
 skin cancers as, 1584–1586, 1587f–1588f
 skin structure and function and, 1577
- Dermatomyositis, 1441
- Dermatophytes, 1967, 1968t
- Desensitization
 for allergic rhinitis, 1573
 for aspirin sensitivity, 523
 penicillin, 1456, 1456t, 1457t
 trimethoprim-sulfamethoxazole, 1456–1457
- Desipramine
 dosages of, adult, 1127t
 pharmacokinetics of, 1131t
 potencies of, relative, 1128t
- Desirudin, for venous thromboembolism, 344t, 345t, 345–346
- Desmopressin
 adverse effects of, 1038
 for central diabetes insipidus, 855, 855t
 for coagulopathy in liver disease, 1683
 for enuresis, 1038
 for von Willebrand disease, 1677–1678
- Desmopressin acetate, for hemophilia A, 1671–1672
- Desonide, for psoriasis, vasoconstricting potency of, 1607t
- Desoximetasone, for psoriasis, vasoconstricting potency of, 1607t
- Desoxyn (methamphetamine), for narcolepsy, 1197t
- Detoxification, rapid, for opioids, 1080
- Detrusor hyperactivity with impaired contractility, 1401
- Developmental disability (DD), O118–O133
 autistic disorder as, O122–O128. *See also* Autistic disorder.
 Down's syndrome as, O119–O122. *See also* Down's syndrome (DS).
 Rett's syndrome as, O128–O130
- Dexamethasone
 for acute lymphoblastic leukemia, 2264
 as adjunctive treatment of meningitis, 1753–1754
 as antiemetic, 611
 in delayed intensification therapy for acute lymphoblastic leukemia, 2265
 for multiple myeloma, 2298, 2298t, 2299, 2299t
 in prophylaxis
 of chemotherapy-induced nausea and vomiting, 612
 of delayed chemotherapy-induced nausea and vomiting, 613
 of postoperative nausea and vomiting, 614
 of radiation-induced nausea and vomiting, 614
 for psoriasis, vasoconstricting potency of, 1607t
 for refractory diffuse large B-cell lymphomas, 2239
- Dexamethasone sodium phosphate, for psoriasis, vasoconstricting potency of, 1607t
- Dexamethasone suppression test (DST)
 in Cushing's syndrome diagnosis, 1269
 in depression, 1124
- Dexedrine. *See* Dextroamphetamine (Dexedrine).
- Dexfenfluramine, pulmonary hypertension induced by, 531
- Dexmethylphenidate, for attention-deficit/hyperactivity disorder, 1030–1031, 1032t
- Dextran, as plasma expander, 446–447
- Dextroamphetamine (Dexedrine)
 for attention-deficit/hyperactivity disorder, 1030–1031, 1032t
 for narcolepsy, 1197t
- Dextrose, in parenteral nutrition, 2382
- DHA (docosahexaenoic acid), for secondary prevention of myocardial infarction, 271
- DHAP regimen, for refractory diffuse large B-cell lymphomas, 2239
- DHF. *See* Diastolic heart failure (DHF).
- DI. *See* Diabetes insipidus (DI).

 for heart failure, information on, 198–200
 pediatric dosage of, 50
 pharmacokinetics of, 198t, 198–199
 for pulmonary hypertension, O97
 toxicity of, signs and symptoms of, 199t
 Dihydroergotamine, for migraine, 1010t, 1012–1013
 Dihydropyridines
 for hypertension, 160–161
 for ST-segment elevation acute coronary syndromes, 263–264
 Dihydroergotamine, in aborting cluster headache, 1017
 Dilantin. *See* Phenytoin (Dilantin).
 Diloxanide furoate (Furamide)
 for amebiasis, 1889
 for parasitic diseases, 1898t
 Diltiazem
 for acute coronary syndromes, adverse effects of, monitoring for, 272t
 as antiarrhythmic drug, 284t, 286
 for diastolic heart failure, 321
 dosing of, 288t
 for hypertension, side effects of, 161
 pharmacokinetics of, 287t
 for pulmonary hypertension, O97, O99t
 toxicity of, 81. *See also* Calcium channel blockers (CCBs), poisoning by.
 Dilution techniques, in total lung capacity measurement, 457
 Dimenhydrinate (Dramamine)
 as antiemetic, 610t
 for nausea and vomiting of pregnancy, 614
 Dimercaprol, for lewisite exposure, O84
 Dinoprostone (Prepidil, Cervidil), for cervical ripening, 1308
 Dipeptidyl peptidase-IV (DPP-IV) inhibitors
 in diabetes management, 1226–1227
 dosages and duration of action of, 1221t
 in type 2 diabetes management, 1230, 1231
 Diphenhydramine (Benadryl)
 for allergic rhinitis, 1570
 dosages of, 1571t

- as antiemetic, 610t
- for drug-induced anaphylaxis, 1456
- for nausea and vomiting of pregnancy, 614
- Diphenoxylate, for diarrhea, 620, 622t
- Diphenylheptanes, characteristics of, 994t
- Diphenylmethane, for generalized anxiety disorder, dosages of, 1165t
- Diphenylmethane derivatives, for constipation, 627
- Diphtheria antitoxin, 2045
- Diphtheria toxoid adsorbed, 2045
- Dipivefrin
 - for closed-angle glaucoma, 1562
 - for open-angle glaucoma, 1558, 1559t
- Dipstick tests, in kidney disease assessment, 708–709
- Dipyridamole
 - extended-release, plus aspirin, in ischemic stroke management, information on, 380
 - extended-release (Aggrenox), for peripheral arterial disease, 412–413, 413t
 - for ischemic stroke, 378
 - plus aspirin in secondary prevention of ischemic stroke, 377
- Dipyridamole stress testing, 112
- Direct Coombs test, in diagnosing drug-induced immune hemolytic anemia, 1707
- Direct-current cardioversion (DCC)
 - for paroxysmal supraventricular tachycardia, 297
 - for sinus rhythm restoration in atrial fibrillation, 294
 - for torsade de pointes, 307
 - for ventricular tachycardia, 302
- Direct renin inhibitor, for hypertension, 152t
- Direct thrombin inhibitors (DTIs)
 - for heparin-induced thrombocytopenia, 366
 - for venous thromboembolism, 344t, 344–346, 345f, 345t
- Disaster response, clinician's role in, O88f, O88–O89
- Disease-modifying drugs
 - antirheumatic, for rheumatoid arthritis, 1510f, 1510–1514, 1511t
 - for osteoarthritis, 1533
- Disease states, concomitant, in antimicrobial selection, 1734
- Disk diffusion assay, in antimicrobial susceptibility testing, 1721, 1722f
- Disopyramide
 - as antiarrhythmic drug, 283, 284t
 - for hypertrophic cardiomyopathy, 327
 - pharmacokinetics of, 287t
 - side effects of, 286t
- Disseminated coccidioidomycosis, treatment of, 1984–1985
- Disseminated histoplasmosis, clinical presentation of, 1978
- Disseminated intravascular coagulation (DIC), 1678–1681
 - clinical presentation of, 1679
 - complicating sepsis, 1946–1947
 - conditions associated with, 1680t
 - laboratory diagnosis of, 1679–1680
 - pathophysiology of, 1679f
 - treatment of, 1680–1681
- Distal intestinal obstruction syndrome, in cystic fibrosis, 536
 - treatment of, 540
- Disulfiram
 - for alcohol dependence, 1087, 1088
 - in alcohol dependence treatment, 1087t
- Diuresis
 - osmotic, hyponatremia in, clinical presentation of, 854
 - in poisoning treatment, 74
- Diuretics
 - for acute renal failure, 736
 - in ascites management, 642–643
 - for chronic heart failure, 186–187, 187t
 - for chronic kidney disease, 772
 - for decompensated heart failure, 205–206
 - for diastolic heart failure, 320–321
 - digoxin interaction with, 199t
 - for edema, 857t, 857–858
 - in heart failure, information on, 195
 - for hypertension, 149, 150t
 - in chronic kidney disease, 787
 - mechanisms of action of, 158
 - hyperuricemia induced by, gout precipitated by, 158
 - interactions of, with other antihypertensives, 158
 - for left ventricular dysfunction with hypertension, 153
 - loop. *See* Loop diuretics.
 - osmotic, 857
 - in intracranial hypertension management, 971–972
 - potassium-sparing, 857
 - hyperkalemia induced by, 882
 - in hypokalemia management, 881
 - in prevention of acute renal failure, 732–733
 - for pulmonary hypertension, O96–O97
 - resistance to, in acute renal failure, 736–737, 737t
 - for restrictive cardiomyopathy, 328
 - thiazide. *See* Thiazide diuretics.
- Diurnal intraocular pressure, 1552
- Divalproex sodium (Depakote)
 - for bipolar disorder
 - efficacy ratings of, 1147t
 - product information on, 1151t
 - clinical considerations with, 946–947
 - in migraine prophylaxis, 1011t, 1014
- Dizziness, 614
- DLV (delavirdine), for HIV infection, 2071, 2073t
- DM. *See* Diabetes mellitus (DM).
- DNA, structure of, 2094, 2095f
- DNA hypomethylating agents, for myelodysplastic syndromes, O140–O141
- DNA repair genes, in carcinogenesis, 2088
- DNA synthesis of, 2095
- DNase, recombinant human, for cystic fibrosis, 540
- Dobutamine
 - for decompensated heart failure, 206t, 207
 - for septic shock, clinical application of, 430–431
 - for shock, clinical pharmacology of, 425, 426t
- Dobutamine stress testing, 112–113
- Docetaxel
 - allergic drug reactions to, 1455
 - for breast cancer, metastatic, 2148
 - in breast cancer chemotherapy, 2137, 2138t, 2139t
 - dose modification of, in hepatic dysfunction, 2097t
 - for non–small cell lung cancer, 2162t, 2164–2166, 2165t
 - for ovarian cancer, 2252, 2252t
 - recurrent, 2254t
 - for prostate cancer, 2214–2215, 2215t
- Docosahexaenoic acid (DHA), for secondary prevention after myocardial infarction, 271
- Documentation
 - billing considerations and, O40–O41
 - case study of, O42, O42–O44f
 - clinical
 - forces affecting, O35
 - key characteristics of, O36
 - technology in, O41
 - communication of, O37–O40

 - structure and organization of, O35–O36
- training considerations for pharmacists and support staff in, O41–O42
- Docusate
 - for constipation, 626–627
 - in constipation prevention, 628
- Dofetilide
 - as antiarrhythmic drug, 284t, 285
 - in atrial fibrillation recurrence prevention, 295
 - pharmacokinetics of, 287t
 - for post-MI patients, 301
 - side effects of, 286t
- Dog bites, 1804t, 1805t, 1814–1816
- Dolophine. *See* Methadone (Dolophine).
- Domperidone
 - in GERD treatment, 563
 - for migraine, 1012
- Donepezil (Aricept), for Alzheimer's disease, 1057, 1058t
 - with Down's syndrome, O121
- Donor lymphocyte infusions, for posttransplant immunotherapy, 2338–2339
- L-Dopa
 - motor complications of, 983, 983t
 - for Parkinson's disease, 981t, 982–984
- Dopamine agonists
 - for acromegaly, 1284–1285
 - for menstrual disorders, pharmacologic properties and interactions of, 1334t
 - for Parkinson's disease, 985–986
 - for restless legs syndrome, 1199
- Dopamine antagonists
 - for migraine, 1012
 - for nausea and vomiting of pregnancy, 614
- Dopamine (DA)
 - for decompensated heart failure, 206t, 208
 - in depression, 1124
 - low-dose, for septic shock, 429
 - in prevention of acute renal failure, controversy over, 732
 - for septic shock
 - clinical application of, 426, 428–429
 - clinical pharmacology of, 425, 426t
- Dopamine receptor, defects in, in schizophrenia, 1100–1101
- Dopaminergic receptors, pharmacology and organ distribution of, 423t
- Doppler echocardiography, 110
- Doppler ultrasound, in neurologic illness diagnosis, 910
- Doral (quazepam), for insomnia, 1194t
- Dorzolamide
 - for closed-angle glaucoma, 1561
 - for open-angle glaucoma, 1559t
- Down's syndrome (DS)
 - Alzheimer's disease and, O120–O122
 - clinical presentation of, O119–O120
 - diagnosis of, O119–O120
 - epidemiology of, O119
 - etiology of, O119
 - immune system and, O122
 - pathophysiology of, O119
 - treatment of, O120
- Doxazosin (Cardura)
 - for benign prostatic hyperplasia, 1392t, 1392–1393
 - for hypertension, 163
- Doxepin
 - in alcohol dependence treatment, 1087
 - dosages of, adult, 1127t
 - in migraine prophylaxis, 1011t
 - pharmacokinetics of, 1131t
 - potencies of, relative, 1128t
- Doxorubicin (Adriamycin)
 - for acute myeloid leukemia, 2268, 2269
 - in breast cancer chemotherapy, 2137, 2138t
 - in cancer chemotherapy, 2099
 - in delayed intensification therapy for acute lymphoblastic leukemia, 2265
 - for diffuse large B-cell lymphomas, 2237–2239
 - dose modification of, in hepatic dysfunction, 2097t
 - for follicular lymphomas, 2234, 2234t

- Doxorubicin (Adriamycin) (*Cont.*)
 for Hodgkin's lymphoma, 2223, 2224, 2225t
 liposomal, for multiple myeloma, 2298t
 for multiple myeloma, 2298, 2298t, 2299, 2299t
 pegylated-liposomal, for recurrent ovarian cancer, 2254t
- Doxycycline
 for acne vulgaris, 1598
 for anthrax, O61, O61t
 for *Bartonella* endocarditis, 1829t
 for brucellosis, O71
 for chloroquine-resistant malaria, 1893
 for enterotoxigenic diarrhea, 1860t
 for osteoarthritis, 1533
 for plague, O64–O65, O65t
 for syphilis, 1921, 1922t
 for tularemia, O68, O68t
 for urinary tract infections, 1905t, 1906t
- DPC-4, inactivation of, in colorectal cancer, 2182
- Drainage procedures, for intraabdominal infections, 1879–1880
- Dramamine (dimenhydrinate)
 as antiemetic, 610t
 for nausea and vomiting of pregnancy, 614
- Dronabinol (Marinol), as antiemetic, 610t, 611
- Droperidol (Inapsine)
 as antiemetic, 610t, 611
 in prophylaxis, of postoperative nausea and vomiting, 614
- Drospirenone, for acne vulgaris, 1598
- Drotrecogin alfa
 for disseminated intravascular coagulation, 1681
 for septic shock, 434–435
- Drowning, resuscitation after, 133
- Drowsiness, from antihistamines, 1569–1570
- Drug(s)
 absorption of
 altered, in aging, 59
 effect of chronic kidney disease on, 833–834
 effects of liver diseases on, 695
 in pediatric patients, 48
 abuse of, intravenous, hepatitis C treatment and, 689
 administration of
 during CPR, 134
 for pediatric patients, 52–53
 affecting electrocardiogram, 102t
 allergic reactions to, 1447–1458. *See also* Allergic drug reactions.
 antiarrhythmic, 283–286. *See also* Antiarrhythmic drugs.
 antithrombotic, chemical and pharmacokinetic properties of, 338t
 apnea induced by, 521–522, 522t
 approval process for, O47–O49
 bioavailability of, 11–12. *See also* Bioavailability of drugs.
 bioequivalence of, 11–12
 bronchospasm induced by, 522t, 522–523
 cardiac, altered responses to, in denervated transplanted heart, 1462t
 causing acute pancreatitis, 661, 661t
 causing allergic interstitial nephritis, 805t
 causing cancer, 2087t
 causing constipation, 624, 624t
 causing diarrhea, 619t
 causing gastrointestinal injury, 548t
 causing GERD symptoms, 556t
 clearance of, 12
 intrinsic, 12–13
 concentrations of, steady-state, use of, 19
 concomitant, in antimicrobial selection, 1734
 delivery of, via enteral feeding tubes, 2411–2413
 development of, novel sites for, 39–40
 distribution of
 altered, in aging, 60
 effect of chronic kidney disease on, 834t, 834–835
 in pediatric patients, 48–49
 doses of, initial, selection of, 18–19
 dosing of
 in acute renal failure, 738–740
 computer programs for, 20–26
 individualization of, in chronic kidney disease patients, 836–839, 837t, 838f
 receiving chronic hemodialysis, 840f, 840t, 840–842
 receiving chronic peritoneal dialysis, 839–840
 receiving continuous renal replacement therapy, 839
 in liver impaired patient, 697
 multiple, steady-state equations and, 16
 in patients with genetically altered metabolic capacities, 698–700
 effects of hypothyroidism on, 1258
 efficacy of, in pediatric patients, 49–50
 elimination of
 in geriatric patients, 60
 hepatic, 693
 altered, in liver diseases, 694–695
 pharmacokinetic basis of, 693–694
 in pediatric patients, 49
 for erectile dysfunction, dosing regimens for, 1373t
 excretion of
 biliary, liver diseases and, 696
 effects of liver diseases on, 695–696
 renal, renal insufficiency and, 836
 folic acid deficiency anemia from, 1654
 half-life of, 13f, 13–14
 hyperpigmentation from, 1579f, 1584
 hypokalemia induced by, 878t, 878–879
 inappropriate prescribing of, for geriatric patients, 62
 inducing hyperuricemia and gout, 1541t
 inducing hypocalcemia, 867
 interactions of
 with nutrients, 2363–2364
 in enteral nutrition, 2401t, 2412–2413
 in pediatric patients, 53
 kidney disease induced by, 795–810. *See also* Drug-induced nephrotoxicity (DIN).
 liver disease induced by, 651–658
 metabolism of
 effects of chronic kidney disease on, 835–836
 in geriatric patients, 60
 in pediatric patients, 49
 nausea and vomiting from, 607
 nephrolithiasis induced by, 804
 pharmacodynamics of. *See* Pharmacodynamics.
 precipitating/exacerbating heart failure, 180t
 pulmonary disorders induced by, 521–534
 monitoring of therapeutic outcomes in, 532
 pulmonary eosinophilia induced by, 527
 pulmonary fibrosis induced by, 528–530
 pulmonary hypertension induced by, 531
 response to
 age-related changes in, 60–61
 enzyme genes and, 37–38
 receptor genotypes and, 36–37
 safety of, for pediatric patients, 54
 selection of, during pregnancy, 1298–1299
 serum concentrations of, in infective endocarditis treatment evaluation, 1834
 skin disorders induced by, 1583–1584, 1584t, 1587f
 clinical manifestations of, 1451, 1451t
 surveillance of, postmarketing, O47, O49, O50f
 systemic lupus erythematosus induced by, 1439, 1439t
 teratogenic effects of, 1298
 therapeutic range of, 10t
 definition of, 10
 therapy with. *See* Pharmacotherapy.
 torsades de pointes induced by, congenital long QT syndrome and, 39
 toxicity of, in pediatric patients, 50
 transplacental transfer of, 1298
 transport proteins and, 17
 underuse of, by geriatric patients, 62
 use of, by geriatric patients, monitoring guidelines for, 63t
 vasculitis induced by, 1442
 warfarin interactions with, 352
 weight gain and, 2441

Kegel, for urinary incontinence, 1405t
lack of, colorectal cancer risk and, 2178t, 2178–2179
leg, antiembolic, for deep vein thrombosis, 362
in osteoarthritis management, 1525
in osteoporosis prevention and treatment, 1491–1492
in peripheral arterial disease therapy, 411
for stable exertional angina, 228
- Exercise-induced bronchospasm (EIB), 469–470, 470f
- Exercise stress (tolerance) testing (ETT), 106t, 106–109, 107t, 108t
after myocardial infarction, 106t, 106–107
before and after revascularization, 108t
close-ended, 107
contraindications to, 108, 108t
guideline recommendations for, 107, 107t
for ischemic heart disease, 224, 225f
open-ended, 107
protocols for, 107
termination of, indications for, 108t
training effect in, 107
- Exercise testing, cardiopulmonary, 460–461
indications and contraindications for, 460t
- Exercise training, in COPD management, 503
- Exons, function of, 32
- Expectorants, in COPD management, 512
- Experimental study designs, in pharmacopeidemiology, O53
- Expiratory reserve volume (ERV), definition of, 456, 456f
- Extracellular buffering, in acid-base homeostasis regulation, 890–891
- Extracellular space, redistribution of potassium into, hyperkalemia from, 882
- Extrapolated concentration, 15
- Extrapramidal system, adverse effects of antipsychotics on, 1111–1113, 1112t
- Extravasation, of chemotherapeutic agents, management of, 2116
- Exubera. *See* Insulin, human inhalation powder (Exubera).
- Exudative diarrhea, 618
- Eye(s)
anatomy of, 1552f
anterior chamber of, 1552f
aqueous humor of, dynamics of, 1551–1553
complications of rheumatoid arthritis involving, 1509
complications of ulcerative colitis involving, 592
effects of antipsychotics on, 1114
fundus of, normal, 1553f
glaucoma and, 1551–1564. *See also* Glaucoma.
pressure in, 1551–1553. *See also* Intraocular pressure (IOP).
- Ezetimibe (Zetia)
dosage form and doses of, 396t
effects of, on lipids and lipoproteins, 395t
- F**
- Fab (fragments of antigen binding), 1422, 1423f
- Factor III, high concentrations of, hypercoagulability and, 332
- Factor V genes, oral contraception and, 39
- Factor V Leiden, hypercoagulability and, 332
- Factor VIII concentrate replacement, for hemophilia A, 1670t, 1670–1671
- Factor VIII products, for hemophilia A, 1669–1671, 1670t
- Factor IX, high concentrations of, hypercoagulability and, 332
- Factor IX concentrate replacement, for hemophilia B, 1672
- Factor IX products, for hemophilia B, 1672
- Factor XI, high concentrations of, hypercoagulability and, 332
- Factor replacement therapy
inhibitor development complicating, 1673–1674
prophylactic, for hemophilia, 1672–1673
- Failure to thrive, malnutrition in, consequences of, 2372–2373
- Fallout from nuclear weapons, O86
- Falls
fractures from, 1486
prevention of, 1492, 1492t
- Famciclovir, for genital herpes, 1926t
- Familial adenomatous polyposis (FAP), 2179
- Familial combined hyperlipidemia, 390, 390t
- Familial hypercholesterolemia, 389
- Familial lipoprotein lipase (LPL) deficiency, 389, 390t
- Family history, prostate cancer and, 2208
- Famotidine (Pepcid AC)
as antiemetic, 610, 610t
as antiulcer agent, 582
in cotherapy for NSAID-induced ulcers, 580
in GERD treatment, 562
- Fas ligand pathway, in cytotoxicity, 1421, 1422
- Fasciitis, necrotizing, 1804t, 1809–1810
- Fat(s)
dietary intake of, colorectal cancer and, 2177
digestion and absorption of, 2400, 2400f
disorders of
in acute renal failure, 2418
in chronic renal failure, 2421
in liver failure, 2424–2425
in pulmonary failure, 2432
in enteral feeding formulas, 2405t, 2406
requirements for, in nutrient requirement assessment, 2361
- Fat emulsion, intravenous, in parenteral nutrition, 2382–2383
- Fat substitutes, in hyperlipidemia management, 394
- Fatty acids
in enteral feeding formulas, 2406
essential, status of, 2357
 ω -3, for secondary prevention after myocardial infarction, 271
- Fatty liver, complicating ulcerative colitis, 591–592
- Febrile mucocutaneous syndromes, from allergic drug reactions, 1450
- Febrile neutropenia, 2007–2015
clinical presentation of, 2007
prophylaxis of, 2015–2016
treatment of, 2007–2015
aminoglycoside plus antipseudomonal β -lactam in, 2010t, 2011
antifungal therapy in, 2013–2014, 2014t
antiviral therapy in, 2014t, 2014–2015
approach to, 2007–2011, 2008f, 2009t, 2010t
colony-stimulating factors in, 2015
duration of, 2015
fluoroquinolone-containing empirical regimens in, 2010t, 2012
initiation of, antimicrobial therapy after, 2012–2015
 β -lactam monotherapy in, 2010t, 2011
oral antibiotic therapy in, 2010t, 2012
outcomes of, evaluation of, 2017
pharmacoeconomic considerations on, 2017
vancomycin-containing empirical regimens in, 2010t, 2011–2012
- Febuxostat, in intercritical gout prophylaxis, 1547
- Fecal occult blood test (FOBT), for colorectal cancer, 2183–2184
- Feeding tubes, for enteral nutrition, 2402–2404
drug delivery via, 2411–2413
- Felbamate
clinical considerations with, 941
dosing of, 939t
drug interactions with, 936t
pharmacokinetic data on, 934t
serum concentrations of, target, 939t
side effects of, 934t
- Felodipine, for ST-segment elevation acute coronary syndromes, 263–264
- Felty syndrome, in rheumatoid arthritis, 1509
- Female athlete triad, 1044
- Female hormones, asthma and, 471
- Fenamates, dosing of, 993t
- Fenfluramine, pulmonary hypertension induced by, 531
- Fenofibrate (TriCor)
for diabetic dyslipidemia, 399
dosage form and doses of, 396t
effects of, on lipids and lipoproteins, 395t
in intercritical gout prophylaxis, 1547
for type III hyperlipoproteinemia, 398
- Fenoldopam mesylate
for hypertensive emergency, 165t, 166
in prevention of drug-induced nephrotoxicity, 733
- Fenoprofen (Nalfon), dosing of, 993t
- Fentanyl (Sublimaze, Duragesic)
characteristics of, 994t
cough induced by, 526
dosing guidelines for, 995t
intraspinal, 998t
for pain, 998–999
for vasoocclusive pain crisis in sickle cell disease, 1696
- Ferric hexacyanoferrate, for radioactive isotope exposure, O87
- Ferric pyrophosphate, for anemia of chronic kidney disease, 779
- Ferritin
normal values for, 1644t
serum, 1646
- Ferrous sulfate, in Down's syndrome prevention, O119
- Fertility
male, reduced, from antiepileptic drugs, 938
return of, after oral contraceptive use, 1323
- Fertilization, 1297
- Ferumoxytol, for anemia of chronic kidney disease, 779
- Fetal hemoglobin inducers, in sickle cell disease management, 1691–1693, 1692f
- Fetus, development of, 1298

- Fever(s)
 complicating sickle cell disease, 1688
 treatment of, 1694–1695
 in confirming presence of infection, 1732
 drug-induced, 1450
 fever of infectious origin differentiated from, 1732
 enteric, in salmonellosis, 1865
 hemorrhagic, viral, O69f, O69–O70, O70t Q, O71
- Fexofenadine, for allergic rhinitis, dosages of, 1571t
- Fiber
 dietary intake of
 colorectal cancer and, 2177
 increased, in hyperlipidemia management, 394
 in enteral feeding formulas, 2406
 requirements for, in nutrient requirement assessment, 2361
- Fiber therapy
 for constipation, 625–626
 for constipation-predominant irritable bowel syndrome, 629–630
- Fiberoptic catheters, 419
- Fibric acid derivatives
 for diabetic dyslipidemia, 399
 for type III hyperlipoproteinemia, 397–398
- Fibric acids, for lipid disorders in chronic kidney disease, 787
- Fibrillation
 atrial, 288–295. *See also* Atrial fibrillation.
 ventricular, 307–309. *See also* Ventricular fibrillation.
- Fibrinolysis, in hemostasis, 1666
- Fibrinolytic therapy
 for acute coronary syndromes, adverse effects of, monitoring for, 272t
 for non–ST-segment elevation acute coronary syndromes, 265
 for ST-segment elevation acute coronary syndromes, 256, 258t, 260–261
 agents for, comparison of, 261t
 indications and contraindications to, 260t
- Fibroblast growth factors, basic (bFGF), in melanoma, 2313
- Fibroblasts, in airways inflammation in asthma, 467
- Fibrocystic breast disease, breast cancer risk and, 2123
- Fibrosis, definition of, 633
- Filgrastim (G-CSF)
 for drug-induced agranulocytosis, 1707
 for febrile neutropenic cancer patients, 2015
 for myelodysplastic syndromes, O139
- Filtration barrier, of glomerulus, 811
- Filtration capacity, of kidney, 707
- Finasteride, for benign prostatic hyperplasia, 1393
- Fingers, clubbing of, in infective endocarditis, 1823
- Fish oil(s)
 for immunoglobulin A nephropathy, 824
 for secondary prevention after myocardial infarction, 271
- Fish oil supplementation
 in hyperlipidemia management, 394
 for hypertriglyceridemia, 397
 for type III hyperlipoproteinemia, 398
- Fistula formation, in Crohn's disease, 592
- 5 α -reductase inhibitors, for benign prostatic hyperplasia, 1393t, 1393–1394
- Fixed splitting of S₂, 98
- Flagyl. *See* Metronidazole (Flagyl).
- Flashbacks, from LSD, 1075–1076
- Flecainide
 as antiarrhythmic drug, 284, 284t
 pharmacokinetics of, 287t
 side effects of, 286t
- Floccor (poloxamer 188), for vasoocclusive pain crisis in sickle cell disease, 1697
- Flofan (epoprostenol), for pulmonary hypertension, O98, O99, O99t, 531
- Flomax (tamsulosin), for benign prostatic hyperplasia, 1392t, 1392–1393
- Fluorinated pyrimidines, in cancer chemotherapy, 2095
- Flow, definition of, 456
- Flow-volume loops, 457, 457f
- FLOX regimen, for colorectal cancer, 2190t
- Flucinonide, for psoriasis, vasoconstricting potency of, 1607t
- Fluconazole, 1998
 for coccidioidomycosis, 1984
 for cryptococcal meningitis, 1755
 in-vitro susceptibility of non-*Candida* fungal pathogens for, 1975t
 intraperitoneal dosing of, O114t
 for invasive candidiasis, 1990t
 for mucosal candidiasis, 1963t
 for sepsis related to candidiasis, 1950
 susceptibility and interpretive breakpoints of *Candida* species for, 1975t
 for vulvovaginal candidiasis, 1959
- Flucytosine, 1997
- Fludarabine
 for chronic lymphocytic leukemia, 2289t, 2290
 in conditioning for hematopoietic stem cell transplantation, 2337
 dose modification of, in renal impairment, 2097t
- Fludarabine monophosphate, in cancer chemotherapy, 2097
- Fludarabine phosphate, for follicular lymphomas, 2234
- Fluid(s)
 crystalloid, in alcohol withdrawal treatment, 1086t
 disorders of
 in acute renal failure, 2418
 in chronic renal failure, 2421
 complicating chronic kidney disease
 pathophysiology of, 766
 treatment of, 771–772
 in liver failure, 2425
 in pulmonary failure, 2432
 in short-bowel syndrome, 2428
 distribution of, 446t
 for hypovolemic hyponatremia, 855
 requirements for, in nutrient requirement assessment, 2361, 2361t
 restriction of
 in chronic kidney disease, 772
 in end-stage renal disease, 786
 retention of, as compensatory response in heart failure, 176
 therapy
 for intraabdominal infections, 1880
 for sepsis/septic shock, 1948t, 1951
- Flumazenil, for hepatic encephalopathy, 645
- Flunisolide, for allergic rhinitis, dosages of, 1572t
- Flunitrazepam, abuse of, 1070
- Fluorescence-polarization immunoassay, in antimicrobial concentration determination, 1726
- Fluorescent antinuclear antibody (ANA) test, for SLE, 1434–1435, 1435t
- Fluoride, recommendations for, 2362t
- Fluoropyrimidines, oral, in cancer chemotherapy, 2095
- Fluoroquinolones
 for acute pyelonephritis, 1907
 for acute uncomplicated cystitis, 1904
 for brucellosis, O71
 for chlamydial infections, 1923
 empirical regimens containing, for febrile neutropenic cancer patients, 2010t, 2012
 for enteric fever, 1866
 for gram-negative bacillary meningitis, 1752
 for meningococcal meningitis, 1749
 for pediatric patients, clinical controversy over, 50
 for plague, O64–O65, O65t
 for pneumonia, 1776
 prophylactic, in acute pancreatitis, 666, 666t
- for sepsis, 1949t
 for spontaneous bacterial peritonitis, 643
 for tularemia, O68, O68t
 for urinary tract infections, 1905t
- Fluorouracil (5-FU)
 adjuvant
 for colorectal cancer, 2189–2191, 2190t
 for operable rectal cancer, 2191–2192
 in breast cancer chemotherapy, 2138t
 in cancer chemotherapy, 2095
 for metastatic colorectal cancer, 2193t, 2193–2196, 2198–2199
 topical
 for actinic keratoses, 1585
 for basal cell carcinoma, 1585
- Fluoxetine (Prozac)
 in alcohol dependence treatment, 1087
 for anorexia nervosa, 1045
 for bulimia nervosa, 1046
 dosages of, adult, 1127t
 drug interactions with, 1133t
 in migraine prophylaxis, 1011t, 1014
 for narcolepsy, 1197t
 for panic disorder, 1170t
 pharmacokinetics of, 1131t
 for posttraumatic stress disorder, 1182
 dosages of, 1182t
 potencies of, relative, 1128t
 in schizophrenia management, 1108
- Fluoxymesterone, for metastatic breast cancer, 2145t
- Fluphenazine (Prolixin)
 doses and dosage forms of, 1105t
 pharmacokinetics of, 1109t
 for schizophrenia, long-acting, 1107
 side effects of, incidence of, 1110t
- Flurandrenolide, for psoriasis, vasoconstricting potency of, 1607t
- Flurazepam (Dalmane), for insomnia, 1194t
- Flushing, from niacin therapy, management of, 397
- Flutamide
 for acne vulgaris, 1598
 for prostate cancer, 2212, 2213t
- Fluticasone, for allergic rhinitis, dosages of, 1572t
- Fluticasone propionate, for psoriasis, vasoconstricting potency of, 1607t
- Flutter devices, in pulmonary therapy for cystic fibrosis, 540
- Fluvastatin
 effects of, on lipids and lipoproteins, 395t
 for immunoglobulin A nephropathy, 824
 pharmacokinetics of, 396t
- Fluvoxamine (Luvox)
 dosages of, adult, 1127t
 drug interactions with, 1133t
 for panic disorder, 1170t
 pharmacokinetics of, 1131t
 for posttraumatic stress disorder, 1182
 dosages of, 1182t
 potencies of, relative, 1128t
 in schizophrenia management, 1108
- Foam cells, 388
- FOBT (fecal occult blood test), for colorectal cancer, 2183–2184
- Focal segmental glomerulosclerosis (FSGS), 819–820
 drug-induced, 804
- Folate. *See* Folic acid.
- FOLFOX4 regimen
 for colorectal cancer, 2190t
 for metastatic colorectal cancer, 2196
- FOLFOX6 regimen, for metastatic colorectal cancer, 2196
- Folic acid, 1646
 for colorectal cancer, 1290t
 deficiency of, 2357t
 drug-induced megaloblastic anemia in, 1709
 dietary intake of, colorectal cancer, 2177–2178, 2183
 in Down's syndrome prevention, O119
 food sources of, 1655t
 in neural tube defect prevention, 1299

- Folic acid (*Cont.*)
 normal values for, 1644t
 recommendations for, 2363t
 in sickle cell disease management, 1691
- Folic acid deficiency anemia, 1654–1655
- Follicle-stimulating hormone (FSH)
 physiologic effects of, 1283t
 release of, 1282
 regulation of, 1283t
- Follicular cancer, thyrotoxicosis from, 1249
- Follicular lymphomas
 advanced, treatment of, 2233–2236
 chemotherapy in, 2234, 2234t
 hematopoietic stem cell transplantation in, 2236
 interferon- α in, 2234–2235
 investigational therapies in, 2236
 purine analogs in, 2234
 radiation in, 2234
 radioimmunotherapy in, 2235–2236
 rituximab in, 2235
 watch-and-wait approach to, 2234
 localized, treatment of, 2233
 treatment of, 2232–2236
- Follicular phase, of menstrual cycle, 1313, 1314f
- Folliculitis, 1803–1804, 1804t, 1805t
- Fondaparinux
 for acute coronary syndromes, 257t
 adverse effects of, monitoring for, 272t
 for non-ST-segment elevation acute coronary syndromes, 266, 267
 for ST-segment elevation acute coronary syndromes, 263
 for venous thromboembolism, 343–344
 in venous thromboembolism management, 359
 in venous thromboembolism prevention, 355
- Food(s)
 allergies to, in atopic dermatitis, 1620
 calcium content of, 1492t
 causing GERD symptoms, 556t
 cross-sensitivity of aspirin sensitivity with, 523–524
 thermogenic effect of, 2441
 vitamin D content of, 1492t
 vitamin K content of, 351t
 warfarin interactions with, 352
- Food, Drug, and Cosmetic Act of 1938, O47–O48
 1962 Amendments to, O48
- Food and Drug Administration, pharmacopeidemiology and, O49–O51
- Food and Drug Administration Modernization Act of 1997, O48, O49
- Food poisoning, 1870–1871, 1871t
- Foot (feet)
 athlete's, 1967, 1968t
 rheumatoid arthritis involving, 1508
 ulcers on, diabetic, treatment of, 1235
- Forazolidone (Furoxone), for parasitic diseases, 1898t
- Forced expiratory flow (FEF), definition of, 456
- Forced expiratory volume in first second of expiration (FEV₁), definition of, 456
- Forced vital capacity (FVC), definition of, 456
- Formaldehyde, as pulmonary agent, O81
- Formoterol, inhaled, in COPD management, 506
- Formulations, enteral feeding
 classification of, 2407t, 2407–2409, 2408t
 disease specific, 2407t, 2408–2409
 elemental, 2407t, 2408
 high caloric density, 2407, 2407t
 high protein, 2407, 2407t
 modular, 2409
 nutrient complexity of, 2405t
 oral supplements, 2407t, 2409
 pediatric, classification system for, 2408t
 peptide based, 2407t, 2408
 rehydration, 2409
 selection of, 2405–2406
 standard polymeric, 2407, 2407t
- Fosamax. *See* Alendronate (Fosamax).
- Fosamprenavir (FPV), for HIV infection, 2072, 2072t, 2073t
- Foscarnet, drug interactions of, 1735t
- Fosfomycin, for urinary tract infections, 1905t, 1906t
- Fosinopril (Monopril). *See also* Angiotensin-converting enzyme (ACE) inhibitors.
 dosage and elimination of, 196t
- Fosphenytoin, for generalized convulsive status epilepticus, 958–959, 959t
- Fotemustine, for melanoma, 2323
- FPV (fosamprenavir), for HIV infection, 2072, 2072t, 2073t
- Fracture(s)
 from falls, 1486
 osteoporosis-related, 1487
- Fragment crystallizable (Fc fragment) portion of antibody, 1422, 1423f
- Fragments of antigen binding (Fab), 1422, 1423f

 for contraception, 1324–1325
 for dysmenorrhea, 1340
 for endometriosis, 1348t, 1348–1349
 pharmacologic properties and interactions of, 1334t
- MedWatch system of FDA, O49
- Mefenamic acid (Ponstel), dosing of, 993t
- Mefloquine (Lariam)
 for parasitic diseases, 1898t
 prophylactic, for chloroquine-resistant malaria, 1893

- Megacolon, toxic
complicating inflammatory bowel disease, 600–601
in ulcerative colitis, 591
- Megakaryocytes, colony-forming unit, 1630, 1632f
- Megaloblastic anemias, 1651–1655
drug-induced, 1709–1710
folic acid deficiency, 1654–1655
vitamin B₁₂ deficiency, 1652–1654
- Megaloblastosis, drug-induced, 1651f
- Megestrol acetate, for metastatic breast cancer, 2145t, 2147
- Melanocortin, appetite and, 2439
- Melanoma
clinical presentation of, 2314–2315
detection of, 2325
epidemiology of, 2312
etiology of, 2312
histologic subtypes of, 2313–2314
incidence of, 2311
malignant, 1585–1586, 1588f
mortality rates of, 2311
pathogenesis of, 2312–2313
prevention of, 2325, 2325t
prognostic factors for, 2315–2317, 2317t
risk factors for, 2312t
self-examination for, 2315, 2315t
staging of, 2315t, 2315–2317, 2316t, 2317t
treatment of, 2317–2326
adjuvant therapy in, 2324
biochemotherapy in, 2324
chemotherapy in, 2322–2323
endocrine therapy in, 2323–2324
immunotherapy in, 2318–2322
interferon in, 2318–2320, 2319t
interleukin-2 in, 2320–2321
limb perfusion and limb infusion in, 2324
by stage, 2324–2325
surgical, 2317–2318
targeted therapy in, 2323
vaccines in, 2321–2322
- Melatonin, for parasomnias, 1199
- Mellaril. *See* Thioridazine (Mellaril).
- Melphalan
for multiple myeloma, 2298t, 2298–2299, 2299t
pulmonary fibrosis associated with, 530
- Memantine, in Alzheimer's disease
for cognitive symptoms, 1057–1058
for noncognitive symptoms, 1061
- Membrane and cation theories, of bipolar disorder, 1142t
- Membranoproliferative glomerulonephritis, 822–823, 823f
- Membranous nephropathy, 820–822, 821f
drug-induced, 804
- Memory
of immune system, 1417
loss of, in Alzheimer's disease, 1055
- Meninges, anatomy of, 1744
- Meningitis, 1744
Bacillus anthracis causing, 1753
coccidioidal, treatment of, 1985
cryptococcal, in HIV-infected patients, therapy for, 1987
Cryptococcus neoformans causing, 1755
gram-negative, 1752–1753
Haemophilus influenzae causing, 1751
Listeria monocytogenes causing, 1751–1752
Mycobacterium tuberculosis causing, 1754–1755
Neisseria meningitidis causing, 1748–1750
organisms causing and therapy for, by age, 1747t
pathophysiology of, 1745f, 1745–1746
Streptococcus pneumoniae causing, 1750–1751
treatment of
adjunctive, dexamethasone as, 1753–1754
antimicrobials in, 1748t
length of, 1748
tuberculous, treatment of, 1847
- Meningococcal conjugate vaccine, 2049
- Meningococcal polysaccharide vaccine, 2048–2049
- Meningococcus, meningitis from, 1748–1750
- Menopause
age of, 1351
clinical presentation of, 1352–1353
definition of, 1351
osteoporosis after, 1486–1487
physiology of, 1352
symptoms of, postmenopausal hormone therapy for, 1358–1359
treatment of, 1353–1364
hormones in, 1353–1363. *See also* Postmenopausal hormone therapy.
- Menorrhagia
clinical presentation of, 1333
epidemiology of, 1332
etiology of, 1332
pathophysiology of, 1330t, 1333
treatment of, 1333–1336
algorithm for, 1333f, 1336f
general approach to, 1333
nonpharmacologic, 1333
outcome of
desired, 1333
evaluation of, 1335t, 1336
pharmacoeconomic considerations on, 1335
pharmacologic, 1333–1335
- Menstrual cycle, 1313–1314, 1314f
hormonal fluctuations with, 1330f
normal, summary of, 1337f
seizures and, 938
- Menstruation, disorders related to, 1329–1343
amenorrhea as, 1329–1332
anovulatory bleeding as, 1336–1338
dysmenorrhea as, 1338–1340
menorrhagia as, 1332–1336. *See also* Menorrhagia.
premenstrual syndrome/premenstrual dysphoric disorder as, 1340–1341
- Mental health conditions, in pregnancy, management of, 1305–1306
- Mental retardation
autism and, O125
clinical presentation of, O119t
epilepsy and, 927
- Mental status examination (MSE), in psychiatric disorder evaluation, 1023–1024
- Meperidine (Demerol)
for abdominal pain in acute pancreatitis, 664
characteristics of, 994t
dosing guidelines for, 995t
for pain, 998
- Mephenytoin
dosing of, 939t
serum concentrations of, target, 939t
- Mephobarbital
dosing of, 939t
serum concentrations of, target, 939t
- Mepivacaine (Polocaine), 1000t
- Mercaptopurine
for active Crohn's disease, 599
for acute lymphoblastic leukemia, 2265
adverse reactions to, 602
in cancer chemotherapy, 2097
for inflammatory bowel disease, 595
to maintain remission of Crohn's disease, 600
metabolism of, in pediatric patients, 49
- Meropenem
for anthrax, O61t
for gram-negative bacillary meningitis, 1752
for meningococcal meningitis, 1749
for pneumococcal meningitis, 1750
for urinary tract infections, 1905t
- Mesalamine
for active Crohn's disease, 599
for inflammatory bowel disease, 595, 595t
to maintain remission of Crohn's disease, 600
to maintain remission of ulcerative colitis, 597
for ulcerative colitis, 597
- Mesangium, in glomerulus, 811, 812f
- Mesna, for refractory diffuse large B-cell lymphomas, 2239
- Metabolic abnormalities, in antimicrobial selection, 1734
- Metabolic acidosis
acute severe, treatment of, 897
causes of, 893t
chronic, treatment of, 896–897
clinical presentation of, 895–896
compensation for, 896
complicating chronic kidney disease
clinical presentation of, 770
pathophysiology of, 767
treatment of, 785–786
elevated anion gap, 894–895
hypochloremic, 893–894
pathophysiology of, 893
plasma bicarbonate concentration in, 892
with respiratory acidosis, 905
with respiratory alkalosis, 905
- Metabolic alkalosis
causes of, 900t
clinical presentation of, 900
compensation for, 900
generation of, 899
hyperkalemia in, 878
maintenance of, 899–900
pathophysiology of, 899–900
plasma bicarbonate concentration in, 892
with respiratory acidosis, 905–906
with respiratory alkalosis, 905
sodium chloride-resistant, treatment of, 902
sodium chloride-responsive, treatment of, 900–902, 901f
- Metabolic bone diseases, 1483–1504
osteogenesis imperfecta as, 1501–1502
osteomalacia as, 1501
osteoporosis as, 1483–1501. *See also* Osteoporosis.
Paget disease as, 1501
parenteral nutrition-associated, 2393
- Metabolic complications, of enteral nutrition, 2410
- Metabolic encephalopathy syndrome, from hypophosphatemia, 872
- Metabolic function, of kidney, 707–711
- Metabolic pathways, clearance for, 13
- Metabolic syndrome, 143, 1207
definition of, 1212t, 1212–1213
hypertension with, treatment of, 157
prevalence of, 1213
- Metaglip (glipizide/metformin), dosages and duration of action of, 1222t
- Metastasis. *See specific type of cancer.*
brain, from melanoma, 2318
definition of, 2090
pathways of, 2090
- Metered-dose inhalers (MDIs), in aerosol therapy for asthma, 472f, 472t, 472–473
- Metformin (Glucophage)
for anovulatory bleeding, 1338
for diabetes in chronic heart failure, 194–195
in diabetes management, 1223–1224
dosages and duration of action of, 1221t
lactic acidosis induced by, 895
pharmacologic properties and interactions of, 1334t
in type 2 diabetes management, 1230
- Methadone (Dolophine)
characteristics of, 994t
dosing guidelines for, 995t
for opioid withdrawal, 1079
for pain, 999
for vasoocclusive pain crisis in sickle cell disease, 1696
- Methamphetamine, abuse of, 1073–1074
- Methamphetamine (Desoxyn), for narcolepsy, 1197t
- Methazolamide, for open-angle glaucoma, 1559t
- Methicillin, resistance of, detection of, 1724
- Methimazole (MMI)
agranulocytosis induced by, mechanism of, 1706
for hyperthyroidism, 1250–1252

- Methotrexate
for active Crohn's disease, 599–600
in breast cancer chemotherapy, 2138t
in cancer chemotherapy, 2098
for chronic asthma, 490
dose modification of, in renal impairment, 2097t
for inflammatory bowel disease, 595
intrathecal
in CNS prophylaxis in acute lymphoblastic leukemia, 2264
in delayed intensification therapy for acute lymphoblastic leukemia, 2265
to maintain remission of Crohn's disease, 600
in maintenance therapy for acute lymphoblastic leukemia, 2265
for psoriasis, 1611–1612
pulmonary fibrosis associated with, 530
for rheumatoid arthritis, 1511t, 1509
toxicity of, drugs increasing, 1612t
- Methsuximide
dosing of, 939t
serum concentrations of, target, 939t
- Methyl dopa
for chronic hypertension in pregnancy, 156, 156t
for hypertension, 163
- 3,4-Methylenedioxyamphetamine (MDA) abuse, 1074
- 3,4-Methylenedioxymethamphetamine (MDMA, ecstasy) abuse, 1074–1075
- Methylmalonic acid, 1647
- N^l-Methylnicotinamide (NMN), in tubular function assessment, 718
- Methylparaben, allergic drug reactions to, 1454
- Methylphenidate (Ritalin)
for attention-deficit/hyperactivity disorder, 1030–1031, 1032t
for narcolepsy, 1197t
for Tourette's disorder with ADHD, 1036
- Methylprednisolone
for immunoglobulin A nephropathy, 824
for membranous nephropathy, 821
for multiple sclerosis exacerbations, 917–918
for psoriasis, vasoconstricting potency of, 1607t
for refractory diffuse large B-cell lymphomas, 2239
for severe ulcerative colitis, 598
for systemic lupus erythematosus, 1436t, 1437
- Methylxanthines
for chronic asthma, 488, 488f, 488t
in COPD management, 507–508
- Methysergide
in cluster headache prophylaxis, 1017–1018
in migraine prophylaxis, 1011t, 1015
pulmonary toxicity from, 531
- Metipranolol
for closed-angle glaucoma, 1560
for open-angle glaucoma, 1559t
- Metoclopramide (Reglan)
in anorexia nervosa management, 1045–1046
as antiemetic, 610t, 611
digoxin interaction with, 199t
in GERD treatment, 563
for migraine, 1010t
in migraine management, 1012
for nausea and vomiting of pregnancy, 614
for relactation, 1310
for Tourette's disorder, 1036
- Metopirone (metyrapone), for Cushing's syndrome, 1270, 1270t
- Metoprolol
for diastolic heart failure, 321
in migraine prophylaxis, 1011t, 1014
- Metoprolol controlled-release/extended-release (CR/XL)
for chronic heart failure, 188–189, 189t
in heart failure, information on, 197–198
- Metronidazole (Flagyl)
for active Crohn's disease, 599
adverse reactions to, 602
for amebiasis, 1889, 1890
drug interactions of, 1735t
for enterotoxigenic diarrhea, 1860t
for giardiasis, 1888
for hepatic encephalopathy, 646
for inflammatory bowel disease, 595–596
for intraabdominal infections, 1881
for parasitic diseases, 1898t
prophylactic, in acute pancreatitis, 666
for pseudomembranous colitis, 1863
for sepsis, 1949t
for trichomoniasis, 1928t, 1928–1929
- Metyrapone (Metopirone), for Cushing's syndrome, 1270, 1270t
- Mevacor. *See* Lovastatin (Mevacor).
- Mexiletine
pharmacokinetics of, 287t
side effects of, 286t
- MHC. *See* Major histocompatibility complex (MHC).
- MI. *See* Myocardial infarction (MI).
- Miacalcin. *See* Calcitonin (Miacalcin).
- Micafungin
in-vitro susceptibility of non-*Candida* fungal pathogens for, 1975t
for invasive candidiasis, 1990t
for mucosal candidiasis, 1963t
susceptibility and interpretive breakpoints of *Candida* species for, 1975t
- Michaelis-Menten kinetics, 14
- Miconazole, for vulvovaginal candidiasis, 1959t
- Microalbuminuria
development of, in diabetic kidney disease, ACE inhibitors and, 754
in diabetes, treatment of, 1235
as renal disease marker, 717–718
- Microbial flora, alteration in, as risk factor for infection, 2004–2005, 2005t
- Microbiologic assay, in antimicrobial concentration determination, 1726–1727
- Microbiologic tests, in infective endocarditis treatment evaluation, 1834
- Microconstants, 14
- Micronutrients
deficiencies of, parenteral nutrition-associated, 2393
requirements for, in nutrient requirement assessment, 2361, 2362–2363t
- Microorganisms, detection of, molecular techniques for, 1719–1720
- Microscan Walkaway system, for automated antimicrobial susceptibility testing, 1723
- Microtubule-targeting drugs, in cancer chemotherapy, 2098–2099
- Midarm muscle circumference, in nutrition status assessment, 2353
- Midazolam
apnea induced by, 521
for generalized convulsive status epilepticus, 957, 959t
- Midodrine, for hypotension complicating hemodialysis, 0108
- Midostaurin, for acute myeloid leukemia in elderly, 2272
- Mifepristone (RU-486)
for cervical ripening, 1308
in Cushing's syndrome, 1271
- Miglitol (Glyset)
in diabetes management, 1225–1226
dosages and duration of action of, 1221t
- Migraine headache, 1005–1016
classification of, 1006t
clinical presentation of, 1007–1008
combined hormonal contraceptive use and, 1319
diagnostic criteria for, 1008t
epidemiology of, 1005
etiology of, 1005–1006
pathophysiology of, 1005–1006, 1007f
in pregnancy, management of, 1303
treatment of, 1008–1015
general approach to, 1008–1009
nonpharmacologic, 1009
outcomes of, desired, 1008, 1009t
pharmacoeconomic considerations on, 1015
pharmacologic, 1010–1014
prophylactic, 1011f, 1011t, 1014–1015
- Miliary tuberculosis, pathophysiology of, 1842
- Milk-alkali syndrome, 582
- Milrinone, for decompensated heart failure, 206t, 207–208
- MINE regimen, for refractory diffuse large B-cell lymphomas, 2239
- Mineral oil, for constipation, 627
- Mineralocorticoids, elevated levels of, in metabolic alkalosis generation, 899
- Minerals
intake of, adequate, in osteoporosis prevention and treatment, 1490
interactions of, with nutrients, 2363
recommendations for, 2362t
- Mini Mental Status Examination (MMSE), 1025–1026
- Minimal bactericidal concentration (MBC), in antimicrobial activity testing, 1724
- Minimal-change nephropathy, 817–819, 818f
- Minimal inhibitory concentrations (MICs), in antimicrobial susceptibility testing, 1720–1721, 1721f
- Minipress. *See* Prazosin (Minipress).
- Minocycline
for acne vulgaris, 1598
for urinary tract infections, 1905t
- Minoxidil, for hypertension, 164
- Mirtazapine
for depression, 1129
dosages of, adult, 1127t
drug interactions with, 1133t
pharmacokinetics of, 1131, 1131t
for posttraumatic stress disorder, 1182
dosages of, 1182t
potencies of, relative, 1128t
- Misoprostol
as antitumor agent, 582
for cervical ripening, 1308
- Misoprostol cotherapy, for NSAID-induced ulcers, 579
- Mithramycin (Plicamycin), for hypercalcemia, 865t, 866
- Mitochondrial injury, in drug-induced liver disease, 654–655
- Mitomycin
for lung cancer
advanced, 2164
early stage, 2163t
pulmonary fibrosis associated with, 529
- Mitomycin C, in cancer chemotherapy, 2101
- Mitotane (Lysodren), for Cushing's syndrome, 1271
- Mitoxantrone (Novantrone)
for acute myeloid leukemia, 2268, 2269
in cancer chemotherapy, 2099
dose modification of, in hepatic dysfunction, 2097t
for multiple sclerosis, 920
for refractory diffuse large B-cell lymphomas, 2239
- MM. *See* Multiple myeloma (MM).
- MMF. *See* Mycophenolate mofetil (MMF).
- MMI. *See* Methimazole (MMI).
- MMPs. *See* Matrix metalloproteinases (MMPs).

- imaging studies in, 916–917
laboratory studies in, 916–917
major depression in, management of, 923
pathophysiology of, 914, 915f
primary progressive, 916
prognostic indicators in, 916t
progression of, 916
progressive-relapsing, 916
relapsing-remitting, 916
management algorithm for, 918f
secondary-progressive, 916
sensory symptoms in, management of, 923
sexual dysfunction in, management of, 923
spasticity in, management of, 922
treatment of, 917–924
for acute exacerbations, 917–918
disease-modifying, 918–922
questions for, 920–922
glatiramer acetate in, 919–920
interferon β_{1a} in, 919, 919t
interferon β_{1b} in, 918–919, 919t
mitoxantrone in, 920
natalizumab in, 920
outcomes of, evaluation of, 923–924
pharmacoeconomic considerations on, 923
symptomatic, 922–923
tremor in, management of, 922
- Mumps vaccine, 2049
- Murmurs, heart, in physical exam, 98–100, 99f, 99t
- Muromonab-CD3, in immunosuppression, for solid-organ transplantation, 1474
- Muscarinic receptors, effects of acetylcholinesterase inhibition on, 78t
- Muscle(s)
cramps in, complicating hemodialysis, management of, O108–O109, O109t
insulin resistance in, 1211–1212
smooth, airway, in asthma, 468
- Musculoskeletal system, in systemic lupus erythematosus, 1433–1434
- Mutagenesis, insertional, 40
- Mutations
frameshift, 33
genetic, in carcinogenesis, 2089
- MVPP regimen, for Hodgkin's lymphoma, 2224
- Mycobacteria, antimicrobial susceptibility testing for, 1723
- Mycobacterium tuberculosis*
central nervous system infections from, 1754–1755
tuberculosis from, 1839–1856. *See also* Tuberculosis (TB).
- Mycophenolate mofetil (MMF)
for atopic dermatitis, 1624
for focal segmental glomerulosclerosis, 820
in immunosuppression, for solid-organ transplantation, 1470–1471
for lupus nephritis, 826
for minimal-change nephropathy, 819
for psoriasis, 1612
adverse effects of, 1606t
- Mycoplasma pneumoniae*, pneumonia caused by, 1770–1771
- Myelin sheath, around CNS axons, stripping of, in multiple sclerosis, 914
- Myeloablative conditioning regimens, for hematopoietic stem cell transplantation, 2335–2336
dose-limiting toxicities for, 2339t
- Myelodysplastic syndromes (MDS), O118–O133
classification of, O136–O137, O137t
clinical presentation of, O136
diagnosis of, O136
epidemiology of, O134
etiology of, O134–O135
pathophysiology of, O135–O136
prognosis of, O136–O137, O137t
therapies associated with, O135
treatment of
based on IPSS risk stratification, O141–O142

- Myelodysplastic syndromes (MDS) (*Cont.*)
 general approach to, O137–O138, O138f
 goals of, O137
 outcomes of, evaluation of, O141
 pharmacoeconomic considerations on, O142
 pharmacologic, O139–O141, O140t
 supportive care in, O138–O139
- Myelosuppression, in cancer chemotherapy, management of, 2112–2115
- Myleran. *See* Busulfan (Myleran).
- Myocardial dysfunction, in shock monitoring, 422
- Myocardial infarction (MI)
 acute, ventricular remodeling following, 251
 cardiac arrest from, 123
 complications of, 251–252
 exercise stress testing after, 106t, 106–107
 hypertension after, pharmacotherapy for, 153
 prior, ECG findings in, 103
 risk factors for, modifiable, 271–272
 secondary prevention following, 268–272
 therapies not useful and potentially harmful after, 272
- Myocardial ischemia
 ambulatory electrocardiogram monitoring in, 95t, 105
 diastolic heart failure from, 316
 ECG findings in, 104
 in hypertrophic cardiomyopathy, 324
 silent, treatment of, 241–243
- Myocardial oxygen demand (MVO₂), determinants of, 218–219
- Myocardium, “stunned,” 221
- Myoclonic jerks, 929
- Myofibroblasts, in airways inflammation in asthma, 467
- Myogenic control, of coronary artery tone, 220
- Myonecrosis, clostridial, 1810
- Myxedema coma, treatment of, 1258
- N
- N-3 PUFAs, for osteoarthritis, 1533
- Nabilone (Cesamet), as antiemetic, 610t, 611
- Nadolol
 in migraine prophylaxis, 1011t, 1014
 in schizophrenia management, 1108
 in variceal bleeding prophylaxis, 638–639
 in variceal rebleeding prophylaxis, 641
- Nafarelin, for endometriosis, 1348t, 1349
- Nafillin
 for osteomyelitis, 1939t
 for peritonitis complicating peritoneal dialysis, O114t
 for staphylococcal endocarditis, 1827t
- Nail infections, fungal, superficial, 1968t, 1968–1971
- Nalbuphine (Nubain)
 characteristics of, 994t
 dosing guidelines for, 996t
- Nalfon (fenoprofen), dosing of, 993t
- Naloxone (Narcan)
 for acute opiate toxicity, 1078
 with buprenorphine, for opioid dependency, 1079
 characteristics of, 994t
 dosing guidelines for, 996t
 for pain, 999
- Naltrexone
 for alcohol dependence, 1088
 in alcohol dependence treatment, 1087t
- NANC (nonadrenergic noncholinergic) nervous system, in inflammation in asthma, 468
- Naproxen (Naproxyn, Anaprox, Aleve)
 in Alzheimer’s disease prevention, 1059
 dosing of, 993t
 for endometriosis, 1347–1348, 1348t
 for migraine, 1010t
 in migraine prophylaxis, 1011t
 for NSAID-induced ulcers, 580
- Naproxyn. *See* Naproxen (Naproxyn, Anaprox, Aleve).
- Naratriptan
 for migraine, 1010t, 1013
 pharmacokinetic characteristics of, 1013t
- Narcan. *See* Naloxone (Narcan).
- Narcolepsy, 1197–1198
- Narcotics
 in COPD management, 512
 for pain, in chronic pancreatitis, 669
 pulmonary edema induced by, 526t, 526–527
- Nardil. *See* Phenelzine (Nardil).
- Naropin (ropivacaine), 1000t
- Nasoduodenal route for enteral nutrition, 2402, 2402t, 2403f
- Nasogastric route for enteral nutrition, 2402t, 2402–2403, 2403f
- Nasojejunal route for enteral nutrition, 2402, 2402t, 2403f
- Natalizumab (Tysabri), for multiple sclerosis, 920
- Nateglinide (Starlix)
 in diabetes management, 1223
 dosages and duration of action of, 1221t
- National Electronic Injury Surveillance System (NEISS), 70t
- National Survey on Drug Use and Health, 1068
- National Vaccine Injury Compensation Act, 2045
- Natriuretic hormone, blood pressure and, 143
- Natriuretic peptides
 B-type, N-terminal, in diastolic heart failure diagnosis, 317
 in heart failure, 179
- Natural disasters, infectious diseases related to, O72, O72t
- Natural rubber latex allergy, 525
- Nausea, 608
 anticipatory, 609
 chemotherapy-induced, 612–613
 clinical presentation of, 609, 609t
 etiology of, 607, 608t
 pathophysiology of, 608
 pharmacoeconomic considerations on, 615
 postoperative, 613t, 613–614
 radiation-induced, 614
 treatment of
 general approach to, 609
 nonpharmacologic, 609
 outcomes of
 desired, 609
 evaluation of, 615
 pharmacologic, 609–612, 610t, 612t
 antiemetic drugs in, 609–458. *See also* Antiemetic drugs.
 and vomiting, in pregnancy, 1300
- Nebivolol, for hypertension, 164
- Nebulizers, in aerosol therapy for asthma, 472t, 473, 473t
- Neck surgery, antimicrobial prophylaxis in, 2033t, 2035
- Necrotizing soft-tissue infections, 1804t, 1809–1810
- Nedocromil sodium, for chronic asthma, 488–489
- Needle-stick exposures to hepatitis C, treatment of, 688
- Nefazodone
 dosages of, adult, 1127t
 pharmacokinetics of, 1131t
 potencies of, relative, 1128t
- Neisseria gonorrhoeae*, in pregnancy, management of, 1302–1303
- Neisseria meningitidis*, central nervous system infections from, 1748–1750
- Nelarabine, for T-cell disease, 2265
- Nelfinavir (NFV), for HIV infection, 2072, 2073t
- Nematodes, 1890–1892
- Neomycin
 digoxin interaction with, 199t
 for hepatic encephalopathy, 645m 646
- Neonatal sepsis, immunoglobulin for, 2055
- Neonate(s). *See also* Infant(s); Premature infant(s).
 definition of, 47
 disseminated candidiasis in, treatment of, 1990–1991
- drug absorption through skin in, 48
 drug distribution in, 48
 epilepsy treatment in, 938
 immunizations of, 2043
 malnutrition in, consequences of, 2373, 2373t
 sexually transmitted diseases in, sequelae of, 1916
- Nephritic syndrome, 813
- Nephritis
 anti-GBM, complicating kidney transplantation, 828
 interstitial
 acute allergic, drug-induced, 805
 chronic, drug-induced, 805–807
 lupus, 825–827, 826f
- Nephrocalcinosis
 drug-induced, 807
 from hypercalcemia, 863
- Nephrogenic diabetes insipidus, treatment of, 855t, 855–856
- Nephrolithiasis
 associated with chronic hypercalcemia and hypercalciuria, treatment of, 866t
 drug-induced, 804
 from hypercalcemia, 863
 uric acid
 clinical presentation of, 1542–1543
 treatment of, 1546
- Nephron, structures of, 706f
- Nephropathy(ies)
 Chinese herb, 806–807
 diabetic, treatment of, 1235
 gouty, clinical presentation of, 1543
 immunoglobulin A, 823–825, 825f
 membranous, 820–822, 821f
 drug-induced, 804
 minimal-change, 817–819, 818f
- Nephrosis, osmotic, drug-induced, 800–801
- Nephrotic syndrome, 813–814
 edema in, diuretic therapy for, 857t
 hyperlipidemia and, 400
- Nephrotoxicity
 aminoglycoside, 797t, 797–798
 amphotericin B-induced, 800
 calcineurin inhibitor, 1469, 1469t
 carboplatin-induced, 799–800
 cisplatin-induced, 799–800
 drug-induced, 795–810. *See also* Drug-induced nephrotoxicity (DIN).
 radiographic contrast media, 798–799

- for osteomyelitis, 1939t
 - for peritonitis complicating peritoneal dialysis, O114t
 - for staphylococcal endocarditis, 1827t
- Oxacillin disks, in methicillin resistance detection, 1724
- Oxaliplatin
- adjuvant, for colorectal cancer, 2189, 2190, 2190t
 - allergic drug reactions to, 1455
 - in cancer chemotherapy, 2100
 - for metastatic colorectal cancer, 2193t, 2199, 2191–2202
- Oxazepam (Serax)
- dosage of, 1165t
 - for generalized anxiety disorder, pharmacokinetics of, 1167t
- Oxcarbazepine (Trileptal)
- for bipolar disorder
 - efficacy ratings of, 1147t
 - monitoring of, laboratory tests in, 1153t
 - product information on, 1152t, 1156–1157
 - clinical considerations with, 943–944
 - dosing of, 939t
 - drug interactions with, 936t
 - pharmacokinetic data on, 934t
 - serum concentrations of, target, 939t
 - side effects of, 934t
- Oxidative hemolytic anemia, drug-induced, 1708–1709
- treatment of, 1709
- Oxidative stress, in Parkinson’s disease, 977–978
- Oxybutynin
- immediate-release, for urge urinary incontinence, 1404, 1406t
 - oral, extended-release, for urge urinary incontinence, 1404, 1406
 - transdermal, extended-release, for urge urinary incontinence, 1406–1407
- Oxycodone, 998
- characteristics of, 994t
 - dosing guidelines for, 995t
 - for osteoarthritis, 1533
- OxyContin, abuse of, 1072
- Oxygen, in aborting cluster headache, 1017
- Oxygen delivery and consumption, in shock management, 420–421
- Oxygen demand, myocardial, determinants of, 218–219
- Oxygen tension and saturation monitoring, in shock management, 420
- Oxygen therapy
- controlled, for COPD exacerbation, 510
 - for cyanide poisoning, O79
 - long-term, in COPD management, 503–504
 - for pulmonary hypertension, O97
- Oxygen toxicity, pulmonary, 527–528
- Oxymorphone (Numorphan, Opana), 998
- characteristics of, 994t
 - dosing guidelines for, 995t
- Oxypurinol, in intercritical gout prophylaxis, 1547

- Oxytocin
functions of, 1281–1282
for labor induction, 1308
physiologic effects of, 1283t
release of, regulation of, 1283t
- P**
- P53, inactivation of, in colorectal cancer, 2182
- P-glycoprotein, in drug disposition, 696
- P wave on ECG, 102, 103
- Pachymeninges, 1744
- Pacifier, with sucrose, for minimizing pain from injection, 52t
- Paclitaxel (Abraxane)
allergic drug reactions to, 1455
for breast cancer, metastatic, 2148, 2149
in breast cancer chemotherapy, 2137, 2138t, 2139t
dose modification of, in hepatic dysfunction, 2097t
for non–small cell lung cancer, 2162t, 2163t, 2164–2166, 2165t
for ovarian cancer, 2251, 2252, 2252t
recurrent, 2254t
protein-bound, for metastatic breast cancer, 2148
- PAD. *See* Peripheral arterial disease (PAD).
- Paget's disease, 1501
of breast, 2130
- PAH (pulmonary arterial hypertension), O92–O102
- Pain
abdominal
in acute pancreatitis, relief of, 664, 665f
in chronic pancreatitis, management of, 668, 669, 669t
acute, 991
characteristics of, 991t
management of, special considerations in, 1000
cancer, 991
management of, special considerations in, 1000, 1001f
chronic, 991
characteristics of, 991t
noncancer, management of, special considerations in, 1000
pharmacologic management of, 999t
classification of, 991
clinical presentation of, 991–992
definition of, 989
epidemiology of, 989
functional, pathophysiology of, 991
in hemophilia, management of, 1674
inflammatory, 990–991
from injections, techniques for minimizing, 52t
in irritable bowel syndrome, 630
management of, 989–1003
nonopioid agents in, 992, 993t
nonpharmacologic, 992
opioid agents in, 992–999, 994t, 995–996t, 997t
outcomes of, evaluation of, 1000–1001
in pediatric patients, 51, 52t
pharmacoeconomic considerations on, 1000
pharmacologic, 992–1000
psychological intervention in, 992
regional analgesia in, 999–1000, 1000t
for special populations, 1000
stimulation therapy in, 992
modulation of, 990
neuropathic, pathophysiology of, 991
nociceptive, pathophysiology of, 990f, 990–991
in osteoarthritis, 1522
pathophysiology of, 989–991
perception of, 990
in pediatric patients, 51
PQRST characteristics of, 991t
stimulation of, 990, 990f
transmission of, 990
- Paliperidone (Invega)
doses and dosage forms of, 1105t
- pharmacokinetics of, 1109t
for schizophrenia, 1103
- Palmar erythema, in cirrhosis, 636
- Palmar-plantar erythrodysesthesia, from IV fluorouracil, 2190
- Pamelor. *See* Nortriptyline (Aventyl, Pamelor).
- Pamidronate
for hypercalcemia, 865, 865t
in osteoporosis prevention, 1359
in prostate cancer palliation, 2214
- Pancolitis, 593
- Pancreas
exocrine, secretion of, physiology of, 659–660
inflammation of, 659–673. *See also* Pancreatitis.
necrosis of, from acute pancreatitis, prevention of, 665
transplantation of, for type 1 diabetes, 1229, 1236
- Pancreatic cholera, 622
- Pancreatic digestive enzymes, deficiency of, in cystic fibrosis, 536
- Pancreatic enzymes
for malabsorption in chronic pancreatitis, 669–670, 670t
for pain in chronic pancreatitis, 669
phase 1, alteration in, drug dosing and, 698–700
phase 2, alteration in, drug dosing and, 700
products containing, 539t
supplementation of, for cystic fibrosis, 539–540
- Pancreatic polypeptide, secretion site and actions of, 2400t
- Pancreatitis, 659–673
acute, 660–666
clinical course of, 663
clinical presentation of, 662t, 662–663
complications of, 662
systemic, limitation of, 665
diagnosis of, 662–663
etiology of, 660t, 660–661
medications associated with, 661, 661t
pathophysiology of, 661f, 661–662
prognosis for, 663
severity of, prediction of, 662t, 662–663
signs and symptoms of, 662
treatment of, 663–666
general approach to, 663, 664f
for infection prevention, 665–666, 666t
nonpharmacologic, 663–664
nutritional support in, 664
outcomes of, desired, 663
outcomes of, evaluation of, 671
for pain control, 664, 665f
pharmacoeconomic considerations on, 670–671
pharmacologic, 664–666
probiotics in, 664
chronic, 666–670
clinical course of, 667
clinical presentation of, 667, 667t
diagnosis of, 667
etiology of, 666t, 666–667
pathophysiology of, 667
prognosis for, 667
signs and symptoms of, 667, 667t
treatment of, 667–670
general approach to, 668, 668f
nonpharmacologic, 668
outcomes of, desired, 667–668
outcomes of, evaluation of, 671
pharmacoeconomic considerations on, 670–671
pharmacologic, 668–670, 669t
epidemiology of, 659
post-ERCP, 666
- Pancytopenia, in drug-induced hematologic disorders, 1703
- Pandemics, influenza
antigenic drift and, 1792–1793
preparedness for, 1793
- Panhypopituitarism, 1293
- Panic disorder
clinical presentation of, 1164, 1164t
treatment of, 1170–1173
alternative drug treatments in, 1171
antidepressants in, 1171–1172
general approach to, 1170
nonpharmacologic, 1170
outcomes of
desired, 1170
evaluation of, 1172–1173
pharmacoeconomic considerations on, 1172
pharmacologic, 1170t, 1170–1172
phases of, 1172
for special populations, 1171
- Panitumumab (ABX-EGF, Vectibix), for metastatic colorectal cancer, 2200
- Pannus, in rheumatoid arthritis, 1505
- Pantoprazole
as antiulcer agent, 581, 581t
in GERD treatment, 562–563
for Zollinger-Ellison syndrome, 583
- Pantothenic acid
deficiency of, 2357t
recommendations for, 2363t
- Papaverine, for erectile dysfunction, 1383
- Papillary serous adenocarcinoma of ovary, 2246
- Papilledema, from hypertension, 146
- Papules, 1579, 1580f
- Parabens, allergic drug reactions to, 1454
- Paracervical blocks, for labor analgesia, 1308
- Paradoxical splitting of S₂, 98
- Paralysis, hypokalemic periodic, in Graves' disease, 1247–1248
- Paraquat, lung damage from, 528
- Parasitic diseases, 1887–1898
amebiasis as, 1889t, 1889–1890
American trypanosomiasis as, 1894, 1894t
ascariasis as, 1890–1891
ectoparasites as, 1894–1895
enterobiasis as, 1891
giardiasis as, 1888t, 1888–1889
helminthic, 1890–1892
hookworm disease as, 1890
lice as, 1894–1895
malaria as, 1892t, 1892–1894
nematodes as, 1890–1892
neurocysticercosis as, 1891–1892
protozoan, 1888–1890
scabies as, 1895
strongyloidiasis as, 1891
- Parasomnias, 1199
- Parasympathetic innervation, of airway smooth muscle in asthma, 468
- Parasympathetic nervous system, in coronary blood flow regulation, 458
- Parasympathomimetic agents, for closed-angle glaucoma, 1561–1562
- Parathyroid, 1866
- Parathyroid hormone (PTH), in calcium homeostasis, 1485
- Paregoric, for diarrhea, 620, 622t
- Parenteral nutrition (PN), 2379–2397
administration of
routes of, 2384–2386, 2385f
central, 2385f, 2385–2386
peripheral, 2384–2385, 2385f
techniques of, 2387
amino acids in, 2381–2382
complications of, 2392–2394
infectious, 2392
mechanical, 2392
metabolic, 2392t, 2392–2394
nutritional, 2392–2394
technical, 2392
components of, 2381t, 2381–2384
dextrose in, 2382
electrolytes in, 2384
enteral nutrition versus, 2401–2402
home, 2394
indications for, 2380t, 2380–2381
infection control for, 2390
for inflammatory bowel disease, 594

- Parenteral nutrition (PN) (*Cont.*)
 infusion of
 continuous versus cyclic, 2389
 initiating and advancing, 2387–2389
 intravenous fat emulsion in, 2382–2383
 nutrients for, osmolarities of, 2385t
 outcomes of
 desired, 2379–2380
 therapeutic, evaluation of, 2389–2390, 2390f
 pharmacoeconomic considerations on, 2394
 preparations for
 compounding, 2390–2391
 stability and compatibility of, 2391–2392
 storage of, 2390–2391
 regimen for
 constructing, 2386–2387, 2387f
 designing, 2384–2387
 total, for anorexia nervosa, 1045
 trace elements in, 2384
 vitamins in, 2383–2384
- Parent's Evaluation of Developmental Status, O124
- Parkinson's disease, 977–988
 clinical presentation of, 979–980
 diagnostic criteria for, 979t
 differential diagnosis of, 979t
 epidemiology of, 977

 Rabeprazole
 as antiulcer agent, 581, 581t
 dosing for, CYP2C19 polymorphism and, 698
 in GERD treatment, 562–563
 for Zollinger-Ellison syndrome, 583
 Rabies immunoglobulin, 2052
 Rabies vaccines, 2051–2052
 Race
 prevalence of osteoarthritis by, 1520
 prostate cancer and, 2207–2208
 tuberculosis risk and, 1840
 Racecadotril, in diarrhea, 623

- Radiation, breast cancer risk and, 2125
- Radiation therapy
adjuvant
for non-small cell lung cancer, stages I and II, 2162
for operable colon cancer, 2189
for operable rectal cancer, 2191–2192
- for breast cancer
locally advanced, 2144
metastatic, 2150
- for follicular lymphomas, 2234
- for Hodgkin's lymphoma, 2223
advanced, 2226
- for lung cancer
non-small cell
advanced, 2167–2168
stages IIb and III, 2163
small cell, 2168–2169
- nausea and vomiting induced by, 614
- for ovarian cancer, 2250
- postmastectomy, 2133
- for prostate cancer, 2212
- for squamous cell cancer, 2327
- Radical prostatectomy, for prostate cancer, 2212
- Radioactive agents
concentrated isotopes as, O85–O86
exposure to
clinical presentation of, O84–O85
treatment of, O86–O88, O87t
nuclear weapons and fallout as, O86, O86f
radiation dispersal devices as, O86
risk factors from, O86
toxicity of, mechanism of, O85
- Radioactive iodine (RAI)
for hyperthyroidism, 1250t, 1252–1253
uptake of
elevated, causes of thyrotoxicosis associated with, 1246
suppressed, causes of thyrotoxicosis associated with, 1249–1250
- Radioactive isotope imaging, in intraabdominal abscess diagnosis, 1879
- Radiocontrast dyes. *See* Contrast media.
- Radiofrequency catheter ablation, for paroxysmal supraventricular tachycardia, 298–299, 299f
- Radiography
barium, in gastroesophageal reflux disease diagnosis, 558
chest
in cardiovascular testing, 101
in lung cancer diagnosis, 2160
in cirrhosis diagnosis, 638
in colorectal cancer diagnosis, 2186
in intraabdominal abscess diagnosis, 1879
- Radioimmunoassay (RIA), in antimicrobial concentration determination, 1726
- Radioimmunoscintigraphy, in colorectal cancer diagnosis, 2186
- Radioimmunotherapy, for follicular lymphomas, 2235–2236
- Radiolabeled markers, in GFR measurement, 713
- Radiologic studies, in renal function assessment, 719
- Radiology, in gastrointestinal tract disorders, 549–550
- Radionuclide angiocardigraphy, in ischemic heart disease, 224
- Radionuclide imaging, in GI disorder diagnosis, 550–551, 552f
- Radiotherapy. *See* Radiation therapy.
- RADT (rapid antigen-detection test), in group A streptococcal pharyngitis diagnosis, 1786
- RAI. *See* Radioactive iodine (RAI).
- Rales, in heart failure, 182
- Raloxifene (Evista)
in breast cancer prevention, 2151
in osteoporosis prevention, 1359, 1359t, 1494t, 1497
in osteoporosis treatment, 1494t, 1497
in postmenopausal hormone therapy, 1357
- Ramelteon, for insomnia, 1193
- Ramipril (Altace). *See also* Angiotensin-converting enzyme (ACE) inhibitors.
dosage and elimination of, 196t
- Ranitidine (Zantac 75)
as antiemetic, 610, 610t
as antiulcer agent, 582
in cotherapy for NSAID-induced ulcers, 580
in GERD treatment, 562
for stress-related mucosal bleeding, 585
- Rapid antigen-detection test (RADT), in group A streptococcal pharyngitis diagnosis, 1786
- Rapid-identification tests, in drug susceptibility testing, 1841
- Rapid plasma reagin (RPR) card test for syphilis, 1920
- Rasagiline, for Parkinson's disease, 985
- RATG (Thymoglobulin), in immunosuppression, for solid-organ transplantation, 1472–1473
- Rating Scale for Extrapyrimal Side Effects (Simpson-Angus EPS Scale), 1026t
- Raynaud phenomenon, in systemic sclerosis, 1440
- Razadyne (galantamine), for Alzheimer's disease, 1057, 1058t
- RBCs. *See* Red blood cells (RBCs).
- RBF (renal blood flow), antihypertensive agent effects on, 754t
- RDW, Red blood cell distribution width (RDW)
- Rebound vasodilation, from topical decongestants, 1571
- Receptors, sensitivity of, postsynaptic changes in, theories of depression related to, 1124
- Reclast. *See* Zolidronic acid (Reclast).
- Recombinant factor VIIa, for inhibitors in hemophilia, 1674
- Recombinant factor VIII, for hemophilia A, 1669–1670, 1670t
- Recombinant factor IX, for hemophilia B, 1672
- Recombinant growth hormone, for growth hormone-deficient short stature, 1287–1288
- Recombinant human DNase, for cystic fibrosis, 540
- Recombinant insulin-like growth factor-1, for growth hormone-deficient short stature, 1289–1290
- Recombivax HB, 681
- Rectum
anatomy of, 2180f
cancer of, 2175–2206. *See also* Colorectal cancer.
- Red blood cell count, 1644
- Red blood cell distribution width (RDW), 1645
normal values for, 1644t
- Red blood cell indices, 1644–1645
- Red blood cells (RBCs)
abnormal levels of, causes of, 1634
destruction of, normal, 1642, 1643f
functions of, 1629
maturation and development of, 1641f, 1641–1642
normal values for, 1644t
packed, transfusions of, 1636
proliferation and differentiation of, regulation of, 1632–1633
splenic sequestration of, in sickle cell disease, 1689
treatment of, 1695–1696
transfusion of, for anemia of chronic kidney disease, 779
in urine, in kidney disease assessment, 709
- Reduced-intensity conditioning (RIC) regimens, for hematopoietic stem cell transplantation, 2336–2338, 2337f
- Redundancy, in immune system, 1417
- REE. *See* Resting energy expenditure (REE).
- Reed-Sternberg cells, in Hodgkin's lymphoma, 2220
- Reentry
intraarterial, paroxysmal supraventricular tachycardia caused by, 297
- paroxysmal supraventricular tachycardia caused by, 295–299. *See also* Paroxysmal supraventricular tachycardia, caused by reentry.
- sinus node, paroxysmal supraventricular tachycardia caused by, 297
- tachycardias associated with, 282–283, 283f
- Refeeding, for anorexia nervosa, 1045
- Refeeding syndrome, 1044
complications of, 2393
- Regional analgesia, 999–1000, 1000t
- Reglan. *See* Metoclopramide (Reglan).
- Regulatory regions, function of, 32
- Rehabilitation, pulmonary, in COPD management, 503
- Rehydration therapy
for acute renal failure, 733–734
in diarrhea management, 1858–1859
for food poisoning, 1871
solutions used in, comparison of, 1859t
- Rejection, in solid-organ transplantation, 1462–1465. *See also* Solid-organ transplantation, graft rejection in.
- Relactation, 1309–1310
- Relapsar, definition of, 687
- Relaxation therapy, in COPD management, 504
- Relaxation training, for tension-type headache, 1016
- Reliability
of health-related quality of life measurement instrument, O20
of psychiatric rating scales, 1025
- Remodulin (treprostinil) for pulmonary hypertension, O98, O100t
- Renal blood flow (RBF), antihypertensive agent effects on, 754t
- Renal insufficiency. *See also* Chronic kidney disease (CKD).
drug therapy individualization in, 833–844
functional, from ACE inhibitors, 196
- Renal osteodystrophy (ROD), complicating chronic kidney disease, secondary hyperparathyroidism causing, 767, 767f. *See also* Hyperparathyroidism, secondary, complicating chronic kidney disease.
- Renal plasma flow (RPF), measurement of, 718
- Renal replacement therapies (RRTs)
for acute renal failure, 723, 734–736
continuous, 734–736, 735f
drug dosing and, 738–740
intermittent hemodialysis as, 734
indications for, 734t
- Renal solute load, of enteral feeding formulas, 2406
- Renal tubular acidosis, 894
- Renal vasculitis, drug-induced, 807–808
- Renin inhibitor, direct, for hypertension, 152t
- Renin-angiotensin-aldosterone system (RAAS), 142f, 142–143
activation of, as compensatory response in heart failure, 176, 177f
blood pressure and, 13–14
- Repaglinide (Prandin)
in diabetes management, 1223
dosages and duration of action of, 1221t
- Reperfusion, in ischemic stroke patients, 380
- Replication, in immune system, 1417
- Reproductive system
in cystic fibrosis, 537
female, disorders of, 1297–1368. *See also* Gynecologic disorders.
obesity and, 2443
- Research, outcomes, definition of, O2
- Reserpine, for hypertension, 163–164
- Residual concentration, 15
- Residual volume (RV), definition of, 456, 456f
- Resistance
to antifungal agents, 1974–1976, 1975t, 1976f
to antimicrobials
detection of, 1723–1724
prevention of, combination therapy in, 1736
surgical site infections and, 2030

- Resistance (*Cont.*)
 to azoles, vulvovaginal candidiasis management with, 1959
 bacterial, in antibiotic therapy for cystic fibrosis, 543
 to chemotherapeutic agents, 2110
 to imatinib, 2285
 to insulin
 in hypertension, 143
 in obesity, 2442
 in type 2 diabetes. *See also* Insulin, resistance to, in type 2 diabetes.
 mucosal, gastroesophageal reflux disease and, 557
 to social anxiety disorder treatment, 1175
- Respiratory acidosis
 causes of, 904t
 clinical presentation of, 903–904
 compensation for, 904
 with metabolic acidosis, 905
 with metabolic alkalosis, 905–906
 partial pressure of carbon dioxide from arterial blood in, 892
 pathophysiology of, 903
 treatment of, 904–905
- Respiratory alkalosis, 902–903
 causes of, 902t
 clinical presentation of, 902–903
 compensation for, 903
 hypophosphatemia associated with, 872
 with metabolic acidosis, 905
 with metabolic alkalosis, 905
 partial pressure of carbon dioxide from arterial blood in, 892
 pathophysiology of, 902
 treatment of, 903
- Respiratory tract
 allergic drug reactions involving, clinical manifestations of, 1451–1452
 in cystic fibrosis, 536–537
 clinical presentation of, 538
 treatment of, 540–543
 antibiotic, 541–543
 antiinflammatory, 541
 antib obstructive, 540–541
 outcomes of, evaluation of, 543–544
 disorders of
 chronic obstructive pulmonary disease as, 495–517. *See also* Chronic obstructive pulmonary disease (COPD).
 cystic fibrosis as, 535–546. *See also* Cystic fibrosis.
 drug-induced, 521–534
 pulmonary function testing in, 455–462. *See also* Pulmonary function tests (PFTs).
 infections of, tuberculosis as, 1770
 lower, infections of, 1761–1778
 bronchiolitis as, 1766–1768, 1767t
 bronchitis as, 1762–1766. *See also* Bronchitis.
 pneumonia as, 1768–1776. *See also* Pneumonia.
 stimulants of, in COPD management, 512
 upper, infections of, 1779–1790
 otitis media as, 1779–1782. *See also* Otitis media.
 pharyngitis as, 1785–1788. *See also* Pharyngitis.
 sinusitis as, 1782–1785. *See also* Sinusitis.
 “Response-to-injury” hypothesis, of atherosclerosis, 388
- Responsiveness, of health-related quality of life measurement instrument, O20
- Resting energy expenditure (REE)
 definition of, 2441
 equations for, 2359–2360
- Resting membrane potential (RMP), 280
- Restless legs syndrome, 1199
- Restoril (temazepam), for insomnia, 1194t
- Restrictive cardiomyopathy, 327–328
- Restrictive lung disease, 459–460
 causes of, 459t
- Resuscitation
 cardiopulmonary, 123–137. *See also* Cardiopulmonary resuscitation (CPR).

in morbid obesity, treatment of, 1850
multidrug resistance, treatment of, 1847
pathogenesis, HIV infection and, 1842–1843
pathophysiology of, 1841–1843
in pregnancy, treatment of, 1847, 1849
progressive primary, 1843
reactivation, pathophysiology of, 1842
with renal failure, treatment of, 1849t, 1849–1850
risk factors for, 1840
skin testing for, 1843–1844
transmission of, 1841
treatment of, 1844–1854
p-aminosalicylic acid in, 1852
azalides in, 1852
Bacille Calmette-Guérin vaccine in, 1853
clofazimine in, 1852
corticosteroids in, 1853
cyclserine in, 1852
ethionamide in, 1852
general approaches to, 1844
isoniazide in, 1845, 1845t, 1846t, 1848t, 1849t, 1850
 β -lactam and β -lactamase inhibitor combinations in, 1852
linezolid in, 1852–1853
macrolides in, 1852
new delivery systems in, 1853
nitroimidazopyran PA 824 in, 1852
nonpharmacologic, 1845
outcomes of
desired, 1844
evaluation of, 1853–1854
pharmacoeconomic considerations on, 1853
pharmacologic, 1845–1853
pyrazinamide in, 1851–1852
quinolones in, 1852
rifampin in, 1845, 1845t, 1846t, 1848t, 1849t, 1850–1851
rifamycins in, 1851
streptomycin in, 1848t, 1849t, 1852
thiacetazone in, 1852
- Tuberculous meningitis, treatment of, 1847
- Tubules
damage to, in acute renal failure, 727
drug-induced obstruction of, 804
epithelial cell damage to, drug-induced, 797–800
unresponsiveness of, to aldosterone, hyperkalemia from, 882
- Tubulointerstitial disease, drug-induced, 805–807
- TUIP (transurethral incision of prostate), for benign prostatic hyperplasia, 1395
- Tularemia, O67–O69, O68t
- Tumor(s)
characteristics of, 2089–2090
classification of, by tissue type, 2089t
growth of, principles of, 2092–2093, 2093f
hypercalcemia associated with, 862, 862t
invasion by, 2090
origin of, 2089, 2089t
proliferation of, 2093–2094
size of, as prognostic factor in breast cancer, 2131
solid
hematopoietic stem cell transplantation for, conditioning for, 2336
response criteria for, 2109
synchronous, 2159
- Tumor lysis syndrome, hyperphosphatemia in, 870
- Tumor necrosis factor- α (TNF- α)
in Crohn's disease, 590
in heart failure, 180
in inflammatory response, 1428
- Tumor necrosis factors
inhibitors of, for psoriasis, 1609–1610
in sepsis initiation, 1945
- Tumor suppressor genes, in carcinogenesis, 2088, 2088t
- Tumorigenesis, mechanisms of, 2090, 2090f
- Tunica albuginea, 1370, 1370f
- TURP (transurethral resection of prostate), for benign prostatic hyperplasia, 1394–1395
- TVUS (transvaginal ultrasound), in ovarian cancer screening, 2246
- Twinrix, 678, 681
- Two-dimensional echocardiography, 109, 109f
- Typhoid, 1866
- Tyrosine kinase inhibitors
for chronic myelogenous leukemia, 2284–2286
for metastatic breast cancer, 2150
- Tysabri (natalizumab), for multiple sclerosis, 920
- TZD drugs. *See* Thiazolidinedione (TZD) drugs.
- U
- U waves on ECG, 103
- UBT (urea breath test), for *Helicobacter pylori*, 574, 575t
- UFH. *See* Heparin, unfractionated (UFH).
- UI. *See* Urinary incontinence (UI).
- Ulcer(s)
decubitus, 1812t, 1812–1814, 1813f
diabetic, treatment of, 1235
genital, pathogens and clinical manifestations of, 1917t
stress, prophylaxis for, in sepsis, 1948t, 1953
- Ulcerative colitis. *See also* Inflammatory bowel disease (IBD).
chronic, colorectal cancer risk and, 2179
clinical presentation of, 592–593, 593t
description of, 589
mild to moderate, treatment of, 597–598

- Ulcerative colitis (*Cont.*)
 pathophysiology of, 591t, 591–592
 remission of, maintenance of, 598
 severe or intractable, treatment of, 598
- Ultrafiltration, for heart failure, 210
- Ultram. *See* Tramadol (Ultram).
- Ultrasonic nebulizer, in aerosol therapy for asthma, 472t, 473, 473t
- Ultrasonography
 endoscopic
 in colorectal cancer diagnosis, 2186
 in GI disorder diagnosis, 554
 in GI disorder diagnosis, 550, 551f
 in intraabdominal abscess diagnosis, 1879
 intravascular, in cardiovascular disorders, 118, 118f
 in neurologic illness diagnosis, 910
 renal, in renal function assessment, 719
 transvaginal, in ovarian cancer screening, 2246
- Ultraviolet B light therapy
 for atopic dermatitis, 1623–1624
 for psoriasis, 1613
- Undernutrition, 2349
- Unheated serum reagin (USR) test for syphilis, 1920
- United Kingdom, pharmacist-directed documentation initiatives in, O38–O39
- United Kingdom Prospective Diabetes Study (UKPDS), implications of, 1227
- United States, pharmacist-directed documentation initiatives in, O39
- Upper airway obstruction, 458–459
- Upper GI series, 549, 550f
- Uracil mustard, pulmonary fibrosis associated with, 530
- Urea breath test (UBT), for *Helicobacter pylori*, 574, 575t
- Urea nitrogen, serum or blood, in kidney disease assessment, 709
- Uremic bleeding, complicating chronic kidney disease, 788–789
- Urethra
 overactivity, urinary incontinence related to, clinical presentation of, 1402
 overactivity of, overflow incontinence from, 1401
 underactivity of
 bladder overactivity differentiated from, 1402t
 imipramine in, 1406t
 treatment of
 α -adrenergic agonists in, 1406t, 1410
 duloxetine in, 1406t, 1410–1411
 estrogens in, 1406t, 1410
 urinary incontinence from, 1400
 clinical presentation of, 1402
- Urethritis, pathogens and clinical manifestations of, 1917t
- Urge urinary incontinence (UUI), 1400–1401
 treatment of
 botulinum toxin A in, 1409–1410
 catheterization combined with medications in, 1410
 darifenacin in, 1407t, 1409
 oxybutynin in, 1404, 1406t, 1406–1407, 1407t
 pharmacologic, 1404, 1406t, 1406–1410
 solifenacin succinate in, 1407t, 1408–1409
 tolterodine in, 1407t, 1407–1408
 trospium chloride in, 66, 1407t, 1408
- Uric acid
 elevated serum levels of, in gout, 1539
 overproduction of, in gout, 1540
 underexcretion of, in gout, 1540–1541
- Uric acid nephrolithiasis
 clinical presentation of, 1542–1543
 treatment of, 1546
- Uric acid oxidase (uricase), in intercritical gout prophylaxis, 1547
- Uricosuric drugs, in intercritical gout prophylaxis, 1547
- Uridine diphosphate glucuronosyltransferase, polymorphic, irinotecan dosing and, 701
- Urinalysis
 in glomerulonephritis diagnosis, 815
 in kidney disease assessment, 708–709
- Urinary enzymes, in tubular function assessment, 719
- Urinary incontinence (UI), 1399–1415
 clinical presentation of, 1402
 epidemiology of, 1399
 etiology of, 1399–1403
 functional, 1401
 mechanisms of, 1400–1402
 mixed, 1401–1402
 overflow, 1401
 treatment of, 1406t, 1411
 pathophysiology of, 1399–1403
 prior medical or surgical illness and, 1403
 signs of, 1403
 stress, 1400
 treatment of
 α -adrenergic agonists in, 1406t, 1410
 duloxetine in, 1406t, 1410–1411
 estrogens in, 1406t, 1410
 imipramine in, 1406t
 symptoms of, 1402–1403
 treatment of, 1403–1412
 nonpharmacologic, 1403, 1405–1406t
 outcomes of, evaluation of, 1412
 surgical, 1411–1412
- urge, 1400–1401
 treatment of
 botulinum toxin A in, 1409–1410
 catheterization combined with medications in, 1410
 darifenacin in, 1407t, 1409
 oxybutynin in, 1404, 1406t, 1406–1407, 1407t
 pharmacologic, 1404, 1406t, 1406–1410
 solifenacin succinate in, 1407t, 1408–1409
 tolterodine in, 1407t, 1407–1408
 trospium chloride in, 1407t, 1408
- urine leakage in, 1402
- Urinary tract
 lower
 anatomy of, 1399–1400
 function of, medications influencing, 1401t
 structures of, 706f
- Urinary tract infections (UTIs), 1899–1910
 bacterial virulence factors in, 1901
 clinical presentation of, 1902t, 1902–1903
 diagnostic criteria for, 1900t
 epidemiology of, 1900
 etiology of, 1900
 host defense mechanisms in, 1901
 pathophysiology of, 1900–1901
 predisposing factors to, 1901–1902
 in pregnancy, management of, 1302route of, 1900–1901
 treatment of, 1903–1910
 in acute uncomplicated cystitis, 1904
 with asymptomatic bacteriuria, 1905–1907
 in catheterized patients, 1909–1910
 for complicated infections, 1906t, 1907–1909
 in males, 1908
 management in, 1903–1904
 outcomes of, desired, 1903
 pharmacologic, 1904, 1905t, 1906t
 in pregnancy, 1906t, 1909
 for recurrent infections, 1908–1909
 with symptomatic bacteriuria, 1904–1905
- Urine
 analysis of, in acute renal failure assessment, 730, 731t
 collection of, in urinary tract infection diagnosis, 1902
 leakage of, 1402
 output of, in acute renal failure assessment, 730
- Urine drug screening, evaluating results of, 71t
- Urokinase, for thrombosis of venous catheters complicating hemodialysis (HD), O109
- Urologic disorders
 benign prostatic hyperplasia as, 1387–1397. *See also* Benign prostatic hyperplasia (BPH).
 erectile dysfunction as, 1369–1385. *See also* Erectile dysfunction.
 urinary incontinence as, 1399–1415. *See also* Urinary incontinence.
- Urologic surgery, antimicrobial prophylaxis in, 2033t, 2034
- Uroxatral (alfuzosin), for benign prostatic hyperplasia, 1392t, 1392–1393
- Uterus, abnormalities of, amenorrhea from, 1330
- UTIs. *See* Urinary tract infections (UTIs).
- UUI. *See* Urge urinary incontinence (UUI).
- Uveitis, in ulcerative colitis, 592
- V**
- Vaccination(s)
 influenza, 1794t, 1794–1796, 1795t
 otitis media and, 1782
 preexposure, for bioterrorism agents, O59
 smallpox, O66–O67, O67f, O67t
- Vaccines, 2046–2054. *See also* Immunizations.
 administration of, 2042–2043, 2043t
 Bacille Calmette-Guérin, in tuberculosis management, 1853
 cholera, 1861–1862
 in COPD management, 503
 delivery of, 2044–2045
Haemophilus influenzae type b, 2046t, 2046–2047
 for hepatitis A, 677–678
 for hepatitis B, 681, 681t
 human papillomavirus, 2047

 in efficacy trials versus generalizability in effectiveness trials, O47f
 of health-related quality of life measurement instrument, O20
 of psychiatric rating scales, 1025
- Valium. *See* Diazepam (Valium).
- Valopicitabine (NM283), for hepatitis C, 688
- Valproate, with lamotrigine, allergic drug reactions to, 1455
- Valproate sodium
 for bipolar disorder
 monitoring of, laboratory tests in, 1153t
 product information on, 1151t, 1157

- in migraine prophylaxis, 1014
for refractory generalized convulsive status epilepticus, 960, 960t, to 961
use of, in pregnancy, risks associated with, 1150
- Valproic acid (Depakene)
in alcohol dependence treatment, 1087
for bipolar disorder, product information on, 1151t, 1157
clinical considerations with, 946–947
dosing of, 939t
drug interactions with, 936t
in migraine prophylaxis, 1011t, 1014
pharmacokinetic data on, 934t
in schizophrenia management, 1108
serum concentrations of, target, 939t
side effects of, 935t
- Valsartan
for chronic heart failure, 190–191
for diastolic heart failure, 322
in heart failure, information on, 197
for secondary prevention after myocardial infarction, 270
- Valve, aortic, replacement of, for diastolic heart failure, 318
- Valved holding chambers (VHCs), in aerosol therapy for asthma, 472t, 472–473
- Vancomycin
dosing of, computer programs for, 22–24, 23t
empirical regimens containing, for febrile neutropenic cancer patients, 2010t, 2011–2012
for infection complicating sickle cell disease, 1695
for infective endocarditis, 1825t, 1826t, 1827t, 1828t, 1829t
intraperitoneal dosing of, O114t
for peritonitis complicating peritoneal dialysis, O114, O114t
for pneumococcal meningitis, 1750
for pseudomembranous colitis, 1863
resistance to, detection of, 1724
for sepsis, 1949t
therapy with, laboratory monitoring of, 1727t, 1728
- Vapocoolant sprays, for minimizing pain from injection, 52t
- Vapreotide, for diarrhea, 622
- Vaqua, 677, 677t
- Vardenafil (Levitra)
for erectile dysfunction, 1375–1378. *See also* Phosphodiesterase inhibitors, for erectile dysfunction.
pharmacodynamics and pharmacokinetics of, 1374t
- Varenicline, for smoking cessation, 503, 503t, 1091t
- Varenicline (Chantix), for smoking cessation, 1094
- Variable-dose prandial insulin, 1228
- Variant allele, 33
- Varicella vaccine, 2052–2053
- Varicella-zoster immunoglobulin, 2053–2054, 2055
- Varices
bleeding from
acute, management of, 639f, 639–640
balloon tamponade in, 640
drug therapy in, 639–640
endoscopic band ligation in, 640
sclerotherapy in, 640
transjugular intrahepatic portosystemic shunting in, 640, 641f
prophylaxis of
primary, 638–639
secondary, 641
treatment recommendations for, 641–642
from cirrhosis, 635
management of, 638–642
- Variola major, smallpox from, O05–O07
- Vascular. *See also* Blood vessels.
- Vascular endothelial growth factor, in cancer chemotherapy, 2106–2107

Common Laboratory Tests

Laboratory	Conventional Units	Conversion Factor	SI Units
Acid phosphatase			
Male	2–12 units/L	16.7	33–200 nkat/L
Female	0.3–9.2 units/L	16.7	5–154 nkat/L
Activated partial thromboplastin time (aPTT)	25–40 s		
Adrenocorticotrophic hormone (ACTH)	15–80 pg/mL or ng/L	0.2202	3.3–17.6 pmol/L
Alanine aminotransferase (ALT, SGPT)	7–53 IU/L	0.01667	0.12–0.88 μ kat/L
Albumin	3.5–5.0 g/dL	10	35–50 g/L
Albumin:creatinine ratio (urine)			
Normal	Less than 30 mg/g creatinine		
Microalbuminuria	30–300 mg/g creatinine		
Proteinuria	Greater than 300 mg/g creatinine		
or	or		
Normal			
Male	Less than 2.0 mg/mmol creatinine		
Female	Less than 2.8 mg/mmol creatinine		
Microalbuminuria			
Male	2.0–20 mg/mmol creatinine		
Female	2.8–28 mg/mmol creatinine		
Proteinuria			
Male	Greater than 20 mg/mmol creatinine		
Female	Greater than 28 mg/mmol creatinine		
Aldosterone			
Supine	Less than 16 ng/dL	27.7	Less than 444 pmol/L
Upright	Less than 31 ng/dL	27.7	Less than 860 pmol/L
Alkaline phosphatase			
10–15 years	130–550 IU/L	0.01667	2.17–9.17 μ kat/L
16–20 years	70–260 IU/L	0.01667	1.17–4.33 μ kat/L
Greater than 20 years	38–126 IU/L	0.01667	0.13–2.10 μ kat/L
Alpha-fetoprotein (AFP)	Less than 15 ng/mL	1	Less than 15 mcg/L
Alpha ₁ -antitrypsin	80–200 mg/dL	0.01	0.8–2.0 g/L
Amikacin, therapeutic	15–30 mg/L peak	1.71	25.6–51.3 μ mol/L peak
	Less than or equal to 8 mg/L trough		Less than or equal to 13.7 μ mol/L trough
Amitriptyline	80–200 ng/mL or mcg/L	3.4	272–680 nmol/L
Ammonia (plasma)	15.33–56.20 mcg NH ₃ /dL	0.5872	9–33 μ mol NH ₃ /L
Amylase	25–115 IU/L	0.01667	0.42–1.92 μ kat/L
Androstenedione	50–250 ng/dL	0.0349	1.7–8.7 nmol/L
Angiotensin-converting enzyme	15–70 units/L	16.67	250–1167 nkat/L
Anion gap	7–16 mEq/L	1	7–16 mmol/L
Anti-double-stranded DNA (anti-ds DNA)	Negative		
Anti-HAV	Negative		
Anti-HBc	Negative		
Anti-HBs	Negative		
Anti-HCV	Negative		
Anti-Sm antibody	Negative		
Antinuclear antibody (ANA)	Negative		
Apolipoprotein A-1			
Male	95–175 mg/dL	0.01	0.95–1.75 g/L
Female	100–200 mg/dL	0.01	1.0–2.0 g/L
Apolipoprotein B			
Male	50–110 mg/dL	0.01	0.5–1.10 g/L
Female	50–105 mg/dL	0.01	0.5–1.05 g/L
Aspartate aminotransferase (AST, SGOT)	11–47 IU/L	0.01667	0.18–0.78 μ kat/L
Beta ₂ -microglobulin	Less than 0.2 mg/dL	10	2 mg/L
Bicarbonate	22–26 mEq/L	1	22–26 mmol/L
Bilirubin			
Total	0.3–1.1 mg/dL	17.1	5.13–18.80 μ mol/L
Direct	0–0.3 mg/dL	17.1	0–5.1 μ mol/L
Indirect	0.1–1.0 mg/dL	17.1	1.71–17.1 μ mol/L
Bleeding time	3–7 minutes		
Blood gases (arterial)			
pH	7.35–7.45	1	7.35–7.45
PO ₂	80–105 mm Hg	0.133	10.6–14.0 kPa
PCO ₂	35–45 mm Hg	0.133	4.7–6.0 kPa
HCO ₃	22–26 mEq/L	1	22–26 mmol/L
O ₂ saturation	Greater than or equal to 95%	0.01	0.95
Blood urea nitrogen	8–25 mg/dL	0.357	2.9–8.9 mmol/L
B-type natriuretic peptide (BNP)	0–99 pg/mL	1	0–99 ng/L
BUN-to-creatinine ratio	10:1 to 20:1		
C-peptide	0.51–2.70 ng/mL	330	170–900 pmol/L or 0.172–0.900 nmol/L
C-reactive protein	Less than 0.8 mg/dL	10	Less than 8 mg/L
CA 125	Less than 35 units/mL	1	Less than 35 kilounits/L
CA 15-3	Less than 30 units/mL	1	Less than 30 kilounits/L
CA 19-9	Less than 37 units/mL	1	Less than 37 kilounits/L
CA 27-29	Less than 38 units/mL	1	Less than 38 kilounits/L
Calcium			
Total	8.6–10.3 mg/dL	0.25	2.15–2.58 mmol/L
	4.3–5.16 mEq/L	0.50	2.15–2.58 mmol/L
Ionized	4.5–5.1 mg/dL	0.25	1.13–1.28 mmol/L
	2.26–2.56 mEq/L	0.50	1.13–1.28 mmol/L
Carbamazepine, therapeutic	4–12 mg/L	4.23	17–51 μ mol/L
Carboxyhemoglobin (nonsmoker)	Less than 2%	0.01	Less than 0.02
Carcinoembryonic antigen (CEA)			
Nonsmoker	Less than 2.5 ng/mL	1	Less than 2.5 mcg/L
Smoker	Less than 5 ng/mL		Less than 5 mcg/L
Cardiac troponin I (see troponin I)	Variable ng/mL	1	Variable mcg/L
CD4 lymphocyte count	31–61% of total lymphocytes		

(continued)

Laboratory	Conventional Units	Conversion Factor	SI Units
CD8 lymphocyte count	18–39% of total lymphocytes		
Cerebrospinal fluid (CSF)			
Pressure	75–175 mm H ₂ O		
Glucose	40–70 mg/dL	0.0555	2.2–3.9 mmol/L
Protein	15–45 mg/dL	0.01	0.15–0.45 g/L
WBC	Less than 10/mm ³		
Ceruloplasmin	18–45 mg/dL	10	180–450 mg/L
		0.063	1.1–2.8 μ mol/L
Chloride	97–110 mEq/L	1	97–110 mmol/L
Cholesterol			
Desirable	Less than 200 mg/dL	0.0259	Less than 5.18 mmol/L
Borderline high	200–239 mg/dL	0.0259	5.18–6.19 mmol/L
High	Greater than or equal to 240 mg/dL	0.0259	Greater than or equal to 6.2 mmol/L
Chorionic gonadotropin (β -hCG)	Less than 5 milliu/ml	1	Less than 5 units/L
Clozapine	Minimum trough 300–350 ng/mL or mcg/L	3.06	918–1071 nmol/L
CO ₂ content	22–30 mEq/L	1	22–30 mmol/L
Complement component 3 (C3)	70–160 mg/dL	0.01	0.7–1.6 g/L
Complement component 4 (C4)	20–40 mg/dL	0.01	0.2–0.4 g/L
Copper	70–150 mcg/dL	0.157	11–24 μ mol/L
Cortisol (fasting, morning)	5–25 mcg/dL	27.6	138–690 nmol/L
Cortisol (free, urinary)	10–100 mcg/day	2.76	28–276 nmol/day
Creatine kinase			
Male	30–200 IU/L	0.01667	0.50–3.33 μ kat/L
Female	20–170 IU/L	0.01667	0.33–2.83 μ kat/L
MB fraction	0–7 IU/L	0.01667	0.0–0.12 μ kat/L
Creatinine clearance (CrCl) (urine)	85–135 mL/minute/1.73 m ²	0.00963	0.82–1.3 mL/s/m ²
Creatinine			
Male 4–20 years	0.2–1.0 mg/dL	88.4	18–88 μ mol/L
Female 4–20 years	0.2–1.0 mg/dL	88.4	18–88 μ mol/L
Male (adults)	0.7–1.3 mg/dL	88.4	62–115 μ mol/L
Female (adults)	0.6–1.1 mg/dL	88.4	53–97 μ mol/L
Cyclosporin			
Renal transplant	100–300 ng/mL or mcg/L	0.832	83–250 nmol/L
Cardiac, liver, or pancreatic transplant	200–350 ng/mL or mcg/L	0.832	166–291 nmol/L
Cryptococcal antigen	Negative		
D-dimers	Less than 250 ng/mL	1	Less than 250 mcg/L
Desipramine	75–300 ng/mL or mcg/L	3.75	281–1125 nmol/L
Dexamethasone suppression test (DST) (overnight)	8:00 am cortisol less than 5 mcg/dL	0.0276	Less than 0.14 μ mol/L
DHEAS			
Male	170–670 mcg/dL	0.0271	4.6–18.2 μ mol/L
Female			
Premenopausal	50–540 mcg/dL	0.0271	1.4–14.7 μ mol/L
Postmenopausal	30–260 mcg/dL	0.0271	0.8–7.1 μ mol/L
Digoxin, therapeutic	0.5–1.0 ng/mL or mcg/L	1.28	0.6–1.3 nmol/L
Erythrocyte count (blood) See under Red blood cell count			
Erythrocyte sedimentation rate (ESR)			
Westergren			
Male	0–20 mm/hour		
Female	0–30 mm/hour		
Wintrobe			
Male	0–9 mm/hour		
Female	0–15 mm/hour		
Erythropoietin	2–25 mIU/mL	1	2–25 IU/L
Estradiol			
Male	10–36 pg/mL	3.67	37–132 pmol/L
Female	34–170 pg/mL	3.67	125–624 pmol/L
Ethanol, legal intoxication	Greater than or equal to 50–100 mg/dL	0.217	10.9–21.7 mmol/L
	Greater than or equal to 0.05–0.1%	217	
Ethosuccimide, therapeutic	40–100 mg/L or mcg/mL	7.08	283–708 μ mol/L
Factor VIII or factor IX			
Severe hemophilia	Less than 1 IU/dL	0.01	Less than 0.01 units/mL
Moderate hemophilia	1–5 IU/dL	0.01	0.01–0.05 units/mL
Mild hemophilia	Greater than 5 IU/dL	0.01	Greater than 0.05 units/mL
Usual adult levels	60–140 IU/dL	0.01	0.60–1.40 units/mL
Ferritin			
Male	20–250 ng/mL	1	20–250 mcg/L
Female	10–150 ng/mL	1	10–150 mcg/L
Fibrin degradation products (FDP)	2–10 mg/L		
Fibrinogen	200–400 mg/dL	0.01	2.0–4.0 g/L
Folate (plasma)	3.1–12.4 ng/mL	2.266	7.0–28.1 nmol/L
Folic acid (RBC)	125–600 ng/mL	2.266	283–1360 nmol/L
Follicle-stimulating hormone (FSH)			
Male	1–7 mIU/mL	1	1–7 IU/L
Female			
Follicular phase	1–9 mIU/mL	1	1–9 IU/L
Midcycle	6–26 mIU/mL	1	6–26 IU/L
Luteal phase	1–9 mIU/mL	1	1–9 IU/L
Postmenopausal	30–118 mIU/mL	1	30–118 IU/L
Free thyroxine index (FT ₄ I)	6.5–12.5		
Gamma glutamyl transferase (GGT)	0–30 IU/L	0.01667	0–0.5 μ kat/L
Gastrin (fasting)	0–130 pg/mL	1	0–130 ng/L
Gentamicin, therapeutic	4–10 mg/L peak	2.09	8.4–21 μ mol/L peak
	Less than or equal to 2 mg/L trough		Less than or equal to 4.2 μ mol/L trough
Globulin	2.3–3.5 g/dL	10	23–35 g/L
Glucose (fasting, plasma)	65–109 mg/dL	0.0555	3.6–6.00 mmol/L
Glucose, two hour postprandial blood (PPBG)	Less than 140 mg/dL	0.0555	Less than 7.8 mmol/L
Granulocyte count	1.8–6.6 $\times 10^3/\mu$ L	10 ⁶	1.8–6.6 $\times 10^3$ /L
Growth hormone (fasting)			
Male	Less than 5 ng/mL	1	Less than 5 mcg/L
Female	Less than 10 ng/mL	1	Less than 10 mcg/L

(continued on back inside cover)

Laboratory	Conventional Units	Conversion Factor	SI Units
Haptoglobin	60–270 mg/dL	0.01	0.6–2.7 g/L
HBeAg	Negative		
HbsAg	Negative		
HBV DNA	Negative		
Hematocrit			
Male	40.7–50.3%	0.01	0.407–0.503
Female	36.1–44.3%	0.01	0.361–0.443
Hemoglobin (blood)			
Male	13.8–17.2 g/dL	10	138–172 g/L
Female	12.1–15.1 g/dL	Alternate SI: 0.62 10	8.56–10.67 mmol/L 121–151 g/L
Hemoglobin A1c	4.0–6.0%	Alternate SI: 0.62 0.01	7.5–9.36 mmol/L 0.04–0.06
Heparin			
Via protamine titration method	0.2–0.4 mcg/mL		
Via anti-factor Xa assay	0.3–0.7 mcg/mL		
High-density lipoprotein (HDL) cholesterol	Greater than 35 mg/dL	0.0259	Greater than 0.91 mmol/L
Homocysteine	3.3–10.4 μ mol/L		
Ibuprofen			
Therapeutic	10–50 mcg/mL	4.85	49–243 μ mol/L
Toxic	100–700 mcg/mL or more	4.85	485–3395 μ mol/L or more
Imipramine, therapeutic	100–300 ng/mL or mcg/L	3.57	357–1071 nmol/L
Immunoglobulin A (IgA)	85–385 mg/dL	0.01	0.85–3.85 g/L
Immunoglobulin G (IgG)	565–1765 mg/dL	0.01	5.65–17.65 g/L
Immunoglobulin M (IgM)	53–375 mg/dL	0.01	0.53–3.75 g/L
Insulin (fasting)	2–20 microunits/mL or milliunits/L	7.175	14.35–143.5 pmol/L
International normalized ratio (INR), therapeutic	2.0–3.0 (2.5–3.5 for some indications)		
Iron			
Male	45–160 mcg/dL	0.179	8.1–31.3 μ mol/L
Female	30–160 mcg/dL	0.179	5.4–31.3 μ mol/L
Iron binding capacity (total)	220–420 mcg/dL	0.179	39.4–75.2 μ mol/L
Iron saturation	15–50%	0.01	0.15–0.50
Lactate (plasma)	0.7–2.1 mEq/L	1	0.7–2.1 mmol/L
	6.3–18.9 mg/dL	0.111	
Lactate dehydrogenase	100–250 IU/L	0.01667	1.67–4.17 μ kat/L
Lead	Less than 25 mcg/dL	0.0483	Less than 1.21 μ mol/L
Leukocyte count	3.8–9.8 $\times 10^3/\mu$ L	10 ⁶	3.8–9.8 $\times 10^3$ /L
Lidocaine, therapeutic	1.5–6.0 mcg/mL or mg/L	4.27	6.4–25.6 μ mol/L
Lipase	Less than 100 IU/L	0.01667	1.7 μ kat/L
Lithium, therapeutic	0.5–1.25 mEq/L	1	0.5–1.25 mmol/L
Low-density lipoprotein (LDL) cholesterol			
Desirable	Less than 130 mg/dL	0.0259	Less than 3.36 mmol/L
Borderline high risk	130–159 mg/dL	0.0259	3.36–4.11 mmol/L
High risk	Greater than or equal to 160 mg/dL	0.0259	Greater than or equal to 4.13 mmol/L
Luteinizing hormone (LH)			
Male	1–8 milliunits/mL	1	1–8 units/L
Female			
Follicular phase	1–12 milliunits/mL	1	1–12 units/L
Midcycle	16–104 milliunits/mL	1	16–104 units/L
Luteal phase	1–12 milliunits/mL	1	1–12 units/L
Postmenopausal	16–66 milliunits/mL	1	16–66 units/L
Lymphocyte count	1.2–3.3 $\times 10^3/\mu$ L	10 ⁶	1.2–3.3 $\times 10^3$ /L
Magnesium	1.3–2.2 mEq/L	0.5	0.65–1.10 mmol/L
	1.58–2.68 mg/dL	0.411	0.65–1.10 mmol/L
Mean corpuscular volume	80.0–97.6 μ m ³	1	80.0–97.6 fL
Mononuclear cell count	0.2–0.7 $\times 10^3/\mu$ L	10 ⁶	0.2–0.7 $\times 10^3$ /L
Nortriptyline, therapeutic	50–150 ng/mL or mcg/L	3.8	190–570 nmol/L
NT-ProBNP (see Pro-BNP)			
Osmolality (serum)	275–300 mOsm/kg	1	275–300 mmol/kg
Osmolality (urine)	250–900 mOsm/kg	1	250–900 mmol/kg
Parathyroid hormone (PTH), intact	10–60 pg/mL or ng/L	0.107	1.1–6.4 pmol/L
Parathyroid hormone (PTH), N-terminal	8–24 pg/mL or ng/L		
Parathyroid hormone (PTH), C-terminal	50–330 pg/mL or ng/L		
Phenobarbital, therapeutic	15–40 mcg/mL or mg/L	4.31	65–172 μ mol/L
Phenytoin, therapeutic	10–20 mcg/mL or mg/L	3.96	40–79 μ mol/L
Phosphate	2.5–4.5 mg/dL	0.323	0.81–1.45 mmol/L
Platelet count	140–440 $\times 10^3/\mu$ L	10 ⁶	140–440 $\times 10^3$ /L
Potassium (plasma)	3.3–4.9 mEq/L	1	3.3–4.9 mmol/L
Prealbumin (adult)	19.5–35.8 mg/dL	10	195–358 mg/dL
Primidone, therapeutic	5–12 mcg/mL or mg/L	4.58	23–55 μ mol/L
ProBNP	Less than 125 pg/mL or ng/L	0.118	Less than 14.75 pmol/L
Procainamide, therapeutic	4–10 mcg/mL or mg/L	4.23	17–42 μ mol/L
Progesterone			
Male	13–97 ng/dL	0.0318	0.4–3.1 nmol/L
Female			
Follicular phase	15–70 ng/dL		0.5–2.2 nmol/L
Luteal phase	200–2500 ng/dL		6.4–79.5 nmol/L
Prolactin	Less than 20 ng/mL	1	Less than 20 mcg/L
Prostate-specific antigen (PSA)	Less than 4 ng/mL	1	Less than 4 mcg/L
Protein, total	6.0–8.0 g/dL	10	60–80 g/L
Prothrombin time (PT)	10–12 seconds		
Quinidine, therapeutic	2–5 mcg/mL or mg/L	3.08	6.2–15.4 μ mol/L
Radioactive iodine uptake (RAIU)	Less than 6% in 2 hours		
Red blood cell (RBC) count (blood)			
Male	4–6.2 $\times 10^6/\mu$ L	10 ⁶	4–6.2 $\times 10^{12}$ /L
Female	4–6.2 $\times 10^6/\mu$ L	10 ⁶	4–6.2 $\times 10^{12}$ /L
Pregnant			
Trimester 1	4–5 $\times 10^6/\mu$ L	10 ⁶	4–5 $\times 10^{12}$ /L
Trimester 2	3.2–4.5 $\times 10^6/\mu$ L	10 ⁶	3.2–4.5 $\times 10^{12}$ /L
Trimester 3	3–4.9 $\times 10^6/\mu$ L	10 ⁶	3–4.9 $\times 10^{12}$ /L
Post partum	3.2–5 $\times 10^6/\mu$ L	10 ⁶	3.2–5 $\times 10^{12}$ /L

(continued)

Laboratory	Conventional Units	Conversion Factor	SI Units
Red blood cell distribution width (RDW)	11.5–14.5%	0.01	0.115–0.145
Reticulocyte count			
Male	0.5–1.5% of total RBC count	0.01	0.005–0.015
Female	0.5–2.5% of total RBC count	0.01	0.005–0.025
Retinol-binding protein (RBP)	2.7–7.6 mg/dL	10	27–76 mg/L
Rheumatoid factor (RF) titer	Negative		
Salicylate, therapeutic	150–300 mcg/mL or mg/L	0.00724	1.09–2.17 mmol/L
	15–30 mg/dL	0.0724	
Sodium	135–145 mEq/L	1	135–145 mmol/L
Tacrolimus			
Renal transplant	6–12 ng/mL or mcg/L		
Liver transplant	4–10 ng/mL or mcg/L		
Pancreatic transplant	10–18 ng/mL or mcg/L		
Bone marrow transplant	10–20 ng/mL or mcg/L		
Testosterone (total)			
Men	300–950 ng/dL	0.0347	10.4–33.0 nmol/L
Women	20–80 ng/dL		0.7–2.8 nmol/L
Testosterone (free)			
Men	9–30 ng/dL	0.0347	0.31–1.04 nmol/L
Women	0.3–1.9 ng/dL		0.01–0.07 nmol/L
Theophylline			
Therapeutic	5–15 mcg/mL or mg/L	5.55	28–83 μ mol/L
Toxic	20 or more mcg/mL or mg/L	5.55	111 or more μ mol/L
Thrombin time	20–24 seconds		
Thyroglobulin	Less than 42 ng/mL	1	Less than 42 mcg/L
Thyroglobulin antibodies	Negative		
Thyroxine-binding globulin (TBG)	1.2–2.5 mg/dL	10	12–25 mcg/L
Thyroid-stimulating hormone (TSH)	0.35–6.20 microunits/mL	1	0.35–6.20 milliunits/L
TSH receptor antibodies (TSH Rab)	0–1 unit/mL		
Thyroxine (T_4)			
Total	4.5–12.0 mcg/dL	12.87	58–155 nmol/L
Free	0.7–1.9 ng/dL	12.87	9.0–24.5 pmol/L
Thyroxine index, free (FT_4)	6.5–12.5		
TIBC (See Iron-binding capacity [total])			
Tobramycin, therapeutic	4–10 mcg/mL or mg/L peak	2.14	8.6–21.4 μ mol/L
	Less than or equal to 2 mcg/mL mg/L trough	2.14	Less than or equal to 4.28 μ mol/L
Transferrin	200–430 mg/dL	0.01	2.0–4.3 g/L
Transferrin saturation	30–50%	0.01	0.30–0.50
Triglycerides (fasting)	Less than 160 mg/dL	0.0113	Less than 1.8 mmol/L
Triiodothyronine (T_3)	45–132 ng/dL	0.0154	0.91–2.70 nmol/L
Triiodothyronine (T_3) resin uptake	25–35%		
Troponin I	Less than 0.6 ng/mL	1	Less than 0.6 μ g/L
Uric acid	3–8 mg/dL	59.48	179–476 μ mol/L
Urinalysis (urine)			
pH	4.8–8.0		
Specific gravity	1.005–1.030		
Protein	Negative		
Glucose	Negative		
Ketones	Negative		
RBC	1–2 per low-power field		
WBC	3–4 per low-power field		
Valproic acid, therapeutic	50–100 mcg/mL or mg/L	6.93	346–693 μ mol/L
Vancomycin, therapeutic trough for CNS infections	20–40 mcg/mL or mg/L peak	0.690	14–28 μ mol/L peak
	5–20 mcg/mL or mg/L trough	0.690	3–14 μ mol/L trough
	15–20 mcg/mL or mg/L trough	0.690	10–14 μ mol/L trough
Vitamin A (retinol)	30–95 mcg/dL	0.0349	1.05–3.32 μ mol/L
Vitamin B_{12}	180–1000 pg/mL	0.738	133–738 pmol/L
Vitamin D_3 , 1, 25-dihydroxy	20–76 pg/mL	2.4	48–182 pmol/L
Vitamin D_3 , 25-hydroxy	10–50 ng/mL	2.496	25–125 nmol/L
Vitamin E (alpha tocopherol)	0.5–2.0 mg/dL	23.22	12–46 μ mol/L
WBC count	$4-10 \times 10^3/\mu\text{L}$ or $4-10 \times 10^3/\text{mm}^3$	10^6	$4-10 \times 10^9/\text{L}$
WBC differential (peripheral blood)			
Polymorphonuclear neutrophils (PMNs)	50–65%		
Bands	0–5%		
Eosinophils	0–3%		
Basophils	1–3%		
Lymphocytes	25–35%		
Monocytes	2–6%		
WBC differential (bone marrow)			
Polymorphonuclear neutrophils (PMNs)	3–11%		
Bands	9–15%		
Metamyelocytes	9–25%		
Myelocytes	8–16%		
Promyelocytes	1–8%		
Myeloblasts	0–5%		
Eosinophils	1–5%		
Basophils	0–1%		
Lymphocytes	11–23%		
Monocytes	0–1%		
Zinc	60–150 mcg/dL	0.153	9.2–23.0 μ mol/L

This table is a modification of the Medical Algorithms Project (Chapter 40), unit conversions of the following Excel worksheets: Conversion of Conventional to SI units: Blood Chemistries; Conversion of Conventional to SI units: Urine Chemistries; Conversion of Conventional to SI units: Hematology and Coagulation; and Conversion of Conventional to SI units: Therapeutic Drug Monitoring.
