- Antithyroid peroxidase antibodies and antithyroglobulin antibodies are likely to be elevated in autoimmune thyroiditis.
- An increase in the TSH level is the first evidence of primary hypothyroidism. Many patients will have a free T_4 level within the normal range (compensated hypothyroidism) and few, if any, symptoms of hypothyroidism. As the disease progresses the free T_4 concentration will drop below the normal level. Interestingly, as a result of TSH stimulation, thyroidal production will shift toward greater amounts of T_3 , and thus T_3 concentrations will often be maintained in the normal range in spite of a low T_4 . The RAIU is not a useful test in the evaluation of a hypothyroid patient, as it can be low, normal, or even elevated.

CAUSES OF HYPOTHYROIDISM

Table 78–7 outlines the causes of hypothyroidism.

Chronic Autoimmune Thyroiditis

8 Autoimmune thyroiditis (Hashimoto's disease) is the most common cause of spontaneous hypothyroidism in the adult.¹⁰³ Patients can present with either goitrous thyroid gland enlargement and mild hypothyroidism, or thyroid gland atrophy and more severe thyroid hormone deficiency. Both forms of autoimmune thyroiditis probably result from cell- and antibody-mediated thyroid injury. The bulk of evidence suggests that the presence of specific defects in suppressor T-lymphocyte function leads to the survival of a randomly mutating clone of helper T lymphocytes, which are directed against normally occurring antigens on the thyroid membrane. Once these T lymphocytes interact with thyroid membrane antigen, B lymphocytes are stimulated to produce thyroid antibodies.¹⁰⁴

TABLE 78-7 Causes of Hypothyroidism

Primary hypothyroidism

Enzyme defects
Thyroid hypoplasia
Goitrogens

Secondary hypothyroidism

Pituitary disease
Hypothalamic disease

Antimicrosomal antibodies are present in virtually all patients with Hashimoto's thyroiditis and appear to be directed against the enzyme thyroid peroxidase.¹⁰⁵ These antibodies are capable of fixing complement and inducing cytotoxic changes in thyroid cells. Antibodies that are capable of stimulating thyroid growth through interaction with the TSH receptor can occasionally be found particularly in goitrous hypothyroidism; conversely, antibodies that inhibit the trophic effects of TSH are present in the atrophic type.

Iatrogenic Hypothyroidism

Iatrogenic hypothyroidism follows exposure to excessive amounts of radiation (radioiodine or external radiation) or surgery. Hypothyroidism occurs within 3 months to a year after ^{131}I therapy in most patients treated for Graves' disease. Thereafter it occurs at a rate of approximately 2.5% each year. External radiation therapy to the region of the thyroid using doses of greater than 2,500 cGy for therapy of neck carcinoma also causes hypothyroidism. This effect is dose-dependent, and more than 50% of patients who receive more than 4,000 cGy to the thyroid bed develop hypothyroidism. Total thyroidectomy causes hypothyroidism within 1 month.

Other Causes of Primary Hypothyroidism

Iodine deficiency, enzymatic defects within the thyroid gland, thyroid hypoplasia, and maternal ingestion of goitrogens during fetal development can cause cretinism. Early recognition and treatment of the resultant thyroid hormone deficiency is essential for optimal mental development.^{106,107} Large-scale neonatal screening programs in North America, Europe, Japan, and Australia are now in place.¹⁰⁸ The frequency of congenital hypothyroidism in North America and Europe is 1 per 3,500 to 4,000 live births. In the United States, there are racial differences in the incidence of congenital hypothyroidism, with whites being affected seven times as frequently as blacks.

In the adult, hypothyroidism can rarely be caused by iodine deficiency and goitrogens. Rarely, iodine ingestion in the form of expectorants can lead to hypothyroidism. In sensitive persons (particularly those with autoimmune thyroiditis), the iodide blocks the synthesis of thyroid hormone, leading to an increased secretion of TSH and thyroid enlargement. Thus both iodine excess and iodine deficiency can cause decreased secretion of thyroid hormone.

Causes of Secondary Hypothyroidism

Pituitary Disease TSH is required for normal thyroid secretion. Thyroid atrophy and decreased thyroid secretion follow pituitary failure. Pituitary insufficiency can be caused by destruction of thyrotrophs by either functioning or nonfunctioning pituitary tumors, surgical therapy, external pituitary radiation, postpartum pituitary necrosis (Sheehan's syndrome), trauma, and infiltrative processes of the pituitary such as metastatic tumors, tuberculosis, histiocytosis, and autoimmune mechanisms.^{109,110} In all these situations, TSH deficiency most often occurs in association with other pituitary hormone deficiencies. The identification of secondary hypothyroidism because of bexarotene use has led to recognition of the role of retinoids and retinoids to cause dysregulation of TSH production.^{22,111}

In most hypothyroid patients with pituitary disease, serum TSH concentrations are generally low or normal. A serum TSH concentration in the normal range is clearly inappropriate if the patient's T_4 is low.

Note that pituitary enlargement in hypothyroidism does not invariably indicate the presence of a primary pituitary tumor. Pituitary enlargement is seen in patients with severe primary hypothyroidism because of compensatory hyperplasia and hypertrophy of the thyrotrophs.¹¹² With thyroid hormone replacement therapy, serum TSH concentrations decline, indicating that the TSH secretion is not autonomous, and the pituitary resumes a more

normal configuration. These patients are easily separated from patients with primary pituitary failure by measuring a TSH level.

Hypothalamic Hypothyroidism TRH deficiency also causes a rare form of central hypothyroidism. In both adults and children it can occur as a result of cranial irradiation, trauma, infiltrative diseases, or neoplastic diseases.

TREATMENT

Hypothyroidism

■ PHARMACOLOGIC THERAPY

Desired Outcomes

The goals of therapy are to restore normal thyroid hormone concentrations in tissue, provide symptomatic relief, prevent neurologic deficits in newborns and children, and reverse the biochemical abnormalities of hypothyroidism.

General Approach

Any of the commercially available thyroid preparations accomplish this goal (Table 78–8); however, levothyroxine (L-thyroxine; T₄) is considered to be the drug of choice. The thyroid preparations are either natural (i.e., desiccated thyroid and thyroglobulin) or synthetic (levothyroxine, liothyronine, and liotrix) in origin. The availability of sensitive and specific assays for total and free hormone levels as well as TSH now allow more definitive dose titration to allow adequate replacement without inadvertent overdose. The response of TSH to TRH had been advocated for use by for “fine-tuning” thyroid replacement, but this is not necessary if the sensitive immunoradiometric assays for TSH are used. Minimum clinical guidelines for the treatment of hypothyroidism have been published by the American Thyroid Association⁵⁶ and the American Association of Clinical Endocrinologists.¹¹³

Natural Thyroid Hormones

Desiccated thyroid is derived from hog, beef, or sheep thyroid gland. The *United States Pharmacopeia, 23rd Edition*, requires thyroid USP

to contain 38 mcg (±15%) of levothyroxine and 9 mcg (±10%) of liothyronine for each 65 mg (1 grain) of the labeled content of thyroglobulin. Thyroglobulin USP should contain 36 mcg (±15%) of levothyroxine and 12 mcg (±10%) of liothyronine for each 65 mg (1 grain) of the labeled content of thyroglobulin. Not all generic brands can be bioequivalent, and switching among brands in patients stabilized on one product should be discouraged. Thyroid USP, as an animal protein–derived product, can be antigenic in allergic or sensitive patients. Even though desiccated thyroid is inexpensive, its limitations preclude it from being considered as a drug of choice for hypothyroid patients. Thyroglobulin is a purified hog-gland extract, but it has no clinical advantages and is not widely used.

Synthetic Thyroid Hormones

Levothyroxine (T₄; L-thyroxine) is the drug of choice for thyroid replacement and suppressive therapy because it is chemically stable, relatively inexpensive, and free of antigenicity, and has uniform potency. Whereas T₃ and not T₄ is the biologically more active form of thyroid hormone, levothyroxine administration results in a pool of thyroid hormone that is readily and consistently converted to T₃; in this regard levothyroxine can be thought of as a prohormone. The half-life of levothyroxine is approximately 7 days. This long half-life is responsible for a stable pool of prohormone and the need for only once-daily dosing with levothyroxine. Older studies with levothyroxine suggested that bioavailability was low and erratic; however, this product has been reformulated, and the average bioavailability is now approximately 80%.^{114–116} The bioavailability of Synthroid, Levoxine, and generic levothyroxine preparations were compared in a blinded, randomized, four-way crossover trial.¹¹⁷ The study was sponsored by the manufacturers of Synthroid, who have challenged the authors’ conclusions that the levothyroxine preparations are bioequivalent and should be interchangeable for the majority of patients. However, because the relationship between T₄ concentration and TSH is not linear, very small changes in T₄ concentration can lead to substantial changes in TSH, which is a more accurate reflection of hormone replacement status. Currently, the Food and Drug Administration mandates that levothyroxine bioequivalency testing be done in normal volunteers (600 mcg in the fasted state) and three baseline free-T₄ concentrations be used to correct for endogenous T₄ production. Bioequivalency is based on the area under the curve (AUC) and

TABLE 78-8 Thyroid Preparations Used in the Treatment of Hypothyroidism			
Drug/Dosage Form	Content	Relative Dose	Comments/Equivalency
Thyroid USP			
Armour Thyroid (T ₄ :T ₃ ratio) 9.5 mcg:2.25 mcg, 19 mcg:4.5 mcg, 38 mcg:9 mcg, 57 mcg:13.5 mcg, 76 mcg:18 mcg, 114 mcg:27 mcg, 152 mcg:36 mcg, 190 mcg:45 mcg tablets	Desiccated beef or pork thyroid gland	1 grain (equivalent to 60 mcg of T ₄)	Unpredictable hormonal stability, inexpensive generic brands may not be bioequivalent
Thyroglobulin			
Prolid 32-mg, 65-mg, 100-mg, 130-mg, 200-mg tablets	Partially purified pork thyroglobulin	1 grain	Standardized biologically to give T ₄ :T ₃ ratio of 2.5:1; more expensive than thyroid extract; no clinical advantage
Levothyroxine			
Synthroid, Levothyroid, and other generics 25-, 50-, 75-, 88-, 100-, 112-, 125-, 137-, 150-, 175-, 200-, 300-mcg tablets; 200- and 500-mcg/vial injection	Synthetic T ₄	50–60 mcg	Stable; predictable potency; generics are bioequivalent; when switching from natural thyroid to L-thyroxine, lower dose by 1/2 grain; variable absorption between products; half-life = 7 days, so daily dosing; considered to be drug of choice
Levoxyl, Thyro-Tabs, Unithroid			
Liothyronine			
Cytomel 5-, 25-, and 50-mcg tablets	Synthetic T ₃	15–37.5 mcg	Uniform absorption, rapid onset; half-life = 1.5 days, monitor TSH assays
Liotrix			
Thyrolar 1/4-, 1/2-, 1-, 2-, and 3-strength tablets	Synthetic T ₄ :T ₃ in 4:1 ratio	50–60 mcg T ₄ and 12.5–15 mcg T ₃	Stable; predictable; expensive; lacks therapeutic rationale because T ₄ is converted to T ₃ peripherally

TSH, thyroid-stimulating hormone; T₃, triiodothyrene; T₄, thyroxine.

maximum concentration (C_{\max}) of T_4 out to 48 hours. Approximately 70% of the AUC is derived from endogenous production. TSH is not considered, and it is now very clear that T_4 is too insensitive as a measure of bioequivalency.^{118,119} To avoid over- and undertreatment, once a product is selected, therapeutic interchange should be discouraged. Currently, there are nine levothyroxine products available, and a number of permutations for interchange are available considering that there are AB1, AB2, AB3 and BX products available as no reference listed drug is mandated in bioequivalency testing. The time to maximal absorption is 2 hours, and this should be considered when T_4 and TSH concentrations are determined. Mucosal diseases such as sprue, diabetic diarrhea, and ileal bypass surgery can also reduce absorption. Cholestyramine, calcium carbonate, sucralfate, aluminum hydroxide,¹²⁰ ferrous sulfate,¹²¹ soybean formula,¹²² and dietary fiber supplements¹²³ can also impair the absorption of levothyroxine from the gastrointestinal tract. Acid suppression with histamine blockers and proton pump inhibitors can also reduced levothyroxine absorption. Drugs that increase T_4 clearance include rifampin, carbamazepine, and possibly phenytoin. Selenium deficiency and amiodarone can block the conversion of T_4 to T_3 .

Liothyronine (T_3) is chemically pure with known potency and has a shorter half-life of 1.5 days. Although it is widely used diagnostically in the T_3 -suppression test, T_3 has some clinical disadvantages, including a higher incidence of cardiac adverse effects, higher cost, and difficulty in monitoring with conventional laboratory tests. Liotrix is a combination of synthetic T_4 and T_3 in a 4:1 ratio that attempts to mimic natural hormonal secretion. It is chemically stable and pure and has a predictable potency. The major limitations to this product are high cost and lack of therapeutic rationale because approximately 35% of T_4 is peripherally converted T_3 .

Trials comparing levothyroxine alone to a combination of levothyroxine plus partial replacement with liothyronine (T_3) have generally shown that combinations of T_4 plus T_3 are no better than T_4 alone.^{124,125} Clyde and colleagues in a trial of combination therapy, when compared with levothyroxine alone, treatment of primary hypothyroidism with combination levothyroxine plus liothyronine demonstrated no beneficial changes in body weight, serum lipid levels, hypothyroid symptoms as measured by a health-related quality of life questionnaire, and standard measures of cognitive performance.¹²⁵

Dosing and Monitoring During the mid-1980s the average dose of levothyroxine was approximately 160 mcg/day. With the advent of more sensitive assay methods for TSH and the reformulation of levothyroxine, it is now apparent that many patients have been treated with excessive amounts of levothyroxine. More recent studies suggest that the average maintenance dose for most adults should be closer to about 125 mcg per day.¹⁰¹ Indeed, as many as one-third of patients receiving levothyroxine 150 mcg daily will be over-replaced. There is, however, a wide range of replacement doses, necessitating individualized therapy and appropriate TSH monitoring to determine an adequate but not excessive dose.

The initial dose of levothyroxine is dependent on the patient's age, and the presence of associated disorders, as well as the severity and duration of hypothyroidism.¹²⁶ Most patients will require approximately 1.7 mcg/kg/day once they reach steady state for full replacement. In young patients with long-standing disease and patients older than 45 years of age without known cardiac disease, therapy should be initiated with 50 mcg daily of levothyroxine and increased to 100 mcg daily after 1 month. The recommended initial daily dose for older patients or those with known cardiac disease is 25 mcg per day titrated upward in increments of 25 mcg at monthly intervals to prevent stress on the cardiovascular system. Some patients can experience an exacerbation of angina with higher doses of thyroid hormone. Although the TSH is very sensitive for under- or overreplacement, clinicians often fail to alter the dose of T_4 based on TSH clearly outside of the normal range.^{127,128}

Patients with subclinical or mild hypothyroidism (seen more commonly in the elderly and women) have no or few signs or symptoms, normal serum T_3 and T_4 concentrations, and an elevated basal TSH concentration.^{129,130} The prevalence of this disorder in the NHANES III study was found to be 4.3%.¹⁸ Although the treatment of subclinical hypothyroidism is controversial, patients presenting with marked elevations in TSH (>10 mIU/L) and high titers of thyroperoxidase antibody (TPO Ab) or prior treatment with ^{131}I can be most likely to benefit from treatment. Other patients who can improve with replacement include those with mild symptoms of hypothyroidism and depression. It should be noted that some studies find that only one of four treated patients experienced improvement.¹³¹ Conservative treatment goals in this situation would be to maintain serum T_4 and T_3 levels in the normal range and reduce TSH to a value of 1 mIU/L.

Once euthyroidism is attained, the daily maintenance dose of levothyroxine does not fluctuate greatly. As patients age, the dosing requirement can need to be reduced.¹¹³ The ability to measure serum TSH concentrations has improved the accuracy with which thyroid hormone replacement can be monitored. Many clinicians now consider serum TSH concentration to be the most sensitive and specific monitoring parameter for adjustment of levothyroxine dose. Plasma TSH concentrations begin to fall within hours and are usually normalized within 2 weeks but can take up to 6 weeks in some patients, depending on the baseline value. TSH and T_4 concentrations are both used to monitor therapy, and they should be checked every 6 weeks until a euthyroid state is achieved. Serum T_4 concentrations can be useful in detecting noncompliance, malabsorption, or changes in levothyroxine product bioequivalence. An elevated TSH concentration indicates insufficient replacement. The appropriate dose maintains the TSH concentration in the normal range. T_4 disposal is accelerated by nephritic syndrome, other severe systemic illnesses, and several antiepileptic medications (phenobarbital, phenytoin, and carbamazepine) and rifampin. Pregnancy increases the T_4 dose requirement in 75% of women, probably because of increased degradation by the placental deiodinase. Initiating postmenopausal hormone replacement therapy increases the dose needed in 35% of women, perhaps because of an increased circulating T_4 -binding globulin level. Patient noncompliance with prescribed T_4 , the most common cause of inadequate treatment, might be suspected in patients with a dose that is higher than expected, variable thyroid function test results that do not correlate well with prescribed doses, and an elevated serum thyrotropin concentration with serum-free T_4 at the upper end of the normal range, which can suggest improved compliance immediately before testing because of a lag in the thyrotropin response. The metabolism of other pharmacologic agents can be altered in patients with hypothyroidism. The mechanism might be decreased expression of hepatic enzymes involved in drug metabolism, as seen in hypothyroid rats. As a result, increased sensitivity to anesthetic and sedative agents and higher serum levels of phenytoin have been reported. Hypothyroidism can also cause higher serum digoxin values, an effect attributed to a decreased volume of drug distribution. Conversely, hypothyroidism might decrease sensitivity to warfarin because of slowed metabolism of the vitamin K-dependent clotting factors, and restoration of euthyroidism can then increase the warfarin dose requirement.

In patients with hypothyroidism caused by hypothalamic or pituitary failure, alleviation of the clinical syndrome and restoration of serum T_4 to the normal range are the only criteria available for estimating the appropriate replacement dose of levothyroxine. Concurrent use of dopamine, dopaminergic agents (bromocriptine), somatostatin or somatostatin analogs (octreotide), and corticosteroids suppresses TSH concentrations and can confound the interpretation of this monitoring parameter.¹¹³

TSH-suppressive levothyroxine therapy can also be given to patients with nodular thyroid disease and diffuse goiter, to patients with a

history of thyroid irradiation, and to patients with thyroid cancer. The rationale for suppression therapy is to reduce TSH secretion, which promotes growth and function in abnormal thyroid tissue. In patients with solitary nodules who have not received radiation, TSH should be suppressed to 0.05 to 0.1 mIU/L in premenopausal women and in men <60 years old. A dose of levothyroxine of 100 to 150 mcg per day is usually sufficient. In men older than 60 years of age and postmenopausal women, TSH levels should be reduced to 0.1 to 0.3 mIU/L because of the risk of more serious adverse effects in this population and reduced clearance of levothyroxine with advanced age. Levothyroxine can be given in nontoxic MNG to suppress the TSH to low-normal levels of 0.5 to 1 mIU/L if the baseline TSH is >1 mIU/L. Goiter size and thyroid volume can be reduced with suppression therapy. Diffuse goiter associated with autoimmune thyroiditis can also be treated with levothyroxine to reduce goiter size and thyroid volume. In patients with follicular or papillary thyroid cancer, current recommendations are to suppress the TSH to <0.02 mIU/L. Doses of levothyroxine of up to 2.2 to 2.5 mcg/kg can be needed to provide TSH levels of <0.02 mIU/L in this population, and free T₃ and T₄ levels are useful in detecting hyperthyroidism.¹³²

Adverse Effects Serious untoward effects are unusual if dosing is appropriate and the patient is carefully monitored during initial treatment. Levothyroxine replacement in athyrotic hypothyroid patients restores systolic and diastolic left ventricular performance within 2 weeks, and the use of levothyroxine can increase the frequency of atrial premature beats but not necessarily ventricular premature beats. Excessive doses of thyroid hormone can lead to heart failure, angina pectoris, and myocardial infarction; rarely, the latter can be caused by coronary artery spasm. Allergic or idiosyncratic reactions can occur with the natural animal-derived products such as desiccated thyroid and thyroglobulin, but these are extremely rare with the synthetic products used today. The 0.05-mg Synthroid tablet is the least allergenic (caused by a lack of dye and few excipients) and should be tried in the patient suspected to be allergic to thyroid hormone.

Hyper-remodeling of cortical and trabecular bone caused by hyperthyroidism leads to reduced bone density and can increase the risk of fracture. Compared with normal controls, excess exogenous thyroid hormone results in histomorphometric and biochemical changes similar to those observed in osteoporosis and untreated hyperthyroidism; however, at routinely used replacement doses, bone mineral density loss is less than that seen with untreated hyperthyroidism and only slightly greater than in controls.^{133,134} The risk for this complication of therapy seems to be related to the dose of levothyroxine, patient age, and gender. Markers for bone turnover include urinary cross-linked *N*-telopeptides, pyridinoline of type I collagen, osteocalcin, and bone-specific alkaline phosphatase. When doses of levothyroxine are used to suppress TSH concentrations to below-normal values (less than 0.3 mIU/L) in postmenopausal women, this adverse effect is more likely to be seen. Cortical bone is affected to a greater degree than trabecular bone at suppressive doses of 1-thyroxine. In contrast, it appears to be much less likely in men and in premenopausal women. Maintaining the TSH between 0.7 and 1.5 mIU/L with approximately 150 mcg/day of levothyroxine does not alter bone mineral density in premenopausal women.

SPECIAL CONDITIONS

Myxedema Coma

Myxedema coma is a rare consequence of decompensated hypothyroidism.^{135,136} Clinical features include hypothermia, advanced stages of hypothyroid symptoms, and altered sensorium ranging from delirium to coma. Mortality rates of 60% to 70% necessitate immediate and aggressive therapy. Traditionally, the initial treat-

ment has been intravenous bolus levothyroxine 300 to 500 mcg. However, as deiodinase activity is markedly reduced, impairing T₄ to T₃ conversion, initial treatment with intravenous T₃ or a combination of both hormones has also been advocated.¹³⁶ Glucocorticoid therapy with intravenous hydrocortisone 100 mg every 8 hours should be given until coexisting adrenal suppression is ruled out. Consciousness, lowered TSH concentrations, and normal vital signs are expected within 24 hours. Maintenance doses of levothyroxine are typically 75 to 100 mcg given intravenously until the patient stabilizes and oral therapy is begun. Supportive therapy must be instituted to maintain adequate ventilation, euglycemia, blood pressure, and body temperature. Any underlying disorder, such as sepsis or myocardial infarction, obviously must be diagnosed and treated.

Congenital Hypothyroidism¹³⁷

In congenital hypothyroidism, full maintenance therapy should be instituted early to improve the prognosis for mental and physical development.¹³⁸ The average maintenance dose in infants and children depends on the age and weight of the child. Several studies demonstrate that aggressive therapy with levothyroxine is important for normal development and current recommendations are for initiation of therapy within 45 days of birth at a dose of 10 to 15 mcg/kg per day.¹⁰⁸ This dose is used to keep T₄ concentrations at about 10 mcg/dL within 30 days of starting therapy and is associated with improved intelligence quotients (IQs) in treated infants. The dose is progressively decreased to a typical adult dose as the child ages, the adult dose being given in the age range of 11 to 20 years.

Hypothyroidism in Pregnancy⁸⁶

Hypothyroidism during pregnancy leads to an increased rate of stillbirths and possibly lower psychologic scores in infants born of women who received inadequate replacement during pregnancy.¹³⁹ Thyroid hormone is necessary for fetal growth and must come from the maternal side during the first 2 months of gestation. Although liothyronine can cross the placental membrane slightly better than levothyroxine, the latter is considered to be the drug of choice. The objective of treatment is to decrease TSH to 1 unit/mL and maintain free T₄ concentrations in the normal range. Based on elevated TSH levels during pregnancy, it was found that the mean dose of levothyroxine had to be increased by 36 mcg/day to suppress TSH into the normal range. Increased production of binding proteins, a marginal decrease in free hormone concentration, modification of peripheral thyroid hormone metabolism, and increased T₄ metabolism by the fetal-placental unit also contributes to increased thyroid hormone demand and the need for increased doses decreases after delivery.⁸⁷ Up to 60% of women need to have levothyroxine dose adjustment during pregnancy. Upward adjustment will be needed by week 8 of pregnancy. After delivery the levothyroxine can need to be reduced based on T₃ concentrations and measurement of TSH, typically approximately 6 to 8 weeks after delivery.⁸⁶

Effects of Hypothyroidism on Selected Medications

Hypothyroidism can affect the metabolism and clinical efficacy of several medications. Digitalis preparations have a decreased volume of distribution in the hypothyroid state, resulting in increased sensitivity to the digitalis effect. Therefore, many hypothyroid patients achieve a therapeutic effect at lower digitalis doses. Insulin degradation can be delayed in hypothyroidism, thereby requiring a lower insulin dose. Hypothyroidism delays the catabolism of clotting factors, and if a patient stabilized on warfarin is made euthyroid with levothyroxine, the patient can become excessively anticoagulated. Respiratory depressants such as barbiturates, phenothiazines, and opioid analgesics should be avoided, because increased sensitivity can increase carbon dioxide retention and precipitate myxedema coma.

RECOMBINANT TSH IN THYROID CANCER

Patients with previously treated differentiated (papillary, follicular, or their respective variants) thyroid carcinoma require lifelong monitoring for recurrent disease.^{140,141} Two diagnostic tests that play a central role in followup of these patients—serum thyroglobulin measurement and radioiodine whole body scanning—are most accurate during TSH stimulation. Temporary discontinuation of thyroid hormone therapy was previously the sole effective approach for TSH-stimulated testing. However, hormone withdrawal is associated with the morbidity of hypothyroidism and occasional tumor progression. The introduction of recombinant TSH (rTSH)-stimulated testing offers an alternative therapy. Recent clinical trials have shown that the sensitivity of combined rTSH-stimulated radioiodine scanning and serum thyroglobulin measurement has nearly equivalent sensitivity to testing after thyroid hormone withdrawal.^{111,142} Furthermore, measurement of the rTSH-stimulated thyroglobulin concentration is a more sensitive way to detect residual thyroid cancer or normal tissue than thyroglobulin measurement or thyroid hormone therapy alone. Post-thyroidectomy adjuvant radioiodine therapy can also be administered following rTSH, instead of thyroid hormone withdrawal, with equivalent rates of remnant ablation.¹⁴³ Patients in whom thyroid hormone withdrawal would be contraindicated can also be successfully treated with radioiodine following rTSH.¹⁴⁴

NONTHYROIDAL ILLNESS

A wide variety of abnormalities of hypothalamic-pituitary-thyroid function, serum thyroid hormone binding, and extrathyroidal thyroid hormone metabolism occur in patients with nonthyroidal illness.^{11,12} These abnormalities frequently result in decreased serum T_3 concentrations and, with more severe nonthyroidal disease, lead to a decreased serum free T_4 concentration as well. Serum TSH concentrations are usually within the normal range, although low levels can occur with severe or critical illness. The presence of coexisting primary hypothyroidism can be recognized in patients who have other illnesses by an elevation in the TSH concentration.

The degree and extent of the abnormality in thyroid function generally correlates with the severity of the nonthyroidal illness. These conditions are frequently referred to as the “euthyroid sick syndrome.” However, it is likely that these changes represent adaptive forms of hypothyroidism that serve to reduce the availability of thyroid hormones to lessen the catabolic impact of the nonthyroidal illness.

Decreased serum T_3 concentrations occur in patients with both acute and chronic illnesses. The fundamental cause of decreased serum T_3 concentrations in these situations is decreased extrathyroidal conversion of T_4 to T_3 , normally mediated by T_4 -5'-deiodinase. A circulating inhibitor of this enzyme, perhaps interleukin-6, is present in patients with nonthyroidal illness.¹⁴⁵ Serum total and free T_4 concentrations are usually normal in mild illness. The serum reverse T_3 concentration is characteristically high because the same enzyme, 5'-deiodinase, that is necessary to convert T_4 to T_3 , is necessary to convert reverse T_3 to its breakdown products.

Low serum T_4 is seen in most critically ill patients.^{146–148} This change is caused by diminished serum T_4 synthesis as well as impaired binding to serum transport proteins, resulting either from decreased serum concentrations of thyroid-binding globulin, thyroid-binding prealbumin, or albumin, or from inhibitors of T_4 binding. The free T_4 concentration is generally normal early in critical illness but also declines with more severe disease. This more severe degree of hypothyroidism, which occurs in severely ill patients, produces a greater reduction in thyroid hormone availabil-

ity. The low serum T_4 concentrations in patients with nonthyroidal illness indicates a grave prognosis. In two studies, more than 60% of hospitalized patients with a low serum free T_4 index died. Although controversial, T_4 or T_3 supplementation has been of no benefit in this situation and in fact has increased morbidity.

To confuse matters, some patients with nonthyroidal illness have elevation of their serum T_4 concentration. Most commonly, this is seen in patients with psychiatric disorders during acute psychotic breaks. Thyroid hormone levels return to normal within 2 weeks after successful treatment of the underlying psychiatric disease. The occurrence of these abnormalities requires that care be taken in diagnosing hypothyroidism or hyperthyroidism in patients who have nonthyroidal illnesses.

GOITROUS THYROID DISEASE

Endemic goiter is the major thyroid disease throughout the world, affecting more than 200 million people. Many goitrous glands contain one or more nodules. The introduction of iodide supplementation has eliminated goiter as a major medical problem in developed countries, although it continues to be a problem in developing countries with geographic positions that make them more susceptible to iodide deficiency. In 1924, Marine postulated that periods of iodide deficiency resulted in cyclic hyperplasia and involution of thyroid follicular cells with eventual development of nodular hyperplasia.^{44,149} This hypothesis is still used to explain goiter formation today. Whatever the specific cause, the final common pathway appears to result from an inadequate thyroid hormone secretion with compensatory TSH secretion and eventual thyroid gland enlargement. The essential factor for the conversion of a hyperplastic iodine-deficiency goiter into a colloid goiter appears to be an acute reduction of TSH stimulation; therefore, any situation that would result in a cyclical increase and decrease in TSH secretion might eventually result in the production of a nodular goiter.

There has been an interest in the possibility that growth factors other than TSH play a role in the development of a goiter. Immunoglobulin fractions capable of stimulating thyroid growth have been found in patients with nontoxic goiter and Graves' disease. In these patients, thyroid growth-promoting immunoglobulin titers correlate with goiter size rather than with the thyroid hormone concentration.

Sporadic goiter is defined as a goiter occurring in a nonendemic goiter region. Although a number of known goitrogens and errors in thyroid hormone biosynthesis can cause goiter, the majority of cases of sporadic goiter have no known etiology.

Treatment of all goiters is a trial of thyroid hormone suppression in an effort to eliminate TSH as a possible stimulus for continued thyroid growth. Large, long-standing goiters seldom undergo significant reduction in size. If the patient is symptomatic (with dysphagia or dyspnea) or there is a question of malignant thyroid involvement, surgery is recommended.

PHARMACOECONOMIC CONSIDERATIONS

Although the initial expense of surgery would seem to make it the most expensive treatment option, the relapse rates for thionamides and RAI are higher and in longer-term followup, there is not much difference between treatment options nor patients' opinions concerning treatment preferences.¹⁵⁰ The cost proportion between the medical and surgical treatment in younger patients is 1:2.5 (1 = US \$1126) before and 1:1.3 (1 = US \$2284) after inclusion of the relapse costs. The proportion between the medical, surgical, and ¹³¹I treatment in older patients is 1:2.5:1.6 (1 = US \$1164) before and 1:1.6:1.4 (1 = US \$1972) after inclusion of the relapse costs.

CLINICAL CONTROVERSIES

Although the current FDA standards of bioavailability for T_4 products suggest that several products are bioequivalent, the relationship between T_4 serum concentration and TSH response suggests that the products are not truly bioequivalent. New standards of bioequivalency might need to be developed for drug products such as T_4 .

Combination therapy of T_4 plus T_3 for hypothyroidism seems to improve cognitive function over monotherapy with T_4 ; however, there are not corresponding improvements in biochemical markers of thyroid hormone nor differences in TSH response.

Multiple studies have addressed the role of thyroid supplementation in critically ill patients with cardiac disease, sepsis, pulmonary disease (e.g., acute respiratory distress syndrome), or severe infection, or with burn and trauma patients. In spite of a very large number of published studies, it is very difficult to form clear recommendations for treatment with thyroid hormone in the intensive care unit.

EVALUATION OF THERAPEUTIC OUTCOMES

Patients on optimal thyroid hormone replacement therapy should have TSH and free T_4 serum concentrations in the normal range with idiopathic hypothyroidism and Hashimoto's thyroiditis. Those who are being treated for thyroid cancer should have TSH suppressed to very low levels and thyroglobulin should be undetectable. Given the half-life of 7 days of T_4 , the appropriate monitoring interval is no more often than 4 weeks. The signs and symptoms of hypothyroidism should be improved or absent (see clinical presentation of hypothyroidism, above), although this can take several months for most to improve.

ABBREVIATIONS

ClO_4^- : perchlorate
 DIT: diiodotyrosine
 FSH: follicle-stimulating hormone
 $G_s\alpha$: α subunit of the stimulatory guanine-nucleotide-binding protein
 hCG: human chorionic gonadotropin
 HLA: human leukocyte antigen
 ^{131}I : sodium iodide 131
 L-Thyroxine: levothyroxine
 LH: luteinizing hormone
 MIT: monoiodotyrosine
 MMI: methimazole
 MNG: multinodular goiter
 PRTH: pituitary resistance to thyroid hormone
 PTU: propylthiouracil
 RAI: radioactive iodine
 RAIU: radioactive iodine uptake
 rTSH: recombinant thyroid-stimulating hormone
 SCN^- : thiocyanate
 SSKI: saturated solution of potassium iodide
 T_3 : triiodothyronine
 T_4 : thyroxine
 TBG: thyroid-binding globulin

TG: thyroglobulin

TPO Ab: thyroperoxidase antibody

$\text{TR}\beta$, $\text{TR}\beta$, $\text{TR}\alpha$: thyroid hormone receptors

TRH: thyrotropin-releasing hormone

TSAb: thyroid-stimulating antibody

TSH: thyroid-stimulating hormone

JOHN G. GUMS AND SHAWN ANDERSON

KEY CONCEPTS

- 1 Glucocorticoid secretion from the adrenal cortex is stimulated by corticotropin or adrenocorticotrophic hormone (ACTH) that is released from the anterior pituitary in response to hypothalamic-mediated release of corticotropin-releasing hormone (CRH).
- 2 To ensure the proper treatment of Cushing's syndrome, diagnostic procedures should (1) establish the presence of hypercortisolism and (2) discover the underlying etiology of the disease.
- 3 The rationale for treating Cushing's syndrome is to reduce the morbidity and mortality resulting from disorders such as diabetes mellitus, cardiovascular disease, and electrolyte abnormalities.
- 4 The treatment of choice for both ACTH-dependent and ACTH-independent Cushing's syndrome is surgery, whereas pharmacologic agents are reserved for adjunctive therapy, refractory cases, or inoperable disease.
- 5 Pharmacologic agents that can be used to manage the patient with Cushing's syndrome include: steroidogenic inhibitors, adrenolytic agents, neuromodulators of ACTH release, and glucocorticoid-receptor blocking agents.
- 6 Spironolactone, a competitive inhibitor of aldosterone, is the drug of choice in bilateral adrenal hyperplasia (BAH)-dependent hyperaldosteronism.
- 7 Addison's disease (primary adrenal insufficiency) is a deficiency in cortisol, aldosterone, and various androgens resulting from the loss of function of all regions of the adrenal cortex.
- 8 Secondary adrenal insufficiency usually results from exogenous steroid use, leading to hypothalamic-pituitary-adrenal (HPA)-axis suppression followed by a decrease in ACTH release, and low levels of androgens and cortisol.
- 9 Virilism results from the excessive secretion of androgens from the adrenal gland and is usually seen as hirsutism in females.

The adrenal glands were first characterized by Eustachius in 1563. After Addison identified a case of adrenal insufficiency in humans, adrenal anatomy and physiology flourished. Most of the work done in the early and mid-1900s centered on the glucocorticoid cortisol. With the discovery of aldosterone by Simpson and Tait in 1952,

adrenal pharmacology turned toward the mineralocorticoid. Conn¹ followed with his classical description of primary aldosteronism in 1955, and numerous clinicians and investigators have continued the discovery of the variety of disease processes promoted through the adrenal gland.

PHYSIOLOGY, ANATOMY, AND BIOCHEMISTRY

There are two adrenal glands located extraperitoneally to the upper poles of each kidney (Fig. 79–1). On average, each adrenal gland weighs 4 g and is 2 to 3 cm in width and 4 to 6 cm in length. The gland is fed by small arteries from the abdominal aorta and renal and phrenic arteries. Drainage of the adrenal gland occurs via the renal vein on the left and the inferior vena cava on the right.

The adrenal medulla occupies 10% of the total gland and is responsible for the secretion of catecholamines. The adrenal cortex accounts for the remaining 90% and is responsible for the secretion of three types of hormones (Fig. 79–2) from three separate zones.²

The zona glomerulosa, 15% of the total adrenal cortex, is responsible for mineralocorticoid production, of which aldosterone is the principal end product. Aldosterone maintains electrolyte and volume homeostasis by altering potassium and magnesium secretion and renal tubular sodium reabsorption. The zona fasciculata, the middle zone, makes up 60% of the cortex, is high in cholesterol, and is responsible for basal and stimulated glucocorticoid production. Glucocorticoids, mainly cortisol, are responsible for the regulation of fat, carbohydrate, and protein metabolism. The zona reticularis occupies 25% of the adrenal cortex, and is responsible for all adrenal androgen production. The androgens, testosterone and estradiol, are the major end products and have influence within the reproductive system as well as affecting primary and secondary sex characteristics.

HORMONE PRODUCTION AND METABOLISM

Cortisol production is accomplished via two successive hydroxylations: the first at the 21-position by 21-hydroxylase (yielding 11-deoxycortisol) and the second at the 11-position by 11-hydroxylase, yielding cortisol or hydrocortisone.

Aldosterone is a by-product of the 21-hydroxylation of pregnenolone to form deoxycorticosterone. The oxidation of 18-hydroxycorticosterone to aldosterone is a unique feature of the zona glomerulosa, explaining why aldosterone is not affected during disease processes limited to the fasciculata and/or reticularis.

Androgens have a 19-carbon nucleus and serve as precursors to more potent analogs produced in the periphery. The adrenal gland can synthesize estradiol and estrone from testosterone and androstenedione, respectively; however, the quantities are extremely small. The rates of production for the various steroids produced by the adrenal gland are listed in Table 79–1.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

FIGURE 79-1. Anatomy of the adrenal gland.

Metabolism of glucocorticoids occurs in the liver and is responsible for converting inactive steroids to active metabolites, as well as deactivating the active steroids to less active or inactive metabolites. Most pharmaceutical steroid products are active; however, in the case of prednisone and cortisone, metabolism is necessary for the conversion to the active prednisolone and cortisol, respectively. Following metabolic conversion, glucocorticoids are excreted renally as less active or inactive metabolites.

After metabolism, glomerular filtration is primarily responsible for the elimination of endogenously produced glucocorticoids. The half-life of cortisol is 70 to 120 minutes; with aldosterone, the half-life is only 15 minutes because of an extremely high intrinsic clearance.

Metabolism and conversion of the various steroids can be altered by a variety of disease states and medicinal compounds. Drugs and diseases known to result in enhanced clearance of steroids include phenytoin, phenobarbital, rifampin, mitotane, aminoglutethimide, hyperthyroidism, and renal disease (dexamethasone only). Drugs and diseases known to result in reduced clearance of steroids include estrogens and estrogen-containing oral contraceptives, liver disease, age, pregnancy, hypothyroidism, anorexia nervosa, protein-calorie malnutrition, and renal disease (prednisolone only). Plasma glucocorticoids are bound to one of three plasma proteins in varying degrees. Corticosteroid-binding globulin (CBG), albumin, and α_1 -glycoprotein are capable of binding glucocorticoids, with CBG being the principal binding protein.

The function of steroid binding is to serve as a reservoir of steroids in their inactive state. This binding can change the availability of glucocorticoids to receptor-activating sites. Therefore, a final but important variable in altered plasma concentration of free (active) steroids is concentration of plasma proteins.

REGULATION OF HORMONE SECRETION

1 The regulation of glucocorticoid secretion is accomplished by the pituitary hormone, ACTH. Under normal conditions, ACTH is released from the anterior pituitary in response to CRH, which is secreted by the median eminence of the hypothalamus (Fig. 79–3). Vasopressin and oxytocin have weak ACTH-releasing activity through binding to the inferior V₃ receptor. CRH, in combination with vasopressin and oxytocin, stimulates greater ACTH secretion than each hormone individually.

Additionally, histochemical studies have demonstrated that certain neurotransmitters have the unique ability to stimulate production of CRH or ACTH directly. 5-Hydroxytryptamine and norepinephrine have both been shown to increase levels of ACTH. 5-Hydroxytryptamine causes a release of CRH through excitation of a cholinergic intervention. Norepinephrine can cause direct stimulation of ACTH release, although this effect is still controversial. After release, ACTH stimulates the adrenal gland to release cortisol and to a lesser extent aldosterone and androgens. The rising cortisol concentration inhibits the secretion of CRH and ACTH through a negative-feedback mechanism. In addition, leptin, an adipocyte hormone, can have inhibitory effects on HPA activity.

Regulation of adrenal androgens is accomplished in a manner similar to cortisol regulation. When plasma androgen reaches sufficient concentrations, production is terminated via a negative-feedback loop. Androgen release is increased during puberty and in women with hirsutism. Adrenal androgen release is decreased in fasting, anorexia nervosa, and aging.

Regulation of aldosterone secretion is considerably more complex. The renin-angiotensin system has the ability to respond to electrolyte and volume changes to increase or decrease aldosterone secretion. Renin production and subsequent aldosterone secretion is stimulated by blood pressure lowering, erect posture, salt depletion, β -adrenergic stimulation, and central nervous system excitation. Renin production is inhibited by salt loading, angiotensin II, vasopressin, potassium, calcium, blood pressure increases, and a variety of drugs. The conversion of renin substrate angiotensinogen

to angiotensin I and subsequently to angiotensin II is the initial stimulus for aldosterone synthesis. Angiotensin II is acted on by aminopeptidase and converted to angiotensin III. Angiotensin II and III are both capable of stimulating the zona glomerulosa to secrete aldosterone. Following aldosterone secretion, increases in renal sodium and water retention as well as blood pressure are seen, thereby turning off the stimulus for renin release.

HYPERFUNCTION OF THE ADRENAL GLAND

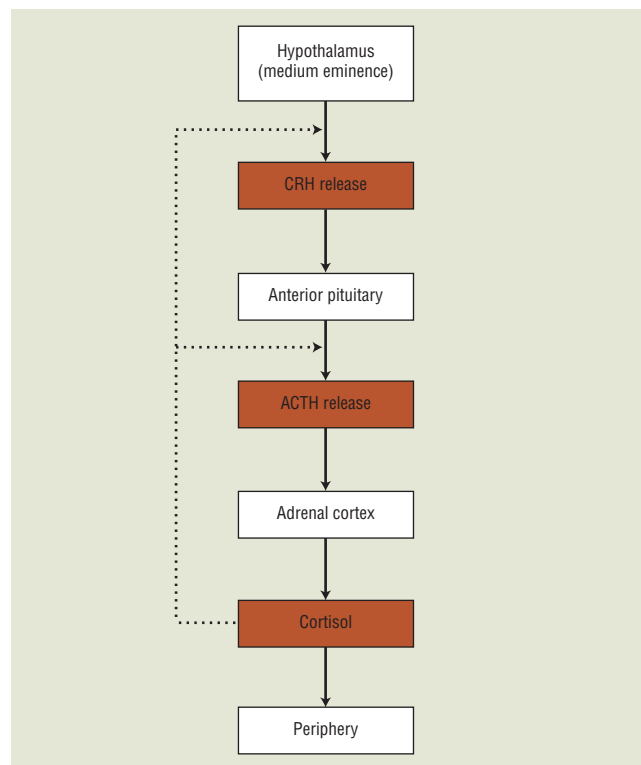

CUSHING'S SYNDROME

In 1932, Cushing first described a syndrome of pituitary basophilism that attracted national attention. It was not until this time that patients with unexplained central obesity, cutaneous striae, osteoporosis, weakness, hypertension, diabetes mellitus, and congestion had a definite diagnosis. Cushing emphasized that the disease was of pituitary origin. Ten years later, Albright focused his attention on the sugar hormone, which he believed originated from the adrenal cortex.³

After the development of the method for measuring urinary steroids, Daughaday discovered elevated steroids in the urine of patients with Cushing's disease. Finally, the end product was identified, and Cushing's syndrome was correctly explained as an excess of cortisol in the plasma (hypercortisolism).

Etiology

Cushing's syndrome results from the effects of supraphysiologic levels of glucocorticoids originating either from exogenous administration or from endogenous overproduction by the adrenal glands (ACTH-dependent) or by abnormal adrenocortical tissues (ACTH-

**FIGURE 79-3.** Negative feedback system involved in the regulation of cortisol secretion under normal conditions. (ACTH, adrenocorticotrophic hormone; CRH, corticotropin-releasing hormone.)

independent). ACTH-dependent Cushing's syndrome is usually (≈70% of Cushing's cases) caused by overproduction of ACTH by the pituitary gland, causing adrenal hyperplasia (Cushing's disease). Pituitary adenomas account for approximately 85% of these cases. Ectopic ACTH-secreting tumors and non-neoplastic corticotropin hypersecretion, possibly secondary to excess CRH production, are thought to be responsible for the remaining 20% of ACTH-dependent causes.⁴ Ectopic ACTH syndrome refers to excessive ACTH production resulting from an endocrine or nonendocrine tumor, usually of the pancreas, thyroid, or lung. Small-cell carcinoma of the lung will lead to ectopic ACTH secretion in 0.5% to 2% of cases, whereas bronchial carcinoid tumors are usually the most common.⁵ To distinguish between the various etiologies, a careful history and some pertinent laboratory work are required (Table 79-2).

The remaining 20% of Cushing's syndrome cases are ACTH-independent and are almost equally divided between adrenal adenomas and adrenal carcinomas, with rare cases caused by macronodular hyperplasia, primary pigmented nodular adrenal disease, and McCune-Albright syndrome.^{4,6,7} The majority of adrenal cortex tumors are benign adenomas. Adrenal carcinoma is found more often in children than in adults with Cushing's syndrome.

TABLE 79-2 Various Etiologies of Cushing's Syndrome and Their Respective Differences

	Pituitary-Dependent	Ectopic ACTH Syndrome	Adrenal Adenoma	Adrenal Carcinoma
Course	Slow	Rapid	Slow	Rapid
Symptoms	Mild to moderate	Atypical	Mild to moderate	Severe
Dominant sex/age	Female/male	Male	None noted	Children

Dexamethasone suppression test	≥50% Suppression	No suppression	No suppression	No suppression
Iodocholesterol scan	Bilateral uptake	Bilateral uptake	Unilateral	None

ACTH, adrenocorticotrophic hormone.

Clinical Presentation

The most common findings in patients with Cushing's syndrome, which are present in 90% of patients, are central obesity and facial rounding. In addition, approximately 50% of patients will exhibit some peripheral obesity and fat accumulation. Fat accumulation in the dorsocervical area (buffalo hump) can be associated with any major weight gain, whereas increased supraclavicular fat pads are more specific for Cushing's syndrome.⁷ Striae are usually present along the lower abdomen and take on a red to purple color. Hypertensive complications have traditionally been major contributors to the morbidity and mortality of Cushing's syndrome. Hypertension is seen in 75% to 85% of patients, with diastolic blood pressures greater than 119 mm Hg noted in over 20% of patients.⁸ In addition, glucose intolerance is present in 60% of patients. Central obesity, hypertension, and glucose intolerance are components of metabolic syndrome and can increase the risk of coronary heart disease (CHD) and stroke threefold. Screening for Cushing's syndrome in this population and in patients with uncontrolled diabetes mellitus is warranted.^{9,10}

Diagnosis

② The diagnosis of Cushing's syndrome involves two steps: (1) establishing the presence of hypercortisolism, which is relatively easy; and (2) differentiating between etiologies, which can be quite a challenge (Fig. 79-4).^{6,7,10,11} The presence of hypercortisolism can be established via the following tests: 24-hour urine free cortisol, midnight plasma cortisol, late-night salivary cortisol, and/or the low-dose dexamethasone suppression test (DST) (using 1 mg for the overnight test or 0.5 mg/6 h for the classic 2-day study). However, because these tests

cannot determine the etiology of Cushing's syndrome, other tests and procedures subsequently will be employed. They can include any of the following: high-dose DST; plasma ACTH via immunoradiometric assay (IRMA) or radioimmunoassay (RIA); adrenal vein catheterization; metyrapone stimulation test; adrenal, chest, or abdominal computed tomography (CT); CRH stimulation test; inferior petrosal sinus sampling (IPSS); jugular venous sampling (JVS); cavernous sinus sampling; and pituitary magnetic resonance imaging (MRI). Other possible tests and procedures include insulin-induced hypoglycemia; somatostatin receptor scintigraphy; the desmopressin stimulation test; naloxone CRH stimulation test; loperamide test; the hexarelin stimulation test; and radionuclide imaging.^{6-8,10-16} Table 79-3 summarizes some of the tests used to diagnose Cushing's syndrome.

Elevated urinary free cortisol concentrations are highly suggestive of Cushing's syndrome, especially values fourfold greater than the upper limit of normal.^{4,13} Normal reference values for urinary free cortisol are 20 to 90 mcg per 24-hour period. It is not unusual to detect a twofold or threefold increase in urine cortisol in the patient with hyperfunction of the adrenal gland. Starvation, topical steroid application, hydration from water loading, alcoholism, and acute stress all are capable of elevating urine cortisol concentrations. Conversely, renal impairment (glomerular filtration rate [GFR] of less than 30 mL/min) can falsely lower urinary free cortisol concentrations. Because other pathologic conditions can increase the amount of free cortisol, additional tests should be performed to confirm the diagnosis, or the diagnostic evaluation should be repeated when the acute stress has resolved. Of all urinary measures, urinary free cortisol is the most useful for assessment of any patient with suspected Cushing's syndrome.^{10,11,13}

CLINICAL PRESENTATION: CUSHING'S SYNDROME

General

- The most common findings, which are present in 90% of patients, are central obesity and facial rounding.

Symptoms

- Approximately 65% and 58% of patients complain of myopathies and muscular weakness, respectively.

Signs

- Peripheral obesity and fat accumulation is found in 50% of patients.
- Facial plethora is caused by an underlying atrophy of the skin and connective tissue and is seen in approximately 84% of patients.
- Patients often are described as having moon facies with a buffalo hump.
- Hypertension is seen in 75% to 85% of patients.
- Psychiatric changes can occur in as many as 55% of patients.
- Approximately 50% to 60% of patients will develop Cushing-induced osteoporosis. Of these, 40% will present with back pain and 20% will progress to compression fractures of the spine.
- Gonadal dysfunction is common with amenorrhea seen in up to 75% of females.

- Excess androgen secretion is responsible for 80% of females presenting with hirsutism.

Laboratory Tests

- A midnight plasma cortisol, late-night salivary cortisol, 24-hour urine free cortisol, and/or low-dose DST will establish the presence of hypercortisolism.

Other Diagnostic Tests

- The high-dose DST, plasma ACTH test, metyrapone stimulation test, CRH stimulation test, or inferior petrosal sinus sampling will help determine the etiology.

The normal circadian rhythm of cortisol will demonstrate a 60% to 80% decline between 8:00 AM and 11:00 PM. This rhythm is lost in the Cushing's syndrome patient. Although many patients with Cushing's syndrome will have serum cortisol values in the high normal range if the serum is assayed in the morning, only 3.4% will have normal

values if measured late at night.¹⁷ Thus, a midnight serum cortisol greater than 7.5 mcg/dL is a highly sensitive assay for Cushing's syndrome. However, this test requires that patients be admitted for more than 48 hours to avoid false-positive responses secondary to the stress of hospitalization. Also if a patient is sleeping, a lower serum cortisol value (>1.8 mcg/dL) should be used. An alternative assay is the measurement of late-night salivary cortisol. Salivary cortisol is highly correlated with free serum cortisol independent of salivary flow rates. This test is used in a similar manner to midnight plasma cortisol, with the exception of an 11 PM sample collection. Salivary cortisol can be considered as an acceptable alternative to urinary free cortisol because of its convenience, stability (1 week), accuracy, and reproducibility. Unfortunately, normal reference ranges are assay-dependent, and cutoff points vary among institutions.^{18,19}

In the overnight DST, 1 mg of dexamethasone is administered at 11:00 PM. The following morning at 8:00 AM fasting plasma cortisol is obtained for analysis. The Cushing's syndrome patient will not exhibit a suppressed cortisol concentration via the negative-feedback loop, and the morning cortisol concentration will be elevated above 5 mcg/dL. However, some Cushing's patients administered the overnight DST can slightly suppress cortisol and using 1.8 mcg/dL as a cutoff can increase sensitivity.^{7,20} The overnight DST is useful only as a screening tool for Cushing's syndrome, not because of high sensitivity, but rather low specificity. Phenytoin, rifampin, phenobarbital, and other drugs that induce liver enzymes can cause an increase in the clearance rate of the dexamethasone, causing decreased levels leading to a false-positive suppression test. In addition, increased concentration of CBG noted in pregnancy and with estrogen use can also illicit a false-positive suppression test.¹³ Plasma dexamethasone measured at the conclusion of this test can clarify results clouded by differences in metabolism from these drug interactions, individual variability, or patient noncompliance.

The first test used to determine the etiology of Cushing's syndrome is the plasma ACTH test. Plasma ACTH concentrations can be measured via RIA or IRMA.¹² In ACTH-dependent Cushing's syndromes, ACTH can be normal or elevated. Very high levels of ACTH favor ectopic production. ACTH values are low (<5 pg/mL) in ACTH-independent (adrenal) Cushing's syndrome. ACTH levels can appear artificially low in some ectopic ACTH-producing tumors because ACTH can be secreted as an active prohormone that is not detected by the assay.

The high-dose DST operates under the same principle as the low-dose test.^{4,12,13} The high-dose test has its main application in differentiating the Cushing's disease patient from the patient with another form of hypercortisolism. The Cushing's disease patient will generally demonstrate a 50% reduction in urinary steroids over baseline, whereas the others will generally not suppress. The high-dose test is based on the principle that patients with Cushing's syndrome not caused by adrenal tumors or ectopic ACTH production will suppress their hypothalamic-pituitary axis in the presence of glucocorticoids, but it takes much higher-than-normal doses. An overnight high-dose DST has been developed, whereby the patient has a baseline serum cortisol drawn at 8:00 AM and dexamethasone 8 mg is taken at 11:00 PM. The next morning, at 8:00 AM, another serum cortisol is drawn.¹⁷ The high-dose test is most useful when the low-dose test and other diagnostic studies have confirmed the diagnosis of Cushing's syndrome. The high-dose DST has been studied in combination with ACTH and metapyrone testing, and results in better specificity than either test alone. In addition, specificity of high-dose DST can be increased by using an 80% reduction in urinary steroids over baseline.¹³

IPSS offers the highest sensitivity and specificity of any test to confirm Cushing's syndrome. This technique requires catheterization of both petrosal sinuses with serial measurements of ACTH in each sinus and a peripheral vein after administration of CRH. A central-to-peripheral ACTH gradient is diagnostic for Cushing's syndrome whereas no gradient indicates ectopic ACTH production.

Complications, such as venous thromboembolism and brain stem vascular damage, cost, and testing expertise can limit use.¹² JVS uses the same concept as IPSS, is less invasive, and produces fewer complications; however, sensitivity is compromised.

Abnormal adrenal anatomy is effectively identified using high-resolution CT scanning and perhaps MRI.²¹ Nodules as small as 1 to 1.5 cm on the adrenal cortex are easily identified by CT. With the use of thin-section scanning, nodules as small as 3 to 5 mm can be visualized.^{22,23} In ACTH-dependent Cushing's syndrome, a pituitary MRI should be performed prior to inferior petrosal sinus sampling detecting 40% to 52% of tumors.^{11,12}

Differential Diagnosis

Although the diagnosis of Cushing's disease is not a difficult one, at times the clinician will need to differentiate it from syndromes that mimic Cushing's. Pseudo-Cushing's syndrome refers to a group of diseases that can mimic Cushing's disease. Patients with obesity, chronic alcoholism, depression, and acute illness of any type can cloud the diagnosis of Cushing's disease. Depressed patients, although mimicking the urinary steroid abnormalities of Cushing's disease, will not resemble a cushingoid patient in appearance. The chronic alcoholic will have his or her laboratory panel returned to baseline after he or she stops drinking. The obese patient often will have normal cortisol concentrations on both serum and urinary screening. Iatrogenic Cushing's syndrome, induced by pharmacologic agents, often is indistinguishable from Cushing's disease. This syndrome can occur from administration of oral, inhaled, intranasal, intra-articular, and topical glucocorticoids, as well as progestins such as medroxyprogesterone acetate and megestrol acetate.²⁴ Patients taking an inhibitor of cytochrome P450 3A4 concomitantly with a glucocorticoid can be at higher risk of developing iatrogenic Cushing's syndrome.^{25,26} A careful history and serum determination in a basal state can aid the clinician in making the diagnosis. If exogenous glucocorticoids are being taken, plasma cortisol levels can increase, while corticosterone levels remain low.^{17,27}

TREATMENT

Cushing's Syndrome

3 If left untreated, Cushing's syndrome is associated with a high percentage of morbidity and mortality owing to associated disorders such as diabetes mellitus, cardiovascular disease, and electrolyte abnor-

malities. These disorders limit the survival of the Cushing's disease patient to 4 to 5 years following initial diagnosis. The desired outcomes of treatment are to limit the morbidity and mortality and return the patient to a normal functional state by removing the source of hypercortisolism without causing any pituitary or adrenal deficiencies.

4 Once the etiology of the disease is identified, the treatment of choice for both ACTH-dependent and ACTH-independent Cushing's syndrome is surgical resection of any offending tumors.^{4,11} However, several secondary pharmacologic treatment plans are available, depending on the etiology of the disease (Table 79-4).²⁸⁻³⁰

PHARMACOLOGIC THERAPY

5 Pharmacotherapy of Cushing's syndrome (dosing can be found in Table 79-4)³¹ can be divided into four categories based on the anatomic site of action of the agent: (1) steroidogenic inhibitors; (2) adrenolytic agents; (3) neuromodulators of ACTH release; and (4) glucocorticoid-receptor blocking agents.²⁸⁻³⁰

Steroidogenic inhibition can be accomplished with the following agents: metyrapone, aminoglutethimide, ketoconazole, and etomidate. Aminoglutethimide used alone has limited efficacy, with relapse occurring after discontinuation of therapy. In addition, steroidogenic inhibitors should not be used after successful surgery. Their use is mainly in preparation for surgery, as adjunctive treatment after unsuccessful surgery or radiotherapy, or for the refractory patient who is not a surgical candidate. Combination therapy with metyrapone and aminoglutethimide appears more effective than either alone and can cause fewer side effects.

Metyrapone inhibits 11-hydroxylase activity, resulting in inhibition of cortisol synthesis. Initially, patients can demonstrate an increase in plasma ACTH concentrations because of a sudden drop in cortisol. As such, increased ACTH concentrations can cause an increase in androgenic and mineralocorticoid hormones resulting in hypertension, acne, and hirsutism. Metyrapone is biologically active following oral administration. Nausea, vomiting, vertigo, headache, dizziness, abdominal discomfort, and allergic rash have been reported following administration.^{28-30,32}

Initially, aminoglutethimide was used to treat refractory forms of epilepsy, but it was later discovered to be a potent inhibitor of cortisol synthesis. Aminoglutethimide inhibits the conversion of cholesterol to pregnenolone early in the cortisol pathway.³³ Plasma cortisol concentrations are reduced by up to 50% following aminoglutethimide therapy. Side effects include severe sedation, nausea, ataxia, and skin rashes.²⁸⁻³⁰ Most of these reactions are dose-depen-

TABLE 79-4 Possible Treatment Plans in Cushing's Syndrome Based on Etiology

Etiology	Nondrug	Generic (Brand) Drug Name	Treatment		
			Initial	Usual	Max
Ectopic ACTH syndrome	Surgery, chemotherapy, irradiation	Metyrapone (Metopirone) 250-mg capsules	0.5–1 g/day, divided every 4–6 h	1–2 g/day, divided every 4–6 h	6 g/day
		Aminoglutethimide (Cytadren) 250-mg tabs	0.5–1 g/day, divided two to four times a day for 2 weeks	1 g/day, divided every 6 h	2 g/day
Pituitary-dependent	Surgery, irradiation	Cyproheptadine (Periactin) 2 mg/5 mL syrup or 4-mg tabs	4 mg twice a day	24–32 mg/day, divided four times a day	32 mg/day
		Mitotane (Lysodren) 500-mg tabs	0.5–1 g/day, increased by 0.5–1 g/day every 1–4 weeks	1–4 g daily, with food to decrease GI effects	12 g/day
		Metyrapone	See above	See above	See above
Adrenal adenoma	Surgery, postoperative replacement	Ketoconazole (Nizoral) 200-mg tabs	200 mg once or twice a day	200–1200 mg/day, divided twice a day	1600 mg/day divided four times a day
Adrenal carcinoma	Surgery	Mitotane	See above	See above	See above

ACTH, adrenocorticotrophic hormone.

dent and limit the use of aminoglutethimide in most patients. Aminoglutethimide can decrease the anticoagulant effect of warfarin. As aminoglutethimide can induce the metabolism of exogenous glucocorticoids, careful titration is required with steroid replacement. Aminoglutethimide also blocks the synthesis of thyroxine, which can result in elevated thyroid-stimulating hormone (TSH) levels and hypothyroidism.²⁹

Alone, aminoglutethimide is indicated for short-term use in inoperable Cushing's disease with ectopic ACTH syndrome as the suspected underlying etiology. Aminoglutethimide can be used in combination with metyrapone. Smaller doses of both drugs can be used, thereby minimizing the toxicity associated with either agent. The combination therapy appears effective for various etiologies of Cushing's disease and is useful in the inoperable patient.

The imidazole derivative antifungal ketoconazole is highly effective in lowering cortisol in Cushing's disease, resulting in normal corticosteroid values in 84% of patients, with an additional 11% of patients reporting improvement.²⁸⁻³⁰ Patients can be maintained successfully for months to years on ketoconazole therapy. In addition to lowering serum cortisol levels, ketoconazole can cause gynecomastia and lower plasma testosterone values. All of these effects are attributed to its inhibition of a variety of cytochrome P450 enzymes, including 11-hydroxylase and 17-hydroxylase.²⁹ In some patients, ACTH levels actually decrease suggesting ketoconazole has a secondary inhibitory effect on ACTH. The most common adverse effects are reversible elevation of hepatic transaminases, gynecomastia, and gastrointestinal upset.²⁸⁻³⁰

The anesthetic etomidate is an imidazole derivative similar to ketoconazole that inhibits 11-hydroxylase.²⁹ Etomidate is only available in a parenteral formulation; therefore, use is limited to patients with acute hypercortisolemia awaiting surgery.

The adrenolytic agent mitotane is a cytotoxic drug that structurally resembles the insecticide dichlorodiphenyltrichloroethane (DDT). Mitotane inhibits the 11-hydroxylation of 11-desoxycortisol and 11-desoxycorticosterone in the cortex. The net result is a reduced synthesis of cortisol and corticosterone. It decreases the cortisol secretion rate, plasma cortisol concentrations, urinary free cortisol, and plasma concentrations of the 17 substituted steroids.³¹ This drug appears to selectively inhibit adrenocortical function without causing cellular destruction. Degeneration of cells within the zona fasciculata and reticularis occurs with resultant atrophy of the adrenal cortex. The zona glomerulosa is minimally affected during acute therapy but can become damaged following long-term treatment.^{28,31,34}

Because mitotane can severely reduce cortisol production, the patient should be hospitalized before initiating therapy. Mitotane should be continued as long as clinical benefits occur. Mitotane increases production of corticosteroid binding globulin resulting in elevated plasma cortisol; thus, urinary free cortisol, and urinary steroid production should be monitored to assess response to therapy.²⁹ If necessary, steroid replacement therapy can be given. Nausea and diarrhea are common adverse effects that occur at doses greater than 2 g/day and can be avoided by gradually increasing the dose and/or administering the agent with food. Approximately 80% of mitotane-treated patients develop lethargy and somnolence, and other central nervous system adverse drug reactions occur in approximately 40% of patients. Furthermore, significant but reversible hypercholesterolemia can result from mitotane use.^{29,30}

Neuromodulatory agents include cyproheptadine, ritanserin, bromocriptine, cabergoline, valproic acid, octreotide, lanreotide, risoglitazone, and tretinoin. None of the neuromodulatory agents has demonstrated consistent clinical efficacy in the treatment of Cushing's disease. The existence of a bromocriptine-responsive subset of patients remains controversial.^{28,29} Combination therapy with these agents can prove more efficacious than any one agent alone. For example, cabergoline plus lanreotide successfully normalized urinary

free cortisol in one patient when treatment failed on either agent alone.³⁵

Cyproheptadine can decrease ACTH secretion in the Cushing's disease patient. Morning plasma cortisol concentrations, as well as 24-hour urinary cortisol (free) concentrations should be monitored. Side effects are minor and include sedation and hyperphagia. Cyproheptadine should be reserved for nonsurgical candidates who fail more conventional therapy. Because the response rate is no more than 30%, patients should be followed closely for relapses.

Tretinoin, also known as all-*trans*-retinoic acid, is a derivative of vitamin A that has been used for the treatment of acute promyelocytic leukemia. Tretinoin can reduce the secretion of ACTH through inhibition of transcriptional activities.³⁶ In addition to ACTH suppression, tretinoin inhibits tumor growth, which is consistent with its use as an antineoplastic agent. The use of this agent has been limited to animal models; thus, efficacy in humans is yet undetermined.

Glucocorticoid receptor antagonism can be accomplished via RU-486 (mifepristone). RU-486 is a progesterone-, androgen-, and glucocorticoid-receptor antagonist that inhibits dexamethasone suppression and increases endogenous cortisol and ACTH values in normal subjects.^{29,32} Limited clinical experience in Cushing's suggests that RU-486 is highly effective in reversing the manifestation of hypercortisolism. Because of its novel site of action as a receptor antagonist leading to higher cortisol and ACTH levels, the diagnosis of treatment-induced glucocorticoid insufficiency must rest on clinical signs only. The efficacy and long-term effects of RU-486 remain to be determined.

Spironolactone has been used for its competitive antagonism of aldosterone in the treatment of Cushing's syndrome. Spironolactone can provide symptomatic relief of the hypertension and hypokalemia often seen in Cushing's syndrome.

Close monitoring of 24-hour urinary free cortisol levels and serum cortisol levels are essential to monitor for adrenal insufficiency. Steroid secretion should be monitored with all of these drugs and steroid replacement given as needed. Whatever the choice, pharmacologic therapy in pituitary-dependent disease is mainly centered around patient stabilization prior to surgery or in patients waiting for potential response to other therapies.

■ NONPHARMACOLOGIC THERAPY

Surgery

During the last decade, the treatment of choice for Cushing's disease has been transsphenoidal resection of the pituitary microadenoma.^{4,11,32,37} The advantages to this procedure include preservation of pituitary function, low complication rate, and high clinical improvement rate. The overall cure rate of histologically proven tumors approaches 98%.

Bilateral adrenalectomy surgery had been the mainstay of therapy for years. Laparoscopic surgery is now the treatment of choice in patients for whom transsphenoidal surgery and pituitary radiotherapy have failed or cannot be used, with primary pigmented nodular adrenal disease, and with macronodular adrenal hyperplasia.^{4,11,32,38} Bilateral adrenalectomy rapidly reverses hypercortisolism. However, patients can develop Nelson syndrome, which involves sella turcica enlargement and hyperpigmentation, caused by postoperative hypothalamic stimulation. Therefore if bilateral adrenalectomy is used it should be accompanied by some form of hypothalamic inhibition, such as cyproheptadine or pituitary radiation.

Irradiation of the pituitary has provided clinical improvement in approximately 50% of patients. Improvement is usually not seen until 6 to 12 months after therapy and can create pituitary-dependent hormone deficiencies (hypopituitarism). Most clinicians will reserve pituitary radiotherapy for the patient with persistent hypercortisolemia after transsphenoidal surgery.^{4,39}

TABLE 79-5 Alternative Steroid Replacement Regimens in the Adrenal Adenoma Patient

Time	Hydrocortisone Dose (mg)		
	IV	IM	PO
Operation day	300	50 before surgery and 50 after surgery	
Postoperative day 1	200	50 every 12 h	
Postoperative day 2	150	50 every 12 h	
Postoperative day 3	100	50 every 12 h	
Postoperative day 4		50 every 12 h	25 every 6 h
Postoperative day 5		25 every 12 h	25 every 6 h ^a
Postoperative day 7			25 every 6 h
Postoperative days 8–10			25 every 8 h
Postoperative days 11–20			25 every 12 h
Postoperative days 21+			20 at 8 AM 10 at 4 PM

PO, orally.

^aAdd fludrocortisone 0.05–2 mg orally once daily starting on postoperative day 5. Adjust dose based on blood pressure, body weight, and serum electrolytes.

Adrenal Adenoma

Surgical resection of benign adrenal adenoma is associated with relatively few side effects and a high cure rate (95%). The contralateral gland in the patient with adrenal adenoma is usually atrophic, therefore steroid replacement is needed both perioperatively and postoperatively. Table 79–5 outlines an approach to steroid replacement for three separate routes of hydrocortisone. Therapy should be continued for 6 to 12 months following surgery. Before replacement therapy is discontinued, recovery of the adrenal axis can be assessed by measuring the morning (8 AM) cortisol level. Cortisol levels should exceed 20 mcg/dL before discontinuance of the exogenous steroids.²⁴

Adrenal Carcinoma

Unlike the benign adenoma patient, patients with adrenal carcinoma have an unpredictable and unfavorable outcome with surgical resection.¹¹ Often the complete tumor cannot be excised, leaving the patient with some degree of symptomatology and extra-adrenal involvement. Radiotherapy can be used if metastases are discovered. In the patient with adrenal carcinoma who is not a surgical candidate, the focus of treatment is on palliative pharmacologic intervention (e.g., mitotane).

Mitotane appears to be the drug of choice in inoperable functional and nonfunctional adrenal carcinoma. Tumor regression is seen in approximately 35% to 50% of patients, with most regression occurring between the second and fourth month of therapy. Seventy-five percent of patients will exhibit a 30% decrease in urinary steroids, with 50% of patients showing an improved clinical response after 5 months of treatment. Patient survival appears prolonged, although no adequate clinical trials are available to support this assumption.

Metirapone, aminoglutethimide, and ketoconazole can be given to attempt control of steroid hypersecretion. 5-Fluorouracil has also been used in combination therapy.

Ectopic ACTH Syndrome

In the ectopic ACTH syndrome, multiple sites of tumors exist, and locating the ectopic sites are essential but often difficult. Therefore only approximately 10% to 30% of patients are cured following surgery, and the remaining 70% to 90% receive postoperative medication.

Surgical excision remains optimal in these patients. Pharmacologic management with metirapone and ketoconazole is effective in ectopic ACTH syndrome. Aminoglutethimide is an alternative agent but is more effective when combined with other inhibitors, usually

metirapone.^{5,29,40} Mitotane has been tried in patients with ectopic ACTH syndrome; however, its side-effect profile generally limits its use. RU-486 and the somatostatin analog octreotide have been reported to reduce the clinical signs of the ectopic ACTH syndrome.²⁸ Bilateral adrenalectomy is performed when surgical excision of the tumor and pharmacologic treatments fail.

HYPERALDOSTERONISM

Excess aldosterone is categorized as either primary or secondary hyperaldosteronism.^{41–46}

Primary Aldosteronism

Etiology Primary aldosteronism (PAL) implies that the physiologic abnormality is within the adrenal cortex. The most common causes include BAH (70%) and aldosterone-producing adenoma (APA) (30%). Historically, APA was the most common cause, but screening normokalemic, hypertensive patients has detected less severe forms of PAL more commonly diagnosed as BAH.⁴⁷ Other rare causes include unilateral adrenal hyperplasia, adrenal cortex carcinoma, primary adrenocortical hyperplasia, renin-responsive adrenocortical adenoma, and two forms of familial hyperaldosteronism (FH): FH type 1, or glucocorticoid-remediable aldosteronism (GRA), and FH type II.^{41,42,44}

Clinical Presentation The incidence of primary aldosteronism is disputed, with estimates ranging from approximately 3% to 32%, depending on the selection of hypertensive populations.^{41,43} The disease is more common in women aged 30 to 50 years. Signs and symptoms can include arterial hypertension, muscle weakness, fatigue, and headache, although many patients are asymptomatic.

Diagnosis The absolute diagnosis is obtainable through screening, confirmatory tests, and subtype differentiation by skilled clinicians. As in Cushing's disease, the discovery of the underlying etiology is mandatory to ensure proper treatment. Table 79–6 lists the various abnormalities that must be ruled out when suspicion of hyperaldosteronism is high.

CLINICAL PRESENTATION: PRIMARY ALDOSTERONISM

Symptoms

- Patients may complain of muscle weakness, fatigue, paresthesias, and headache.
- Signs
- Hypertension
- Tetany/paralysis
- Polydipsia/nocturnal polyuria

Laboratory Tests

- A plasma-aldosterone-to-plasma-renin-activity ratio (PA:PRA), or aldosterone-to-renin ratio (ARR) greater than 20 is suggestive of primary aldosteronism
- Common laboratory findings include suppressed renin activity, elevated plasma aldosterone concentrations, hypernatremia (>142 mEq/L), hypokalemia, hypomagnesemia, elevated bicarbonate concentration (>31 mEq/L), and glucose intolerance

Confirmatory Tests

- Oral or intravenous saline loading, fludrocortisone suppression test (FST), and genetic testing

TABLE 79-6 Differential Diagnosis of Primary Aldosteronism

Disease	Plasma Renin Concentration	Plasma Aldosterone Concentration	Blood Pressure
Primary aldosteronism	Low	High	High
Edematous disorders	High	High	Normal
Malignant hypertension	High	High	High
Congenital adrenal hyperplasia	Low	Low	High
Cushing's syndrome	Low to normal	Low to normal	High
Liddle's syndrome	Low	Low	High
Bartter's syndrome	High	High	Low to normal
Licorice ingestion	Low	Low	High
Low-renin essential hypertension	Low	Low to normal	High

Although serum potassium concentration of less than 3.5 mEq/L with a concurrent urinary potassium content greater than 30 mEq per 24 hours is suggestive of primary aldosteronism, normokalemia can be present in up to 80% of diagnosed patients.⁴⁸ Initial diagnosis is made through proper screening of patients with suspected primary aldosteronism, such as resistant hypertensives with or without hypokalemia. Some institutions choose to screen patients with stage 2 hypertension realizing that the prevalence of PAL increases with hypertensive severity.^{47,49} Screening for primary aldosteronism is most often done by using the plasma-aldosterone-concentration-to-plasma-renin-activity ratio (PAC:PRA), or aldosterone-to-renin ratio (ARR). An elevated ARR is highly suggestive of PAL; however, an optimal cutoff level is nonexistent because of testing conditions (posture, time, drug therapy), patient characteristics, and variable levels of specificity and sensitivity. For example, Hirohara and colleagues⁵⁰ found an ARR greater than 32 to be 100% sensitive and 61% specific in patients with aldosterone-producing adenomas, whereas Giacchetti and colleagues⁵¹ determined that a supine ARR cutoff of 25 was 98% sensitive and 67% specific and an upright ARR cutoff of 40 was 100% sensitive and 84% specific in patients with confirmed PAL and hypertension. ARR cutoffs of 20 to 40 or 20 with an aldosterone level greater than 15 ng/dL are most commonly used.^{43,52,53}

Confirmatory testing must be done after a positive ARR screening test. Oral or intravenous saline loading and the FST are the most widely used, with FST being the most reliable.^{43,47} Positive tests demonstrate autonomous aldosterone secretion under inhibitory pressures and are diagnostic for PAL. After diagnosis, all patients should undergo genetic testing to properly identify GRA or FH type I.⁴²

Differentiating between an APA and BAH is imperative to formulate a proper treatment plan. A majority of the adenomas are singular and small, less than 1 cm. The left adrenal gland is affected at a higher rate than the right. Patients with APA generally have more severe hypertension, more profound hypokalemia, and higher plasma and urinary aldosterone levels compared to patients with BAH. CT scanning can usually detect most adenomas, although an incidentaloma can occasionally cause confusion. If CT scanning is inconclusive, adrenal venous sampling (AVS) is performed to indicate lateralization, or aldosterone secretion from one adrenal gland.^{43,47,49,54,55}

The underlying abnormality in BAH remains a mystery, but some investigators believe that a hormone factor stimulates the zona glomerulosa, resulting in increased sensitivity to angiotensin II. In contrast to APA patients, patients with BAH are able to maintain control of the renin-angiotensin system, with little effect following doses of ACTH.

Therapeutic Management

6 BAH-Dependent Aldosteronism. Spironolactone, the drug of choice in BAH-dependent aldosteronism, competitively inhibits aldosterone biosynthesis within the adrenal gland, making it extremely useful in overstimulated BAH patients.^{43,56,57} It is available in oral form, with most patients responding to doses of 25 to 400 mg/day. The clinician should wait 4 to 8 weeks before reassessing the patient for

urinary electrolytes and blood pressure control. Adverse effects of spironolactone include gastrointestinal discomfort, impotence, gynecomastia, and menstrual irregularities, and are dose-dependent. Additionally, because salicylates increase the renal secretion of canrenone, the active metabolite, patients should be advised to avoid concomitant therapy with salicylates. Because spironolactone blocks testosterone biosynthesis, it often is not used in men. In patients intolerant of spironolactone, eplerenone and amiloride are options.^{43,49,56–58} Eplerenone, an aldosterone antagonist with high affinity for the aldosterone receptor and low affinity for androgen and progesterone receptors, has been approved for the treatment of hypertension. It appears to be more beneficial than spironolactone because of its limited progestational and antiandrogenic side effects. Dosing starts at 50 mg daily, with titration to 50 mg twice a day.⁴⁹ Again, titration should occur at 4 to 8 week intervals. In addition, eplerenone is a substrate of CYP3A4 and should not be taken with potent CYP3A4 inhibitors. Eplerenone has been proven effective in low-renin hypertension; however, its role in the management of hyperaldosteronism has not been established.⁵⁹

The usual dose of amiloride is 5 mg twice a day up to 30 mg/day if necessary. Unfortunately, amiloride is not as effective as aldosterone antagonists in BAH; thus second-line therapy is often required to control the blood pressure. Agents useful as second-line choices include the calcium channel blockers, angiotensin-converting enzyme inhibitors, and low-dose diuretics such as hydrochlorothiazide.^{55,56}

APA-Dependent Aldosteronism. The treatment of choice for APA-dependent aldosteronism remains laparoscopic resection of the adenoma.⁶⁰ Nearly 100% of patients show blood pressure improvement with 30% to 60% resulting in long-term cure.^{57,61} If no primary lesion is found, resection of one and a half of the adrenal glands can be attempted, followed by supplemental spironolactone therapy. However, a recent retrospective analysis of patients with aldosterone-producing adenomas who chose medical management instead of surgical resection, revealed medical management to be efficacious in this population and should be considered as an alternative in patients in whom surgery is contraindicated.⁶²

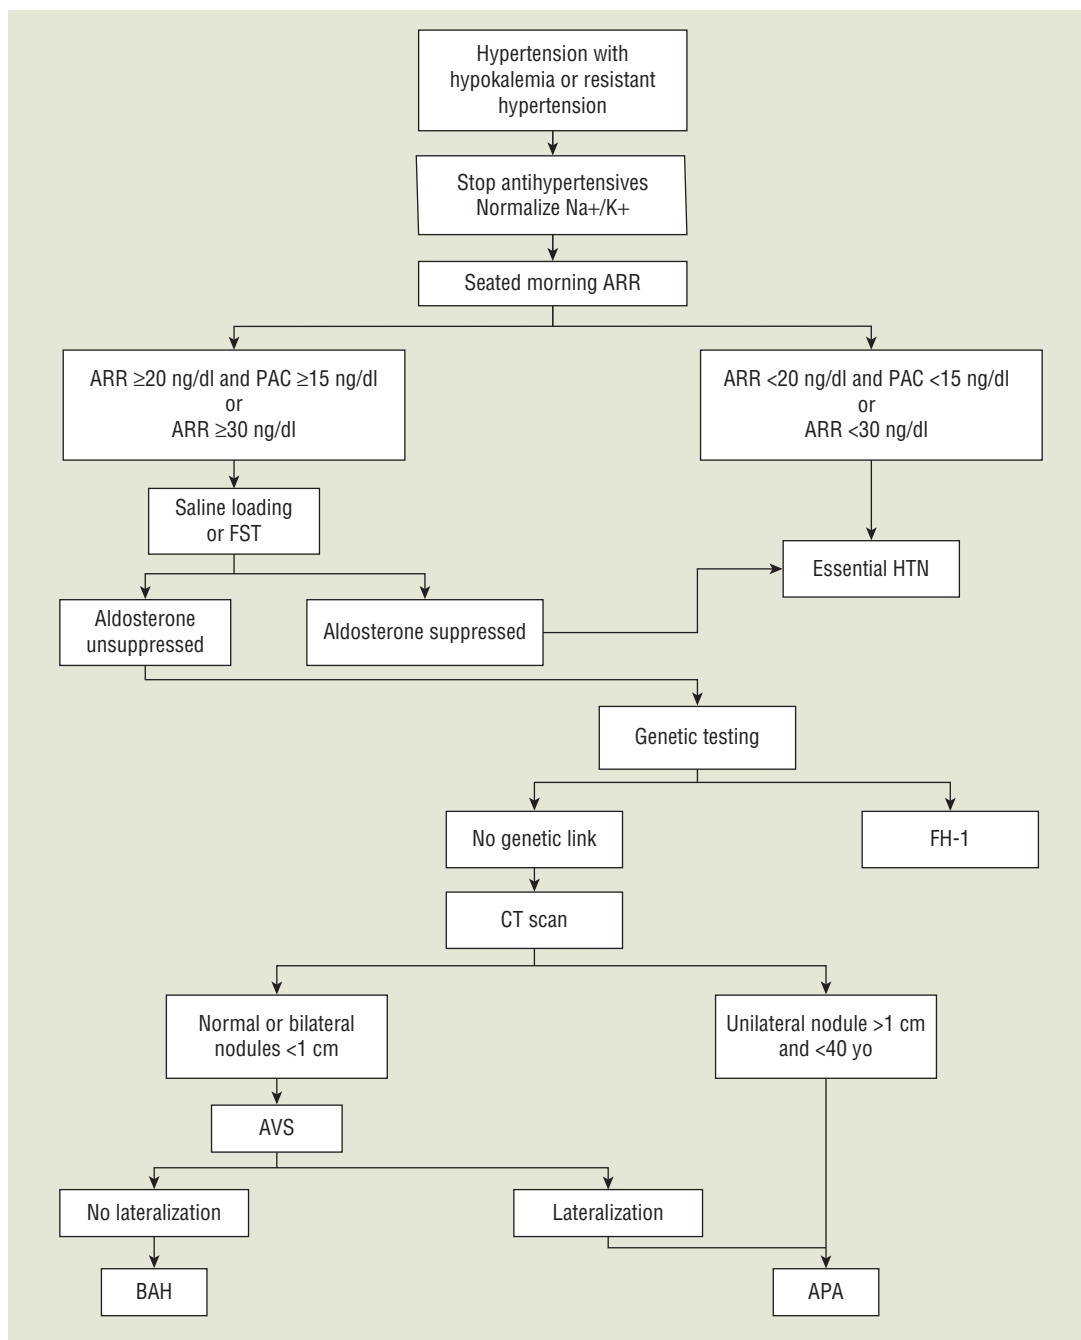

Glucocorticoid-Remediable Aldosteronism. Glucocorticoids are very effective in treating GRA.⁴² Low doses are typically used (0.125 to 0.5 mg/day of dexamethasone or 2.5 to 5 mg/day of prednisone) because complete suppression of ACTH-stimulated aldosterone release is unnecessary. Spironolactone, eplerenone, and amiloride are alternative treatment options.⁴³

Summary The diagnosis of primary aldosteronism is made through proper screening of suspected patients and confirmatory testing. Differentiating between the various etiologies is mandatory (Fig. 79–5). Patients with adrenal adenomas can be distinguished from patients with hyperplasia by CT scan, but adrenal venous sampling provides increased sensitivity and specificity. Treatment depends on the etiology with surgical resection, well accepted as the treatment of choice in adenomas, and spironolactone, eplerenone, or amiloride plus second-line agents in patients with hyperplasia.

Secondary Aldosteronism

Secondary aldosteronism results from stimulation of the zona glomerulosa by an extra-adrenal factor, usually the renin-angiotensin system. Excessive potassium intake can create a physiologic increase in aldosterone, as can oral contraceptive use, pregnancy (10 times normal by the third trimester), and menses. Congestive heart failure, cirrhosis, renal artery stenosis, and Bartter syndrome also can lead to elevated aldosterone concentrations.

Treatment of secondary aldosteronism is dictated by etiology. Control or correction of the extra-adrenal stimulation of aldosterone secretion should resolve the disorder. Medical therapy with spironolactone is the mainstay of treatment until an exact etiology can be located.

ARR = aldosterone to renin ratio
 PAC = plasma aldosterone concentration
 FST = fludrocortisone suppression test
 FH-1 = familial hyperaldosteronism type 1

AVS = adrenal venous sampling
 BAH = bilateral adrenal hyperplasia
 APA = aldosterone-producing adenoma

FIGURE 79-5. Algorithm for the diagnosis of primary aldosteronism.

HYPOFUNCTION OF THE ADRENAL GLAND

7 Primary adrenal insufficiency, or Addison's disease, most often involves the destruction of all regions of the adrenal cortex. Deficiencies arise in cortisol, aldosterone, and the various androgens. Approximately 40% to 53% of patients with idiopathic primary adrenal insufficiency present with one or more clinical disorders involving multiple endocrine organs. The organs involved can include ovary, thyroid, pancreas, and parathyroid gland. This polyglandular failure syndrome is associated with the idiopathic etiology only and has not been seen with adrenal insufficiency

associated with tuberculosis or other invasive diseases. Medications that inhibit cortisol synthesis (ketoconazole), or accelerate cortisol metabolism (phenytoin, rifampin, phenobarbital) can also cause primary adrenal insufficiency.^{63,64}

8 Secondary insufficiency most commonly results from exogenous steroid use, leading to suppression of the HPA axis and decreased release of ACTH, resulting in impaired androgen and cortisol production. This has been reported from oral, inhaled, intranasal, and topical glucocorticoid administration.^{65–67} Moreover, mirtazapine and progestins, such as medroxyprogesterone acetate and megestrol acetate have been reported to induce secondary adrenal insufficiency.^{68,69} Chronic suppression also can result in atrophy

TABLE 79-7 Etiologies of Primary and Secondary Adrenal Insufficiency

Primary Insufficiency	Secondary Insufficiency
<i>Slow onset</i>	Craniopharyngioma
Acquired immunodeficiency syndrome	Cure of Cushing's syndrome
Adrenomyeloneuropathy	Empty sella syndrome
Adrenoleukodystrophy	Tumors of the third ventricle
Amyloidosis	Histiocytosis
Autoimmune adrenalitis ^a	Hypothalamic tumors
Bilateral adrenalectomy	Hypopituitarism
Congenital adrenal hypoplasia	Long-term corticosteroid administration
Hemochromatosis	Lymphocytic hypophysitis
Isolated glucocorticoid deficiency	Pituitary surgery, radiation, or tumor
Metastatic neoplasia	Sarcoidosis
Systemic fungal, bacterial, or viral infections	Medications—progestins and glucocorticoid discontinuation
Tuberculosis ^b	Postpartum pituitary necrosis
Medications—ketoconazole, etomidate, rifampin, phenytoin, phenobarbital	Necrotic or bleeding pituitary macroadenoma
<i>Fast onset</i>	Head trauma, lesions of the pituitary stalk
Adrenal thrombosis, hemorrhage, sepsis, trauma, or necrosis	Pituitary or adrenal surgery for Cushing's syndrome

^aAccounts for approximately 70% of cases.^bAccounts for approximately 20% of cases.

of the anterior pituitary and hypothalamus, impairing recovery of function if the exogenous steroid is reduced. Secondary disease classically presents with normal concentrations of mineralocorticoids.

Approximately 90% of the adrenal cortex must be destroyed before adrenal insufficiency symptoms will occur.⁷⁰ Specific etiologies for both primary and secondary insufficiency are listed in Table 79-7. Adrenal hemorrhage can result from multiple etiologies including traumatic shock, coagulopathies, ischemic disorders, and other situations of severe stress, but septicemia is the most common. Symptoms include truncal pain, fever, shaking, chills, hypotension preceding shock, anorexia, headache, vertigo, vomiting, rash, psychiatric symptoms, abdominal rigidity or rebound, and death in 6 to 48 hours if not treated. The most common organisms found on autopsy are *Neisseria meningitidis*, *Pseudomonas aeruginosa*, *Streptococcus pneumoniae*, Group A *Streptococcus*, and *Haemophilus influenzae*.^{70,71}

ADDISON'S DISEASE

Distinguishing Addison's disease from secondary insufficiency is difficult; however, the following guidelines may be helpful:

1. Hyperpigmentation usually is not seen in secondary adrenal insufficiency because of low amounts of melanocyte-stimulating hormone. Low amounts of melanocyte-stimulating hormone are present owing to a deficient pituitary secretion of ACTH and β -lipotropin, all of which are synthesized together in a common precursor peptide, proopiomelanocortin (POMC).
2. Aldosterone secretion usually is preserved in secondary insufficiency.
3. Weight loss, dehydration, hyponatremia, hyperkalemia, and elevated blood urea nitrogen are common in Addison's disease.
4. Addison's disease will have an abnormal response to the rapid ACTH-stimulation test. Plasma ACTH levels are usually 400 to 2000 pg/mL in primary insufficiency, versus normal to low (0 to 50 pg/mL; see Table 79-3) in secondary insufficiency. A normal cosyntropin-stimulation test does not rule out secondary adrenal insufficiency.

The short cosyntropin-stimulation test can be used to assess patients suspected of hypocortisolism. Patients are given 250 mcg of

synthetic ACTH intravenously or intramuscularly, with serum cortisol levels drawn at baseline and 30 to 60 minutes after the injection. An increase to a cortisol level ≥ 18 mcg/dL (500 nmol/L) rules out adrenal insufficiency.⁷² Although this test remains the most commonly used method, in some patients with secondary adrenal insufficiency or mild primary adrenal insufficiency, this test will be normal. This result can be owing to the high dose of corticotropin given. Thus some suggest that higher cutoff values (≥ 22 to 25 mcg/dL) should be used.⁷³ Alternatively, studies have demonstrated that equivalent results can be seen using 1 mcg of cosyntropin. The normal response is an increase to a cortisol level ≥ 18 mcg/dL 30 minutes after the injection. Other tests include the insulin hypoglycemia test, the metyrapone test, and the corticotropin-releasing hormone stimulation test.^{63,72,74}

Cortisol levels greater than 18 to 20 mcg/dL 30 minutes after a cosyntropin-stimulation test are not useful in patients who are acutely ill.⁷⁵ Severe infection, trauma, burns, illnesses, or surgery can increase cortisol production by as much as a factor of six, making the recognition of adrenal insufficiency in this population extremely difficult. In the critically ill, a random cortisol level below 15 mcg/dL is indicative of adrenal insufficiency, whereas a level greater than 34 mcg/dL suggests that adrenal insufficiency is unlikely.⁷⁵ For patients who fall between these two values, a poor response to corticotropin (less than 9 mcg/dL increase in plasma cortisol from baseline at 30 or 60 minutes) indicates the possibility of adrenal insufficiency and a need for corticosteroid supplementation.⁷⁵ A severe hypoproteinemic patient (albumin <2.5 g/L) will have markedly lower CBG, which can falsely underestimate the free fraction of cortisol. These patients can benefit from retesting as an outpatient to prevent indefinite glucocorticoid therapy.⁶³

Treatment of Addison's disease must include adequate patient education, so that the patient is aware of treatment complications, expected outcome, missed doses, and drug side effects. The agents of choice are hydrocortisone, cortisone, and prednisone, administered twice daily with the treatment objective being the establishment of the lowest effective dose while mimicking the normal diurnal adrenal rhythm.⁶³ Usually a twice-daily dosing schedule is adequate with the dose depending on the agent used.

Endogenous cortisol production varies between 5 and 10 mg/m² per day.⁷⁶ Hence, the classic 12- to 15-mg/m² per day rule for cortisol supplementation can be excessive in most patients. Recommended starting doses to properly mimic endogenous cortisol production is 15 mg of hydrocortisone daily, which is roughly equal to 20 mg of cortisone acetate or 2.5 mg of prednisone.^{63,76} The majority of the dose (67%) is given in the morning, whereas the remainder (33%) is given in the evening to duplicate the normal circadian rhythm of cortisol production. The patient's symptoms should be monitored every 6 to 8 weeks to assess proper glucocorticoid replacement. To replace mineralocorticoid loss, fludrocortisone acetate can be used. A dose of 0.05 to 0.2 mg by mouth once a day is adequate. If parenteral therapy is needed, 2 to 5 mg of deoxycorticosterone trimethylacetate in oil intramuscularly every 3 to 4 weeks can be used. The main reason for adding the mineralocorticoid is to minimize the development of hyperkalemia. Adverse effects must be monitored closely. Symptoms include gastric upset, edema, hypertension, hypokalemia, insomnia, excitability, and diabetes mellitus. In addition, patient weight, blood pressure, and electrocardiogram should be monitored regularly.⁷⁴

In women, the primary source of dehydroepiandrosterone (DHEA) and androgens is the adrenal cortex, specifically the zona reticularis. As such, women with adrenal insufficiency can have decreased libido. Although clinical trials are conflicting, 25 to 50 mg DHEA can increase energy levels and libido. Currently, the use of DHEA, a dietary supplement, is an option for female patients with adrenal insufficiency complaining of decreased libido and low energy.⁷⁷

Most adrenal crises occur secondary to glucocorticoid dose reduction or lack of stress-related dose adjustments. It is recommended that patients receiving corticosteroid-replacement therapy add 5 to 10 mg hydrocortisone to their normal daily regimen shortly before strenuous activities such as hiking.⁷⁴ Likewise, during times of severe physical stress such as febrile illnesses or after accidents, patients should be instructed to double their daily dose until recovery.^{78,79}

The end point of therapy is difficult to assess in most patients, but a reduction in excess pigmentation is a good clinical marker. The development of features of Cushing's syndrome indicates excessive replacement. Treatment of secondary adrenal insufficiency is identical to primary disease treatment with the exception that mineralocorticoid replacement usually is not necessary. Patient education still should be stressed with emphasis placed on establishing an alternate-day regimen.

Acute Adrenal Insufficiency

Adrenal crisis, or Addisonian crisis, is characterized by an acute adrenocortical insufficiency. Adrenal crisis represents a true endocrine emergency. Anything that increases adrenal requirements dramatically can precipitate an adrenal crisis. Stressful situations, surgery, infection, and trauma all are potential triggering events, especially in the patient with some underlying adrenal or pituitary insufficiency. The most common cause of adrenal crisis is HPA-axis suppression brought on by chronic use of exogenous glucocorticoids and abrupt withdrawal.

Treatment of adrenal crisis involves the administration of parenteral glucocorticoids. Hydrocortisone is the agent of choice owing to its combined mineralocorticoid and glucocorticoid activity. Hydrocortisone is started at 100 mg intravenously through rapid infusion, and followed by a continuous infusion or intermittent bolus of 100 to 200 mg every 24 hours.⁸⁰ Intravenous administration is continued for 24 to 48 hours, at which time if the patient is stable, oral hydrocortisone can be started at a dose of 50 mg every 8 hours for another 48 hours. Following oral maintenance therapy, a hydrocortisone taper is initiated until the dosage is 30 to 50 mg/day in divided doses. Fluid replacement often is required and can be accomplished with dextrose 5% in normal saline solution (D₅NS) at a rate to support blood pressure. If hyperkalemia is present after the hydrocortisone maintenance phase, additional mineralocorticoid usually is required. Fludrocortisone acetate in a dose of 0.1 mg by mouth daily is the agent of choice.

Patients with adrenal insufficiency should be instructed to carry a card or wear a bracelet or necklace, such as MedicAlert, that contains information about their condition. Patients should also have easy access to injectable hydrocortisone or glucocorticoid suppositories in case of an emergency or during times of physical stress, such as febrile illness or injury.⁷⁴

CLINICAL PRESENTATION: ADRENAL INSUFFICIENCY

Symptoms

- Patients commonly complain of weakness, weight loss, gastrointestinal symptoms, craving for salt, headaches, memory impairment, depression, and postural dizziness.
- Early symptoms of acute adrenal insufficiency also include myalgias, malaise, and anorexia. As the situation progresses, vomiting, fever, hypotension, and shock will develop.

Signs

- Increased pigmentation
- Hypotension (postural)
- Fever
- Decreased body hair

- Vitiligo
- Features of hypopituitarism (amenorrhea and cold intolerance)

Laboratory Tests

- The short cosyntropin stimulation test can be used to assess patients suspected of hypercortisolism.

Other Diagnostic Tests

- Other tests include the insulin hypoglycemia test, the metyrapone test, and the corticotropin-releasing hormone stimulation test.

HYPOALDOSTERONISM

Hypoaldosteronism is rare and usually is associated with low renin status, diabetes, complete heart block, or severe postural hypotension, or it can occur postoperatively following tumor removal.² Hypoaldosteronism can be part of a larger adrenal insufficiency or be the only defect the patient has. In nonselective hypoaldosteronism, the etiology of the low aldosterone is most likely generalized adrenocortical insufficiency (see Addison's Disease). In selective hypoaldosteronism, the etiology is usually a specific defect in the stimulation of adrenal aldosterone secretion (21-hydroxylase deficiency being most common) or a defect in peripheral aldosterone action (decreased aldosterone receptors).

Laboratory analysis reveals low serum sodium and high serum potassium concentrations. Patients often will present with hyperchloremic metabolic acidosis. Because the deficiency is in the mineralocorticoid, replacement with fludrocortisone in a dose of 0.1 to 0.3 mg is usually effective. Patients should be followed for blood pressure response as well as electrolyte status.

CONGENITAL ADRENAL HYPERPLASIA

Because many enzyme systems are needed to complete the complex cholesterol-to-cortisol pathway, enzyme deficiencies can lead to disruptions of the normal cascade of events (see Fig. 79-2). This group of enzyme disorders is known as congenital adrenal hyperplasia, mainly because of the resultant chronic adrenal gland stimulation that occurs following enzyme deficiency.^{81,82} The most frequent is steroid 21-hydroxylase deficiency, accounting for more than 90% of cases. Any enzyme deficiency is capable of affecting any one or all three of the steroid pathways. Therefore, treatment should be focused on replacement of the deficient hormone, psychologic support, and surgical repair of the external genitalia in most female patients.⁸³ In Table 79-8, six of the most common enzyme deficiencies are briefly outlined.

ADRENAL VIRILISM

9 Virilism, excessive secretion of androgens from the adrenal gland, is more commonly seen in females, with hirsutism being the dominant feature. Women who present with hirsutism also can have voice deepening, acne, increased muscle mass, menstrual abnormalities, clitoral enlargement, redistribution of body fat and loss of female body contour, breast atrophy, and hair recession and crown balding.⁸⁴ Although virilism can be easy to diagnose based on clinical symptoms, making the diagnosis on a biochemical basis is difficult.⁸⁵ The most common etiology of adrenal virilism involves one of many possible congenital enzyme defects. Depending on the enzyme deficiency, accumulation of a variety of androgens, notably testosterone, can develop.

Treatment of virilism centers around suppression of the pituitary-adrenal axis with exogenous glucocorticoids. Choice of steroids is variable. In adults, the usual steroids used are dexamethasone (0.25 to 0.5 mg), prednisone (2.5 to 5 mg), or hydrocortisone (10 to 20 mg).⁸⁶ Antiandrogen use can allow lower steroid doses to be used.

TABLE 79-8 Congenital Adrenal Hyperplasia (CAH)

Enzyme Deficiency (Disorder)	Symptoms	Laboratory Tests	Comments
21-Hydroxylase (nonvirilizing CAH)	Enlarged female genitalia and adrenal gland (caused by cholesterol)	All steroids are low in blood and urine	Poor prognosis for infants
17-Hydroxylase (nonvirilizing CAH)	Hypertension usually present	Low concentrations of cortisol and estrogens	Mineralocorticoid replacement not necessary
21-Hydroxylase (virilizing CAH)	Pubertal irregularities (acne, early pubic hair, voice lowering, and increased muscularity); mature normally with replacement	High progesterone, renin, 17-hydroxyprogesterone and ACTH; low cortisol, sodium, and aldosterone	Most common form of CAH (90% of total), incidence of 1:10,000; monitor growth velocity, bone age, renin, and 17-hydroxyprogesterone
11-Hydroxylase (virilizing CAH)	Hypertension secondary to high deoxycortisol and virilism from androgen excess; mistaken for Cushing's, but no glucose intolerance	Low plasma cortisone and aldosterone; high ACTH and MSH concentrations	Second most common form of CAH (9% of total), incidence of 1:100,000; final step in biosynthesis of corticosterone and cortisol; found only in adrenal cortex
3-Hydroxysteroid dehydrogenase (mixed CAH)	Both cortisol and aldosterone deficiencies	Decreased aldosterone, cortisol, estrogens, and androgens; increased pregnenolone and cholesterol	Defect affects both adrenals and gonads
18-Hydroxysteroid dehydrogenase (corticosterone methyloxidase deficiency)	Hypotension	Restricted to zona glomerulosa; sole aldosterone defect; hyponatremia, hyperkalemia, increased renin	Mineralocorticoid replacement without glucocorticoid replacement

ACTH, adrenocorticotropic hormone; MSH, melanocyte-stimulating hormone.

HIRSUTISM

Hirsutism is defined as excessive male pattern terminal hair growth in women, which is distinguishable for hypertrichosis, or nonspecific excessive hair growth.⁸⁶ Common causes of hypertrichosis are genetic predisposition or the use of drugs such as minoxidil, phenytoin, cyclosporine, methyl dopa, danazol, metoclopramide, phenothiazines, reserpine, and diazoxide. The majority of cases of hirsutism occur in women with some degree of excess androgen production. Androgen excess can be derived from either the ovaries or the adrenal glands, with a small fraction coming from pituitary disorders. Ovarian excess is described as polycystic ovarian syndrome (PCOS) and can manifest as obesity, insulin resistance, and menstrual abnormalities. In the patient with hirsutism, congenital adrenal hyperplasia, adrenal tumors, and ovarian tumors should be ruled out.^{86,87}

Cosmetic approaches are generally tried first, with laser photothermolysis offering the greatest long-term success. Only when cosmetic surgery is ineffective should suppressive therapy be used. Eflornithine hydrochloride, an ornithine decarboxylase inhibitor, is a topical cream that is applied as a thin layer to the affected area twice daily, at least 8 hours apart. Reduction in unwanted hair can be noted as soon as 4 weeks with a maximal effect at 8 to 24 weeks.^{86,88} Skin irritation can occur that resolves on discontinuation. Glucocorticoids, such as dexamethasone, can be used if the androgen source is adrenal, but can induce cushingoid symptoms even in doses of 0.5 mg/day. Oral contraceptives can be used in patients who require contraception concurrently. If oral contraceptives are used, a progestin with low androgen activity (norethindrone, ethynodiol diacetate, or drospirenone) should be employed. Gonadotropin-releasing hormone can be an effective adjunct or alternative to oral contraceptives if the source of androgen is ovarian. In addition, insulin sensitizers, such as metformin or thiazolidinediones, can show moderate improvement in women with PCOS. Antiandrogens are often added to the more specific therapies. The most common include spironolactone, flutamide, and finasteride, although none of these is approved by the Food and Drug Administration for the treatment of hirsutism. It can take 6 to 12 months for the antiandrogens to alleviate hirsutism, and treatment should be continued for 2 years. Subsequently, a slow reduction in the dose should be achieved.⁸⁷

CLINICAL CONTROVERSY

Some clinicians believe that the usual starting doses for glucocorticoid supplementation are high and unnecessarily increase a patient's risk for adverse outcomes such as osteoporosis.

PRINCIPLES OF GLUCOCORTICOID ADMINISTRATION

Originally, the term *glucocorticoid* was given to these agents to describe their glucose-regulating properties. However, carbohydrate metabolism is only one of a multitude of effects that steroids can exhibit. The activity produced is a function of the receptor activated (glucocorticoid versus mineralocorticoid) as well as the agent and dose prescribed.

The mechanism of glucocorticoids is complex and not fully known. The glucocorticoid enters the cell through passive diffusion and binds to its specific receptor. There are between 5,000 and 100,000 receptors per cell. Steroids exhibit various binding affinities to the vast number of receptors in almost every tissue and therefore elicit a wide variety of biologic effects.

After binding to the receptor, there is a structural change that occurs in the receptor, known as *activation*. After activation, the receptor-steroid complex binds to deoxyribonucleic acid sites in the cell called *glucocorticoid response elements* (GREs). This binding to the GREs stimulates or inhibits transcription of nearby genes.

The pharmacokinetics of the glucocorticoids varies with the agent given and the route of administration. In general, most steroids given by the oral route are well absorbed. Water-soluble agents are more rapidly absorbed following intramuscular injection than are lipid-soluble agents. Intravenous administration is recommended when a quick onset of action is needed. A summary of the steroids is provided in Table 79-9.

In addition to systemic steroids causing iatrogenic Cushing's syndrome, they also can lead to increased susceptibility to infection, osteoporosis, sodium retention with resultant edema, hypokalemia, hypomagnesemia, cataracts, peptic ulcer disease, seizures, and generalized suppression of the HPA-axis. Long-term complications tend to be insidious and less likely to respond to steroid withdrawal.

TABLE 79-9 Relative Potencies of Glucocorticoids

Glucocorticoid	Anti-Inflammatory Potency	Equivalent Potency (mg)	Approximate Half-Life (min)	Sodium-Retaining Potency
Cortisone	0.8	25	30	2
Hydrocortisone	1	20	90	2
Prednisone	3.5	5	60	1
Prednisolone	4	5	200	1
Triamcinolone	5	4	300	0
Methylprednisolone	5	4	180	0
Betamethasone	25	0.6	100–300	0
Dexamethasone	30	0.75	100–300	0

Suppression of the HPA-axis is a major concern whenever systemic steroids are tapered or withdrawn. Single doses of glucocorticoids can prevent the axis from responding to major stressors for several hours. In general, the longer the steroid is administered and the higher the dose used, the more suppression of the axis occurs. However, the possibility of suppression occurs any time the patient is exposed to supraphysiologic doses of a steroid.^{24,89} Symptoms of steroid withdrawal resemble those seen in a patient with adrenocortical deficiency.

A variety of recommendations for steroid tapering are available.^{24,90–92} In general, patients who have been on long-term steroid therapy will need to be gradually withdrawn toward physiologic doses over months. On average, the normal adult produces approximately 10 to 30 mg of cortisol per day with the peak concentration occurring around 8:00 AM. As the steroid or steroid-equivalent dose approaches the 20- to 30-mg level, the taper should be slowed and the patient checked for axis function. The primary modes to test HPA integrity are the ACTH test, either high- or low-dose, or a morning (8:00 AM) serum cortisol. A normal morning serum cortisol (>20 mcg/dL) or a normal ACTH test would indicate that daily steroid maintenance therapy is not needed. If morning serum cortisol is between 3 and 20 mcg/dL, an ACTH test or an CRH stimulation test can be useful in the assessment of pituitary-adrenal function.²⁴ A morning cortisol less than 3 mcg/dL indicates axis suppression and the need for continued replacement therapy. Suppression can be noted for up to a year in some patients. Caution should be used to prevent disease exacerbation during the steroid taper to prevent the need for rebolusing the patient with another course of high-dose steroids. The dilemma of prolonged steroid administration is sometimes lessened by the use of an alternate day therapy (ADT) regimen.^{24,92} ADT theoretically minimizes the hypothalamic-pituitary suppression as well as some of the adverse effects seen with once-daily therapy. This can be especially important in the treatment of the child and young adult, in whom growth suppression is a major concern. ADT is not recommended for initial management, but rather in the management of the stabilized patient who needs long-term therapy. The patient will be exposed to “on” and “off” days, with the “on” day dose gradually increased with concurrent reduction in the “off” day dose over a period of 14 days. By the day 14, the patient will be consuming medication only on the “on” day. It should be noted that not all patients will have equivalent disease control on ADT, and it should be avoided in certain indications.^{24,92}

EVALUATION OF THERAPEUTIC OUTCOMES

Successful glucocorticoid therapy involves counseling the patient, monitoring the patient, and recognizing complications of therapy (Table 79–10). The risk-to-benefit ratio of glucocorticoid administration should always be considered, especially with concurrent disease states such as hypertension, diabetes mellitus, peptic ulcer disease, and uncontrolled systemic infections.

TABLE 79-10 Factors in Successful Glucocorticoid Therapy

Monitoring	Glucose concentrations (serum and urine) Electrolytes (serum and urine) Ophthalmologic examinations Stool tests for occult blood loss Growth and development (children and adolescents)
Counseling	Take with food to minimize gastrointestinal discomfort Never discontinue medication on your own; check with your physician; gradual dose reduction is usually necessary Carry or wear medical identification indicating that you are on long-term glucocorticoid therapy Dosage increases can be necessary at times of increased stress (surgery or emergency treatments) Be aware of potential side effects (i.e., visual disturbances, bruising, and delayed wound healing) What to do if you miss a dose: If your dosing schedule is <i>Every other day</i> : Take as soon as possible if remembered that morning. If not remembered until later, skip that day. Take the next morning, then skip the following day. <i>Every day</i> : Take as soon as possible, but skip if almost time for the next dose. Never double doses.
Recognizing complications	Early in therapy and essentially unavoidable: insomnia, enhanced appetite, weight gain Common in patients with underlying risk factors: hypertension, diabetes mellitus, peptic ulcer disease Long-term intense treatment: cushingoid habitus, hypothalamic-pituitary-adrenal suppression, impaired wound healing Delayed and insidious: cataracts, atherosclerosis Rare and unpredictable: psychosis, glaucoma, pancreatitis

From United States Pharmacopeial Convention⁹⁴ and Barlow.⁹⁵

CLINICAL CONTROVERSY

Some clinicians believe that twice-daily administration of glucocorticoids in patients with adrenal insufficiency is not as effective as three-times daily. If a twice-daily regimen is used, the second dose should be administered 6 to 8 hours after the first.

ABBREVIATIONS

ACTH: adrenocorticotrophic hormone
ADT: alternate day therapy
APA: aldosterone-producing adenoma
ARR: aldosterone-to-renin ratio
AVS: adrenal venous sampling
BAH: bilateral adrenal hyperplasia
CBG: corticosteroid-binding globulin
CRH: corticotropin-releasing hormone
CT: computed tomography
D₅NS: dextrose 5% in normal saline solution
DDT: dichlorodiphenyltrichloroethane
DST: dexamethasone suppression test
FH: familial hyperaldosteronism
FST: fludrocortisone suppression test
GRA: glucocorticoid-remediable aldosteronism
GRE: glucocorticoid response element
HPA: hypothalamic-pituitary-adrenal
IPSS: inferior petrosal sinus sampling
IRMA: immunoradiometric assay
JVS: jugular venous sampling

MRI: magnetic resonance imaging

PAC:PRA: plasma-aldosterone-concentration-to-plasma-renin-activity (ratio)

PAL: primary aldosteronism

RIA: radioimmunoassay

RU-486: mifepristone

KEY CONCEPTS

- 1 Pharmacologic therapy for acromegaly should be considered when surgery and irradiation are contraindicated, when rapid control of symptoms is needed, or when other treatments have failed to normalize growth hormone (GH) and insulin-like growth factor-1 (IGF-1) concentrations.
- 2 Pharmacotherapy for acromegaly using dopamine agonists provide advantages of oral dosing and reduced cost compared to somatostatin analogs and pegvisomant. However, dopamine agonists effectively normalize IGF-1 concentrations in only 10% of patients.
- 3 Octreotide therapy for acromegaly should be initiated using the short-acting subcutaneous formulation. Patients who have been maintained on subcutaneous octreotide for at least 2 weeks and have shown response to therapy can be converted to the long-acting depot form of octreotide.
- 4 Blood glucose concentrations should be monitored frequently in the early stages of octreotide therapy in all acromegalic patients.
- 5 Pegvisomant appears to be the most effective agent for normalizing IGF-1 concentrations. However, further study is needed to determine the long-term safety and efficacy of this agent for the treatment of acromegaly.
- 6 Recombinant GH is currently considered the mainstay of therapy for treatment of children with growth hormone-deficient (GHD) short stature. Prompt diagnosis of GHD and initiation of replacement therapy with recombinant GH is crucial for optimizing final adult heights.
- 7 All GH products are generally considered to be equally efficacious. The recommended dose for treatment of GHD short stature in children is 0.3 mg/kg/wk.
- 8 Pharmacologic agents that antagonize dopamine or increase the release of prolactin can induce hyperprolactinemia. Discontinuation of the offending medication and initiation of an appropriate therapeutic alternative usually normalize serum prolactin concentrations.
- 9 Cabergoline appears to be more effective than bromocriptine for the medical management of prolactinomas and offers the advantage of less-frequent dosing and decreased adverse events.

- 10 Although preliminary data do not suggest cabergoline has significant teratogenic potential, cabergoline is not recommended for use during pregnancy, and patients receiving cabergoline who plan to become pregnant should discontinue the medication or substitute bromocriptine for cabergoline at least 1 month before planned conception.
- 11 Pharmacologic treatment of panhypopituitarism consists of glucocorticoids, thyroid hormone preparations, sex steroids, and recombinant GH, where appropriate, as lifelong replacement therapy.

In the 1950s, Geoffrey Harris and his colleagues uncovered the physiologic importance of pituitary hormones and proposed the theory of neurohormonal regulation of the pituitary by the hypothalamus.¹ Today the pituitary gland is recognized for its essential role in body homeostasis, and for this reason it often is referred to as the “master gland.” The hypothalamus and the pituitary gland are closely connected, and together they provide a means of communication between the brain and many of the body’s endocrine organs. The hypothalamus uses nervous input and metabolic signals from the body to control the secretion of pituitary hormones that regulate growth, thyroid function, adrenal activity, reproduction, lactation, and fluid balance.

ANATOMY AND PHYSIOLOGY

The hypothalamus (Fig. 80–1) is a small region at the base of the brain that receives autonomic nervous input from different areas of the body to regulate limbic functions, food and water intake, body temperature, cardiovascular function, respiratory function, and diurnal rhythms. In addition, the hypothalamus controls the release of hormones from the anterior and posterior regions of the pituitary gland. Neurons in the hypothalamus produce vasopressin and oxytocin and make many hormone-releasing factors that stimulate or inhibit the release of trophic hormones. At the base of the hypothalamus, a projection known as the *median eminence* is rich with nerve axons and blood vessels and provides both chemical and physical connections between the hypothalamus and the pituitary gland.

The pituitary gland, also referred to as the *hypophysis*, is located at the base of the brain in a cavity of the sphenoid bone known as the *sella turcica*. The pituitary is separated from the brain by an extension of the dura mater known as the *diaphragma sella*. The pituitary is a very small gland, weighing between 0.4 and 1 g in adults. It is divided into two distinct regions, the anterior lobe, or adenohypophysis, and the posterior lobe, or the neurohypophysis (see Fig. 80–1).

The posterior pituitary gland secretes two major hormones: oxytocin and vasopressin (antidiuretic hormone) (Table 80–1). Oxyto-

FIGURE 80-1. Pituitary gland.

cin release from the posterior pituitary causes contraction of the smooth muscles in the breast during lactation. It also plays a role in uterine contraction during parturition. Vasopressin is essential for proper fluid balance and acts on the renal collecting ducts to conserve water. Oxytocin and vasopressin are synthesized in the paraventricular and supraoptic nuclei of the hypothalamus. The posterior pituitary gland contains the terminal nerve endings of these two nuclei as well as specialized secretory granules that release hormones in response to appropriate signals. Loss of anterior pituitary function does not necessarily affect the release of vasopressin or oxytocin because these hormones actually are synthesized in the hypothalamus.

Unlike the posterior pituitary, the release of anterior pituitary hormones is not regulated by direct nervous stimulation but rather is controlled by specific hypothalamic-releasing and inhibitory hormones. The median eminence of the hypothalamus contains a large number of capillaries that converge to form a network of veins known as the *hypothalamic-hypophyseal portal circulation*. Inhibiting and releasing hormones synthesized in the neurons of the hypothalamus reach the anterior pituitary via the hypothalamic-hypophyseal portal vessels to control release of anterior pituitary hormones. Although there is a direct arterial blood supply to the anterior pituitary lobe, the hypothalamic-hypophyseal portal vessels provide the primary blood supply (see Fig. 80–1). In contrast to the posterior pituitary, the anterior pituitary lobe is extremely vascular and has the highest rate of blood flow of all body organs.

The specialized secretory cells of the anterior pituitary lobe secrete six major polypeptide hormones (see Table 80–1). These include growth hormone (GH) or somatotropin, adrenocorticotrophic hormone (ACTH) or corticotropin, thyroid-stimulating hormone (TSH) or thyrotropin, prolactin, follicle-stimulating hormone (FSH), and luteinizing hormone (LH). The release of these hormones is regulated primarily by hypothalamic-releasing and inhibiting hormones. Thyrotropin-releasing hormone (TRH) stimulates anterior pituitary release of TSH and prolactin, corticotropin-releasing hormone (CRH) stimulates anterior pituitary release of ACTH, growth hormone-releasing hormone (GHRH) stimulates anterior pituitary release of GH, and gonadotropin-releasing hormone (GnRH) stimulates anterior pituitary release of LH and FSH. Hypothalamic release of somatostatin inhibits release of GH, and hypothalamic release of dopamine (prolactin inhibitory hormone) inhibits the secretion of prolactin. Prolactin differs from the other anterior lobe hormones in that an inhibiting factor, rather than a stimulating factor, is primarily

responsible for controlling its secretion. In the absence of hypothalamic input, an excess of prolactin is produced, whereas a deficiency state of other anterior pituitary hormones results. Physiologic regulation and action of anterior and posterior pituitary hormones are summarized in Table 80–1.^{2–4}

Destruction of the pituitary gland may result in secondary hypothyroidism, hypogonadism, adrenal insufficiency, GH deficiency, and hypoprolactinemia. The formation of certain types of pituitary tumors may result in pituitary hormone excess. Pituitary tumors may physically compress the pituitary and prevent the release of trophic hypothalamic factors that regulate pituitary hormones. In this chapter, the pathophysiology and role of pharmacotherapy in the treatment of acromegaly, short stature, hyperprolactinemia, and panhypopituitarism are discussed.

GROWTH HORMONE

GH has direct antiinsulin effects on lipid and carbohydrate metabolism. GH decreases utilization of glucose by peripheral tissues, increases lipolysis, and increases muscle mass. GH also stimulates gluconeogenesis in hepatocytes, impairs tissue glucose uptake, decreases insulin-receptor sensitivity, and impairs postreceptor insulin action. The growth-promoting effects of GH are largely mediated by insulin-like growth factors (IGFs) also known as *somatomedins*. GH stimulates the formation of insulin-like growth factor-1 (IGF-1) in the liver as well as in other peripheral tissues. This anabolic peptide acts as a direct stimulator of cell proliferation and growth. There are two types of insulin-like growth factors: IGF-1 and IGF-2. IGF-1 regulates growth to some extent before, and largely after, birth. In contrast, IGF-2 is thought to primarily regulate growth in utero.⁵ GH is secreted by the anterior pituitary in a pulsatile fashion, with several short bursts that occur mostly at night. Because of the short half-life of GH in the plasma (approximately 30 minutes), measurements of circulating GH concentrations throughout the waking hours usually are very low or undetectable. Daytime GH pulses are most likely to occur after meals, following exercise, or during periods of stress. The greatest amount of GH secretion occurs during the night within the first 1 to 2 hours of slow-wave sleep (stage III or IV). Secretion of GH is lowest during infancy, increases slightly during childhood, reaches its peak during adolescence, and then begins to gradually decline during the middle-age years.³

GROWTH HORMONE EXCESS

Acromegaly is a pathologic condition characterized by excessive production of GH. This is a rare disorder that affects approximately 50 to 70 adults per million.⁶ Gigantism, which is even more rare than acromegaly, is the excess secretion of GH prior to epiphyseal closure in children.⁷ Patients diagnosed with acromegaly are reported to have a twofold to threefold increase in mortality, usually related to cardiovascular, respiratory, or neoplastic disease.^{8–10} Most patients are middle-aged at the time of diagnosis, and this disorder does not appear to affect one gender to a greater extent than the other. The most common cause of excess GH secretion in acromegaly is a GH-secreting pituitary adenoma, accounting for approximately 98% of all cases.⁸ Rarely, acromegaly is caused by ectopic GH-secreting adenomas, GH cell hyperplasia, or excess GHRH secretion, or is one of the manifestations of multiple endocrine neoplasia syndrome type 1, McCune-Albright's syndrome, or the Carney complex, all very rare hypersecretory endocrinopathies.⁸

The clinical signs and symptoms of acromegaly develop gradually over an extended period of time. In fact, because of the subtle and slowly developing changes in physical appearance caused by GH excess, most patients are not definitively diagnosed with acromegaly

until 7 to 10 years after the presumed onset of excessive GH secretion.⁹ Excessive secretion of GH and IGF-1 adversely affects several organ systems. Almost all acromegalic patients will present with physical signs and symptoms of soft-tissue overgrowth. Table

80–2 summarizes the classic clinical presentation of patients with acromegaly.^{8–13} Some patients with acromegaly present with only a few of these classic signs and symptoms, making recognition of this disease extremely difficult.

TABLE 80-2 Clinical Presentation of Acromegaly

General
The patient will experience slow development of soft-tissue overgrowth affecting many body systems. Signs and symptoms may gradually progress over 7 to 10 years.
Symptoms
The patient may complain of symptoms related to local effects of the growth hormone (GH)-secreting tumor, such as headache and visual disturbances. Other symptoms related to elevated GH and insulin-like growth factor-1 (IGF-1) concentrations include excessive sweating, neuropathies, joint pain, and paresthesias.
Signs
The patient may exhibit coarsening of facial features, increased hand volume, increased ring size, increased shoe size, an enlarged tongue, and various dermatologic conditions.
Laboratory tests
The patient's GH concentration will be >1 mcg/L following an oral glucose tolerance test (OGTT) and IGF-1 serum concentrations will be elevated. Glucose intolerance may be present in up to 50% of patients.
Additional clinical sequelae
<ul style="list-style-type: none"> Cardiovascular diseases such as hypertension, coronary heart disease, cardiomyopathy, and left ventricular hypertrophy are common in patients with acromegaly. Osteoarthritis and joint damage develops in up to 90% of acromegalic patients. Respiratory disorders and sleep apnea occur in up to 60% of acromegalic patients. Type 2 diabetes develops in approximately 25% of acromegalic patients. Patients with acromegaly may have an increased risk for development of esophageal, colon, and stomach cancer.

From Ben-Shlomo and Melmed,⁸ Melmed,⁹ Kauppinen-Makelin et al.,¹⁰ Fatti et al.,¹¹ Vitale et al.,¹² and Webb et al.¹³

The diagnosis of acromegaly is based on a combination of diagnostic tests and clinical signs and symptoms. Random measures of plasma GH levels are not usually dependable because of the pulsatile pattern of release. The oral glucose tolerance test (OGTT) is commonly used as an important diagnostic tool. Postprandial hyperglycemia inhibits the secretion of GH for at least 1 to 2 hours. Therefore, an oral glucose load would be expected to suppress GH concentrations. However, patients with acromegaly continue to secrete GH during the OGTT. Because GH stimulates the production of IGF-1, serum IGF-1 concentrations can also be measured to aid in the diagnosis of acromegaly. Circulating IGF-1 is cleared from the body at a much slower rate than is GH, and measurements can be collected at any time of the day to identify patients with GH excess.⁹ Current criteria for the diagnosis of acromegaly include failure of GH suppression <1 mcg/L following an OGTT in the presence of elevated IGF-1 serum concentrations.^{14,15} With the development of more sensitive GH and IGF-1 assays, the cutoff value for diagnosis of acromegaly will likely decrease in the future. Insulin-like growth factor-1 binding protein-3 (IGFBP-3) also can be measured because it is positively regulated by GH and binds to circulating IGF-1 with high affinity. This test may be useful in monitoring response to therapy.⁸ Computed tomography and magnetic resonance imaging of the pituitary are important diagnostic tests to confirm the presence of a pituitary adenoma.^{9,14,15}

TREATMENT

Acromegaly

The primary treatment goals for patients diagnosed with acromegaly are to reduce GH and IGF-1 concentrations, improve the clinical signs and symptoms of the disease, and decrease mortality.¹⁵⁻¹⁷ Many clinicians define cure of acromegaly as suppression of GH concentrations to <1 mcg/L after a standard OGTT in the presence of normal IGF-1 serum concentrations.¹⁶ The treatment of choice for most patients with acromegaly is transsphenoidal surgical resec-

tion of the GH-secreting adenoma.^{9,15,17,18} Postsurgical cure rates have been reported to range from 50% to 90%, depending on the type of adenoma and the expertise of the neurosurgeon.^{8,17,18} Complications of transsphenoidal surgery are relatively infrequent and include cerebrospinal fluid leak, meningitis, arachnoiditis, diabetes insipidus, and pituitary failure.⁸ For patients who are poor surgical candidates, those who have not responded to surgical interventions, or others who refuse surgical treatment, radiation therapy may be considered. Radiation, however, may take several years to relieve the symptoms of acromegaly.

Because neither radiation therapy nor surgery will cure all patients with acromegaly, adjuvant drug therapy is often needed to control symptoms.^{9,17,18}

■ PHARMACOLOGIC THERAPY

1 Drug therapy should be considered for acromegalic patients in whom surgery and irradiation are contraindicated, when rapid control of symptoms is indicated, or when other treatments have failed to normalize GH and IGF-1 concentrations. Pharmacologic treatment options include dopamine agonists, somatostatin analogs, and the GH receptor antagonist pegvisomant. Dopamine agonists such as bromocriptine and cabergoline are effective in a small subset of patients and provide the advantages of oral dosing and reduced cost. Somatostatin analogs are more effective than dopamine agonists, reducing GH concentrations and normalizing IGF-1 in approximately 50% to 60% of patients. Pegvisomant, a GH receptor antagonist, is highly effective in normalizing IGF-1 concentrations in up to 97% of patients. However, additional long-term data are needed to establish the safety and efficacy of pegvisomant in the management of acromegaly.

■ DOPAMINE AGONISTS

2 In normal healthy adults, dopamine agonists cause an increase in GH production. However, when these agents are given to patients with acromegaly, there is a paradoxical decrease in GH production. Most clinical experience with the use of dopamine agonists in acromegaly is with bromocriptine. Other agents such as pergolide, cabergoline, and lisuride also have been used. Bromocriptine is a semisynthetic ergot alkaloid that acts as a dopamine-receptor agonist. Most trials assessing the efficacy of bromocriptine in the treatment of acromegaly were conducted in the 1970s and early 1980s. These studies determined that certain subsets of acromegalic patients have a favorable response to drug therapy with bromocriptine. These patients include individuals with high circulating concentrations of prolactin and patients who experience GH suppression following a single 2.5-mg dose of bromocriptine, known as a *bromocriptine challenge*.¹⁹ A review evaluating 34 studies concluded that therapy with bromocriptine was effective in suppressing mean serum GH levels to <5 mcg/L in approximately 20% of patients.²⁰ Only 10% of patients experience normalization of IGF-1 concentrations with bromocriptine therapy, but >50% of patients treated with bromocriptine experience improvement in acromegalic symptoms.^{9,21}

In the United States, bromocriptine is commercially available as 2.5-mg oral tablets and 5-mg oral capsules. In acromegalic patients, significant reductions in GH concentrations are observed within 1 to 2 hours of oral dosing. This effect persists for at least 4 to 5 hours. An overall clinical response in acromegalic patients typically occurs after 4 to 8 weeks of continuous bromocriptine therapy. For treatment of acromegaly, bromocriptine is initiated at a dose of 1.25 mg at bedtime and is increased by 1.25-mg increments every 3 to 4 days as needed.^{19,20} Doses as high as 80 mg/day have been used for treatment of acromegaly, but clinical studies have shown that dosages >20 or 30 mg daily do not offer additional benefits in the

suppression of GH.^{18,20,21} When used for treatment of acromegaly, the duration of action of bromocriptine is shorter than that for treatment of hyperprolactinemia. Therefore, the total daily dose of bromocriptine should be divided into three or four doses.^{18,19,21}

The most common adverse effects of bromocriptine therapy include central nervous system (CNS) symptoms such as headache, lightheadedness, dizziness, nervousness, and fatigue. Gastrointestinal effects such as nausea, abdominal pain, or diarrhea also are very common. Some patients may need to take bromocriptine with food to decrease the incidence of adverse gastrointestinal effects. Most adverse effects are seen early in the course of therapy and tend to decrease with continued treatment.^{18,21} Bromocriptine may cause thickening of bronchial secretions and nasal congestion. Rare cases of psychiatric disturbances, pleural diseases, and an erythromelalgic syndrome (painful paroxysmal dilation of the blood vessels in the skin of the feet and lower extremities) have been reported with bromocriptine use. These conditions appear to be associated with higher doses and prolonged duration of therapy.^{20,21}

Bromocriptine generally should be discontinued if a woman becomes pregnant while taking the drug. Surveillance of women who took bromocriptine throughout pregnancy does not suggest that bromocriptine is associated with an increased risk for birth defects.²¹ If a woman becomes pregnant while taking bromocriptine, the risks and benefits of therapy should be fully considered. In most cases, the benefits of successful therapy outweigh the risks, and bromocriptine therapy should be continued if it is effective in improving symptoms and reducing elevated GH concentrations.

Other dopamine agonists that have been used to treat acromegaly include pergolide, cabergoline, lisuride, and quinagolide. Cabergoline may be especially useful in patients with pituitary tumors that secrete both prolactin and GH.^{21,22} Quinagolide, a dopamine agonist available in Europe, has been shown to be more effective than both bromocriptine and cabergoline in normalizing GH and IGF-1 values in acromegalic patients.¹⁹ Because of the potential cost advantages and convenience of oral administration, dopamine agonists are often considered for treatment of acromegaly prior to initiation of somatostatin analogs. However, the availability of long-acting somatostatin analogs has made these agents more attractive for first-line treatment of acromegaly.

■ SOMATOSTATIN ANALOGS

Octreotide is a long-acting somatostatin analog that is approximately 40 times more potent in inhibiting GH secretion than is endogenous somatostatin.^{23,24} It also suppresses the LH response to GnRH; decreases splanchnic blood flow; and inhibits the secretion of insulin, vasoactive intestinal peptide (VIP), gastrin, secretin, motilin, serotonin, and pancreatic polypeptide. Lanreotide is another somatostatin analog, currently not available in the United States, which is a slow-release depot formulation administered twice monthly.²³ See Addendum at end of chapter.

Octreotide (Sandostatin) injection is commercially available in the United States for subcutaneous or intravenous administration. A long-acting intramuscular formulation of octreotide (Sandostatin LAR) is available for monthly administration. In addition to the treatment of acromegaly, octreotide has many other therapeutic uses, including the treatment of carcinoid tumors, vasoactive intestinal peptide-secreting tumors (VIPomas), gastrointestinal fistulas, variceal bleeding, diarrheal states, and irritable bowel syndrome.

The efficacy of octreotide for treatment of acromegaly has been determined by two major multicenter trials.^{25,26} These studies determined that drug therapy with octreotide suppresses mean serum GH concentrations to <5 mcg/L and normalizes serum IGF-1 concentrations in 50% to 60% of acromegalic patients. Octreotide also is beneficial in reducing the clinical signs and symptoms of acromegaly.

In a 6-month multicenter trial, 70% of patients experienced significant relief of headaches.²⁶ In some patients, relief of headache symptoms occurred within minutes of octreotide administration. In addition, middle-finger circumference was reduced significantly, and 50% to 75% of patients experienced improvement in symptoms of excessive perspiration, fatigue, joint pain, and cystic acne. A 2-year followup of 103 patients treated with octreotide showed that octreotide therapy is safe and effective for long-term use in acromegalic patients.²⁷ Octreotide also has been shown to improve the cardiovascular manifestations of acromegaly, including left ventricular hypertrophy and cardiac performance.^{28–31} Data from two major multicenter trials indicate that pituitary tumor growth is halted during octreotide treatment, and a small number of patients experience tumor regression.^{25,26} Data from more recent studies indicate that shrinkage of pituitary tumor mass during octreotide therapy occurs in approximately 50% of patients.³²

The pharmacodynamic effects of long-acting octreotide are similar to those of subcutaneously administered octreotide. Single monthly doses of long-acting octreotide have been shown to be at least as effective as daily doses of 300 or 600 mcg of subcutaneous octreotide administered in divided doses three times daily in normalizing IGF-1 levels and maintaining suppression of mean serum GH concentrations.³³ A large multicenter trial evaluating the efficacy of long-acting octreotide in acromegalic patients who previously had responded to subcutaneously administered octreotide reported suppression of GH concentrations to <5 mcg/L in 94% of patients and normalization of IGF-1 in 66% of patients following 1 year of therapy.³⁴

Response to long-term therapy with octreotide is related to the presence and increased quantity of functioning somatostatin receptors located in the pituitary adenoma.^{26,27} Identification of patients who most likely will respond to octreotide, prior to initiation of therapy, is important when considering the high cost of this medication and the inconvenience of subcutaneous or intramuscular drug administration. Suppression of serum GH concentrations after a single 50-mcg dose of octreotide has been used to predict a favorable long-term response to octreotide therapy.^{35,36}

③ The initial dose of octreotide for treatment of acromegaly is 100 mcg administered every 8 hours.^{17,20,24} Some clinicians recommend a starting dose of 50 mcg every 8 hours, then increasing the dose to 100 mcg every 8 hours after 1 week, to improve the patient's tolerance of adverse gastrointestinal effects.^{14,18} The dose can be increased by increments of 50 mcg every 1 to 2 weeks based on mean serum GH and IGF-1 concentrations. Patients who experience a significant rise in GH prior to the end of the 8-hour dosing interval may benefit from decreasing the dosing interval to every 4 to 6 hours. Although doses as high as 1,500 mcg/day have been used, doses >600 mcg daily generally do not offer additional benefits, and most patients are adequately managed with 100 to 200 mcg three times daily.^{18,25–27} Patients who have been maintained on subcutaneous octreotide for at least 2 weeks and have shown response to therapy can be converted to the long-acting depot form of octreotide. The initial dose of long-acting octreotide is 20 mg administered intramuscularly in the gluteal region every 28 days. Steady-state serum concentrations are not obtained until after 3 months of therapy. Therefore, dosage adjustments for long-acting octreotide should not be considered until after this time. Some patients may require additional subcutaneous injections during the initial dosetitration phase in order to control symptoms. Long-acting octreotide doses >30 mg every 4 weeks have not been studied.

The most common adverse effects of octreotide therapy are gastrointestinal disturbances such as diarrhea, nausea, abdominal cramps, malabsorption of fat, and flatulence.^{17,18,23} These effects are dose dependent and can be seen within a few hours of the first octreotide injection. Gastrointestinal adverse effects occur in approximately 75% of patients but usually subside within 10 to 14 days of continued treatment.^{17,18,23} Octreotide has been reported to cause injection-site

pain (4% to 31%), conduction abnormalities and arrhythmias (9%), biochemical hypothyroidism (2% to 12%), biliary tract disorders (4% to 50%), and abnormalities in glucose metabolism (2% to 18%).^{20,23}

Octreotide also inhibits cholecystokinin release and gallbladder motility, predisposing patients to the development of cholelithiasis.^{17,18,23} The development of gallstones is a long-term adverse effect of octreotide use and is largely dependent on geographic factors, dietary habits, and length of therapy.^{20,24} The incidence of gallstones in acromegalic patients receiving octreotide increases with length of therapy and has been reported to range from 20% to 50%.^{24–27} However, most patients are asymptomatic, and the diagnosis of cholelithiasis usually is made following an ultrasonographic study that is not prompted by patient symptoms. It has been estimated that only 1% of patients will develop symptomatic gallstones during 1 year of octreotide treatment.²⁴ Because octreotide-induced gallstones usually are present without clinical symptoms, the latest International Acromegaly Consensus recommends that treatment of octreotide-induced gallstones be the same as that for gallstones in the general population.^{9,15} Prophylactic cholecystectomy or medical therapy with ursodeoxycholic acid for acromegalic patients with asymptomatic gallstones usually is not recommended. A small number of studies have suggested that the incidence of gallstone development may be lower with long-acting octreotide compared to subcutaneous octreotide.^{33,34} However, further studies are needed to confirm this observation.

4 The effect of octreotide on glucose metabolism in patients with acromegaly is multifactorial. Decreases in serum GH concentrations induced by octreotide should result in decreased hepatic gluconeogenesis and increased insulin-receptor sensitivity. However, octreotide also decreases insulin secretion and increases IGFBP-1, which is known to inhibit the insulin-like effects of IGF-1. In addition, octreotide delays the gastrointestinal absorption of glucose, which may further alter glucose metabolism in acromegalic patients.³⁷ Small studies conducted in acromegalic patients receiving octreotide have reported improvement in insulin sensitivity as well as impaired insulin secretion.^{37,38} Risk factors associated with worsening glucose tolerance included female gender and elevated baseline insulin values. Although octreotide appears to have a beneficial effect on glucose tolerance in most patients, glucose determinations should be obtained frequently in the early stages of octreotide therapy in all acromegalic patients.

■ GROWTH HORMONE RECEPTOR ANTAGONIST

5 Pegvisomant (Somavert) is a genetically engineered GH derivative that binds to GH receptors in the liver and inhibits IGF-1. This agent is different from other medications used in the management of acromegaly because it does not inhibit GH production; rather, it blocks the physiologic effects of GH on target tissues. Therefore, GH concentrations remain elevated during therapy, and response to treatment is evidenced by a reduction in IGF-1 concentrations. Unlike somatostatin analogs, the pharmacologic activity of pegvisomant does not depend on the presence and quantity of somatostatin receptors in the pituitary tumor.³⁹ Studies evaluating the clinical efficacy of pegvisomant in acromegalic patients have reported a dose-dependent normalization of IGF-1 concentrations in 54% to 89% of patients after 12 weeks of therapy and in 97% of patients after 1 year of therapy.^{40,41} Significant improvements in the clinical signs and symptoms of acromegaly were reported and persisted throughout the 1-year treatment period.⁴¹ Adverse effects appeared to be minimal and included injection-site pain, gastrointestinal complaints such as nausea and diarrhea, and flu-like symptoms. Significant elevations in hepatic aminotransferase concentrations, which were reversible upon discontinuation of the drug, were reported in two patients.⁴⁰ As a result, hepatic function tests should be monitored very closely during

therapy as outlined in the product labeling, and the drug should be used with caution in patients with baseline elevations in hepatic aminotransferase concentrations. GH concentrations increased significantly during the first 6 months of therapy. Although tumor size did not change significantly during clinical trials, there are theoretical concerns that persistently elevated GH concentrations may stimulate tumor growth or result in other unfavorable long-term effects.

Pegvisomant is commercially available in the United States for daily subcutaneous use. The first dose should be administered under the supervision of a physician as a 40-mg loading dose. Subsequent doses are self-administered by the patient starting at a dose of 10 mg daily. The dose can be adjusted in 5-mg increments based on serum IGF-1 concentrations every 4 to 6 weeks, up to a maximum daily dose of 30 mg.⁴²

Based on the available data, pegvisomant appears to be among the most effective agents for normalizing IGF-1 serum concentrations. However, given the limited clinical data, further study is needed to determine the long-term safety and efficacy of pegvisomant in the treatment of acromegaly. Pegvisomant is licensed in the European Union for treatment of acromegaly as a third-line agent, for patients with an inadequate response to surgery and/or radiation therapy, and in patients in whom appropriate medical treatment with somatostatin analogs did not normalize IGF-1 concentrations. Use of pegvisomant after failure of other modalities appears to be a reasonable approach to therapy for acromegaly.

■ COMBINATION THERAPY

Several small studies have suggested that combination therapy with octreotide and dopamine agonists (bromocriptine or cabergoline) or octreotide and pegvisomant may be more beneficial than monotherapy with either drug alone.^{20,23,43,44} Because of the potential for additive adverse effects, combination therapy should be considered as a therapeutic option only for refractory patients who have not fully responded to monotherapy.

■ PHARMACOECONOMIC CONSIDERATIONS

Cost-effectiveness comparisons of the various treatment options for patients with acromegaly have not been performed. Considering that approximately 40% of patients are not completely cured after transphenoidal surgery, pharmacologic treatment often becomes necessary. Bromocriptine and cabergoline are considerably less expensive than octreotide and pegvisomant. However, these agents are not effective in the majority of patients. Long-acting octreotide offers a convenient method of octreotide administration for acromegalic patients. Although this formulation is approximately twice the cost of subcutaneous octreotide, it may result in improved patient compliance, quality of life, and overall disease management. Pegvisomant appears to be the most effective agent for normalizing IGF-1 concentrations and may be useful in patients who are intolerant to or have not responded to therapy with dopamine agonists or somatostatin analogs. However, pegvisomant is significantly more expensive than long-acting octreotide and requires daily subcutaneous injections. Long-term studies evaluating the safety of pegvisomant are needed to clearly define its role in the management of acromegaly. The drug therapy of choice for an acromegalic patient should be determined by careful consideration of several patient-specific factors, including clinical response, compliance, tolerability, and cost of therapy.

CLINICAL CONTROVERSY

Some clinicians advocate the use of somatostatin analogs as primary therapy for acromegaly in place of surgery. However, others believe that sufficient long-term safety and efficacy data are lacking.

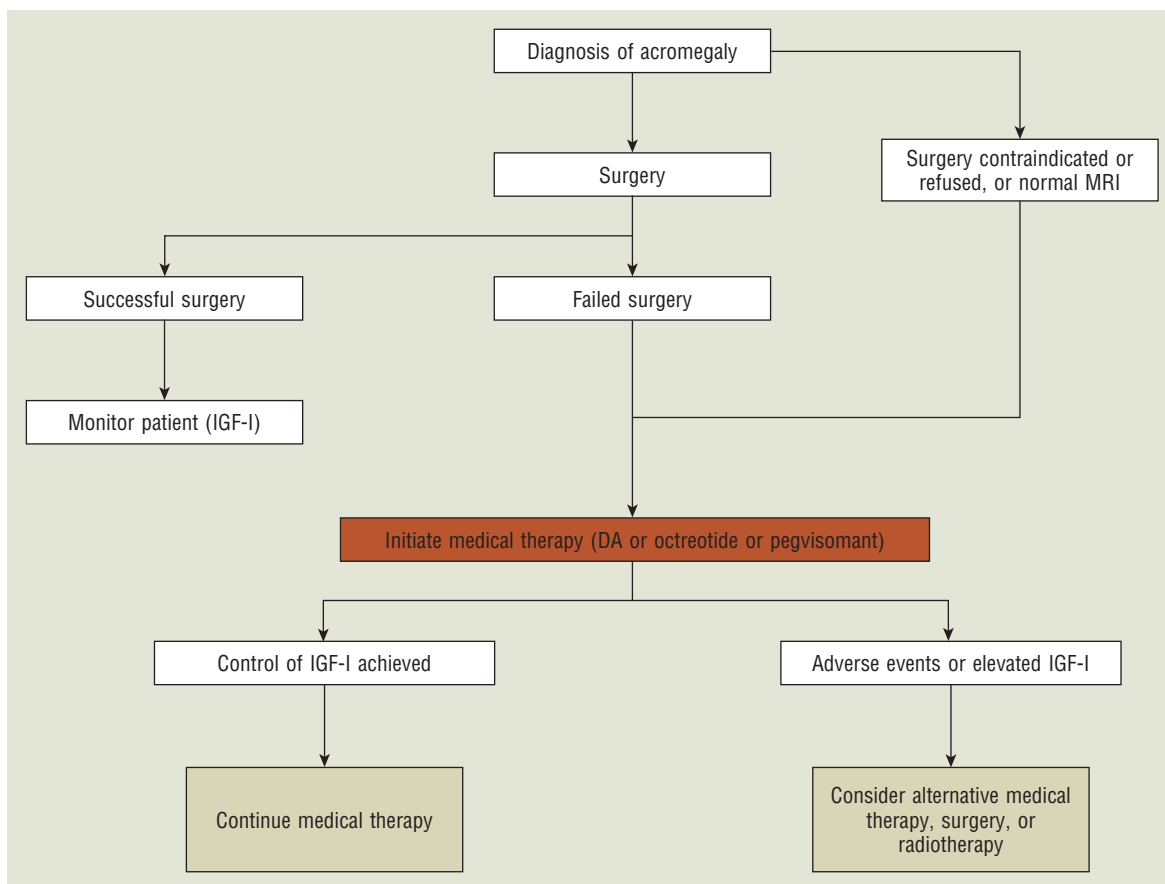

FIGURE 80-2. Treatment algorithm for acromegaly. (DA, dopamine agonist; IGF-I, insulin-like growth factor type I; MRI, magnetic resonance imaging.) (Modified from Clemmons DR, Chihara K, Freda PU, et al. *Optimizing control of acromegaly: integrating a growth hormone receptor antagonist into the treatment algorithm.* *J Clin Endocrinol Metab* 2003;88:4759–4767. Copyright 2003, The Endocrine Society.)

CONCLUSIONS

Acromegaly is a chronic debilitating disease characterized by excess GH secretion most commonly caused by a GH-secreting pituitary adenoma. Transsphenoidal surgical resection of the adenoma is the current treatment of choice for most patients with acromegaly. Patients who are poor surgical candidates may receive radiation therapy or long-term pharmacologic therapy. Drug therapy options within the United States for acromegaly include dopamine agonists, the somatostatin analog octreotide, and pegvisomant. Figure 80–2 shows a treatment algorithm for the management of acromegaly.^{9,39}

GROWTH HORMONE DEFICIENCY

Short stature is a condition that is commonly defined by a physical height that is more than two standard deviations below the population mean and lower than the third percentile for height in a specific age group.^{45–47} It has been estimated that more than 1.8 million children in the United States can be characterized as having short stature.⁴⁷ Short stature is a very broad term describing a condition that may be the result of many different causes. A true lack of GH is among the least common causes and is known as growth hormone-deficient (GHD) short stature. Absolute GH deficiency is a congenital disorder that can result from various genetic abnormalities, such as GHRH deficiency, GH gene deletion, and developmental disorders including pituitary aplasia or hypoplasia.^{45,46} GH insufficiency is an acquired condition that can result secondary to hypothalamic or pituitary tumors, cranial irradiation, head trauma, pituitary infarction, and various types of CNS infections. In addition, psychosocial deprivation, hypothyroidism, poorly controlled diabetes mellitus, treatment of precocious puberty with LH-releasing hormone agonists, and pharmacologic agents such as glucocorticoids,

methylphenidate, and dextroamphetamine may induce transient GH insufficiency.⁴⁵

Short stature also occurs with several conditions that are not associated with a true GH deficiency or insufficiency. These conditions include intrauterine growth restriction; constitutional growth delay; malnutrition; malabsorption of nutrients associated with inflammatory bowel disease, celiac disease, and cystic fibrosis; chronic renal failure; skeletal and cartilage dysplasia; and genetic syndromes such as Turner's syndrome.^{45,46,48} In addition, many children are diagnosed with idiopathic or normal variant short stature. These patients have heights that are significantly lower than the third percentile but present with normal GH serum concentrations and no specific underlying explanation for short stature.⁴⁷

Children with GHD short stature usually are born with an average birth weight. Decreases in growth velocity generally become evident between the ages of 6 months and 3 years.⁴⁵ In contrast, GH insufficiency may arise at any age during growth and development. The clinical characteristics of GHD or GH-insufficient children are listed in Table 80–3.^{45,46}

Several factors must be considered in the diagnosis of GH deficiency or insufficiency. Standard epidemiologic growth charts developed by the National Center for Health Statistics typically are used to determine the percentile of anthropometric measurements, such as height, weight, and head circumference. Pubertal stage typically is determined using the Tanner method. Bone age is determined according to published standards, and growth velocity is calculated to determine the patient's height velocity percentile using standard growth-velocity charts.^{45,46,48} GH deficiency is rarely seen in the absence of delayed skeletal maturation and decreased growth velocity. In addition, several different provocative stimuli that induce GH secretion are used diagnostically to determine GH status. Common

TABLE 80-3 Clinical Presentation of Short Stature

General
<ul style="list-style-type: none"> The patient will have a physical height that is greater than two standard deviations below the population mean for a given age and gender.
Signs
<ul style="list-style-type: none"> The patient will present with reduced growth velocity and delayed skeletal maturation. Children with growth hormone (GH)-deficient or GH-insufficient short stature may also present with central obesity, prominence of the forehead, and immaturity of the face.
Laboratory tests
<ul style="list-style-type: none"> The patient will exhibit a peak GH concentration <10 mcg/L following a GH provocation test. Reduced insulin-like growth factor-1 and insulin-like growth factor-1 binding protein-3 concentrations may be present. Because GH deficiency may be accompanied by loss of other pituitary hormones, hypoglycemia and hypothyroidism may be noted.

From Hindmarsh and Brook⁴⁵ and American Association of Endocrinologists.⁴⁶

provocative pharmacologic GH stimuli include insulin-induced hypoglycemia, clonidine, L-dopa, arginine, glucagon, and GHRH.⁴⁶ A subnormal GH response during childhood is arbitrarily defined as a peak GH serum concentration <10 mcg/L during a 2-hour period after administration of one of these agents.⁴⁶ However, this maximum may be lower, depending on the specific assay and GH reference product used. Assessment of IGF-1 and IGFBP-3 serum concentrations should be made, with measurements exceeding two standard deviations below the standard reference range strongly suggestive of GH deficiency.⁴⁶ The three generally accepted criteria for definitive diagnosis of GH deficiency are subnormal growth velocity, delayed bone age, and subnormal GH response to at least two provocative stimuli.⁴⁹ For prepubertal and early pubertal patients (Tanner stage less than III), priming with sex hormones to improve the specificity of GH provocation tests is often considered. Some patients exhibit clinical signs of GH deficiency, subnormal growth velocity, and delayed bone age despite GH levels that are within normal limits after provocative testing. This makes diagnosis in this group of patients very difficult. Diagnosis based on GH stimulation tests becomes further complicated because of the paucity of data reporting the normal range of GH concentrations after provocative testing in healthy children and the fact that commercial GH assays currently available may not be equivalent. One study comparing several different GH assays found a significant variation between measured GH serum concentrations.⁴⁹ Because of these limitations, careful consideration of multiple factors by a pediatric endocrinology specialist is required to correctly diagnose GH deficiency.

TREATMENT

Growth Hormone Deficiency

■ PHARMACOLOGIC THERAPY

The treatment of GH deficiency with pituitary-derived human GH was first reported in the late 1950s. The National Hormone and Pituitary Program was founded by the National Institutes of Health in 1963 to coordinate the collection of human pituitary glands and purification of GH for administration to children with GH deficiency. In 1985, three deaths linked to Creutzfeldt-Jakob's disease (CJD) were identified in young individuals who were previously treated with human pituitary GH. An evaluation of National Hormone and Pituitary Program data identified 26 cases of fatal CJD in a cohort of 6,107 patients who received treatment with human pituitary-derived GH in the United States between 1963 and 1985.⁵⁰ Human pituitary GH was withdrawn from the U.S. market because

of the strong likelihood that the CJD was transmitted through contaminated human pituitary-derived GH. Shortly after the withdrawal of human pituitary GH, the U.S. Food and Drug Administration approved the first recombinant DNA-derived GH for treatment of GH insufficiency. Prior to the introduction of recombinant GH, the number of individuals who received treatment for GH insufficiency was relatively small because of the limited availability of human pituitary tissue for GH extraction. Currently, with the widespread availability of recombinant GH products, a large number of children can receive GH replacement therapy at higher doses.

6 Recombinant GH is currently considered the mainstay of therapy for treatment of GHD short stature. GH replacement therapy in children with documented GHD short stature produces a significant improvement in growth velocity within the first year of therapy and significantly improves final adult height.^{51–54} The initial increase in growth velocity often is referred to as *catch-up growth*. Most of the initial studies evaluating the efficacy of GH therapy in GHD children were conducted for short periods of time in small numbers of patients, and, until recently, information about the long-term outcome of GH therapy was limited. Initial data suggested that final adult height is not substantially improved, with an average final adult height reported to be two standard deviations below the population mean.^{55–58} Although these results were disappointing, it is important to note that a substantial percentage of patients included in these studies initially had received human pituitary GH in relatively low doses because of its limited availability. In addition, current GH dosing regimens with regard to frequency of administration have changed, making these data difficult to interpret and apply to patients who are receiving GH replacement therapy today. Recent studies evaluating the adult height of children who received only recombinant GH therapy with currently recommended dosing regimens suggest that current recombinant GH therapy has a greater impact on final adult height than previously reported.^{51–54} These studies have reported average final adult heights ranging from 0.5 to 1.7 standard deviations below the population mean. Initiation of therapy at an early chronologic age, prior to the onset of puberty, is associated with a more favorable increase in final height.^{46,52,53} Therefore, prompt diagnosis of GH deficiency and early initiation of replacement therapy with recombinant GH are crucial factors in optimizing the final adult height of children with GH deficiency.

Recombinant GH has been shown to increase the short-term growth rate in pediatric patients with chronic renal insufficiency, intrauterine growth restriction, Turner's syndrome, idiopathic short stature, and Prader-Willi's syndrome and is approved by the FDA for treatment of growth failure associated with these conditions.⁴⁶ GH is also FDA approved for treatment of adult GH deficiency, short bowel syndrome in patients receiving specialized nutritional support, and acquired immunodeficiency syndrome wasting syndrome. When used in adult patients, the recommended dosage of recombinant GH is significantly lower than the dosage used in pediatric patients. Adult patients with GH deficiency during childhood must have the diagnosis of GH deficiency confirmed when they are adults. Long-term GH therapy in GHD adults significantly decreases body fat, increases muscle mass, and improves exercise capacity.⁴⁶ GH therapy in adults has been shown to improve the cardiac risk profile, bone mineral density, and psychological well-being.^{59–61} In addition, GH currently is being investigated for a variety of disorders, including infertility, chronic fatigue, obesity, and natural aging.⁴⁶ Use of GH as an anabolic agent for management of acute catabolism is not recommended.⁴⁶

The majority of short children in the United States do not have an identifiable medical cause for their condition, but with widespread availability of several recombinant GH formulations, many children have received GH therapy regardless of the underlying etiology of

their short stature. The use of recombinant GH therapy in children with non-GHD short stature, also referred to as *idiopathic short stature*, has been studied by many investigators and was approved by the FDA in 2003. However, the use of GH therapy in this patient population remains controversial. A metaanalysis of 38 clinical studies evaluating the efficacy of GH treatment in children with idiopathic short stature reported average increases in final adult height of 4 to 5 cm (1.6 to 2 inches) following a mean duration of therapy of 4.7 years.⁶² This corresponded to an increase above the predicted final adult height of 0.56 to 0.63 standard deviations of the population mean. A more recently published randomized, double-blind, placebo-controlled trial with a mean GH treatment duration of 4.4 years reported an increase in final adult height of 3.7 cm (1.5 inches).⁶³ The slightly smaller height increase reported in the later study may be explained by the more stringent study design, lower mean GH doses, and GH treatment initiation at an older age (peripubertal) compared to the studies included in the metaanalysis.

CLINICAL CONTROVERSY

Most pediatric endocrinologists in the United States believe that GH therapy is appropriate treatment in certain patients with non-GHD short stature. However, given the high cost of therapy and small increases in height, use of GH in this patient population remains controversial.

7 Eleven different recombinant GH products currently are available for use in the United States (Genotropin, Humatrope, Norditropin, Nutropin, Nutropin AQ, Nutropin Depot, Omnitrope, Saizen, Serostim, Tev-Tropin, and Zorbtive). Each of these products contains somatotropin. Somatotropin is composed of the same amino acid sequence as human pituitary GH. Recombinant GH formulations must be administered by intramuscular or subcutaneous injection. Nutropin AQ, Norditropin, and Serostim LQ are the only GH products available as liquid formulations. The remaining products are formulated as lyophilized powders for injection, and patients must be instructed regarding proper administration. A long-acting depot form of GH, Nutropin Depot, is available for once- or twice-monthly subcutaneous injection. This product may be particularly useful for patients who are noncompliant or experience significant adverse effects from frequent injections. The potency of GH products is expressed as international units per milligram (international units/mg), with 1 mg containing approximately 2.6 international units of GH. Direct comparisons between the different recombinant GH products have not been published. However, all GH products are generally considered to be equally efficacious. The recommended dose for treatment of GHD short stature in children is 0.3 mg/kg/wk.⁴⁶ Recombinant GH can be administered daily or in equal doses six times per week, depending on the specific GH product used.⁴⁶ Dosing regimens with greater frequency of administration have been shown to provide more favorable short-term growth responses.⁴⁶ GH replacement therapy should be initiated as early as possible after diagnosis of GH insufficiency and continued until a desirable height is reached or growth velocity has decreased to <2.5 cm per year after the pubertal growth spurt. However, the suitable time point for discontinuation of therapy with growth-promoting doses remains controversial. Glucocorticoids may inhibit the growth-promoting effects of recombinant GH, and concomitant administration of androgens, estrogens, thyroid hormones, or anabolic steroids may accelerate epiphyseal closure and compromise final height.

Three large databases, the National Cooperative Growth Study, the Kabi International Growth Study, and the Australian and New Zealand growth database (OZGROW), have been developed to collect postmarketing adverse effect data or reports associated with

recombinant GH. Development of these databases was prompted by the unexpected and tragic cases of CJD reported in patients treated with human pituitary GH. These databases are maintained by pharmaceutical companies that manufacture GH products.⁶⁴ Recombinant GH is generally well tolerated in children, and adverse effects are relatively uncommon.^{64,65} A small number of patients may complain of injection-site pain or arthralgias. Idiopathic intracranial hypertension, also known as *pseudotumor cerebri*, has been reported in a very small number of children receiving GH therapy. This condition usually develops within the first 8 to 12 weeks of treatment and presents with symptoms such as headache, blurred vision, diplopia, nausea, and vomiting.⁶⁴ The symptoms of idiopathic intracranial hypertension usually resolve after discontinuation of GH therapy, and long-term complications are rare. Cases of slipped capital femoral epiphysis have been reported in children with GH deficiency who are receiving GH therapy.⁶⁴ This condition is thought to occur as a result of the increased width of the femoral plate during GH treatment, but it also has been reported in GHD children who are not receiving GH replacement. Patients with this condition typically complain of hip or knee pain. Slipped capital femoral epiphysis can be managed by an orthopedic surgeon, and GH therapy does not need to be withdrawn. Because GH is known to cause decreased insulin sensitivity, hyperglycemia and diabetes mellitus may develop.⁶⁶ Patients who have specific predisposing risk factors for diabetes mellitus are at greatest risk for this adverse effect.^{64–66} Glycosylated hemoglobin concentrations should be monitored in all patients receiving GH products.⁴⁶ GH may promote the growth of various types of neoplasms and increase tumor recurrence rates in patients with a history of malignancy.^{46,64,65} For this reason, GH should not be administered to patients with an active malignant tumor or a history of recurrent tumor growth. In 1988, a Japanese report indicated that children receiving GH therapy were twice as likely to develop leukemia as children who were not receiving the hormone.⁶⁷ A more recent analysis of all collected reports of leukemia associated with GH therapy determined that these children had other leukemia risk factors (Fanconi's anemia, Bloom's syndrome, or history of cancer).⁶⁸ GH therapy in children without these risk factors does not appear to predispose children to develop leukemia.^{64,65,68} Some patients may develop antibodies to recombinant GH. The development of antibodies during replacement therapy with recombinant GH products has been reported to be relatively low, affecting approximately 15% to 20% of patients.^{69,70} More importantly, the presence of GH antibodies has not been shown to adversely affect growth response and appears to be clinically insignificant except in patients with GH gene deletions. Finally, recent postmarketing reports suggest an increased risk of death associated with long-term GH treatment in children with Prader-Willi's syndrome who are severely obese or have severe respiratory impairment. GH treatment is contraindicated in patients with Prader-Willi's syndrome who have any of these risk factors.

RECOMBINANT INSULIN-LIKE GROWTH FACTOR-1

Recombinant IGF-1 products, consisting of either IGF-1 alone (mecasermin [Increlex]) or IGF-1 in combination with IGFBP-3 (mecasermin rinfabate [Iplex]), have been recently approved by the FDA for the treatment of children with short stature due to severe primary IGF-1 deficiency (defined as children with height standard deviation score ≤ -3.0 plus basal IGF-1 standard deviation score ≤ -3.0 , plus normal or elevated GH concentration) or GH gene deletion with neutralizing antibodies to GH. Recombinant IGF-1 products are not intended for use in subjects with secondary forms of IGF-1 deficiency, such as GH deficiency, malnutrition, hypothyroidism, or chronic treatment with pharmacologic doses of antiinflammatory steroids. Recombinant IGF-1 products have been shown to increase

growth velocity in children with short stature who have low IGF-1 serum concentrations and resistance to GH.^{70–72} However, the efficacy of these agents is less than that reported with GH products in patients with GH deficiency.

The recommended dose of mecasermin is 0.04 to 0.12 mg/kg administered by subcutaneous injection twice daily. Mecasermin rinfabate is administered by once-daily injections at a dose of 1 to 2 mg/kg. Because of the insulin-like effects of these products, patients should be monitored very closely for hypoglycemia, and the drug should be initiated at a dose at the lower end of the dosage range and administered with a meal or snack. The incidence of hypoglycemia may be less frequent with mecasermin rinfabate because of the longer half-life of the combination product.⁷⁰ Additional adverse effects experienced by patients receiving recombinant IGF-1 products include injection-site reactions, tonsillar/adenoidal hypertrophy, lymphoid hypertrophy, coarsening facial features, headache, dizziness, and arthralgia.^{71,72} Intracranial hypertension has been reported in a small number of patients.⁷² Additional studies are needed to elucidate the exact role of recombinant IGF-1 products in the management of short stature not caused by GH gene deletion or GH receptor defects.

■ GROWTH HORMONE-RELEASING HORMONE

A synthetic GHRH product known as sermorelin (Geref) currently is FDA approved for the treatment of idiopathic GH deficiency in children. Sermorelin [GH-RH(1–29)-NH₂] is composed of 29 amino acid residues that are identical to the amino-terminal segment of human GHRH. Although not as effective as recombinant GH therapy, sermorelin has been shown to increase short-term growth velocity in children with idiopathic GH deficiency.⁷³ This product also has been shown to increase growth velocity in children who have GH deficiency secondary to hypothalamic damage rather than pituitary abnormalities, as is observed with radiation-induced GH deficiency.⁷⁴ In most cases of radiation-induced GH deficiency, pituitary somatotropes are capable of secreting endogenous GH, and stimulation of these cells by exogenously administered GHRH may restore the natural pulsatile secretion of GH and result in increased growth rate.

The recommended dose of sermorelin is 0.03 mg/kg administered daily by subcutaneous injection. No serious adverse events have been identified. The most common adverse effect reported by patients receiving sermorelin therapy is injection-site pain. Because normal pituitary function is needed for sermorelin to stimulate GH secretion, children should not receive GHRH therapy with sermorelin unless adequate capacity to secrete GH is documented by provocative GH stimulation testing. Sermorelin may prove to be a beneficial therapeutic option in the treatment of various types of non-GHD short stature. However, because of its mechanism of action, sermorelin does not have a role in the treatment of most cases of true GHD short stature.

■ EVALUATION OF THERAPEUTIC OUTCOMES

Appropriate monitoring of therapy for GHD and non-GHD short stature includes regular assessments of height, weight, growth velocity, serum alkaline phosphatase, and bone age every 6 to 12 months. Additional laboratory tests to monitor for potential adverse effects include serum glucose concentration and thyroid function. The dose of GH will periodically need to be increased as weight increases in growing children.

■ PHARMACOECONOMIC CONSIDERATIONS

The treatment of short stature with recombinant GH is expensive. Despite the prohibitive cost, recombinant GH remains the mainstay

of therapy for children with GHD short stature. However, treatment of non-GHD short stature with recombinant GH is not widely accepted. The benefits in final adult height and increases in growth velocity, particularly in children with true GH deficiency, are associated with significant psychosocial benefits. Many clinicians believe that GH therapy can improve quality of life and should be made available to all children with short stature, regardless of whether or not they are GH deficient.⁷⁵ Until studies using recombinant GH more definitively demonstrate improvements in both final adult height and quality of life, the cost-effectiveness of GH, particularly for non-GHD short stature, remains uncertain.

■ CONCLUSIONS

GH deficiency during childhood results in short stature. Replacement with recombinant GH is considered the mainstay of therapy for patients with GHD short stature, but its use for treatment of non-GHD short stature remains controversial, albeit such treatment is FDA approved. Recombinant GH has proven to be safe for use in children and is associated with few adverse effects. The synthetic GHRH sermorelin and other GH-releasing peptides and preparations of IGF-1 may provide benefit for patients with non-GHD short stature. GH regimens can be particularly demanding and inconvenient for pediatric patients because they must be administered by subcutaneous injection. Knowledge of the long-term benefits and risks is critical to the development of rational, cost-effective treatments for patients with short stature.

PROLACTIN

PHYSIOLOGIC EFFECTS

Prolactin is secreted in a pulsatile fashion by the lactotroph cells of the anterior pituitary, with the highest peak concentrations observed during sleep.⁴ The secretion of prolactin is regulated primarily by tonic hypothalamic inhibitory effects of dopamine. As described earlier in this chapter and as listed in Table 80–1, many factors can affect prolactin secretion. During pregnancy, prolactin serum concentrations rise substantially above normal. All other conditions characterized by excess prolactin serum concentrations, known as *hyperprolactinemia*, are considered pathologic.

HYPERPROLACTINEMIA

Hyperprolactinemia is a state of persistent serum prolactin elevation. Prolactin concentrations >20 mcg/L observed on multiple occasions are generally considered indicative of hyperprolactinemia.^{76,77} Hyperprolactinemia usually affects women of reproductive age.^{76,78} The incidence of hyperprolactinemia in the general population is reported to be <1%.⁷⁷

Hyperprolactinemia has several etiologies. The most common causes are benign prolactin-secreting pituitary tumors, known as *prolactinomas*, and various medications. Prolactinomas are classified according to size. Prolactin-secreting microadenomas are <10 mm in diameter and often do not increase in size.^{4,77} In contrast, macroadenomas are tumors with a diameter >10 mm that continue to grow and can cause invasion of surrounding tissues.^{4,77} In the presence of a prolactinoma, prolactin serum concentrations may remain normal or may be markedly elevated to thousands of micrograms per liter.

8 Any pharmacologic agent that antagonizes dopamine or increases the release of prolactin can induce hyperprolactinemia (Table 80–4). Serotonin is a strong stimulator of prolactin secretion, and selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine, paroxetine, sertraline, and fluvoxamine are the medications

most frequently associated with hyperprolactinemia.⁷⁹ Prior to the increased use of SSRIs, antipsychotic medications with potent dopamine-receptor blockade, such as the phenothiazine derivatives and haloperidol, were most often identified as the cause of drug-induced hyperprolactinemia.⁸⁰ Metoclopramide and domperidone, an antiemetic available in Europe, are potent dopamine-receptor antagonists reported to induce hyperprolactinemia.⁷⁹ Hormones such as estrogen and progesterone, commonly prescribed as oral contraceptives, can stimulate lactotroph growth to promote prolactin secretion and have been implicated in drug-induced hyperprolactinemia. Although the exact mechanism of action remains to be determined, the calcium channel-blocking agent verapamil has been associated with cases of hyperprolactinemia.^{4,79} Methyldopa and reserpine, although not used frequently in clinical practice today, are antihypertensive agents that can stimulate prolactin secretion.⁷⁹ Prolactin concentrations may increase with administration of GnRH analogs such as leuprolide or goserelin.⁷⁹ Other medications rarely reported to cause hyperprolactinemia include H₂-receptor blocking agents, benzodiazepines, tricyclic antidepressants, dexfenfluramine, opioids, protease inhibitors, and monoamine oxidase inhibitors.^{4,77,79} Prolactin levels do not typically rise to >150 mcg/L in cases of drug-induced hyperprolactinemia. Measurement of serum prolactin concentrations prior to the initiation of therapy with medications known to cause prolactin elevation may obviate the need for extensive examination of pituitary function and aid with the appropriate diagnosis of drug-induced hyperprolactinemia.

Less common etiologies include CNS lesions that physically compress the pituitary stalk and interrupt tonic hypothalamic dopamine secretion, resulting in hyperprolactinemia.⁷⁷ Increased TRH concentrations in hypothyroidism can stimulate prolactin secretion and cause hyperprolactinemia. During conditions of renal or hepatic compromise, the clearance of prolactin is decreased, resulting in elevated prolactin concentrations.⁴ Despite vigorous diagnostic effort, the cause of hyperprolactinemia cannot always be determined. This is known as *idiopathic hyperprolactinemia* and most likely is a result of the presence of very small tumors that are not detected by standard imaging techniques.⁷⁶ It should be noted that many physiologic factors, such as stress (including the stress of phlebotomy), sleep, exercise, coitus, and eating, also can induce transiently elevated prolactin levels.^{4,76} This emphasizes the importance of obtaining multiple prolactin measurements to confirm the diagnosis. Ideally, after an intravenous line is placed in the patient's

TABLE 80-5 Clinical Presentation of Hyperprolactinemia

General
Hyperprolactinemia most commonly affects women and is very rare in men.
Signs and symptoms
<ul style="list-style-type: none"> The patient may complain of symptoms related to local effects of the prolactin-secreting tumor, such as headache and visual disturbances, that result from tumor compression of the optic chiasm. Female patients experience oligomenorrhea, amenorrhea, galactorrhea, infertility, decreased libido, hirsutism, and acne. Male patients experience decreased libido, erectile dysfunction, infertility, reduced muscle mass, galactorrhea, and gynecomastia.
Laboratory tests
Prolactin serum concentrations at rest will be >20 mcg/L on multiple occasions.
Additional clinical sequelae
<ul style="list-style-type: none"> Prolonged suppression of estrogen in premenopausal women with hyperprolactinemia leads to decreases in bone mineral density and significant risk for development of osteoporosis. Risk for ischemic heart disease may be increased with untreated hyperprolactinemia.

From Molitch,⁴ Schlechte,⁷⁶ and Mah and Webster.⁷⁷

arm, the patient should rest in a supine position or in a chair for 2 hours before prolactin samples are collected.

Elevated prolactin serum concentrations inhibit gonadotropin secretion and sex-steroid synthesis.⁷⁶ Because prolactin concentrations >60 mcg/L are associated with anovulation, women with hyperprolactinemia typically present with menstrual irregularities such as oligomenorrhea or amenorrhea and infertility.^{7,76,77} In addition, approximately 40% to 80% of women with hyperprolactinemia will have galactorrhea.^{76,77} The clinical presentation of patients with hyperprolactinemia is summarized in Table 80–5.^{4,76,77}

The diagnosis of hyperprolactinemia, as defined by multiple prolactin serum concentrations >20 mcg/L, is relatively simple. However, identifying the underlying cause of this abnormality may be more challenging. Patients with modest prolactin elevations should have multiple prolactin serum determinations to minimize the potential for detecting only transient increases in prolactin. A careful medication history is essential, and the presence of hypothyroidism, renal failure, or hepatic dysfunction should be evaluated. If the cause of hyperprolactinemia remains ambiguous, a computed tomography scan or magnetic resonance imaging study should be performed to determine the presence of a pituitary tumor.^{76,77} If an underlying cause of elevated prolactin serum concentration is not determined, the hyperprolactinemia is considered to be idiopathic.

TREATMENT

Hyperprolactinemia

The treatment of hyperprolactinemia depends on the underlying cause of the abnormality. In cases of drug-induced hyperprolactinemia, discontinuation of the offending medication and initiation of an appropriate therapeutic alternative usually normalizes serum prolactin concentrations.⁷⁹ In cases for which an appropriate therapeutic alternative does not exist, medical therapy with dopamine agonists is warranted. Sex-steroid replacement also should be considered.⁷⁷ Treatment options for the management of prolactinomas include clinical observation, medical therapy with dopamine agonists, radiation therapy, and transsphenoidal surgical removal of the tumor.^{4,76–78} Because prolactin-secreting microadenomas are very small and typically do not increase in size, treatment of these tumors is primarily directed toward alleviating symptoms.^{76–78} The goal of therapy is to normalize prolactin serum concentrations and reestablish gonadotropin secretion to restore fertility and reduce the risk of osteoporosis. In patients with asymptomatic elevations in serum prolactin, observation and close followup are appropriate.^{76–78}

Treatment goals are more aggressive in patients with prolactin-secreting macroadenomas because these tumors are larger and can cause invasion of local tissues with significant visual defects.⁷⁸ Therefore, in addition to normalizing prolactin concentrations, tumor shrinkage and correction of visual defects are primary goals of treatment.

Medical therapy with dopamine agonists usually is more effective than transsphenoidal surgery for both types of pituitary prolactinomas.^{4,76–78} Postsurgical cure rates differ depending on tumor type and expertise of the neurosurgeon. Long-term cure rates are reported to be approximately 60% for microprolactinomas and only 25% for macroprolactinomas.⁴ Transsphenoidal surgery for removal of prolactinomas usually is reserved for patients who are refractory to or cannot tolerate therapy with dopamine agonists and for patients with very large tumors that cause severe compression of adjacent tissues.^{4,76–78} Radiation therapy may require several years for effective tumor shrinkage and reduction in serum prolactin concentrations and usually is used only in conjunction with surgery.⁴

■ PHARMACOLOGIC THERAPY

Medical therapy with dopamine agonists has proven to be very effective in normalizing prolactin serum concentrations, restoring menstruation, and reducing tumor size in approximately 80% to 90% of patients within 3 to 6 months of therapy.^{4,77} Bromocriptine has been the mainstay of therapy since the 1970s. Cabergoline is a long-acting dopamine agonist that offers the advantage of less-frequent dosing. In recent years cabergoline has replaced bromocriptine as the agent of choice for the medical management of prolactinomas.

■ BROMOCRIPTINE

Bromocriptine was the first D₂-receptor agonist to be used in the treatment of hyperprolactinemia and has been the mainstay of therapy for over 20 years. It inhibits the release of prolactin by directly stimulating postsynaptic dopamine receptors in the hypothalamus. Hypothalamic release of dopamine (prolactin-inhibitory hormone) inhibits the release of prolactin. Decreases in serum prolactin concentrations occur within 2 hours of oral administration, with maximal suppression occurring after 8 hours and suppressive effects persisting for up to 24 hours. Medical therapy with bromocriptine normalizes prolactin serum concentrations, restores gonadotropin production, and shrinks tumor size in approximately 90% of patients with microprolactinomas and 70% of patients with macroprolactinomas.⁷⁸

For the management of hyperprolactinemia, bromocriptine therapy typically is initiated at a dose of 1.25 to 2.5 mg once daily at bedtime to minimize adverse effects.^{76,77} The dose can be gradually increased by 1.25-mg increments every week to obtain desirable serum prolactin concentrations. Usual therapeutic doses of bromocriptine range from 2.5 to 15 mg/day, although some patients may require doses as high as 40 mg/day.⁷⁷ Bromocriptine usually is administered in two or three divided doses, but once-daily dosing has also been shown to be effective.⁷⁸

The most common adverse effects associated with bromocriptine therapy include CNS symptoms such as headache, lightheadedness, dizziness, nervousness, and fatigue. Gastrointestinal effects such as nausea, abdominal pain, and diarrhea also are common. Bromocriptine should be administered with food to decrease the incidence of adverse gastrointestinal effects. Although most of these adverse effects diminish with continued treatment, approximately 12% of patients will not tolerate the adverse effects associated with bromocriptine therapy.⁷⁸ Vaginal preparations of bromocriptine have been studied in an effort to decrease the incidence of adverse effects associated with oral dosage forms.^{4,77,81}

Because most patients with hyperprolactinemia are women with a principal complaint of infertility, the safety of bromocriptine in pregnancy must be considered. One report of 100 pregnancies in women who received bromocriptine throughout gestation did not detect an increase in the risk for spontaneous abortion or incidence of congenital anomalies.⁷⁸ Although bromocriptine does not appear to be teratogenic, most clinicians discontinue therapy as soon as pregnancy is detected because the effects of in utero exposure to bromocriptine on gonadal function and fertility of the offspring remain unknown.^{4,76–78} In patients with macroprolactinomas undergoing rapid tumor expansion, bromocriptine therapy may need to be continued throughout pregnancy.

■ PERGOLIDE

Pergolide is a dopamine-receptor agonist with affinity for both D₁- and D₂-receptors. This agent is 10 to 1,000 times more potent than bromocriptine on a per milligram basis. In the United States, pergolide was never FDA approved for treatment of hyperprolactinemia. However, it was used for many years as an effective alternative to bromocriptine in the management of patients with hyperprolactinemia and offered the advantage of once-daily dosing.^{4,78} In 2007, pergolide was withdrawn from the U.S. market because of cases of cardiac valvulopathy.⁸² Pathologic assessment suggested that the valvulopathy associated with pergolide appeared to be similar to that reported with other ergot alkaloids.

■ CABERGOLINE

⑨ Cabergoline is a long-acting dopamine agonist with high selectivity and affinity for dopamine D₂-receptors. This agent is approved for treatment of hyperprolactinemia and has been shown to effectively reduce serum prolactin concentrations in 80% to 90% of hyperprolactinemic patients.^{83–85} Cabergoline also effectively reduces tumor size in patients with both microprolactinomas and macroprolactinomas.^{83–86} In a multicenter randomized trial comparing the efficacy of cabergoline and bromocriptine, serum prolactin levels were normalized in 83% of patients receiving cabergoline and 58% of patients receiving bromocriptine after 6 months of therapy.⁸⁷ Cabergoline also has proved effective in patients who are intolerant of or resistant to bromocriptine, and recent data suggest that cabergoline is as effective in men as in women with microprolactinomas and macroprolactinomas.^{85,88,89}

Cabergoline is commercially available as 0.5-mg oral tablets. The initial dose of cabergoline for treatment of hyperprolactinemia is 0.5 mg once weekly or in divided doses twice weekly. This dose may be increased by 0.5-mg increments at 4-week intervals based on serum prolactin concentrations. The usual dose is 1 to 2 mg weekly; however, doses as high as 4.5 mg weekly have been used.⁹⁰ The efficacy of a vaginal dosage form of cabergoline to reduce the adverse effects associated with oral therapy has been evaluated.⁹¹

Following oral administration, peak serum concentrations are obtained within 2 hours, and food does not affect absorption. Data from animal studies indicate that cabergoline is widely distributed to well-perfused organs, including the pituitary gland.⁹⁰ The elimination of cabergoline from the pituitary appears to be very slow; this rate may explain the long duration of action. Cabergoline is extensively metabolized in the liver by hydrolysis, and the dose should be reduced in patients with severe hepatic failure. This drug is eliminated primarily in the feces, and the elimination half-life ranges from 79 to 155 hours in hyperprolactinemic patients.⁹⁰

The most common adverse effects reported with use of cabergoline are nausea, vomiting, headache, and dizziness.^{78,90} These effects are similar to the adverse effects reported with bromocriptine and pergolide. However, in a large comparative study evaluating bromocriptine and cabergoline, fewer patients receiving cabergoline

reported adverse effects than did patients receiving bromocriptine, and only 3% of the patients in the cabergoline group withdrew from the study because of adverse effects versus 12% of patients taking bromocriptine.⁸⁷ Other adverse events associated with use of cabergoline include gastrointestinal complaints, drowsiness, fatigue, paresthesias, dyspnea, suffocation sensation, and epistaxis.^{78,90} As with other dopamine agonists, adverse events usually occur early in therapy and subside with continued treatment. However, in one study 15% to 20% of patients receiving cabergoline experienced a recurrence of early symptoms or an onset of new symptoms after several weeks of treatment.⁸⁷ Mild-to-moderate decreases in blood pressure have been observed in up to 50% of patients taking cabergoline; however, the incidence of symptomatic orthostatic hypotension has not been significant.^{83,84,87} Transient increases in serum alkaline phosphatase, bilirubin, and aminotransferases have been reported in small numbers of patients receiving cabergoline.⁸⁷ Pleuropulmonary disease⁷⁸ and newly diagnosed cardiac valve regurgitation⁸² have been reported with cabergoline use at the larger doses used in the treatment of Parkinson's disease.

10 Use of cabergoline in pregnancy has not been extensively studied. However, several case reports of women who received cabergoline therapy during the first and second trimesters of pregnancy have not documented an increased risk of spontaneous abortion, congenital abnormalities, or tubal pregnancy.⁹⁰ However, prospective data in large numbers of pregnancies are lacking. Because of the long half-life and limited data on cabergoline use in pregnancy, most clinicians recommend that women receiving cabergoline therapy who plan to become pregnant should discontinue the medication 1 month before planned conception.⁹²

Other dopamine agonists that have been used in the treatment of hyperprolactinemia but are not commercially available in the United States include lisuride, terguride, metergoline, dihydroergocristine, and quinagolide.⁷⁸ Quinagolide, a D₂-receptor agonist used frequently in Europe, is dosed once daily. Quinagolide has been shown to be as effective as bromocriptine for the management of hyperprolactinemia and may be effective in the treatment of patients who are resistant to or intolerant of bromocriptine.⁷⁸

EVALUATION OF THERAPEUTIC OUTCOMES

Prolactin serum concentrations should be monitored every 3 to 4 weeks after the initiation of any dopamine-agonist therapy to assess efficacy and appropriately titrate medication dosage.⁷⁶ In addition, symptoms such as headache, visual disturbances, menstrual cycles in women, and sexual function in men should be evaluated to assess clinical response to therapy. Once prolactin concentrations have normalized and clinical symptoms of hyperprolactinemia have resolved with dopamine-agonist therapy, prolactin serum concentrations should be monitored every 6 to 12 months. In patients receiving long-term treatment, the dose of the dopamine agonist can be gradually reduced or discontinued in some patients. For patients with microprolactinomas who have normal serum prolactin concentrations and at least a 50% reduction in tumor size, medical therapy may be withdrawn every 2 to 5 years to assess if remission has been achieved. In the case of macroprolactinomas, the dose of the dopamine agonist can be gradually reduced in some cases, but complete drug discontinuation should be attempted only if careful monitoring for renewed tumor growth can be ensured.^{76,77,93}

PHARMACOECONOMIC CONSIDERATIONS

Medical therapy with dopamine agonists is more effective than transsphenoidal surgery or radiation for the management of hyperprolactinemia. Because most patients receive therapy for long periods, the medical management of hyperprolactinemia may result in

considerable cost. Cabergoline has been shown to be more effective than bromocriptine and offers additional advantages such as a decreased incidence of adverse effects and improved patient compliance. Most clinicians agree that cabergoline is the most efficacious dopamine agonist currently available. However, the cost of cabergoline therapy is approximately two times greater than that of bromocriptine. Pharmacoeconomic studies are needed to assess whether the higher cost of cabergoline therapy is balanced by the potential added benefits.

CONCLUSIONS

Hyperprolactinemia is a common disorder that can have a significant impact on fertility. Hyperprolactinemia is most commonly caused by the presence of prolactin-secreting pituitary tumors and various medications that antagonize dopamine or increase the secretion of prolactin. Available treatment options for this disorder include medical therapy with dopamine agonists, radiation therapy, and transsphenoidal surgery. In most cases, medical therapy with dopamine agonists is considered the most effective treatment. Cabergoline has replaced bromocriptine as the mainstay of medical therapy because it appears to be better tolerated and more effective. However, because of limited data regarding the safety of cabergoline during pregnancy, bromocriptine remains the preferred agent when fertility is the primary purpose for treatment.

PANHYPOPITUITARISM

11 Panhypopituitarism is a condition of complete or partial loss of anterior and posterior pituitary function resulting in a complex disorder characterized by multiple pituitary hormone deficiencies. Patients with panhypopituitarism may have ACTH deficiency, gonadotropin deficiency, GH deficiency, hypothyroidism, and hyperprolactinemia. Panhypopituitarism can be classified as either primary or secondary depending on the etiology. Primary panhypopituitarism involves an abnormality within the secretory cells of the pituitary, whereas secondary panhypopituitarism is caused by a lack of proper external stimulation needed for normal release of pituitary hormones. Some of the most common causes of panhypopituitarism include primary pituitary tumors, ischemic necrosis of the pituitary, surgical trauma, irradiation, and various types of CNS infections. Pharmacologic treatment of panhypopituitarism is essential and consists of replacement of specific pituitary hormones after careful assessment of individual deficiencies. Replacement most often consists of glucocorticoids, thyroid hormone preparations, and sex steroids. Administration of recombinant GH also may be necessary. Patients with panhypopituitarism will need lifelong replacement therapy and constant monitoring of multiple homeostatic functions.

ABBREVIATIONS

ACTH: adrenocorticotrophic hormone
 CJD: Creutzfeldt-Jakob's disease
 CRH: corticotropin-releasing hormone
 FSH: follicle-stimulating hormone
 GH: growth hormone
 GHD: growth hormone deficient
 GHRH: growth hormone-releasing hormone
 GnRH: gonadotropin-releasing hormone
 IGF: insulin-like growth factor
 IGFBP-3: insulin-like growth factor-1 binding protein-3

LH: luteinizing hormone

OGTT: oral glucose tolerance test

SSRI: selective serotonin reuptake inhibitor

TRH: thyrotropin-releasing hormone

TSH: thyroid-stimulating hormone

VIP: vasoactive intestinal peptide

ADDENDUM

In August 2007, the US FDA approved a depot formulation of the somatostatin analog, lanreotide (Somatuline Depot), for treatment of acromegaly in patients who have failed or are not candidates for surgery or radiation. This agent is currently designated as an orphan drug.

GYNECOLOGIC DISORDERS

CHAPTER

81

Pregnancy and Lactation: Therapeutic Considerations

DENISE L. WALBRANDT PIGARELLI, CONNIE K. KRAUS, AND BETH E. POTTER

KEY CONCEPTS

- 1 Altered drug pharmacokinetics during pregnancy can influence drug selection and dosing. Physiologic changes during pregnancy result in changes in absorption, protein binding, distribution, and elimination.
- 2 Although drug-induced teratogenicity is a serious concern during pregnancy, most drugs required by pregnant women can be used safely. Informed selection of drug therapy is essential.
- 3 Healthcare practitioners must know where to find and how to evaluate evidence related to the safety of drugs used during pregnancy.
- 4 Pregnancy-influenced health issues, such as constipation, gastroesophageal reflux disease, and nausea/vomiting, have been treated safely and effectively with carefully selected drug therapy. Some acute and chronic illnesses pose special risks during pregnancy and should be treated with appropriately selected and monitored drug therapies to avoid harm to both the woman and the fetus.
- 5 Understanding the physiology of lactation and pharmacokinetic factors affecting drug distribution, metabolism, and elimination can assist the clinician in selecting safe and effective medications used during lactation.

Drug use in pregnancy and lactation is a critically important topic that is underemphasized in the education of health professionals. This subject encompasses a dichotomous discussion of the benefits of drug therapy for the mother and the potential risks for the embryo/fetus. Drug use in pregnancy and lactation is a controversial and emotionally charged area because of medicolegal and ethical implications.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

It is the clinician's responsibility to ensure safe and effective therapy before conception, during pregnancy, and after delivery. The patient's active participation is essential. Both acute and chronic illnesses must be managed during pregnancy, and optimal treatments sometimes are different from those used in the nonpregnant patient. Pharmacotherapeutic issues also apply to selection of drugs used during parturition and the postpartum period. Principles of drug use during lactation, although similar, are not the same as those applicable during pregnancy.

In many instances, medication dosing recommendations for acute or chronic illnesses in pregnant women are the same as for the general population. However, in some instances the dosing and selection of medications are quite different.

PHYSIOLOGY OF PREGNANCY

Because of the complexity of fertilization and subsequent pregnancy events, approximately 50% of embryos do not survive.¹ Most losses occur in the first 2 weeks after fertilization before many women realize they were pregnant. About 15% of pregnancies that survive the first 2 weeks of gestation are lost spontaneously later in the course of the pregnancy.

Fertilization occurs when a sperm attaches to a receptor on the outer protein layer of the egg, the zona pellucida.¹ Immediately, the egg becomes unresponsive to other sperm. The attached sperm releases enzymes that cause the egg's chromosomes to mature, allowing the sperm to fully penetrate the zona pellucida and contact the egg's cell membrane. The membranes of the sperm and egg then are fused to create a new, single cell. Male and female chromosomes join in the new cell, fuse to create a single nucleus, and organize to set the stage for cell division.

Fertilization usually occurs in the fallopian tube.¹ Cell division continues for the first 2 days while the fertilized egg travels down the fallopian tube, reaching the uterine cavity on the third day. Cell division continues for another 2 to 3 days in the uterine cavity before implantation begins. Approximately 6 days after fertilization, the cell mass is termed a *blastocyst*. Human chorionic gonadotropin now is produced in amounts that may be detected by commercial laboratories. The blastocyst sloughs the zona pellucida and rests directly on the endometrium, which now responds to the denuded blastocyst by allowing it to begin to grow into the endometrial wall.

After 6 days of this growth, the blastocyst lies implanted under the surface of the endometrium and begins to receive nutrition from maternal blood.¹ Now it is called an *embryo*.²

The embryonic period lasts from approximately 2 weeks after fertilization until 8 weeks after fertilization, when the conceptus is renamed a *fetus*.² Most body structures are formed during the embryonic period, and they continue to grow and mature during the fetal period. The fetal period continues until the pregnancy reaches term, approximately 40 weeks after the last menstrual period.

Gravidity refers to the number of times that a woman experiences pregnancy.² A multiple birth is counted as a single pregnancy. *Parity* refers to the number of a woman's pregnancies that exceeded 20 weeks of gestation and relates information regarding the outcome of each pregnancy. In sequence, the numbers reflect (1) term deliveries, (2) premature deliveries, (3) aborted and/or ectopic pregnancies, and (4) number of living children. A woman who has been pregnant four times; has experienced two term deliveries, one premature delivery, and one ectopic pregnancy; and has three living children would be designated by G₄P₂₁₁₃.

Pregnancy Dating

Approximately 280 days (about 40 weeks or 9 months) constitute the duration of a pregnancy; this time period extends from the first day of the last menstrual period to birth.² *Gestational age* or *menstrual age* refers to the age of the embryo or fetus beginning with the first day of the last menstrual period, which is about 2 weeks prior to fertilization. To calculate an approximate pregnancy due date, the clinician adds 7 days to the first day of the last menstrual period and subtracts 3 months. For simple description purposes, pregnancy is divided into three periods of 3 calendar months, and each period of 3 months is called a *trimester*.

Pregnancy Signs and Symptoms

Early symptoms of pregnancy include fatigue and increased frequency of urination.³ At approximately 6 weeks' gestation, the pregnant woman may experience nausea and vomiting. This is commonly known as *morning sickness* but can occur at any time of the day. Nausea and vomiting usually resolve at 12 to 18 weeks' gestation. Fetal movement is detected in the woman's lower abdomen at 16 to 20 weeks of gestation. Signs of pregnancy may include sudden cessation of menses, changes in consistency of the cervical mucus, bluish discoloration of the vaginal mucosa, increased skin pigmentation, and anatomic breast changes.

MATERNAL PHARMACOKINETIC CHANGES IN PREGNANCY

1 Normal physiologic changes that occur during pregnancy may alter medication effects, resulting in the need to monitor and, sometimes, adjust therapy.⁴ Physiologic changes begin in the first trimester and peak during the second trimester. For medications that can be monitored by blood or serum concentration measurements, monitoring should occur throughout pregnancy.

During pregnancy, maternal plasma volume, cardiac output, and glomerular filtration increase by 30% to 50%, potentially lowering the concentration of renally cleared drugs.⁵ As body fat increases during pregnancy, the volume of distribution of fat-soluble drugs may increase. Plasma albumin concentration decreases, which increases the volume of distribution of drugs that are highly protein bound. However, these unbound drugs are more rapidly cleared by the liver and kidney during pregnancy, resulting in little change in concentration. Nausea and vomiting, as well as delayed gastric emptying, may alter the absorption of drugs. Likewise, a

pregnancy-induced increase in gastric pH may affect the absorption of weak acids and bases. Higher levels of estrogen and progesterone alter liver enzyme activity and increase the elimination of some drugs but result in accumulation of others.

TRANSPLACENTAL DRUG TRANSFER

Although once thought to be a barrier to drug transfer, the placenta is fundamentally the organ of exchange for a number of substances, including drugs, between the mother and fetus.⁶ Most drugs move from the maternal circulation to the fetal circulation by diffusion.⁵ Certain chemical properties, such as lipid solubility, electrical charge, molecular weight, and degree of protein binding of medications, may influence the rate of transfer across the placenta.^{5,6}

Drugs with molecular weights less than 500 Da readily cross the placenta, whereas larger molecules (600–1,000 Da) cross more slowly.^{5,6} Drugs with molecular weights greater than 1,000 Da, such as insulin and heparin, do not cross the placenta in significant amounts.⁵ Lipophilic drugs, such as opiates and antibiotics, cross the placenta more easily than do water-soluble drugs.^{5,6} Maternal plasma albumin progressively decreases while fetal albumin increases during the course of pregnancy, which may result in higher concentrations of certain protein-bound drugs in the fetus.⁵ Fetal pH is slightly more acidic than maternal pH, permitting weak bases to more easily cross the placenta. Once in the fetal circulation, however, the molecule becomes more ionized and less likely to diffuse back into the maternal circulation.

DRUG SELECTION DURING PREGNANCY

2 Although some drugs have the potential to cause teratogenic effects, most medications required by pregnant women can be used safely. There are many misconceptions about the association of medications and birth defects.

The overall incidence of congenital malformations is approximately 3% to 5%.^{7,8} It is estimated that medication exposure accounts for less than 1% of all birth defects.⁸ Genetic causes are responsible for 15% to 25%, other environmental issues (e.g., maternal conditions and infections) account for 10%, and the remaining 65% to 75% of congenital malformations result from unknown causes.

Despite the greater potential of harm with certain drugs, not every exposure results in a birth defect. Factors such as the stage of pregnancy when the exposure occurred, the route of administration, and the dose all can influence outcomes.⁷ In the first 2 weeks after conception, exposure to a teratogen may result in an “all-or-nothing” effect, which could either destroy the embryo or cause no problems. In the period from 18 to 60 days postconception (organogenesis), organ systems are developing, and teratogenic exposures may result in structural anomalies. In the remainder of the pregnancy, exposure to teratogenic agents may result in retardation of growth, central nervous system abnormalities, or death. Examples of medications associated with teratogenic effects in the period of organogenesis include chemotherapy drugs (e.g., methotrexate, cyclophosphamide), sex hormones (e.g., diethylstilbestrol), lithium, retinoids, thalidomide, certain antiepileptic drugs, and coumarin derivatives. Other medications such as nonsteroidal antiinflammatory drugs and tetracycline derivatives are more likely to exhibit effects in the second or third trimester.

In summary, a small number of medications have the potential to cause congenital malformations. Many of these agents can be avoided during pregnancy. In situations where a drug may be harmful to the developing child but is necessary for maternal care, considerations related to route of administration and dosing may lessen the risk of congenital malformations.

METHODS OF DETERMINING SAFETY OF DRUGS IN PREGNANCY

3 Information about medication safety in pregnancy comes from a variety of sources. One of the most important questions for the clinician is how to evaluate the quality of the evidence related to the safety of medications used during pregnancy.

Randomized, controlled trials form the basis for some of the most reliable assessments of drug safety, but pregnant women usually are not eligible for participation in clinical trials. Other types of data often used to estimate the risk associated with medication use during pregnancy are animal studies, case reports, case-control studies, prospective cohort studies, historical cohort studies, and voluntary reporting systems.

Although animal studies are a required component of drug testing, extrapolation of the results of animal testing to humans is not always accurate.⁹ One example is thalidomide, which was found to be safe in some animal models but proved to have teratogenic effects in human offspring.

Case reports may be of limited value because an isolated occurrence of a birth defect in the infant of a woman who used a medication during her pregnancy may have occurred by chance.⁹ Case-control studies identify an outcome (congenital anomaly), match subjects with and without that outcome, and report how often exposure to a suspected agent occurred. The concern with this type of study is recall bias, as a woman with an affected pregnancy may be more likely to recall drugs used during the pregnancy than would a woman who had a normal outcome.

Cohort studies look at the intervention (use of a particular drug) in a group of persons and compare outcomes in a similar group of subjects without the intervention.⁹ Prospective studies eliminate some of the problems with recall bias. This approach has several potential disadvantages, however, such as the need for large numbers of participants, time involved, and potential loss to followup. Despite these disadvantages, cohort studies are used often for evaluating the effects of a drug exposure on pregnancy outcomes. An example of a cohort study is the Michigan Medicaid Study, which consisted of data collected from 229,101 pregnancies over 7 years.

Teratology information services provide pregnant women with information about potential exposures during pregnancy and, in turn, follow these women throughout the pregnancy to assess the outcomes of the pregnancy.⁹ These services may report pooled data to facilitate information sharing about medications used during pregnancy. Some pharmaceutical companies have organized voluntary reporting systems for drugs used during pregnancy.

RESOURCES

3 Computerized databases (e.g., the Canadian database, www.motherisk.org) and textbooks with information from large cohorts of treated women offer valuable assistance. New information regarding drug use in pregnancy can be obtained from searches of the primary literature for cohort and case studies.

One commonly used source of information about drug safety is the category system of the Food and Drug Administration (FDA).¹⁰ The FDA created drug categories to provide guidance on the risk versus benefit for drug use during pregnancy. However, when the FDA categories were compared with two other risk classification systems from other countries, only 61 (26%) of 236 drugs common to all three systems were ranked in the same risk category. Certain agents (e.g., oral contraceptives) classified as teratogenic in the FDA ratings are not considered harmful by other sources. The FDA ranks very few drugs as safe during pregnancy (category A) because the FDA has a requirement for a controlled trial to establish safety, leaving an impression that few drugs are safe.

In summary, drug safety categorizations may provide a rough estimate of risks for medication related adverse fetal outcomes,¹¹ but they must be used in conjunction with other information sources to make decisions about an individual pregnant woman's need for medication therapy.

GENERAL RECOMMENDATIONS FOR OPTIMIZING USE OF MEDICATIONS IN PREGNANCY

2 Many women require medications during pregnancy for treatment of acute and chronic conditions.⁴ Strategies to optimize use of medications during pregnancy include identifying patterns of medication use before conception, eliminating nonessential medications and discouraging self-medication, minimizing exposure to medications known to be harmful, and adjusting doses of necessary medications to optimize the health of the mother while minimizing the risk to the fetus.

PRECONCEPTION PLANNING

Pregnancy outcomes are influenced by maternal health status, lifestyle, and history prior to conception.¹² In the United States, more than 60% of pregnancies are unintended, and many women do not receive prenatal care. Of those who receive prenatal care, 18% do not access care before the end of the first trimester. Preconception care, including evidence-based screening, health promotion, and interventions, should be received by all women of child-bearing age.¹³ Prenatal interventions related to ongoing treatment of chronic conditions and acute treatment of other illnesses are covered in other parts of this chapter.

Neural tube defects, cleft palate and lip, and cardiac anomalies are the most common major congenital anomalies.¹⁴ Approximately 2,500 infants are born with neural tube defects each year in the United States. Neural tube defects occur within 1 month of conception, and folic acid supplementation has been shown to reduce the incidence and recurrence. In women with no history of neural tube defect, four of five studies reported a 40% to 100% decrease in the incidence of neural tube defects with administration of folic acid. The outcome data for women with a history of neural tube defect who received supplementation are similar. Because neural tube closure occurs in the first month of pregnancy and many pregnancies are unplanned and may not be recognized until after the first month, folic acid intake should be encouraged throughout a woman's reproductive years. For women at low risk, folic acid 400 mcg/day is recommended.¹⁵ It should be taken as a supplement because nutritional sources are not sufficient. For women at high risk or who have had a previously affected pregnancy, folic acid 4 mg/day is recommended. Higher doses of folic acid should not be achieved by taking multivitamins because of risk for vitamin A toxicity.

Use of alcohol and recreational drugs during pregnancy is associated with birth defects.¹³ Smoking is associated with preterm birth, low birth weight, and other adverse outcomes. These negative outcomes can be prevented if smoking is discontinued early in pregnancy. A systematic review of 64 trials revealed data on smoking cessation and perinatal outcomes.¹⁶ Incidences of low birth weight and preterm birth were reduced, and birth weight increased by 33 g with smoking cessation. An intervention strategy of rewards plus social support resulted in higher rates of smoking cessation than did other strategies. For women who cannot stop smoking with behavioral interventions alone, nicotine replacement therapies can be used in combination with behavioral therapy.¹⁷ Although the efficacy of nicotine replacement in pregnancy has not been substantiated by clinical trials, this intervention appears to be safe. Intermittent delivery formulations are recommended in order to deliver a smaller daily dose than received from the topically applied

patch. If patches are necessary because of poor tolerability of other agents, they should be applied for 16 rather than 24 hours per day. The initial dose of the patch should be similar or higher than that used for nonpregnant women. Therapeutic drug monitoring of cotinine levels may be considered for dosing nicotine. Bupropion is an alternative to nicotine replacement for women who have not quit smoking with behavioral therapy. The efficacy of this agent for smoking cessation in pregnancy has not been determined. Bupropion use during pregnancy should be reported to the GlaxoSmithKline pregnancy registry.

Prevention of infectious diseases during pregnancy is important for ensuring positive outcomes. Influenza vaccination is generally offered to women who will be in their second or third trimester during influenza season.¹⁸ Women with comorbid conditions that increase risks of complications from influenza should receive vaccine regardless of time of gestation.

PREGNANCY-INFLUENCED ISSUES

4 Pregnant women commonly experience health issues that are either caused by or exacerbated by the pregnant state. Constipation, gastroesophageal reflux, hemorrhoids, and nausea and vomiting may affect many women during pregnancy. Gestational diabetes, gestational hypertension, and venous thromboembolism have the potential to cause adverse pregnancy consequences. Gestational thyrotoxicosis usually is a self-limiting condition.

GASTROINTESTINAL TRACT

Constipation occurs commonly in pregnancy. Therapy should be instituted first with nondrug modalities, such as education, physical exercise, biofeedback, and increased intake of dietary fiber and fluid.¹⁹ If additional therapy is warranted, use of supplemental fiber and/or a stool softener is appropriate. Lactulose, sorbitol, and bisacodyl are acceptable treatments but should be reserved for occasional rather than routine use. Senna can be used occasionally. Castor oil and mineral oil should be avoided.

Gastroesophageal reflux disease occurs in up to 80% of pregnant women.²⁰ Therapy includes lifestyle and dietary modifications (e.g., small, frequent meals; alcohol and tobacco avoidance; food avoidance prior to bedtime; elevation of the head of the bed). Pharmacologic therapy is reserved for patients who do not receive adequate relief from nondrug therapies. Drug therapy can be initiated with aluminum, calcium, or magnesium antacid preparations; sodium bicarbonate should be avoided. Sucralfate is another option, and evidence supports the use of ranitidine and cimetidine. Literature on the use of famotidine and nizatidine is limited. If a patient does not respond to lifestyle changes and histamine-2 receptor blockers, metoclopramide, omeprazole, and lansoprazole are viable options.^{20,21}

The exact prevalence of hemorrhoids during pregnancy is unknown.¹⁹ Therapy is generally conservative; high intake of dietary fiber, adequate oral fluid intake, and use of sitz baths are helpful. Topical anesthetics, skin protectants, and astringents can be used. Other options for refractory hemorrhoids include rubber band ligation, sclerotherapy, and surgery.

Nausea and vomiting affect up to 80% of pregnant women; however, hyperemesis gravidarum (i.e., unrelenting vomiting causing weight loss of more than 5% prepregnancy weight and ketonuria) occurs in only about 1% to 3% of women.²² Dietary modifications, such as eating frequent, small, bland meals and avoiding fatty foods, may be helpful. Lifestyle changes including shorter work days and taking frequent naps. Acupressure and acustimulation may be beneficial.

A number of pharmacotherapeutic approaches have been tried for treatment of nausea and vomiting.²² Multivitamins, pyridoxine (vitamin B₆), and cyanocobalamin (vitamin B₁₂) have shown efficacy. Antihistamines (including doxylamine) have not proved to be toxic

and have shown efficacy. Phenothiazines and metoclopramide have been used widely and are generally considered safe. Efficacy and safety information on ondansetron use are limited, but ondansetron can be considered when other options fail. Corticosteroids (dexamethasone and prednisolone) have shown efficacy for hyperemesis gravidarum, but a small increase in the risk of oral clefts may be associated with use during the first trimester. Ginger has shown efficacy for hyperemesis in five randomized, controlled trials and probably is safe.

GESTATIONAL DIABETES

About 4% of pregnant women develop gestational diabetes (defined as glucose intolerance first identified during pregnancy), although the prevalence may range from 1% to 14%.²³ Whether or not to screen for gestational diabetes is an issue of significant controversy. The U.S. Preventative Services Task Force Independent Expert Panel has concluded that there is a lack of evidence proving that screening for gestational diabetes decreases adverse maternal and fetal outcomes.²⁴ However, the American Diabetes Association recommends screening at her first prenatal visit any woman who has risk factors for developing gestational diabetes mellitus (e.g., obesity, history of the condition, glycosuria, or strong family history of diabetes).²³ If this screening is normal, testing should be repeated between weeks 24 and 28 of gestation. Pregnant women without these risk factors should undergo screening for gestational diabetes mellitus between weeks 24 and 28 of gestation unless they are considered low risk. To be considered low risk, a woman must fulfill *all* the following criteria: (1) age younger than 25 years, (2) normal body weight, (3) no known diabetes in first-degree relatives, (4) no history of abnormal glucose tolerance, (5) no history of adverse obstetric results, and (6) not a member of an ethnic group with a high prevalence of gestational diabetes mellitus (e.g., African Americans, Native Americans, Asian Americans, Latino Americans, Pacific Islanders). Initial screening for hyperglycemia in pregnancy is similar to that in the general population and is described in the American Diabetes Association practice guidelines.²³

First-line therapy for gestational diabetes mellitus includes nutritional interventions for all women and caloric restriction for obese women.²⁵ Daily self-monitoring of blood glucose is necessary for all women with the condition. If nutritional interventions do not result in a fasting plasma glucose concentration ≤ 105 mg/dL, 1-hour postprandial plasma glucose concentration ≤ 155 mg/dL, or 2-hour postprandial plasma glucose concentration ≤ 130 mg/dL, insulin therapy with recombinant human insulin should be instituted. Glyburide may be a reasonable alternative for some women.²⁶ Metformin also may be a practical alternative, but it is less well studied than insulin or glyburide.^{26,27} For women who require insulin therapy, some evidence supports use of postprandial blood glucose monitoring.²⁵ Goals for self-monitored blood glucose are preprandial plasma glucose concentration 80 to 110 mg/dL and 2-hour postprandial plasma glucose concentration < 155 mg/dL.²⁸

Conversely, Cochrane Reviews have revealed that evidence is insufficient to recommend dietary, exercise, or pharmacologic interventions for women with abnormal glucose tolerance in pregnancy.^{29,30} However, a randomized clinical trial revealed that nutritional education, self-monitoring of blood glucose, and insulin therapy as required resulted in reductions in serious perinatal morbidity (death, nerve palsy, bone fracture, and shoulder dystocia).³¹

CLINICAL CONTROVERSY

Despite a lack of evidence for the benefit of screening for gestational diabetes or for implementation of dietary interventions as therapy for gestational diabetes, many clinicians offer screening and dietary guidelines for women with impaired glucose tolerance results.

HYPERTENSION

Broadly stated, hypertension in pregnancy includes gestational hypertension (pregnancy-induced hypertension defined as hypertension without proteinuria), preeclampsia (hypertension with proteinuria), and chronic hypertension (hypertension diagnosed prior to pregnancy with or without overlying preeclampsia).³² Ten percent of pregnancies are complicated by elevated blood pressure at some time during the pregnancy, and 2% to 8% are complicated by preeclampsia. Outcomes of pregnancies complicated by mild-to-moderate hypertension (defined as systolic blood pressure 140–169 mm Hg or diastolic blood pressure 90–109 mm Hg) are similar to normotensive pregnancies; however, blood pressure elevation can become severe (systolic blood pressure 160–170 mm Hg or higher, or diastolic blood pressure 110 mm Hg or higher) and result in maternal complications, hospital admission, and potential premature delivery. Preeclampsia can cause poorer outcomes, including eclampsia (seizures in addition to preeclampsia), renal failure, blood coagulation complications for the mother, preterm delivery, and intrauterine growth limitation for the fetus.

Calcium supplementation may help prevent hypertension in pregnancy. Supplemental calcium 1 g/day has been found to decrease the relative risk of preeclampsia by 50% (range 31%–67%).³³ Although the greatest effect was seen in patients at highest risk and lowest initial calcium intake, even women with baseline adequate dietary calcium intake had a 38% decreased risk of preeclampsia. Therefore, 1 g/day of supplemental calcium is recommended for all pregnant women.

Prevention of preeclampsia in at-risk women includes daily low-dose aspirin therapy after 12 weeks' gestation.³⁴ Factors considered to place a pregnancy at high risk include previous severe preeclampsia, renal disease, autoimmune disease, diabetes, and chronic hypertension. Features associated with moderate risk for preeclampsia include first pregnancy, maternal age 13 to 19 years, mild increase in blood pressure without proteinuria, abnormal uterine artery Doppler scan, family history of severe preeclampsia, and multiple fetuses. Administration of low-dose aspirin therapy has been found to decrease the risk of preeclampsia by 19% in at-risk women. Stated differently, treatment of 69 women will result in prevention of one case of preeclampsia. Pre-term birth may be reduced by 7%, and fetal or neonatal death may be reduced by 16%.

Nondrug therapeutic approaches traditionally have focused on activity restriction, psychosocial therapy, and biofeedback. Currently no evidence indicates that any of these approaches improves pregnancy outcome, and prolonged bed rest may increase the risk of venous thromboembolic disease.

Antihypertensive drug therapy for mild-to-moderate hypertension in pregnancy has not been conclusively shown to positively affect potential negative pregnancy outcomes attributed to hypertension, except for prevention of hypertensive crisis.³² Pregnant women are advised to carefully discuss with their healthcare providers the risks and benefits of treating mild-to-moderate hypertension. No evidence recommends one pharmacologic agent over another. Commonly used drugs include methyldopa, labetalol, and calcium channel blockers.³⁵ Angiotensin-converting enzyme inhibitors should probably be avoided throughout pregnancy.³⁶

Drug therapy is appropriate for women with very high blood pressure, although no conclusive evidence recommends one agent over another.³⁷ Agents to avoid include magnesium sulfate (unless indicated for eclampsia prevention), high-dose diazoxide, nimodipine, and chlorpromazine.

Preeclampsia may progress rapidly to eclampsia, which is a medical emergency, so signs and symptoms of preeclampsia must be monitored carefully.³⁵ Signs and symptoms include blood pressure elevation, proteinuria, ongoing severe headache, ongoing new epigastric pain, visual changes, vomiting, hyperreflexia, sudden and

severe swelling of hands, face, or feet, low platelet count, hemolytic anemia, and elevated liver enzyme tests. The only cure for preeclampsia is timely delivery of the fetus. Drug therapy for hypertension in preeclampsia includes therapy as mentioned previously (i.e., methyldopa, labetalol, calcium channel blockers). Magnesium sulfate is recommended to prevent eclampsia as well as treat eclamptic seizures. Diazepam and phenytoin should be avoided.

THYROID ABNORMALITIES

Human chorionic gonadotropin may stimulate the thyroid gland because the structure of human chorionic gonadotropin is similar to that of thyrotropin.³⁸ Pregnant patients with excessive thyroid gland stimulation have gestational transient thyrotoxicosis. Such thyrotoxic patients usually present with vomiting, which can be severe, an increased serum level of free thyroxine, and a depressed thyrotropin level. No other findings support the diagnosis of true thyrotoxicosis. Gestational transient thyrotoxicosis resolves with declining human chorionic gonadotropin concentrations at the completion of the first trimester. Nausea and vomiting can be treated as for patients without this pseudohyperthyroid state.

Within 1 to 4 months postpartum, about 4% of women may experience transient thyrotoxicosis due to extreme secretion of thyroid hormone.³⁸ Although most cases resolve spontaneously, β -blockers (propranolol or labetalol) can be provided for symptomatic relief; patients should be monitored carefully because transient hypothyroidism may follow. About 2% to 5% of women develop hypothyroidism between 4 and 8 months after delivery, and levothyroxine replacement is suggested for a total of 6 to 12 months.

THROMBOEMBOLISM

The actual incidence of venous thromboembolism during pregnancy is not known but is greater than in nonpregnant women.³⁹

④ Therapy to prevent or treat venous thromboembolism during pregnancy must not include warfarin after the first 6 weeks of gestation because this drug may cause fetal bleeding, malformations of the nose, stippled epiphyses, and central nervous system anomalies.³⁹ For treatment of acute thromboembolism, adjusted-dose low-molecular-weight heparin or unfractionated heparin should be used for the duration of pregnancy and for 6 weeks after delivery. Patients who should receive antepartum and postpartum anticoagulation therapy include women who have a history of a single episode of thromboembolism and who have thrombophilia or a strong family history of thrombosis and are not currently receiving chronic anticoagulation therapy; women with two or more episodes of thromboembolism; and women receiving long-term anticoagulation. Pregnant women with antiphospholipid antibodies and a history of pregnancy complications should receive antepartum aspirin in addition to unfractionated heparin or low-molecular-weight heparin. Women with antiphospholipid antibodies but no history of thromboembolism or pregnancy complications can be treated with careful observation, heparin, low-molecular-weight heparin, and/or low-dose aspirin (up to 325 mg/day).

Women with prosthetic heart valves should receive low-molecular-weight heparin or unfractionated heparin during pregnancy.³⁹ Alternatively, a heparin product can be used until week 13 of gestation, at which time it can be replaced with warfarin until the middle of the third trimester when a heparin product should again be used. High-risk women with prosthetic heart valves may also receive aspirin therapy in doses of 75 to 162 mg/day.

CONCLUSION

Many women with pregnancy-influenced gastrointestinal issues can be treated safely with lifestyle modification or medications, many of

them nonprescription. Gestational diabetes, hypertension, and thyrotoxicosis may or may not require drug therapy. Venous thromboembolism treatment or prevention usually will require therapy with a low-molecular-weight heparin or unfractionated heparin.

ACUTE CARE ISSUES IN PREGNANCY

4 Acute illnesses that occur in pregnant women may present challenges for providers. In some cases, such as asymptomatic bacteriuria, the risks associated with the illness are magnified during pregnancy, and early screening and treatment become critical. In other cases, such as during treatment of certain sexually transmitted diseases, the urgency regarding treatment comes from an increased likelihood of infection leading to preterm labor. Occasionally, common acute care issues, such as migraine headache, actually improve during pregnancy.

URINARY TRACT INFECTION

4 Urinary tract infections are the most common type of bacterial infections in pregnancy.⁴⁰ The incidence of asymptomatic bacteriuria is 2% to 10% and acute cystitis is 1% to 4%. Twenty to forty percent of pregnant women with asymptomatic bacteriuria develop pyelonephritis later in pregnancy, illustrating the importance of early detection. Pyelonephritis may lead to complications such as premature delivery, low infant birth weight, fetal death, preeclampsia, pregnancy-induced hypertension, anemia, thrombocytopenia, and transient renal failure.

With regard to screening for urinary tract infections in pregnant women, the American College of Obstetrics and Gynecology recommends a urine culture both at the initial prenatal visit and during the third trimester.⁴⁰ In contrast, the U.S. Preventive Task Force recommends a urine culture between 12 and 16 weeks' gestation. A urine culture is the preferred method for screening because other methods, such as dipsticks that measure nitrites or leukocyte esterase, require high concentrations of bacteria and may lead to underdiagnosis.

In 95% of cases, *Escherichia coli* is the principal infecting organism.⁴⁰ Other gram-negative rods, such as *Proteus mirabilis* and *Klebsiella pneumoniae*, account for some infections. Group B *Streptococcus* bacteriuria is present in 5% of pregnant women. The presence of group B *Streptococcus* in the urine also may correspond to heavy colonization of the genitourinary tract, increasing the risk for group B *Streptococcus* infection in the newborn.

Treatment of asymptomatic bacteriuria is necessary to reduce the risk of development of pyelonephritis and premature delivery.⁴⁰ The incidence of *E. coli* resistance to ampicillin, amoxicillin, and trimethoprim-sulfa has limited the use of these agents. Cephalexin is considered safe and effective. Nitrofurantoin should not be used after week 37 due to concern for hemolytic anemia in the newborn. Sulfonamide-containing drugs may increase the risk for kernicterus in the newborn and should be avoided during the last weeks of gestation. Folate antagonists, such as trimethoprim, are relatively contraindicated during the first trimester of pregnancy because of associations with cardiovascular malformations. Fluoroquinolones and tetracyclines are contraindicated. The optimal duration of therapy for asymptomatic bacteriuria in pregnancy has not been determined. Courses of 7 to 10 days are common, but some studies have demonstrated that shorter courses of 3 days may be sufficient. A repeat culture 10 days after completion of treatment is recommended.

Signs and symptoms of acute cystitis include urgency, frequency, hematuria, pyuria, and dysuria.⁴⁰ Treatment of acute cystitis is similar to that of asymptomatic bacteriuria. A duration of 7 to 10 days may reduce the risk of recurrence more than 3-day courses of therapy.

A Cochrane Review using outcomes of cure rates, recurrent infection, incidence of preterm delivery or rupture of membranes, admission to neonatal intensive care, need for change of antibiotic, or incidence of prolonged fever demonstrated that antibiotic treatment was effective for symptomatic urinary tract infections (including pyelonephritis) in pregnancy.⁴¹ No specific treatment appeared superior to other commonly used treatments.

Acute pyelonephritis complicates 1% to 2% of pregnancies.⁴⁰ Patients usually present with bacteriuria and systemic symptoms of fever, flank pain, nausea, and vomiting. Hospitalization has been the standard of practice for pregnant women. Inpatient therapy has included parenteral administration of cephalosporins (e.g., cefazolin), ampicillin or cefazolin with gentamicin, or ceftriaxone. Outpatient antibiotic therapy can be considered if the woman has been afebrile for 48 hours and symptoms have resolved; cephalexin has been used. The total duration of antibiotic therapy for acute pyelonephritis is 10 to 14 days. Because up to 23% of women may experience recurrence, suppression therapy with nitrofurantoin 100 mg nightly is recommended for the duration of the pregnancy.

SEXUALLY TRANSMITTED DISEASES

4 Sexually transmitted diseases in pregnant women range from infections that may be transmitted across the placenta and infect the infant prenatally (e.g., syphilis) to organisms that may be transmitted during birth and cause neonatal infection (e.g., *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, or herpes simplex virus) to infections that pose a threat for preterm labor (e.g., bacterial vaginosis). Screening is essential for early detection of most sexually transmitted diseases but may not be beneficial in other instances (e.g., bacterial vaginosis in low-risk patients). Sexual partners of women with certain infections (e.g., syphilis, *N. gonorrhoeae*, *C. trachomatis*) also will require treatment to prevent recurrence of infection.

Syphilis

It is recommended that all women take a serologic test for syphilis at the first prenatal visit.⁴² Additional testing may be warranted for women who live in areas with a high prevalence of syphilis, are at high risk, have not been tested previously, or had positive serology in the first trimester. Penicillin is the drug of choice and is effective in preventing transmission to the fetus and in treating the fetus, if already infected. The dose and route of administration are determined by the stage of syphilis and are the same for pregnant women as for other patients. No alternatives for penicillin are acceptable for pregnant women allergic to penicillin; therefore, penicillin skin testing and desensitization are required.

Women who receive treatment during the second half of pregnancy may be at risk for premature labor and/or fetal distress if treatment results in the Jarisch-Herxheimer reaction.⁴² All women should have serologic titers repeated at 28 to 32 weeks' gestation, at delivery, and as dictated by recommendations for the stage of disease.

Neisseria gonorrhoeae

Perinatal gonococcal infection results from exposure to the infected cervix during birth.⁴² Symptoms generally start within 2 to 5 days of birth. Milder manifestations include rhinitis, vaginitis, urethritis, and infection at the site of fetal monitoring. More severe presentations include ophthalmia neonatorum and sepsis.

N. gonorrhoeae cervicitis coinfection with *C. trachomatis* is common, and treatment of most *N. gonorrhoeae* infections includes treatment for *C. trachomatis*.⁴² Cotreatment regimens for presumptive or diagnosed *C. trachomatis* infection are described in the

TABLE 81-1 Recommended Regimens for Treatment of Cervical Infections Due to *Chlamydia* in Pregnancy**First-line treatment**

Azithromycin 1 g orally in a single dose *or*
 Amoxicillin 500 mg orally three times daily for 7 days

Alternative regimens

Erythromycin base 500 mg orally four times per day for 7 days *or*
 Erythromycin base 250 mg orally four times per day for 14 days
 Erythromycin ethylsuccinate 800 mg orally four times per day for 7 days *or*
 Erythromycin ethylsuccinate 400 mg orally four times per day for 14 days

Data from Centers for Disease Control and Prevention, Workowski KA, Berman SM.⁴²

following section. The treatment of choice for *N. gonorrhoeae* cervical infection is ceftriaxone 125 mg intramuscularly as a single dose or cefixime 400 mg orally in a single dose. For women unable to use a cephalosporin, spectinomycin 2 g intramuscularly as a single dose is appropriate. Quinolones or tetracyclines should not be used.

Chlamydia trachomatis

C. trachomatis infection of the newborn occurs during movement through the birth canal and exposure to the infected cervix.⁴² Perinatal infection most commonly causes conjunctivitis. A subacute, afebrile pneumonia with an onset at ages 1 to 3 months may occur.

The recommended treatment of *C. trachomatis* cervicitis is azithromycin 1 g orally as a single dose or amoxicillin 500 mg three times daily for 7 days.⁴² Erythromycin base or ethylsuccinate regimens can be considered as alternatives. Erythromycin estolate should be avoided because of an increased risk for hepatitis (Table 81-1).

Genital Herpes

4 Neonatal herpes often occurs in infants born of women lacking clinical evidence of genital herpes.⁴² For women who initially acquire genital herpes near the time of delivery, the risk of transmission is 30% to 50%. For women with a history of recurrent herpes at term or who have an initial episode during the first half of the pregnancy, the risk of transmission is less than 1%. However, because recurrent herpes is more common than initial episodes during pregnancy, it remains the cause for most cases of neonatal transmission.

Prevention strategies include counseling uninfected women to avoid intercourse during the third trimester with partners having known or suspected genital herpes infection.⁴² Women with no history of orolabial herpes should avoid receptive oral sex during the third trimester with partners having orolabial herpes. The usefulness of antiviral agents for preventing transmission of genital herpes to pregnant women has not been studied.

All women should be asked about symptoms of genital herpes at the time of delivery and examined for lesions.⁴² Women who have no symptoms or lesions can deliver vaginally. Those who have evidence of outbreak at the time of delivery generally deliver by cesarean section to reduce the risk of transmission to the infant.

Of the agents available for treatment, acyclovir has been used the longest and has not demonstrated an increased risk for birth defects with first-trimester use.⁴² Safety data for valacyclovir and famciclovir are limited. Most women receive oral acyclovir therapy for first or recurrent episodes. Intravenous acyclovir can be used for severe infections. Acyclovir use during late pregnancy has been associated with a reduced frequency of cesarean section because of fewer recurrences. No data suggest benefit of treatment for women who are seropositive for herpes simplex virus but have not experienced a clinical episode. For women with an initial outbreak late in pregnancy, treatment may consist of acyclovir, cesarean section, or a combination of the two.

CLINICAL CONTROVERSY

Although there is evidence that use of antiviral therapy during the last month of pregnancy in women with recurrent genital herpes reduces outbreaks and therefore the need for cesarean section, there is no evidence that use of these agents reduces perinatal transmission.⁴³ Because transmission rates for recurrent herpes are low, the sample size for a study would need to be very large. Several guidelines suggest that prophylactic use of acyclovir during the last month of pregnancy may be warranted.

Bacterial Vaginosis

Although not a sexually transmitted disease, bacterial vaginosis is a risk factor for premature rupture of membranes, preterm labor, preterm birth, spontaneous abortion, and postpartum endometritis.⁴⁴ It is found in 9% to 23% of pregnant women.

Women with a history of preterm delivery should undergo screening for asymptomatic bacterial vaginosis at the first prenatal visit.⁴² If the infection is present, the recommended regimen is metronidazole 500 mg orally twice per day for 7 days, metronidazole 250 mg three times per day for 7 days, or clindamycin 300 mg twice per day for 7 days.

Conflicting data exist with regard to treating women at low risk for preterm labor.⁴² Symptomatic women should be treated using the metronidazole or clindamycin regimen. Vaginal creams have not been found to be effective in reducing the risk of adverse pregnancy outcomes associated with bacterial vaginosis. Use of intravaginal clindamycin cream during the second half of pregnancy has been associated with adverse neonatal effects.

HEADACHE

4 Headaches in pregnant women can be classified as primary (tension, migraine) or secondary (trauma, infection).⁴⁵ Migraine and tension headaches are the most common types.

For more than 60% to 70% of women with a history of migraine headaches, symptoms improve during pregnancy.⁴⁶ The largest improvements in symptoms usually occur in the second and third trimesters.⁴⁵ Women with a history of menstrual migraine are less likely to have remission of symptoms during pregnancy and are more likely to experience postpartum recurrence. Women who have migraine headache without aura are more likely to experience improvement.⁴⁶

Rest, reassurance, and ice packs should be used to initially treat migraine attacks.⁴⁶ Acetaminophen (with or without codeine), codeine, or other narcotic analgesics can be used to treat headaches that do not respond to nonpharmacologic treatment. Nonsteroidal antiinflammatory drugs are considered safe during the first trimester but are generally contraindicated in late pregnancy. Salicylates and indomethacin are potent inhibitors of prostaglandin synthesis and should be avoided throughout the pregnancy if possible, but especially during the third trimester. Use of sumatriptan is controversial, but some clinicians continue the drug in women who have not responded to other agents for treatment of migraine headaches.⁴⁵ Patients who have nausea associated with migraine headaches can be treated with metoclopramide.⁴⁶ Both ergotamine and dihydroergotamine should be avoided. Chronic, preventive treatment can be considered for women who have three to four severe episodes per month that are not responsive to other treatments. β -Blockers, such as propranolol, are commonly used for this purpose but may be associated with side effects, including intrauterine growth retardation.

Tension headaches have been less studied.⁴⁵ Most women report no change in the frequency or intensity of tension headaches.

Tension headaches may be difficult to distinguish from secondary headaches. Primary treatments for tension headache are nonpharmacologic interventions, including exercise, biofeedback, and massage. Simple analgesics such as acetaminophen, ibuprofen, or caffeine can be used if nonpharmacologic treatments fail. Narcotics and benzodiazepines should be avoided.⁴⁶

CHRONIC ILLNESSES IN PREGNANCY

4 For the majority of women and their healthcare providers, pregnancy is a new consideration for a previously diagnosed health condition. Medications used to treat the chronic illness often can be used throughout the pregnancy and during breast-feeding.

ALLERGIC RHINITIS AND ASTHMA

4 Asthma and rhinitis are two of the most common chronic illnesses in pregnancy. Although rhinitis itself is unlikely to cause harm to the mother or fetus, untreated rhinitis may be associated with diminished quality of life. Asthma control may change, and worsening asthma may have significant health consequences to both the mother and the fetus.

Asthma affects approximately 4% of pregnancies.⁴⁷ Asthma severity can change during pregnancy; almost equal proportions of patients have symptoms that worsen, improve, or remain unchanged. Asthma symptoms may worsen during the third trimester but may improve in the last month of pregnancy.

Appropriate treatment is critical to the health of the mother and the infant.⁴⁷ In the mother, undertreated asthma is associated with placenta previa, oligohydramnios, preterm labor, maternal hypertension, preeclampsia, uterine hemorrhage, and need for cesarean section. In the infant, poor maternal asthma control may result in premature birth, low birth weight, and stillbirth.

The treatment goal is to control symptoms in order to maintain maternal health and well-being and promote normal fetal development.⁴⁸ Optimal control is described as (1) minimal use of short-acting β_2 -agonists, (2) achievement of normal or near-normal pulmonary function, (3) lack of adverse effects of treatment, (4) control of symptoms during both day and night, (5) ability to continue normal activities, and (6) avoidance of acute exacerbations.

Treatment of asthma should include (1) assessment and monitoring of asthma (including pulmonary function testing); (2) identifying, controlling, or avoiding allergens and irritants (e.g., tobacco smoke); (3) patient education; and (4) stepwise approach to use of medications.⁴⁸ Treatment of asthma with medications is considered safer than the risks to the fetus from untreated asthma.

All patients with asthma should have access to a short-acting β_2 -agonist for quick relief of symptoms.⁴⁸ Women with mild intermittent asthma require only a short-acting, inhaled β_2 -agonist; albuterol is the preferred agent.

Low-dose inhaled corticosteroids are the treatment of choice for women with mild persistent asthma.⁴⁸ Although budesonide is the preferred agent, other inhaled corticosteroids that were effective prior to pregnancy can be continued. Cromolyn, leukotriene receptor antagonists, and theophylline are considered alternative treatments but are not preferred because of less efficacy (cromolyn), less experience (leukotriene receptor antagonists), and more potential toxicity (theophylline) than inhaled corticosteroids.

For moderate persistent asthma, either a combination of low-dose inhaled corticosteroids with a long-acting β_2 -agonist or an increase in the dose of the inhaled corticosteroids is the recommended treatment option.⁴⁸ Because long-acting bronchodilators have similar pharmacologic and safety profiles compared to short-acting agents, they appear to be safe for use during pregnancy.

For severe persistent asthma, the inhaled corticosteroid dose should be increased to the high-dose range.⁴⁸ Addition of systemic corticosteroids may be warranted if symptoms continue.

As with asthma, allergic rhinitis may improve, worsen, or remain the same during pregnancy.⁴⁹ Treatment strategies include avoidance of allergens, immunotherapy, and pharmacotherapy. World Health Organization standards state that immunotherapy is not contraindicated in pregnancy but advises against dose increases during pregnancy to lessen risk for anaphylaxis.

Intranasal corticosteroids are the most effective treatment for allergic rhinitis during pregnancy and have a low risk of systemic effect.⁴⁸ Beclomethasone and budesonide have been most widely studied.⁴⁹ Nasal cromolyn and first-generation antihistamines (chlorpheniramine, tripelemnamine, and hydroxyzine) are also considered first-line choices. The second-generation antihistamines loratadine and cetirizine do not appear to increase risk to the fetus but have not been studied as extensively as the first-generation products. Oral decongestants, such as pseudoephedrine, may be associated with an increased risk for the rare birth defect gastroschisis.⁴⁸ Use of an external nasal dilator, short-term topical oxymetazoline, or inhaled corticosteroids may be preferable to use of oral decongestants, especially during early pregnancy.

DERMATOLOGIC CONDITIONS

4 Treatment of dermatologic conditions often can be delayed until after the delivery.⁵⁰ If implementation of treatment during pregnancy is necessary, topical agents with minimal pregnancy risk include bacitracin, benzoyl peroxide, ciclopirox, clindamycin, erythromycin, metronidazole, mupirocin, permethrin, and terbinafine. Topical corticosteroids are thought to be safe for use but should be applied at the lowest possible dose for the shortest time. Systemic agents considered safe include acyclovir, amoxicillin, azithromycin, cephalosporins, ciprofloxacin, dicloxacillin, diphenhydramine, erythromycin (except estolates), nystatin, and penicillins. Lidocaine and lidocaine with epinephrine can be used topically during pregnancy. Dermatologic drugs with teratogenic potential that should be avoided include acitretin, fluorouracil, isotretinoin, methotrexate, and thalidomide.

DIABETES

4 Women with diabetes should defer pregnancy until the condition is under control with medication and lifestyle interventions because of increased fetal loss and malformations resulting from suboptimally controlled diabetes.²⁸ In addition, diabetic retinopathy may worsen, hypertension may develop, and renal function may deteriorate during pregnancy. Enhanced monitoring for these target-organ problems is essential.

Insulin is the drug treatment of choice for patients with both type 1 and type 2 diabetes.^{26,28} However, use of glyburide after week 11 of gestation in patients with type 2 diabetes may be acceptable.²⁶ Metformin is another option. Medical nutrition therapy and supervised physical activity programs should continue.^{26,28} Goals for self-monitored blood glucose are the same as for gestational diabetes.²⁸

EPILEPSY

4 Maternal epilepsy complicates 1% of pregnancies.⁵¹ About 35% of women experience an increase in seizure frequency during pregnancy, 55% have no change, and 10% experience a decrease in frequency. Seizures may become more frequent because of changes in maternal hormones, sleep schedule, antiepileptic drug pharmacokinetics, and medication adherence problems (because of perceived teratogenic risk of antiepileptic drug therapy). In addition, free serum concentrations of the antiepileptic drug may change as a result of

maternal increased volume of distribution, decreased protein binding because of hypoalbuminemia, increased hepatic drug metabolism, and increased renal drug clearance. A woman's clinical condition and the free serum concentrations of antiepileptic drug should be the bases for any adjustments in antiepileptic drug dosage. If a woman chooses to breast-feed, her antiepileptic drug requirements will not change until breast-feeding stops.

Major malformations occur in 4% to 6% of offspring of epileptic women taking benzodiazepines, carbamazepine, phenobarbital, phenytoin, or valproic acid.⁵¹ Lamotrigine has been associated with an incidence of oral cleft palate and/or lip of one case per 113 exposed infants.⁵² Minor malformations occur in 6% to 20% of pregnancies affected by epilepsy, which is twice the rate in the general population. The malformations are considered to result from fetal exposure to antiepileptic drug therapy rather than from maternal epilepsy.^{51,53} Combination regimens of antiepileptic drugs are associated with higher malformation rates.⁵¹

Recommendations are use of antiepileptic drug monotherapy, if possible, and optimization of any drug therapy prior to conception.⁵⁴ Medication change exclusively to minimize teratogenic risk, such as the prior recommendation to switch to phenobarbital from other antiepileptic drugs, is *no longer* recommended. Drug withdrawal, if planned, should be attempted at least 6 months before conception is attempted. To correct vitamin K deficiency in newborns, the mother should receive supplementation with 10 mg oral vitamin K₁ daily during the last month of gestation.⁵⁴ In addition, all women with epilepsy should take folic acid supplementation of 0.4 to 5 mg daily.^{51,54}

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

4 Zidovudine is the mainstay of antiretroviral therapy and is recommended for use during pregnancy (after the first trimester), labor, and delivery, as well as during the postpartum period.⁵⁵ If a woman has received prior antiretroviral therapy, continuation should be strongly considered. Without prior therapy, the regimen should be selected from those suggested for nonpregnant adults. If therapy is discontinued during the first trimester because of nausea, vomiting, or other reasons, the woman should wait to resume therapy until her ability to tolerate all medications is determined with certainty. Additionally, all medications should be restarted at the same time to decrease risk of resistance. The current zidovudine dosing recommendation during pregnancy is 100 mg five times daily, 200 mg three times daily, or 300 mg twice daily. Zidovudine should be initiated at the beginning of the second trimester and continued for the duration of the pregnancy. Intravenous zidovudine is recommended during labor, and the infant should receive the drug beginning 8 to 12 hours after birth and continuing for the first 6 weeks of life.

HYPERTENSION

4 For women with stage 1 or 2 chronic hypertension (blood pressure 140–179 mm Hg systolic or 90 to 109 mm Hg diastolic), the decision of whether to continue or stop antihypertensive therapy is controversial because most of the increases in adverse fetal and maternal outcomes are due to preeclampsia superimposed on chronic hypertension.⁵⁶ Therapy should be restarted if medication is discontinued and women are monitored closely but blood pressure exceeds 150 to 160 mm Hg systolic or 100 to 110 mm Hg diastolic or if target-organ damage is present. Alternatively, antihypertensive drugs may be continued (except for angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers) at the lowest effective dose. Use of diuretics is controversial but may be considered for chronic hypertension. For women with severe hypertension (diastolic blood pressure

≥100 mm Hg), the benefit of drug therapy may outweigh the risks. No evidence exists for superior efficacy of one agent versus another for blood pressure reduction.^{32,37,56}

MENTAL HEALTH CONDITIONS

4 An estimated 500,000 pregnancies each year involve women with psychiatric illnesses (either newly or previously diagnosed).⁵⁷ Although depression is the most studied mental health condition during pregnancy, it is not the most common.

Anxiety disorders, including panic disorder, obsessive-compulsive disorder, generalized anxiety disorder, posttraumatic stress disorder, social anxiety disorder, and phobias, are the most commonly occurring psychiatric illnesses in the general population.⁵⁷ Little information is available regarding the incidence and clinical course of these illnesses during pregnancy.

Depression occurs in 10% to 16% of pregnant women.⁵⁷ Maternal depression is associated with greater risk for premature birth and low birth weight. Bipolar disorder affects 1.5% of Americans, but the incidence in pregnancy is unknown. Relapse in bipolar patients may be more likely during pregnancy, especially if pharmacologic treatment is stopped. In addition to the potential impact of maternal depression on obstetric complications, untreated depression may have long-term implications for normal infant development.

Schizophrenia occurs in 1% to 2% of women, but the incidence in pregnancy is unknown.⁵⁷ Because of the risk for decompensation of symptoms during pregnancy and during the postpartum period, drug therapy is often necessary. Maternal schizophrenia is associated with increased risk of perinatal death, low birth weight, preterm delivery, stillbirth, and infant death.

Five percent of Americans, mostly women, suffer from eating disorders.⁵⁷ Some evidence indicates that women with eating disorders may have a more benign course during pregnancy, but common comorbid conditions such as depression and anxiety deserve attention. Eating disorders may pose problems during the postpartum period.

A number of nonpharmacologic options can be used for treatment of psychiatric illness in pregnant women. Both cognitive behavioral therapy and interpersonal psychotherapy have been shown to be beneficial in the treatment of anxiety disorders and depression.⁵⁷ Light therapy also has been effective in treatment of depression. Electroconvulsive therapy is considered safe and effective treatment of major depression and bipolar disorder.

Because many of the psychotropic medications are used to treat more than one condition, the reader should refer to other sources for information about treatment of specific mental health diagnoses. The following section describes medications commonly used for treatment of mental illness, along with implications for use in pregnant women.

Antidepressants have been used with relative safety for more than 40 years.⁵⁷ The selective serotonin reuptake inhibitors are the drugs of first choice in the general population and are widely used by pregnant women. Research findings have revealed adverse events in newborns exposed to selective serotonin reuptake inhibitors in utero.⁵⁸ About one to two babies per 1,000 develop persistent pulmonary hypertension. A study found this risk was six times greater in infants born to women who took selective serotonin reuptake inhibitors after week 20 of pregnancy. Another risk associated with use of selective serotonin reuptake inhibitors late in pregnancy is a withdrawal reaction in the infant consisting of irritability and difficulty with feeding and breathing. Finally, an epidemiologic study suggests that first-trimester use of paroxetine may be associated with an increased risk for cardiac defects in the infant. Despite the concerns about adverse effects in infants born to women who used selective serotonin reuptake inhibitors during

pregnancy, a study indicated that pregnant women who stopped taking antidepressant medications were five times more likely to have a relapse than women who completed treatment, which has implications for the well-being of the infant.

Benzodiazepines are used to treat a number of mental health conditions.⁵⁷ Early studies of benzodiazepine use during pregnancy warned of an increased risk for oral clefts in infants who were exposed to these agents during pregnancy. Later studies did not have the same findings. A meta-analysis estimated an increase in the absolute risk of oral cleft of 0.01% from 6:10,000 to 7:10,000. Benzodiazepine use in the third trimester can be associated with infant sedation and withdrawal symptoms, which are considered more significant than those seen with selective serotonin reuptake inhibitors.⁵⁹ A “floppy baby syndrome,” consisting of low Apgar scores, hypothermia, poor muscle tone, and poor temperature adaptation, has been described.⁵⁹

Mood stabilizers, such as lithium, lamotrigine, carbamazepine, and valproic acid, are often used to treat bipolar disorder.⁵⁷ The reader can find information related to the use of the seizure medications used for mood stabilization in the section on Epilepsy.

Lithium is considered the first-line treatment of bipolar disorder during pregnancy.⁵⁷ Lithium’s place in therapy has been controversial because of concerns about cardiovascular anomalies, especially Ebstein anomaly, in exposed infants. A systematic review calculated that the risk ratio for cardiac malformations was 1.2:7.7 and for all congenital malformations was 1.5:3. Stated differently, the risk for Ebstein anomaly would rise from 1:20,000 to 1:1,000. Other reported side effects in the newborn include “floppy baby syndrome,” nephrogenic diabetes insipidus, hypoglycemia, cardiac arrhythmias, thyroid dysfunction, polyhydramnios, and premature delivery. Several case reports describe adverse effects in infants thought to be due to lithium use by lactating mothers.⁶ During lactation, the infant’s lithium levels and thyroid function should be monitored.

Chlorpromazine, haloperidol, and perphenazine have long histories of use during pregnancy, with no reported significant increase in congenital malformations.⁵⁷ Atypical antipsychotics are now more widely used for treatment of schizophrenia because of their more favorable side-effect profiles compared to the older agents.⁶⁰ However, use of atypical antipsychotics in pregnant women is controversial. Although olanzapine and clozapine have not been associated with increased risk for congenital malformation, they have been associated with weight gain and an increased incidence of glucose intolerance, which have implications for poorer obstetric outcomes. Other agents, such as quetiapine, risperidone, aripiprazole, and ziprasidone, have been used less in pregnancy, so only limited information is available. At present, atypical antipsychotics do not appear to be safer than the typical agents.

THYROID DISORDERS

4 Hypothyroidism affects between 1 and 3 per 1,000 pregnancies.³⁸ Untreated hypothyroidism increases the risk of preeclampsia, premature birth, and low birth weight. Causes of hypothyroidism include autoimmune diseases such as Hashimoto thyroiditis, iodine deficiency (uncommon in the United States), and thyroid dysfunction following surgery or ablative therapy for previous hyperthyroidism. Thyroid replacement therapy should be instituted with levothyroxine if hypothyroidism is diagnosed; the goal is to attain normal thyrotropin concentrations. Women who receive thyroid replacement therapy prior to pregnancy may have an increased dosage requirement during pregnancy; any dose change should follow thyroid function testing. After delivery, maternal thyroid supplementation should be returned to prepregnancy doses, with laboratory followup in 6 to 8 weeks.

Hyperthyroidism affects approximately 2 of every 1,000 pregnancies and may precipitate outcomes of fetal death, low birth weight,

malformations, and maternal heart failure. Graves disease is the most common cause of hyperthyroidism in pregnancy.³⁸ Therapy includes thioamides (e.g., propylthiouracil, methimazole) and surgery. Methimazole crosses the placenta less than propylthiouracil, but both drugs are commonly used to treat the disorder. Iodine-131 is contraindicated because of the risk of thyroid damage in the fetus. The goal of therapy is to attain free thyroxine concentrations in the upper end of the normal range; this allows for minimization of the thioamide dose.

LABOR AND DELIVERY

PRETERM LABOR

Preterm labor is defined as cervical changes and uterine contractions that occur before 37 weeks’ gestation.⁶¹ In the United States, the incidence of preterm births is 11% and is a leading cause of infant morbidity and mortality.^{61,62} Risk factors for preterm delivery include previous preterm delivery, infections, multiple gestation, poverty, nonwhite race, maternal complication factors (e.g., smoking and use of illicit drugs or alcohol), uterine functional causes (e.g., incompetent cervix and uterine septum), and fetal causes (e.g., congenital anomalies and growth retardation).⁶¹

Despite knowledge of the risk factors for preterm labor, no good tests are available for monitoring and preventing preterm labor. No evidence supports the use of routine cervical assessments or home monitoring of uterine activity to improve outcomes.⁶¹ The presence of fetal fibronectin, an extracellular protein in cervical and vaginal secretions, in the cervix or vagina after 20 weeks is associated with a threefold risk of preterm delivery.⁶³ A cervical length less than 30 mm is associated with increased risk of preterm delivery. Fetal fibronectin determinations and cervical ultrasonography have not helped to prevent preterm labor but have been useful for their negative predictive value.⁶⁴

Tocolytic Therapy

The purpose of tocolytic therapy is to postpone delivery long enough to allow for administration of antenatal corticosteroids to improve pulmonary maturity and for transportation of the mother to a facility equipped to deal with high-risk deliveries.⁶¹ Tocolytics have not been shown to reduce the number of premature deliveries. The criteria for starting tocolysis are regular uterine contractions with cervical change; however, tocolytic therapy is less effective when cervical dilatation is greater than 3 cm. Tocolytic therapy should not be used in cases of intrauterine infection, fetal distress, severe preeclampsia, vaginal bleeding, or maternal hemodynamic instability.⁶³

Five classes of tocolytic therapy are available in the United States: β -adrenergic agents, magnesium, calcium channel blockers, non-steroidal antiinflammatory drugs, and ethanol.⁶² The first four therapies have similar effectiveness in prolonging pregnancy from 48 hours to 1 week. Ethanol has not been shown to be effective.

The β -adrenergic agents terbutaline and ritodrine have been used for tocolytic therapy.⁶² (Of the two, only ritodrine had FDA approval for this use but has been withdrawn from the market.) Relative to other agents, β -agonists have a higher incidence of maternal side effects, including hyperkalemia, arrhythmias, hyperglycemia, hypotension, and pulmonary edema. Recommended terbutaline doses range from 250 to 500 mcg subcutaneously every 3 to 4 hours.⁶³

Magnesium sulfate has been used as a tocolytic agent in intravenous infusion form. A Cochrane meta-analysis demonstrates that magnesium sulfate is ineffective as a tocolytic agent and that an association exists between magnesium sulfate use and increased mortality in infants.⁶⁵ Maternal side effects are rare but can include pulmonary edema. At toxic levels, hypotension, muscle paralysis, tetany, cardiac arrest, and respiratory depression may occur.⁶³

Nifedipine is associated with fewer side effects than magnesium or β -agonist therapy.⁶² A few studies have suggested that calcium channel blockers are better than β -agonists at prolonging labor. One concern with the use of nifedipine is the potential negative effect on blood flow between the placenta and the uterus. However, a meta-analysis has not shown increased harm to infants. With the initial diagnosis of preterm labor, 5 to 10 mg nifedipine can be administered sublingually every 15 to 20 minutes for three doses. Once the patient is stabilized and no evidence of continuing cervical dilation is seen, 10 to 20 mg nifedipine can be administered by mouth every 4 to 6 hours for preterm contractions.⁶³

Nonsteroidal antiinflammatory drugs such as indomethacin have been used for tocolysis.⁶³ The drug is first given orally or rectally in a dose of 50 to 100 mg, followed by an oral dose of 25 to 50 mg every 6 hours. An increased rate of premature constriction of the ductus arteriosus has been noted in infants when indomethacin has been used as tocolytic therapy.⁶²

Other Methods for Preterm Labor Prevention

Because infection has been thought to play a role in the etiology of preterm labor, antibiotics have been used, in addition to tocolytics and corticosteroids, to improve the outcome of preterm labor.⁶⁶ Most studies of antibiotic use do not demonstrate a reduction in the incidence of preterm delivery, and a meta-analysis showed a trend toward neonatal mortality in patients who received antibiotics. Therefore, routine use of antibiotics is not recommended.

A low level of maternal serum progesterone has been associated with miscarriage and preterm labor. Several small trials using progesterone and progesterone-like drugs have shown inconclusive results in the prevention of preterm labor. However, studies using 17 α -hydroxyprogesterone caproate have shown some success. In women at high risk for preterm delivery of a singleton pregnancy, administration of 17 α -hydroxyprogesterone caproate as early as 20 weeks' gestation has shown some reduction in preterm delivery.⁶⁷ Additional randomized trials are needed.

CLINICAL CONTROVERSY

Continuation of tocolytic therapy after acute tocolysis has been achieved is controversial. Maintenance therapy with tocolytics has not been shown conclusively to be of value.⁶² However, some clinicians use maintenance tocolytics such as β -agonists or nifedipine to treat patients who experience frequent contractions without cervical change.

Antenatal Corticosteroids

4 A Cochrane meta-analysis demonstrates the benefit of administering antenatal corticosteroids for fetal lung maturation in order to prevent respiratory distress syndrome, intraventricular hemorrhage, and death in infants delivered prematurely.⁶⁸ The current clinical recommendation is to administer betamethasone 12 mg intramuscularly every 24 hours for two doses or dexamethasone 6 mg intramuscularly every 12 hours for four doses to pregnant women between 26 and 34 weeks' gestation who are at risk for preterm delivery within the next 7 days. Benefits from antenatal corticosteroids are believed to begin within 24 hours. A meta-analysis in 2000 did not show a clear benefit to repeat doses of steroids.

GROUP B *STREPTOCOCCUS* INFECTION

4 Maternal infection with group B *Streptococcus* is associated with invasive disease in the newborn.⁶⁹ Women colonized with group B *Streptococcus* have an increased risk for premature delivery and trans-

mission of the bacteria to the infant during delivery. Between 10% and 30% of pregnant women are colonized with group B *Streptococcus*.

With active prevention efforts in the 1990s, the incidence of early-onset disease now is 0.5 cases per 1,000 births, down from 1.8 cases per 1,000 births.⁶⁹ No change has occurred in the incidence of late-onset group B *Streptococcus* disease, which remains consistent at 0.35 cases per 1,000 births. The consequences of neonatal infections include bacteremia, pneumonia, and meningitis in the newborn. The case-fatality rate is approximately 4%.

The recommendations for prevention of group B *Streptococcus* infection were revised in 2002.⁶⁹ Universal prenatal screening for group B *Streptococcus* colonization now is recommended instead of risk-based screening. Antibiotics are given if the woman previously gave birth to an infant with invasive group B *Streptococcus* disease or if the woman had group B *Streptococcus* bacteriuria. In all other pregnant women at 35 to 37 weeks' gestation, a vaginal/rectal culture should be obtained. If negative, no antibiotics are given. If a woman presents in labor and no screening information is available, antibiotics are given for fever $\geq 100.4^{\circ}\text{F}$ (38°C), membrane rupture ≥ 18 hours, or gestation < 37 weeks.

The currently recommended regimen for group B *Streptococcus* disease is 5 million units of penicillin G given intravenously, followed by 2.5 million units given every 4 hours until delivery.⁶⁹ Alternatively, ampicillin 2 g can be given intravenously, followed by 1 g every 4 hours. If the patient is allergic to penicillin and is not at risk for anaphylaxis, cefazolin 2 g intravenously, followed by 1 g every 8 hours, should be used. In patients at high risk for anaphylaxis, clindamycin 900 mg intravenously every 8 hours or erythromycin 500 mg intravenously every 6 hours should be used. For penicillin-allergic women, the group B *Streptococcus* cultures should be sent for sensitivities. If the group B *Streptococcus* is resistant to clindamycin or erythromycin, the woman should receive vancomycin 1 g intravenously every 12 hours until delivery.

CERVICAL RIPENING AND LABOR INDUCTION

Throughout most of pregnancy, the cervix is closed and firm.⁷⁰ During the last few weeks of pregnancy, the cervix becomes softer and thinner in order to facilitate labor. This process is mediated by hormonal changes, including final mediation by prostaglandins E_2 and $\text{F}_2\alpha$, which cause increased collagenase activity in the cervix leading to thinning and dilation.

The rate of pregnancy induction ranges from 9.5% to 33.5%.⁷⁰ The most common reason for induction is postdatism (> 42 weeks), which occurs in 10% of all pregnancies.⁷¹ Other reasons for induction include suspected fetal growth retardation, maternal hypertension, premature rupture of membranes with no active onset of labor, and social factors. Contraindications for induction include placenta previa, oblique or transverse lie, pelvic structure abnormality, prolapsed umbilical cord, and active herpes. Concerns associated with induction of labor are ineffective labor and side effects, such as uterine hyperstimulation, that may adversely affect the infant, increasing the likelihood of cesarean section.

A scoring system has been used to determine the likelihood of successful labor induction.⁷⁰ The most commonly used system is the Bishop scoring system, which is based on five parameters: cervical dilation, cervical effacement (thinning), station of the baby's head, consistency of the cervix, and position of the cervix. A Bishop score < 6 means that a patient requires cervical ripening, and a score > 8 means that the patient most likely will have a successful vaginal delivery.

A number of nonpharmacologic methods are used for cervical ripening. Castor oil, hot baths, sexual intercourse, and nipple stimulation all have been recommended for labor induction.⁷⁰ However, minimal evidence supports the efficacy of these methods. Use of a Foley catheter placed in an unfavorable cervix for ripening

has been found as effective as prostaglandin E₂. Membrane stripping is safe and inexpensive.

Herbal supplements have been used to induce labor. The most commonly used agents are evening primrose oil, black haw, black and blue cohosh, and red raspberry leaves.⁷⁰ Currently, no evidence supports the safety and efficacy of herbal agents.

Prostaglandin E₂ analogs (e.g., dinoprostone [Prepidil, Cervidil]) are pharmacologic agents commonly used for cervical ripening. Prepidil gel is administered intracervically at a dose of 500 mcg.⁷⁰ This can be repeated after 6 hours with up to three doses in 24 hours. After administration, the patient remains supine for 30 minutes. Cervidil, a vaginal insert, contains 10 mg dinoprostone with a slower, more constant release of medication than the gel. The insert can be removed when labor begins or after a maximum of 24 hours. Patients must be attached to a fetal heart rate monitor for the duration of Cervidil use and for 15 minutes after its removal.

Misoprostol, a prostaglandin E₁ analog, is an effective and inexpensive drug for cervical ripening and labor induction.⁷² Intravaginal administration of 25 mcg misoprostol every 4 hours for up to six doses is more effective than other prostaglandin agents and results in a shorter time to delivery. The most commonly encountered side effects are uterine hyperstimulation and meconium-stained amniotic fluid. Use of misoprostol is contraindicated in women with a previous uterine scar because of its association with uterine rupture, a catastrophic medical event. Despite its efficacy and lack of expense, some hospitals have decided not to use misoprostol as an induction agent due to concerns for uterine rupture and lack of FDA indication for cervical ripening.

Mifepristone is an antiprogesterone agent that is being studied as an induction agent.⁷⁰ Preliminary studies show that mifepristone compared with placebo results in a shorter time to delivery and fewer cesarean sections.⁷³ Little information on fetal and maternal outcomes is available because of the small sample sizes.

Oxytocin is the most commonly used agent for labor induction after cervical ripening. By the end of pregnancy, the number of oxytocin receptors has increased by 300-fold.⁷⁰ A solution of 10 milliunits/mL is used for infusion. Oxytocin has been shown to be effective in both low-dose (physiologic) and high-dose (pharmacologic) regimens.

LABOR ANALGESIA

During the first phase of labor, women perceive visceral pain associated with uterine contractions. During the second phase of labor, the pain is associated with perineal stretching.^{74,75} Pain perception is variable among women as a result of physiologic, psychosocial, cultural, and environmental influences.⁷⁴

Nonpharmacologic Approaches to Analgesia

A number of nonpharmacologic strategies have been used to reduce the pain of childbirth. Women who receive continuous support from a doula, a laywoman trained in labor support, have fewer operative vaginal deliveries, cesarean deliveries, and requests for pain medication.⁷⁴ Intermittent support from a caregiver and continuous support from nursing staff have not been shown to affect birth outcomes. Warm water baths provide temporary pain relief but have not been shown to decrease the use of pharmacologic pain treatments. Intradermal injections of sterile water in the sacral area have been shown to decrease back pain during labor for 45 to 90 minutes. However, requests for pain medication did not decrease. Acupuncture is another modality for pain relief. One study of acupuncture versus no acupuncture showed that women required less analgesia but were no more satisfied with this mode of pain control. Methodologically sound studies on acupuncture are sparse.⁷⁶

Pharmacologic Approaches to Labor Pain Management

A joint position statement on pain in labor published in 2000 stated that labor is a medical indication for women to receive pain relief upon request.⁷⁷ The two main types of pharmacologic methods in the United States are parenteral opioids and epidural analgesia.

Between 39% and 56% of women receive parenteral narcotics to alleviate labor pain.⁷⁷ Meperidine, morphine, and fentanyl are the most commonly used agents. In comparison with epidural analgesia, parenteral opioids have lower rates of oxytocin augmentation, result in shorter stages of labor, and require fewer instrumental deliveries.

Approximately 60% of women choose an epidural for pain relief during labor and report better pain relief than with other analgesic modalities.⁷⁵ Epidural analgesia involves introducing a catheter into the epidural space and administering an opioid and/or an anesthetic (e.g., fentanyl and/or bupivacaine) to provide pain relief during labor. Another method is a combined spinal-epidural, which consists of injection of a single bolus of an opioid into the subarachnoid space, providing instant pain relief, and placement of an epidural catheter with a local anesthetic. Side effects of the regional anesthesia include hypotension, pruritus, and inability to void. One study showed difficulty breast-feeding in women who had received labor epidurals.⁷⁸ Epidural analgesia is associated with prolongation of the first and second stages of labor, higher numbers of instrumental deliveries, and maternal fever. A rare complication of epidural anesthesia is puncture of the subarachnoid space leading to a severe headache, which occurs in approximately 2% of women.⁷⁵ Other complications include hypotension, nausea, vomiting, itching, and urinary retention. Low back pain has not been shown to be associated with the use of epidural analgesia.

Paracervical blocks using local anesthesia may decrease pain associated with the first phase of labor.⁷⁷ However, these types of blocks have been associated with fetal bradycardia and are used rarely in clinical practice.

CLINICAL CONTROVERSY

Many clinicians believe that epidural analgesia is associated with a higher number of cesarean deliveries. To the contrary, two systematic reviews have not substantiated an increased rate of cesarean delivery with epidural analgesia compared with parenteral opioids. However, one of the reviews did caution that data are not sufficient to rule out such an association.⁷⁷

POSTPARTUM HEMORRHAGE

The third stage of labor occurs after delivery of the baby. During this stage, the placenta is delivered. Postpartum hemorrhage is defined as loss of more than 500 mL of blood within 24 hours of delivery.⁷⁹ There are few identifiable risk factors for postpartum hemorrhage. In the United States, the postpartum hemorrhage rate is approximately 3.9% in vaginal deliveries.

Active management of the third stage of labor involves administration of a uterotonic medication (intramuscular oxytocin, ergotamine, or combination) before delivery of the placenta; early clamping and cutting of the umbilical cord; and controlled traction of the cord.⁷⁹ Instituting active management of labor after all uncomplicated vaginal deliveries results in reduced maternal blood loss, fewer cases of postpartum hemorrhage, and a lower incidence of prolonged third stage of labor. However, use of ergotamines is associated with an increased risk of maternal elevated blood pressure, nausea, and vomiting.

POSTPARTUM ISSUES

DRUG USE DURING LACTATION

5 Although most drugs diffuse into breast milk, breast-feeding may be continued in most circumstances. Healthcare providers should encourage breast-feeding women who require medications to continue breast-feeding whenever possible. Medications that require the mother to pump and discard milk are few.

Extensive research has demonstrated the wide variety of benefits (health, nutritional, immunologic, psychological, economic, developmental, and social) imparted by breast-feeding to infants, mothers, families, and society.⁸⁰ It is recommended that women breast-feed exclusively for 6 months and continue until at least infant age 12 months while other foods are introduced. Healthy People 2010 set a target of 75% of neonates being breast-fed at the time of birth and 50% of infants continued being breast-fed at 6 months of age.^{6,80}

A number of drug-related factors influence transfer of drug from maternal circulation into breast milk, including (1) degree of protein binding in maternal circulatory system, (2) molecular weight of the drug, (3) lipid solubility of drug and fat content of milk, (4) maternal plasma concentration, (5) half-life of the drug, and (6) pH of the drug.⁸⁰ The degree to which a drug is bound to maternal plasma is one of the most significant factors in transfer to breast milk; highly bound medications transfer in low amounts. Low-molecular-weight (<200 kDa) drugs passively diffuse into breast milk, but larger molecules are not likely to transfer in large amounts. Higher lipid solubility of drugs also increases the likelihood of transfer. Colostrum is lower in fat content than mature milk, so a drug with high lipid solubility will achieve a higher concentration in mature milk. The higher the concentration of drug in the mother's serum, the higher the concentration will be in the breast milk. As mother's serum concentration drops from metabolism and excretion of drug, the concentration of drug in the breast milk may redistribute back into the mother's bloodstream. Maternal plasma pH is 7.4, but the pH of breast milk varies between 6.8 and 7.⁶ Weak bases are un-ionized in the maternal circulation and easily transfer to breast milk. However, upon encountering the lower pH of breast milk, molecules become ionized and less likely to diffuse back into maternal circulation. Likewise, drugs with longer half-lives are more likely to maintain higher levels in breast milk, resulting in greater exposure to the infant.

Infant-related factors also may influence the amount of drug ingested through breast-feeding.⁸⁰ Both the frequency of feedings and the amount of milk ingested are important considerations. Exclusively breast-fed younger infants are more likely to ingest larger amounts of drugs than older infants who receive other foods. Drugs that denature in gastric acid (aminoglycosides, omeprazole, heparin, insulin) are less likely to be absorbed by infants. Finally, infants may vary in their ability to metabolize and excrete ingested medication. Premature and full-term infants may not have full renal and liver function.

Strategies for reducing the amount of drug transferred to the infant may include selection of medicines that would be considered safe for use in the infant.⁶ Medications that have shorter half-lives tend to accumulate less, and those that are more protein bound do not cross into breast milk as well as those that are less protein bound. Drugs with lower oral bioavailability and lower lipid solubility are good choices. If the mother is using a once-daily medication, administration before the infant's longest sleep period may be advised to increase the interval to the next feeding. For medications taken multiple times per day, administration immediately after a breast-feeding session will give the longest interval to allow back diffusion of drug from the breast milk as the mother's serum concentration decreases.

Because of the scarcity of industry-based research on transfer of drugs into breast milk, information from drug manufacturers is

generally a poor source of information for the provider.⁸⁰ Information from expert committees (e.g., American Academy of Pediatrics Committee on Drugs) and evidence-based textbooks may be of assistance in providing reassurance regarding the safe use of medications in the lactating mother.

MASTITIS

Mastitis is an infection in one breast.⁸¹ Women who experience mastitis note breast tenderness, redness, and warmth and have flu-like symptoms. About 1% to 2% of women who breast-feed will experience mastitis, and the highest incidence of mastitis occurs within 1 to 2 weeks of beginning breast-feeding. Mastitis usually is caused by a break in the skin, often a cracked nipple. Risk factors for developing mastitis include breast engorgement, plugged milk ducts, and cracked nipples.

Staphylococcus aureus, *E. coli*, and *Streptococcus* are the most common organisms associated with mastitis.⁸¹ Antibiotics used for treatment of mastitis include penicillinase-resistant penicillins (e.g., cloxacillin, dicloxacillin, and oxacillin) and cephalosporins (e.g., cephalexin).⁸¹ Antibiotics are often given for 10 to 14 days.^{81,82} Antiinflammatory drugs, such as ibuprofen, also can be given for pain. Nondrug therapies that may be helpful are application of warm or cold pack and wearing a bra.⁸² Affected women should be counseled to continue breast-feeding from both breasts throughout treatment and to pump if breasts are not emptied completely with feedings.

POSTPARTUM DEPRESSION

Mood disorders in the postpartum period may include postpartum blues, postpartum depression, and postpartum psychosis.⁸³ Postpartum blues is common, usually affecting 50% to 80% of new mothers within the first 10 days of delivery. Symptoms such as anxiety, anger, and sadness generally resolve within 2 weeks postpartum. Postpartum psychosis is more severe but is rare, affecting one in 1,000 new mothers.

Postpartum depression usually begins within the first 3 months after delivery and affects 8% to 15% of women.⁸³ As many as 50% of women diagnosed with postpartum depression may have symptoms that began during pregnancy, emphasizing the need for screening.^{83,84} Treatment is important for women with postpartum depression, because without treatment 30% to 70% of women may experience depression for 1 year or longer.⁸³ Psychotherapy, including individual interpersonal psychotherapy, cognitive behavioral therapy, and group/family therapy, has been shown to be effective treatment of moderate depression.

In cases where pharmacotherapy is warranted, selection of medication with low transfer to breast milk is desired.⁸³ Antidepressants such as nortriptyline, paroxetine, amitriptyline, clomipramine, desipramine, fluvoxamine, and bupropion appear to be undetectable in breast milk. Treatment should continue for a minimum of 29 weeks, consistent with treatment guidelines for a single episode of depression.⁸⁴

RELACTATION

Declining serum prolactin concentrations cause a decrease in or cessation of lactation. This can be problematic, as well as distressing, for mothers who desire to breast-feed their infants. Relactation is the process of increasing the breast milk supply for such women.⁸⁵ Lactation also can be induced in women who have not recently delivered a baby, such as adoptive mothers. The mainstay of therapy for this condition involves nipple stimulation either by the infant's nursing or by pumping of the breast with a mechanical pump or the hand.

Recommended pharmacologic therapy in the United States for relaxation is metoclopramide, which should be used only if non-drug therapy is ineffective.⁸⁵ The most commonly used dose is 10 mg taken orally three times daily for 7 to 14 days. Breast milk production can be increased up to 100% or more in women who are 1 month postpartum or less. In mothers who are 8 to 12 weeks postpartum, milk production may be increased up to 40%. Breast milk production may decrease after metoclopramide therapy is stopped, but production will continue if lactation has been established successfully.

CONCLUSION

Providing pharmacologic care to women during pregnancy can be rewarding and, at times, difficult. Many women perceive a high inherent risk of birth defects with drug exposure during pregnancy. This perception, linked with a high rate of unplanned pregnancies, may create anxiety because of drug exposure prior to the discovery of pregnancy.

Some medications are considered safe for use in pregnancy because of frequent use with no apparent increase in the rate of congenital problems. Women using these medications should be reassured that these choices are unlikely to increase the risk of birth defects. In some cases, ensuring the health of the mother and, in some instances, of the fetus will require selection or continuation of medications that have been associated with a higher risk of adverse effects to the fetus. In these instances, realistic information about the types and likelihood of adverse effects will aid the patient and her family in making decisions.

Healthcare providers who care for pregnant women must work in collaboration to seek, evaluate, and present the most contemporary and accurate information to their patients. Use of technology to access evidence-based resources, databases related to drug use in pregnancy, and primary and secondary literature may assist healthcare practitioners in accessing relevant medication information to manage drug therapy needs during pregnancy and lactation.

LORI M. DICKERSON, SARAH P. SHRADER, AND VANESSA A. DIAZ

KEY CONCEPTS

- 1 The attitude of both the patient and the sexual partner toward various contraceptive methods, the reliability of the patient in using the method correctly (which may affect the effectiveness of the method), and the patient's ability to pay must be considered carefully when selecting a contraceptive method.
- 2 Patient-specific factors (e.g., frequency of intercourse, age, smoking status, and concomitant diseases, conditions, or medications) that may prove to be a consideration or precaution for use of a specific method must be evaluated when selecting a contraceptive method.
- 3 Adverse effects or difficulties using the chosen method should be monitored carefully and managed in consideration of patient-specific factors.
- 4 Accurate and timely counseling on the optimal use of the contraceptive method and strategies for minimizing sexually transmitted diseases must be provided to all patients when contraceptive pharmacotherapy is initiated and on an ongoing basis.
- 5 Certain oral contraceptives in high doses can be used as emergency contraception to prevent pregnancy after unprotected intercourse.

Unintended pregnancy is a significant public health problem with economic, health, personal, and social consequences. In the United States, approximately 62 million women are of childbearing age (15–44 years), and approximately six million become pregnant each year.¹ The most recent data reveal that 31% of pregnancies are unintended, with the highest rates occurring in women aged 25 to 44 years (38%).¹ About half of all unintended pregnancies end in abortion, and half also occurred in sexually active couples who claimed they used some method of contraception.² If the goal of contraception—for pregnancies to be planned and desired—is to be realized, education on the use and efficacy of contraceptive methods must be improved.

ETIOLOGY AND PATHOPHYSIOLOGY

Comprehension of the hormonal regulation of the normal menstrual cycle is essential to understanding contraception in women (Fig. 82–1).

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

The cycle of menstruation begins with menarche, usually around age 12 years, and continues to occur in nonpregnant women until menopause, usually around age 50 years.^{3,4} The cycle includes the vaginal discharge of sloughed endometrium called *menses* or *menstrual flow*. The menstrual cycle comprises three phases: follicular (or preovulatory), ovulatory, and luteal (or postovulatory).

THE MENSTRUAL CYCLE

The first day of menses is referred to as *day 1 of the menstrual cycle* and marks the beginning of the follicular phase.^{3,4} The follicular phase continues until ovulation, which typically occurs on day 14. The time after ovulation is referred to as the *luteal phase*, which lasts until the beginning of the next menstrual cycle. The median menstrual cycle length is 28 days, but it can range from 21 to 40 days. Generally, variation in length is greatest in the follicular phase, particularly in the years immediately after menarche and before menopause.⁴

The menstrual cycle is influenced by the hormonal relationships among the hypothalamus, anterior pituitary, and ovaries.³ In response to epinephrine and norepinephrine stimulation, the hypothalamus secretes gonadotropin-releasing hormone (GnRH) in a pulsatile fashion every 60 to 90 minutes.^{3,4} These GnRH bursts stimulate the anterior pituitary to secrete bursts of gonadotropins, follicle-stimulating hormone (FSH), and luteinizing hormone (LH). The gonadotropins FSH and LH direct events in the ovarian follicles that result in the production of a fertile ovum.

Follicular Phase

In the first 4 days of the menstrual cycle, FSH levels rise and allow the recruitment of a small group of follicles for continued growth and development (see Fig. 82–1).^{3,4} Between days 5 and 7, one follicle becomes dominant and later ruptures, releasing the oocyte. The dominant follicle develops increasing amounts of estradiol and inhibin, which cause a negative feedback on the hypothalamic secretion of GnRH and pituitary secretion of FSH, causing atresia of the remaining follicles recruited during the cycle.

Once the follicle has received FSH stimulation, it must receive continued FSH stimulation or it will die.^{3,4} Gonadotropin-dependent growth allows the follicle to enlarge, produce other layers of receptors for FSH and LH, and synthesize estradiol, progesterone, and androgen. Estradiol serves to stop the menstrual flow from the previous cycle, thickening the endometrial lining of the uterus to prepare it for embryonic implantation. Estrogen is responsible for increased production of thin, watery cervical mucus, which will enhance sperm transport during fertilization. FSH regulates the aromatase enzymes that convert androgens to estrogens in the follicle. If a follicle has insufficient aromatase, androgen will accumulate, and the follicle will not survive. Therefore, follicles with the most FSH stimulation have the lowest ratios of androgen to estrogen.

FIGURE 82-1. Menstrual cycle events, idealized 28-day cycle. (FSH, follicle-stimulating hormone; HCG, human chorionic gonadotropin, LH, luteinizing hormone.) (From Hatcher et al.³ This figure may be reproduced at no cost to the reader.)

Ovulation

When estradiol levels remain elevated for a sustained period of time (200 pg for at least 50 hours), the pituitary releases a midcycle LH surge (see Fig. 82-1).^{3,4} This LH surge stimulates the final stages of follicular maturation and ovulation (follicular rupture and release of the oocyte). On average, ovulation occurs 24 to 36 hours after the estradiol peak and 10 to 16 hours after the LH peak. The LH surge, which occurs 28 to 32 hours before a follicle ruptures, is the most clinically useful predictor of approaching ovulation. After ovulation, the oocyte is released and travels to the fallopian tube, where it can be fertilized and transported to the uterus for embryonic implantation. Conception is most successful when intercourse takes place from 2 days before ovulation to the day of ovulation.

Luteal Phase

After rupture of the follicle and release of the ovum, the remaining luteinized follicles become the corpus luteum, which synthesizes androgen, estrogen, and progesterone (see Fig. 82-1).^{3,4} Progesterone helps to maintain the endometrial lining, which sustains the implanted embryo and maintains the pregnancy. It also inhibits GnRH and gonadotropin release, preventing the development of

new follicles. If pregnancy occurs, human chorionic gonadotropin (hCG) prevents regression of the corpus luteum and stimulates continued production of estrogen and progesterone secretion to maintain the pregnancy until the placenta is able to fulfill this role (usually 6–8 weeks' gestation).

If fertilization or implantation does not occur, the corpus luteum degenerates, and progesterone production declines.^{3,4} The life span of the corpus luteum depends on the continuous presence of small amounts of LH, and its average duration of function is 9 to 11 days. As progesterone levels decline, endometrial shedding (menstruation) occurs, and a new menstrual cycle begins. At the end of the luteal phase, when estrogen and progesterone levels are low, FSH levels start to rise, and follicular recruitment for the next cycle begins.

EPIDEMIOLOGY

Contraception generally implies the prevention of pregnancy following sexual intercourse by inhibiting viable sperm from coming into contact with a mature ovum (i.e., methods that act as barriers or prevent ovulation) or by preventing a fertilized ovum from

implanting successfully in the endometrium (i.e., mechanisms that create an unfavorable uterine environment).

Commonly used methods of reversible contraception include oral, transdermal, and vaginal ring contraceptives, injectable and implantable progestins, intrauterine devices (IUDs), condoms, spermicides, diaphragms, cervical caps, sponges, withdrawal, and periodic abstinence.³⁻⁵ These methods differ in their relative effectiveness, safety, and patient acceptability.

The actual effectiveness of any contraceptive method is difficult to determine because many factors affect contraceptive failure. A failure in patients who use the contraceptive agent properly is considered a method failure or perfect-use failure. User failure or typical use failure takes into account the user's ability to follow directions correctly and consistently.^{3,4} In a survey of women who had abortions in 2000 to 2001, 46% had not used a contraceptive method in the month they conceived owing to a perceived low risk of pregnancy (33%) and concerns about the use of contraceptives (32%).⁶ The male condom was the most commonly used method (28%), with inconsistent use the cited cause of pregnancy in 49% of cases. Oral contraceptives (OCs) were used by 14% of women, 76% of whom reported inconsistent use resulting in pregnancy.⁶

CLINICAL PRESENTATION

For many young women, a major reason for visiting a clinician is to obtain contraception. Clinicians may use this opportunity to provide health maintenance/disease prevention by counseling about reproductive health and sexually transmitted diseases (STDs). Most health maintenance annual visits should include assessment of and counseling about reproductive health. Traditionally, hormonal contraception is provided subsequent to clinical breast and pelvic examinations. However, the need for the physical examination may delay access to contraception, resulting in unintended pregnancies and other health risks. In addition, requiring the breast and pelvic examinations prior to prescription of hormonal contraception reinforces the incorrect perception that these methods of pregnancy prevention are harmful or dangerous. Therefore, the American College of Obstetrics and Gynecology (ACOG) and other national organizations allow provision of hormonal contraception after a simple medical history and blood pressure measurement.⁷ Other preventive measures, such as pelvic and breast examinations, provision of the human papillomavirus vaccine, screening for cervical neoplasia, and counseling for prevention of STDs, can be accomplished during routine annual office visits.⁸⁻¹⁰

TREATMENT

DESIRED OUTCOME

The obvious goal of treatment with all methods of contraception is to prevent pregnancy. However, many health benefits are associated with contraceptive methods, including prevention of STDs (with condoms), improvements in menstrual cycle regularity (with hormonal contraceptives), prevention of malignancies and other health conditions (with OCs), and management of perimenopause.³

NONPHARMACOLOGIC THERAPY

Periodic Abstinence

1 2 Highly motivated couples may use the abstinence (rhythm) method of contraception, avoiding sexual intercourse during the days of the menstrual cycle when conception is likely to occur. These women rely on physiologic changes, such as basal body temperature and cervical mucus, during each cycle to determine the fertile period.

The major reasons for the lack of acceptance are the relatively high pregnancy rates among users and the need to avoid intercourse for several days during each menstrual cycle. To overcome these drawbacks, many women use barrier methods or spermicides during the fertile period.^{3,4}

Barrier Techniques

1 2 The effectiveness of barrier methods and spermicides depends almost exclusively on a couple's motivation to use them consistently and correctly.^{3,4} These methods include condoms, diaphragms, cervical caps, and sponges (Table 82-1). A major disadvantage is higher failure rates than with most hormonal contraceptives; thus, provision of counseling and an advanced prescription for emergency contraception (EC) are recommended for all patients using barrier methods as their primary means of contraception.

Condoms are devices that create a mechanical barrier, preventing direct contact of the vagina with semen, genital lesions and discharges, and infectious secretions.^{3,4} Most condoms in the United States are made of latex rubber, which is impermeable to viruses. A small proportion (5%) are made from young lamb intestine, which is not impermeable to viruses. Condoms are used worldwide as protection from STDs. When condoms are used in conjunction with any other barrier method, their effectiveness theoretically approaches 98%. Spillage of semen or perforation and tearing of the condom can occur, but proper use minimizes these problems.⁴ Mineral oil-based vaginal drug formulations (e.g., Cleocin vaginal cream, Premarin vaginal cream, Vagistat 1, Femstat, and Monistat Vaginal suppositories), lotions, or lubricants can decrease the barrier strength of latex by 90% in just 60 seconds, thus making water-soluble lubricants (e.g., Astroglide, K-Y Jelly) preferable.⁴ Condoms with spermicides are no longer recommended at all because they provide no additional protection against pregnancy or STDs and may increase vulnerability to human immunodeficiency virus (HIV) infection.⁴

The female condom (Reality) is a prelubricated, soft, loose-fitting polyurethane sheath, closed at one end, with flexible rings at both ends.^{3,4} Properly positioned, the ring at the closed end covers the cervix, and the sheath lines the walls of the vagina. The outer ring remains outside the vagina, covering the labia; this may make the female condom more effective than the male condom in preventing transmission of STDs because it protects the labia from contact with the base of the penis. However, the pregnancy rate is reported to be 21% in the first year of use.

The diaphragm, a reusable dome-shaped rubber cap with a flexible rim that is inserted vaginally, fits over the cervix in order to decrease access of sperm to the ovum. The diaphragm requires a prescription from a physician who has fitted the patient for the correct size.^{3,4} Its effectiveness depends on its function as a barrier and on the spermicidal cream or jelly placed in the diaphragm before insertion. The diaphragm may be inserted up to 6 hours before intercourse and must be left in place for at least 6 hours afterward. With subsequent acts of intercourse, the diaphragm should be left in place, and a condom should be used for additional protection.³ Users of diaphragms appear to have a lower incidence of cervical neoplasia, which may be attributed to the adjunctive spermicide and the diaphragm's barrier effect against the human papillomavirus.

The cervical cap is a soft, deep cup with a firm round rim that is smaller than a diaphragm and fits over the cervix like a thimble.^{3,4} Currently, two latex-free cervical caps are available by prescription in the United States: the FemCap and the Lea's Shield.³ The FemCap is available in three sizes and should be filled with spermicide prior to insertion.^{3,4} It is held in place against the cervix until the cap is removed. The Lea's Shield is available in only one size and is held in place by the vaginal wall; therefore, cervical size is not a factor.³ Both caps can be inserted 6 hours prior to intercourse and remain in place for multiple episodes of intercourse without adding more spermicide.

TABLE 82-1 Comparison of Methods of Nonhormonal Contraception

Method	Absolute Contraindications	Advantages	Disadvantages	Percent of Women with Pregnancy ^a	
				Perfect Use	Typical Use
Condoms, male	Allergy to latex or rubber	Inexpensive STD protection, including HIV (latex only)	High user failure rate Poor acceptance Possibility of breakage Efficacy decreased by oil-based lubricants Possible allergic reactions to latex in either partner	2	15
Condoms, female (Reality)	Allergy to polyurethane History of TSS	Can be inserted just before intercourse or ahead of time STD protection, including HIV	High user failure rate Dislike ring hanging outside vagina Cumbersome	5	21
Diaphragm with spermicide	Allergy to latex, rubber, or spermicide Recurrent UTIs History of TSS Abnormal gynecologic anatomy	Low cost Decreased incidence of cervical neoplasia Some protection against STDs	High user failure rate Decreased efficacy with increased frequency of intercourse Increased incidence of vaginal yeast UTIs, TSS Efficacy affected by oil-based lubricants Cervical irritation	6	16
Cervical cap (Fem-Cap, Leah's Shield)	Allergy to spermicide History of TSS Abnormal gynecologic anatomy Abnormal Papanicolaou smear	Low cost Latex-free Some protection against STDs FemCap reusable for up to 2 years	High user failure rate Decreased efficacy with parity Cannot be used during menses	9	16 ^b
Spermicides alone	Allergy to spermicide	Inexpensive	High user failure rate Must be reapplied before each act of intercourse May enhance HIV transmission No protection against STDs	18	29
Sponge (Today)	Allergy to spermicide Recurrent UTIs History of TSS Abnormal gynecologic anatomy	Inexpensive	High user failure rate Decreased efficacy with parity Cannot be used during menses No protection against STDs	9	16

HIV, human immunodeficiency virus; STD, sexually transmitted disease; TSS, toxic shock syndrome; UTI, urinary tract infection.

^aFailure rates in the United States during first year of use.

^bFailure rate with FemCap reported to be 29% per package insert.

Data from Hatcher et al.^{3,4} and Dickey.⁵

They should not be worn for more than 48 hours at a time to reduce the risk of toxic shock syndrome. Failure rates are higher than with other methods, perhaps due to difficulty in fitting the cap. Some studies have shown an increased risk of cervical dysplasia, so users must have a repeat Papanicolaou (Pap) smear 3 months after starting to use a cervical cap. Followup data showed no increase in dysplasia at 1 year.³

PHARMACOLOGIC THERAPY

Spermicides

1 2 Spermicides, most of which contain nonoxynol-9, are chemical surfactants that destroy sperm cell walls and act as barriers that prevent sperm from entering the cervical os.⁴ They are available as creams, films, foams, gels, suppositories, sponges, and tablets.^{3,4} Unfortunately, spermicides offer no protection against STDs. In fact, when used frequently (more than two times per day), spermicides containing nonoxynol-9 may increase the risk of transmission of HIV by causing small disruptions in the vaginal epithelium.^{11,12} The World Health Organization (WHO) and the Centers for Disease Control and Prevention (CDC) do not promote products containing nonoxynol-9 for protection against STDs. Women at high risk for HIV infection or who are HIV infected should not use spermicides.^{3,13}

Spermicide-Implanted Barrier Techniques

1 2 The vaginal contraceptive sponge (Today) is pillow shaped and contains 1 g of the spermicide nonoxynol-9.⁴ It has a concave dimple on one side (to fit over the cervix and decrease the risk of dislodgement during intercourse) and a loop on the other side (to

facilitate removal). After being moistened with tap water, the sponge is inserted into the vagina up to 6 hours before intercourse. The sponge provides protection for 24 hours, regardless of the frequency of intercourse during this time. After intercourse, the sponge must be left in place for at least 6 hours before removal. Sponges should not be left in place for more than 24 to 30 hours in order to reduce the risk of toxic shock syndrome. After use, sponges should be discarded (they are not effective for reuse). The sponge comes in one size and is available over the counter (OTC).⁴

Hormonal Contraception

Hormonal contraceptives contain either a combination of estrogen and progestin or a progestin alone. OC preparations first became available in the 1960s, but options have expanded to include a transdermal patch, a vaginal contraceptive ring, and long-acting injectable, implantable, and intrauterine contraceptives.

Components Combined hormonal contraceptives (CHCs) work primarily before fertilization to prevent conception. Progestins provide most of the contraceptive effect, by thickening cervical mucus to prevent sperm penetration, slowing tubal motility and delaying sperm transport, and inducing endometrial atrophy. Progestins block the LH surge, therefore inhibiting ovulation. Estrogens suppress FSH release from the pituitary, which may contribute to blocking the LH surge and preventing ovulation. However, the primary role of estrogen in hormonal contraceptives is to stabilize the endometrial lining and provide cycle control.³⁻⁵

Estrogens. Two synthetic estrogens found in hormonal contraceptives available in the United States, ethinyl estradiol (EE) and mestranol, differ only by the presence of a methyl group attached to

mestranol at the C-3 site. Mestranol, which must be converted by the liver to ethinyl estradiol before it is pharmacologically active, is estimated to be 50% less potent than EE.³⁻⁵ Most combined OCs contain estrogen at doses of 20 to 50 mcg of EE, and the transdermal patch releases approximately 20 mcg of EE daily. The contraceptive ring produces half the serum concentration of EE derived from a 30-mcg OC.⁴

Progestins. Progestins currently used in OCs include desogestrel, drospirenone, ethynodiol diacetate, norgestimate, norethindrone, norethindrone acetate, norethynodrel, norgestrel, and levonorgestrel, the active isomer of norgestrel. The transdermal patch contains norelgestromin, the active metabolite of norgestimate. The vaginal ring contains etonogestrel, the metabolite of desogestrel.^{4,5}

Progestins vary in their progestational activity and differ with respect to inherent estrogenic, antiestrogenic, and androgenic effects.³⁻⁵ Estrogenic and antiestrogenic properties are secondary to the extent of progestins' metabolism to estrogenic substances, whereas androgenic activity results from the structural similarity of the progestin to testosterone (receptor binding and activity) and the ability to affect free testosterone concentrations through impact on sex hormone-binding globulin, a major carrier protein for testosterone.⁵

Considerations with Combined Hormonal Contraceptive Use

1 When selecting a CHC, clinicians are challenged by the many formulations, weighing benefits and evaluating potential risks associated with their use. The clinician also must determine if the form of contraception fits the patient's lifestyle and if the patient will be compliant. As previously stated, a complete medical examination and Pap smear are not necessary before a CHC is prescribed. A medical history and blood pressure measurement should be obtained before a patient begins using CHC, and the benefits, adverse effects, and risks should be discussed.^{3-5,14,15,16} For example, OCs are associated with numerous noncontraceptive benefits, including relief from menstruation-related problems (e.g., decreased menstrual cramps, decreased ovulatory pain [mittelschmerz], and decreased menstrual blood loss), improvement in menstrual regularity, increased hemoglobin concentrations, and an improvement in acne. Women who take combination OCs have a reduced risk of ovarian and endometrial cancer, which is detectable within 1 year and persists for years after discontinuation. Combination OCs reduce the risk of ovarian cysts, ectopic pregnancy, pelvic inflammatory disease, and benign breast disease. The CHC transdermal patch is convenient because it is applied only once weekly, and it may be associated with less breast discomfort and dysmenorrhea than OCs. The CHC vaginal ring also has the advantage of convenience, being inserted for 3 weeks at a time.

2 3 Adverse effects may hinder compliance and therefore efficacy, so they should be discussed prior to initiating a hormonal contraceptive agent (Table 82-2). Estrogen excess can cause nausea and bloating, and low-dose estrogen CHCs can cause early or midcycle breakthrough bleeding and spotting. Progestins may be associated with fatigue and changes in mood. Low-dose progestin CHCs may cause late-cycle breakthrough bleeding and spotting. Androgenic activity derived from progestins may cause increased appetite and acne.³⁻⁵ The CHC vaginal ring may be uncomfortable and cause some vaginal discharge.

The main safety concern about the use of CHC is their lack of protection against STDs. Because of their high efficacy in preventing pregnancy, patients may choose not to use condoms, which do protect against STDs. In addition to public health awareness, at every office visit clinicians must encourage their sexually active patients to use condoms for prevention of STDs. OCs have an extensive history of safety concerns, which traditionally were related to high-dose estrogen in early pills. To replace the traditional absolute and relative contraindications to the use of OCs, the WHO developed a graded list of precautions for clinicians to consider when they are initiating OCs

TABLE 82-2 Adverse Effects of Combined Hormonal Contraception and Management^a

Adverse Effects	Management
Estrogen excess	
Nausea, breast tenderness, headaches, cyclic weight gain due to fluid retention	Decrease estrogen content in CHC Consider progestin-only methods or IUD
Dysmenorrhea, menorrhagia, uterine fibroid growth	Decrease estrogen content in CHC Consider extended-cycle or continuous regimen OC Consider progestin-only methods or IUD NSAIDs for dysmenorrhea
Estrogen deficiency	
Vasomotor symptoms, nervousness, decreased libido	Increase estrogen content in CHC
Early-cycle (days 1-9) breakthrough bleeding and spotting	Increase estrogen content in CHC
Absence of withdrawal bleeding (amenorrhea)	Exclude pregnancy Increase estrogen content in CHC if menses is desired Continue current CHC if amenorrhea acceptable
Progestin excess	
Increased appetite, weight gain, bloating, constipation	Decrease progestin content in CHC
Acne, oily skin, hirsutism	Decrease progestin content in CHC Choose less androgenic progestin in CHC
Depression, fatigue, irritability	Decrease progestin content in CHC
Progestin deficiency	
Dysmenorrhea, menorrhagia	Increase progestin content in CHC Consider extended-cycle or continuous regimen OC Consider progestin-only methods or IUD NSAIDs for dysmenorrhea
Late-cycle (days 10-21) breakthrough bleeding and spotting	Increase progestin content in CHC

CHC, combined hormonal contraceptive; IUD, intrauterine device; NSAID, nonsteroidal antiinflammatory drug; OC, oral contraceptive.

^aCHC regimens should be continued for at least 3 months before adjustments are made based on adverse effects.

Data from Hatcher et al.^{3,4} and Dickey.⁵

and other methods of CHC (Table 82-3).^{4,13} For specific clarifications and explanations, please refer to the complete WHO document.¹³

In addition to the WHO precautions, the ACOG provides information for clinicians to use when selecting CHCs for women with coexisting medical conditions.¹⁶ Overall, the health risks associated with pregnancy, the specific health risks associated with CHCs, and the noncontraceptive benefits of CHCs should be factored into risk-to-benefit considerations.

Women Older Than 35 Years. Generally, CHCs containing less than 50 mcg EE are an acceptable form of contraception for nonsmoking women up to the time of menopause. Population-based case-control studies have not demonstrated an increased risk of myocardial infarction (MI) and stroke in healthy nonsmoking women older than 35 years using low-dose OCs. As women approach the perimenopausal stage, CHCs may confer a benefit with respect to bone mineral density (BMD), reduction in vasomotor symptoms, and reduced risk of endometrial and ovarian cancer. However, these benefits must be weighed against the risk of cardiovascular disease in women with risk factors. If women choose to use hormone therapy, they should switch from CHCs to hormone therapy in the perimenopausal period.^{4,16,17}

Smoking. In early studies, OCs with 50 mcg EE or more were associated with MI in women who smoked cigarettes.^{4,14,16,17} United States case-control studies have found that both nonsmoking and

TABLE 82-3 World Health Organization Precautions in the Provision of Combined Hormonal Contraceptives (CHCs)**Category 4: Refrain from providing CHCs for women with the following diagnoses**

- Thrombophlebitis or thromboembolic disorder, or a history of these conditions
- Cerebrovascular disease, coronary artery disease, peripheral vascular disease
- Valvular heart disease with thrombogenic complications (e.g., pulmonary hypertension, atrial fibrillation, history of endocarditis)
- Diabetes with vascular involvement (e.g., nephropathy, retinopathy, neuropathy, other vascular disease or diabetes >20 years' duration)
- Migraine headaches with focal aura
- Migraine headaches without aura in women ≥ 35 years old should discontinue CHC
- Uncontrolled hypertension (≥ 160 mm Hg systolic or ≥ 90 mm Hg diastolic)
- Major surgery with prolonged immobilization
- Thrombogenic mutations (e.g., factor V Leiden, protein C or S deficiency, antithrombin III deficiency, prothrombin deficiency)
- Breast cancer
- Acute or chronic hepatocellular disease with abnormal liver function, cirrhosis, hepatic adenomas, or hepatic carcinomas
- Age >35 years and currently smoking ≥ 15 cigarettes per day
- Known or suspected pregnancy
- Breast-feeding women <6 weeks postpartum

Category 3: Conditions may be adversely impacted by CHCs, and the risks generally outweigh the benefits; providers should exercise caution if combined CHCs are used in these situations and carefully monitor for adverse effects

- Multiple risk factors for arterial cardiovascular disease
- Known hyperlipidemia
- Migraine headache without aura in women ≥ 35 years old
- History of hypertension (systolic 140–159 mm Hg or diastolic 90–99 mm Hg)
- History of cancer, but no evidence of current disease for 5 years
- Cirrhosis, mild and compensated
- Symptomatic gallbladder disease
- Cholestatic jaundice with prior pill use
- Age >35 years and currently smoking <15 cigarettes per day
- Postpartum <21 days, not breast-feeding
- Breast-feeding women 6 weeks to 6 months postpartum
- Commonly used drugs that induce liver enzymes (rifampin, phenytoin, carbamazepine, barbiturates, primidone, topiramate) and reduce efficacy of CHC

Category 2: Some conditions may trigger potential concerns with CHCs, but benefits usually outweigh risks

- Family history of thromboembolism
- Superficial thrombophlebitis
- Uncomplicated valvular heart disease
- Diabetes without vascular disease

- Sickle cell disease
- Migraine headaches without aura in women <35 years old
- Nonmigrainous headaches at any age should discontinue CHC
- Hypertension during pregnancy, resolved postpartum
- Major surgery without prolonged immobilization
- Gallbladder disease (symptomatic and treated by cholecystectomy or asymptomatic)
- Cholestatic jaundice of pregnancy
- Undiagnosed breast mass
- Undiagnosed abnormal genital bleeding
- Cervical intraepithelial neoplasia or cervical cancer
- Obesity (body mass index ≥ 30 kg/m²)
- Age <35 years and currently smoking
- Breastfeeding women ≥ 6 months postpartum
- Age ≥ 40 years
- Drugs that may induce metabolism of CHC and reduce efficacy (griseofulvin, antiretroviral therapy)

Category 1: Do not restrict use of combined oral contraceptives for the following conditions

- Varicose veins
- History of gestational diabetes
- Nonmigrainous headaches
- Thyroid disease
- Thalassemia
- Iron deficiency anemia
- Depression
- Epilepsy
- Infectious diseases (HIV, schistosomiasis, tuberculosis, malaria)
- Minor surgery without immobilization
- Benign ovarian tumors
- Endometriosis
- Irregular or heavy vaginal bleeding, severe dysmenorrhea
- Sexually transmitted diseases
- Uterine fibroids
- Pelvic inflammatory disease
- Endometrial cancer
- Ovarian cancer
- History of pelvic surgery
- Trophoblast disease
- History of ectopic pregnancy
- Postabortion
- Postpartum women ≥ 21 weeks, not breast-feeding
- Menarche to 40 years of age
- Drug interactions with antibiotics other than rifampin and griseofulvin

CHC, combined hormonal contraception; HIV, human immunodeficiency virus.

Data from Hatcher et al.,^{3,4} Dickey,⁵ World Health Organization,¹³ Roddey et al.,¹⁴ and Petitti.¹⁶

smoking women, regardless of age, taking OCs with less than 50 mcg EE did not have an increased risk of MI or stroke. However, these studies included few women older than 35 years who were smokers. European studies, with a higher population of older smoking women, demonstrated an increased risk of MI in this population. Therefore, practitioners should prescribe CHC with caution, if at all, to women older than 35 years who smoke. The WHO precautions further state that smoking 15 or more cigarettes per day by women in this age group is a contraindication to CHC, and that the risks generally outweigh the benefits of CHC in those who smoke fewer than 15 cigarettes per day.¹³ Progestin-only contraceptive methods should be considered for women in this group.

Hypertension. CHCs, even those containing less than 35 mcg of estrogen, can cause small increases (i.e., 6–8 mm Hg) in blood pressure.^{4,14,16,17} This has been documented in both normotensive and mildly hypertensive women given a 30-mcg EE OC. In case-control studies of women with hypertension, OCs have been associated with an increased risk of MI and stroke. Use of low-dose CHC is acceptable in women younger than 35 years with well-controlled and frequently monitored hypertension. If a CHC-related increase in

blood pressure occurs, discontinuing the CHC usually restores blood pressure to pretreatment values within 3 to 6 months.⁴ Hypertensive women who have end-organ vascular disease or who smoke should not use CHCs. Women with hypertension who are taking potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, angiotensin-receptor blockers, or aldosterone antagonists may have increased serum potassium concentrations if they are also using an OC-containing drospirenone (e.g., Yasmin), which has antialdosterone properties.⁴ Progestin-only pills and depot medroxyprogesterone acetate (DMPA) have not been shown to increase blood pressure or increase the risk of vascular events in normotensive or hypertensive women and therefore are choices for women with hypertension.

Dyslipidemia. Generally, synthetic progestins adversely affect lipid metabolism by decreasing high-density lipoprotein (HDL) and increasing low-density lipoprotein (LDL).^{4,16,17} Estrogens tend to have more beneficial effects by enhancing removal of LDL and increasing HDL levels. Estrogens also may moderately increase triglycerides. As a net result, most low-dose CHCs have no significant impact on HDL, LDL, triglycerides, or total cholesterol. CHCs containing more androgenic progestins (e.g., levonorgestrel) may result

in lower HDL levels in some patients. Although the lipid effects of CHCs theoretically can influence cardiovascular risk, the mechanism of increased cardiovascular disease in CHC users is believed to be due to thromboembolic and thrombotic changes, not atherosclerosis. Women with controlled dyslipidemia can use low-dose CHCs, although periodic fasting lipid profiles are recommended. Women with uncontrolled dyslipidemia (LDL >160 mg/dL, HDL <35 mg/dL, triglycerides >250 mg/dL) and additional risk factors (e.g., coronary artery disease, diabetes, hypertension, smoking, or positive family history) should use an alternative method of contraception.

Diabetes. Any effect of CHCs on carbohydrate and lipid metabolism is thought to be due to the progestin component.^{4,17} However, with the exception of some levonorgestrel-containing products, formulations containing low doses of progestins do not significantly alter insulin, glucose, or glucagon release after a glucose load in healthy women or in those with a history of gestational diabetes. The new progestins are believed to have little, if any, effect on carbohydrate metabolism. CHCs do not appear to alter the hemoglobin A_{1c} values or accelerate the development of microvascular complications in women with type 1 diabetes. In the Nurses' Health Study, women who used OCs did not demonstrate any increased risk of developing type 2 diabetes.¹⁷ Therefore, nonsmoking women younger than 35 years with diabetes but no associated vascular disease can safely use CHCs. Diabetic women with vascular disease (e.g., nephropathy, retinopathy, neuropathy, or other vascular disease or diabetes of more than 20 years' duration) should not use CHCs. Copper and progestin-releasing IUDs have not been associated with impaired metabolic control in women with uncomplicated diabetes.

Migraine Headaches. Women in their reproductive years frequently experience headaches, primarily tension headaches. Women with migraine headaches (with and without aura) may experience a decreased or an increased frequency of migraine headaches when using CHCs.^{4,14,16,17} Headaches may even occur during the hormone-free interval (during menses). Most studies have demonstrated a higher risk of stroke in women experiencing migraine with aura compared to women with simple migraines (without aura). In population-based studies, the risk of stroke in women with migraines has been elevated twofold to threefold. However, given the low absolute risk of stroke in young women (age <35 years), the ACOG recommends considering CHCs in healthy, nonsmoking women with migraine headaches if they do not have focal neurologic signs.¹⁶ Women of any age who have migraine with aura should not use CHC. Women who develop migraines (with or without aura) while receiving CHC should discontinue use immediately. Progestin-only, intrauterine, or barrier contraceptives should be considered in these patients.

Breast Cancer. Worldwide epidemiologic data from 54 studies in 25 countries (many of which studied high-dose OCs) were collected to assess the relationship between OCs and breast cancer.¹⁷ Overall, investigators noted a small increased risk of breast cancer associated with current or recent use, but OCs did not further increase risk in women with a history of benign breast disease or a family history of breast cancer. A more recent U.S.-based case-control study found no association between overall breast cancer and current or past OC use.¹⁷ This study also found no association between DMPA and breast cancer. Although some studies have found differences in risk of breast cancer based on the presence of *BRCA1* and *BRCA2* mutations, the most recent cohort study found no association with low-dose OCs and the presence of either mutation. Therefore, the choice to use CHCs should not be affected by the presence of benign breast disease or a family history of breast cancer with either mutation. The WHO precautions state that women with a recent personal history of breast cancer should not

use CHCs, but that CHCs can be considered in women without evidence of disease for 5 years.¹³

Thromboembolism. Estrogens increase hepatic production of factor VII, factor X, and fibrinogen in the coagulation cascade, therefore increasing the risk of thromboembolic events (e.g., deep-vein thrombosis, pulmonary embolism). These risks are increased in women who have underlying hypercoagulable states (e.g., deficiencies in antithrombin III, protein C, and protein S; factor V Leiden mutations, prothrombin G2010 A mutations) or who have acquired conditions (e.g., obesity, pregnancy, immobility, trauma, surgery, and certain malignancies) that predispose them to coagulation abnormalities.^{4,14,16,17} In U.S. case-control studies, the risk of venous thromboembolism (VTE) in women currently using low-dose OCs (<50 mcg EE with norethindrone or levonorgestrel) was four times the risk in nonusers.^{4,16,17} However, this risk is less than the risk of thromboembolic events incurred during pregnancy. OCs containing desogestrel have been associated with a 1.7 to 19 times higher risk of VTE than OCs containing levonorgestrel. Some clinicians argue that this difference reflects preferential prescribing of the newer, and perceived safer, progestin products for women at greater risk for VTE. Estrogen exposure in women using transdermal CHC may be greater than that in women taking OCs or using the vaginal contraceptive ring, but the absolute risk of VTE in this population is unknown. Therefore, CHCs are contraindicated in women with a history of thromboembolic events and in those at risk due to prolonged immobilization with major surgery unless they are currently taking anticoagulants. Women with familial coagulopathies are at particular risk during pregnancy, given the risk of VTE and of fetal exposure to warfarin. CHCs reduce menstrual blood loss and are safe for use by women with appropriate anticoagulation. DMPA and levonorgestrel IUDs are also recommended for this population. EC has not been associated with an increased risk of thromboembolic events.

Obesity. As the proportion of women who are obese (body mass index [BMI] >30 mg/kg²) has increased, the issue of contraception in this population has become more important. Obese women (weight >90 kg) taking OCs or using transdermal contraceptives are at increased risk for contraceptive failure compared to women with a normal BMI.^{4,17} These women who use CHCs also are at increased risk of VTE. Because increased pregnancy rates have not been documented in obese women using DMPA as the method of contraception, this or intrauterine methods of contraception should be considered. Given that the intrauterine levonorgestrel system improves dysfunctional uterine bleeding, a particular problem in obese women, and that DMPA may increase irregular bleeding patterns, the levonorgestrel IUD may be preferred for this population.

Systemic Lupus Erythematosus. Contraception is important in women with systemic lupus erythematosus (SLE) because the risks associated with pregnancy are high in this population. Historically, clinicians have thought that CHCs exacerbated the symptoms of SLE.^{4,17,18} However, randomized controlled trials have shown that OCs do not increase the risk of flare among women with stable SLE and without antiphospholipid/anticardiolipin antibodies. Because 25% of women with SLE who become pregnant choose to terminate the pregnancy, effective contraception is essential for these patients. CHCs should be avoided in women with SLE and antiphospholipid antibodies or vascular complications; progestin-only contraceptives can be used in this situation.

Sickle Cell Disease. Two controlled trials have demonstrated a reduction in risk of vasoocclusive crises in women with sickle cell disease using DMPA as the method of contraception.¹⁷ Theoretical concerns about the effects of CHCs on platelet activation and red cell deformity, for example, led clinicians to avoid their use in women with sickle cell disease. Because pregnancy carries such a

high risk in this population, contraception with DMPA should be considered.

Oral Contraceptives ① ② When OCs are used correctly, their effectiveness approaches that of surgical sterilization.³⁻⁵ With perfect use, their efficacy is greater than 99%, but with typical use, up to 8% of women may experience unintended pregnancy.⁴ The low-dose combination OCs currently available are modifications of the original products introduced in 1960, containing significantly less estrogen and progestin than the earlier pills.^{3-5,14} High-dose formulations were associated with vascular and embolic events, cancers, and significant side effects, but reductions in estrogen and progestin doses have been associated with fewer complications.

Monophasic OCs contain the same amounts of estrogen and progestin for 21 days, followed by 7 days of placebo pills (Table 82-4). Biphasic and triphasic pills contain variable amounts of estrogen and progestin for 21 days, also followed by a 7-day placebo phase. Over the past decade, combination multiphasic formulations have further lowered the total monthly hormonal dose without clearly demonstrating any significant clinical differences.^{3,4,14} Monophasic, biphasic, and triphasic OCs attempted to reduce breakthrough bleeding and other side effects, but reviews from the Cochrane Library found no important differences in bleeding patterns based on phasic composition.^{19,20}

Extended-cycle pills and continuous combination regimens are new developments that may offer some benefits for patients in terms of side effects. Extended-cycle OCs increase the number of hormone-containing pills from 21 to 84 days, followed by a 7-day placebo phase, resulting in four menstrual cycles per year. One unique product provides hormone-containing pills daily throughout the year.¹⁵ Continuous combination regimens provide OCs for 21 days, then very-low-dose estrogen and progestin for an additional 4 to 7 days (during the traditional placebo phase).

OCs containing newer progestins (e.g., desogestrel, drospirenone, gestodene, and norgestimate) are sometimes referred to as *third-generation* OCs. These progestins are potent progestational agents that appear to have no estrogenic effects and are less androgenic compared with levonorgestrel on a weight basis. Therefore, these agents are thought to have improved side-effect profiles, such as improving mild to moderate acne.³⁻⁵ Drospirenone also has antimineralocorticoid and antialdosterone activities, which may result in less weight gain compared to use of OCs containing levonorgestrel.³⁻⁵ Unfortunately, few clinical trials have compared OCs and sample sizes are small, so the actual relevance of these differences in progestational selectivity and lower androgenic activity remains unknown. For example, a review by the Cochrane Library concluded that there was no evidence supporting a causal association between combination OCs or combination skin patches and weight gain.²¹ Table 82-4 lists available OCs products by brand name and specifies hormonal composition.

Also introduced in 1960, the progestin-only “minipills” (28 days of active hormone per cycle) still are available.^{3-5,14} Progestin-only pills tend to be less effective than combination OCs and are associated with irregular and unpredictable menstrual bleeding.³⁻⁵ Minipills must be taken every day of the menstrual cycle at approximately the same time to maintain contraceptive efficacy. If a progestin-only pill is taken more than 3 hours late, patients should use a backup method of contraception for 48 hours.⁴ Because minipills may not block ovulation (nearly 40% of women continue to ovulate normally), the risk of ectopic pregnancy is higher with their use than with use of other hormonal contraceptives.

Initiating an Oral Contraceptive. ④ Historically, women were instructed to initiate OCs at some point after the next menstrual period occurred, several weeks after childbirth, or after a breast-feeding infant was weaned.²¹ However, these recommendations to

delay initiation of contraception resulted in many unintended pregnancies. This practice began in an effort to avoid exposing an unknown pregnancy to hormones. Because a large body of evidence shows that combined estrogens and progestins do not cause birth defects, delaying initiation of OCs is unnecessary.

In the “quick start” method for initiating OCs, the patient takes the first pill on the day of her office visit (after a negative urine pregnancy test).^{3,4,22} Women should be instructed to use a second method of contraception for at least 7 days and informed that the menstrual period will be delayed until completion of the active pills in the current OC pill pack. The quick start method has been shown to be more successful in getting women to start OCs and to continue using OCs through the third cycle of use. No evidence shows increased bleeding irregularities with this method of OC initiation.

In the first-day start method, women take the first pill on the first day of the next menstrual cycle.^{3,4,22} The Sunday start method was the most common method of initiating OCs for years. Women started OCs on the first Sunday after starting the menstrual cycle. Sunday start methods result in “period-free” weekends but may affect compliance if obtaining refills on weekends is difficult.

In the postpartum phase, there is concern about use of OCs because of the mother’s hypercoagulability and the effects on lactation. The WHO precautions state that, in the first 21 days postpartum (when the risk of thrombosis is higher), estrogen-containing hormonal contraceptives should be avoided if possible (Table 82-3).¹³ If contraception is required during this period, progestin-only pills and IUDs (progesterone or copper) are acceptable choices. Although a review by the Cochrane Library indicated that existing randomized, controlled trials were insufficient to establish an effect of CHC, if any, on milk quality and quantity, the WHO recommends that women who are breast-feeding avoid CHC in the first 6 weeks postpartum.^{13,23} WHO precautions cite concerns about hormonal exposure in the newborn and diminished quality and quantity of breast milk due to early exposure to CHCs. Progestin-only pills do not adversely affect milk production, so they can be used after 6 weeks postpartum. Once effective lactation has been established, particularly in women who are not exclusively breast-feeding, estrogen-containing hormonal contraceptives can be safely used.

Choice of Oral Contraceptive. ① ② Because all combined OCs are similarly effective in preventing pregnancy, the initial choice is based on the hormonal content and dose, preferred pattern of pill use, and coexisting medical conditions (Table 82-3). In women without coexisting medical conditions, an OC containing 35 mcg or less of EE and less than 0.5 mg of norethindrone is recommended (Table 82-4).⁵ This strategy is based on evidence that complications and side effects from CHC (i.e., thromboembolic events, stroke, or MI) result from excessive hormonal content.^{3-5,14} Adolescents, underweight women (<110 lb [50 kg]), women older than 35 years, and those who are perimenopausal may have fewer side effects with OCs containing 20 to 25 mcg of EE. Risk of noncompliance with OCs is greater in women taking OCs containing less than 35 mcg of EE and thus should be considered, particularly in adolescents. Women weighing more than 160 lb (72.7 kg) may have higher contraceptive failure rates with low-dose OCs and may benefit from pills containing 35–50 mcg of EE. Women with regular heavy menses initially may benefit from a 50-mcg EE OC as well because of their higher endometrial activity. On the other hand, women with regular light menses can be started on 20-mcg EE OCs. Women with oily skin, acne, and hirsutism should be given low androgenic OCs.⁵

Conventional regimens (21 days of active pills, 7 days of placebo) provide predictable menses. Because monophasic OCs may be easier to take, easier to identify and manage side effects, and easier to manipulate to alter the timing of the menstrual cycle, they are preferred over conventional biphasic or triphasic OCs.³⁻⁵ Extended-cycle OCs either eliminate the menstrual cycle or result in only four

TABLE 82-4 Composition of Commonly Prescribed Oral Contraceptives^a

Product	Estrogen	Micrograms ^b	Progestin	Milligrams ^b	Spotting and Break-through Bleeding
50 mcg estrogen					
Necon, Nelova, Norethin, Norinyl, Ortho-Novum 1/50	Mestranol	50	Norethindrone	1	10.6

^a28-day regimens (21-day active pills, then 7-day pill-free interval) unless otherwise noted.^bNumber in parentheses refers to the number of days the dose is received in multiphasic oral contraceptives.^c28-day regimen (24-day active pills, then 4-day pill-free interval).^d91-day regimen (84-day active pills, then 7-day pill-free interval).^ePercent reporting after 6–12 months of use.Data from Hatcher et al.,^{3,4} Dickey,⁵ and Anonymous.¹⁴

menstrual cycles per year, so they may be associated with less dysmenorrhea and menstrual migraines. Commercially available extended-cycle OCs are available, or monophasic 28 day OCs can be cycled by skipping the 7-day placebo phase for two to three cycles

(sometimes referred to as *bicycling* and *tricycling*). With continued use of extended-cycle OCs for 1 year, no significant changes in blood pressure, weight, or hemoglobin compared with cyclic users have been noted. However, long-term studies have not been per-

formed to assess the risk of cancer, VTE, or changes in fertility. Continuous regimens provide a shortened pill-free interval, from the traditional 7 days to 2 to 4 days. These regimens may be beneficial for women with dysmenorrhea and menstrual migraines.

Coexisting medical conditions and their impact on CHC use have been previously addressed. Women with migraine headaches, history of thromboembolic disease, heart disease, cerebrovascular disease, SLE with vascular disease, and hypertriglyceridemia are good candidates for progestin-only methods (pills, DMPA, and the levonorgestrel intrauterine system). Women older than 35 years who are smokers or are obese, or who have hypertension or vascular disease should use progesterone-only methods.^{13,17}

Managing Oral Contraceptive Side Effects. **3** Many symptoms occurring with early OC use (e.g., nausea, bloating, breakthrough bleeding) improve spontaneously by the third cycle of use after adjusting to the altered hormone levels.³⁻⁵ However, 59% to 81% of women who stopped OCs in one study did so because of the side effects. Therefore, patient education and early reevaluation (i.e., within 3–6 months) are necessary to identify and manage adverse effects, in an effort to improve compliance and prevent unintentional pregnancies. A list of OC-related side effects and their management is given in Table 82–2.

If the patient has symptoms related to OC use, it is necessary to determine if the symptom indicates the presence or potential development of a serious illness (Table 82–5).^{4,5} Patients should be instructed to immediately discontinue CHCs if they experience warning signs, sometimes described as ACHES (abdominal pain, chest pain, headaches, eye problems, and severe leg pain).⁴

CLINICAL CONTROVERSY

There is a widely held belief that antibiotics reduce the efficacy of OCs, increasing the risk of pregnancy. However, few data support this drug interaction with most antibiotics, with the exception of rifampin. Because of this potential risk and considering the fact that OCs are not 100% effective, many practitioners still counsel patients about this issue. The Council on Scientific Affairs at the American Medical Association recommends that women be informed about the small risk of interactions with antibiotics and, if desired, provided with additional nonhormonal contraceptive agents.

Managing Oral Contraceptive Drug Interactions. **3** The effectiveness of an OC is sometimes limited by drug interactions

TABLE 82-5 Serious Symptoms That May Be Associated with Combined Hormonal Contraception

Serious Symptoms	Possible Underlying Problem
Blurred vision, diplopia, flashing lights, blindness, papilledema	Stroke, hypertension, temporary vascular problem of many possible sites, retinal artery thrombosis
Numbness, weakness, tingling in extremities, slurred speech	Hemorrhagic or thrombotic stroke
Migraine headaches	Vascular spasm, stroke
Breast mass, pain, or swelling	Breast cancer
Chest pain (radiating to left arm or neck), shortness of breath, coughing up blood	Pulmonary embolism, myocardial infarction
Abdominal pain, hepatic mass or tenderness, jaundice, pruritus	Gallbladder disease, hepatic adenoma, pancreatitis, thrombosis of abdominal artery or vein
Excessive spotting, breakthrough bleeding	Endometrial, cervical, or vaginal cancer
Severe leg pain (calf, thigh), tenderness, swelling, warmth	Deep-vein thrombosis

Data from Hatcher et al.⁴ and Dickey.⁵

TABLE 82-6 Interactions of Oral Contraceptives with Other Drugs

Interacting Drugs	Outcome and Recommendation
Anticonvulsants (barbiturates, including phenobarbital and primidone; carbamazepine; felbamate; phenytoin; topiramate; vigabatrin)	Decreased contraceptive effect Use OCs containing 50 mcg ethinyl estradiol and a second method of contraception or IUD
Griseofulvin (Fulvicin, Grifulvin V, and others)	Possible decreased contraceptive effect Use second method of contraception
Nonnucleoside reverse transcriptase inhibitors (delavirdine, efavirenz, nevirapine)	Possible decreased contraceptive effect Use IUD
Protease inhibitors (amprenavir, atazanavir, indinavir, lopinavir, nelfinavir, ritonavir, saquinavir)	Increased or decreased contraceptive effect Use IUD
Rifampin	Decreased contraceptive effect Use second method of contraception or alternate method (IUD) if concomitant use is long term

IUD, intrauterine device; OC, oral contraceptives.

Data from Hatcher et al.,⁴ World Health Organization,¹³ ACOG Practice Bulletin,¹⁷ Dickenson et al.,²⁴ and Archer and Archer.²⁵

that interfere with gastrointestinal absorption, increase intestinal motility by altering gut bacteriologic flora, and alter the metabolism, excretion, or binding of the OC (Table 82–6).^{4,17,24} The lower the dose of hormone in the OC, the greater the risk that a drug interaction will compromise its efficacy. Women should be instructed to use an alternative method of contraception (e.g., condoms) if there is a possibility of a drug interacting altering the efficacy of the OC.⁴ Although less well documented, these recommendations generally also apply to patients receiving transdermal and vaginal CHC products.

Several reviews of the interaction between antibiotics and OCs have documented a true pharmacokinetic interaction with rifampin in which the efficacy of OCs is impaired. Pharmacokinetic studies of other antibiotics have not shown any consistent interaction, but case reports of individual patients have shown a reduction in EE levels when OCs are taken with tetracyclines and penicillin derivatives.^{24,25} The ACOG states that ampicillin, doxycycline, fluconazole, metronidazole, miconazole, fluoroquinolones, and tetracyclines do not decrease steroid levels in women taking OCs.¹⁷ The Council on Scientific Affairs at the American Medical Association recommends that women taking rifampin should be counseled about the risk of OC failure and advised to use an additional nonhormonal contraceptive agent during the course of rifampin therapy. The council also recommends that women be informed about the small risk of interactions with other antibiotics, and, if desired, appropriate additional nonhormonal contraceptive agents should be considered. In addition, women who develop breakthrough bleeding during concomitant use of antibiotics and OCs (and other CHCs) should be advised to use an alternate method of contraception during the period of concomitant use.²⁴

Women receiving anticonvulsants for a seizure disorder require special attention with regard to hormonal contraception. Some anticonvulsants (mainly phenobarbital, carbamazepine, phenytoin) induce the metabolism of estrogen and progestin, inducing breakthrough bleeding and potentially reducing contraceptive efficacy. In addition, some anticonvulsants (i.e., phenytoin) are known teratogens. Use of condoms in conjunction with high-estrogen OCs or IUDs can be considered for these women.¹⁷

Patient Instructions with Oral Contraceptives. **4** Many women who take OCs are poorly informed about the proper use of these medications. The patient first should be given the package insert that accompanies all estrogen products and instructed to read it carefully. The written information in the package insert should be

supplemented with verbal information describing the way the medication works (primarily by thickening cervical mucus to prevent sperm penetration), both common and serious side effects, and management of side effects (Table 82–4). Although several transient self-limiting side effects often occur, the patient should be aware of the danger signals that require immediate medical attention (Table 82–5). The benefits and risks should be discussed in terms that the patient can understand, including the fact that OCs provide no physical barrier to the transmission of STDs, including HIV. Detailed instructions on when to start taking the OC, such as the “Quick Start” method, should be provided. Patients should be told the importance of routine daily administration to ensure consistent plasma concentrations and improve compliance, and specific instructions should be given regarding what to do if a pill is missed (Table 82–7). Use of an additional contraceptive method is advisable if the patient misses taking a pill or experiences severe diarrhea or vomiting for several days. Important drug interactions should be discussed. The patient taking combination OCs should expect her menses to start within 1 to 3 days after taking the last active pill. She should start another pack of pills immediately after finishing a 28-day pack (no days between) or 1 week after finishing the previous 21-day pack, even if her menses is not completed.^{3–5}

Discontinuing Oral Contraceptives and Return of Fertility.

The average delay in ovulation after discontinuing OCs is 1 to 2 weeks, but delayed ovulation is more common in women with a history of irregular menses. Post-OC amenorrhea rarely lasts 6 months.^{3–5} Traditionally, women are counseled to allow two to three normal menstrual periods before becoming pregnant to permit the reestablishment of menses and ovulation. However, in several large cohort and case-control studies, infants conceived in the first month after discontinuation of an OC had no greater chance of miscarriage or being born with a birth defect than those born in the general population.

TABLE 82-7 Recommendations for Missed Oral Contraceptive Doses

Number of Pills Missed	Week in Which Pills Were Missed	Recommendation	Use of 7-Day Back Up Method
1	1	Take two pills as soon as possible Finish the pill pack Use emergency contraception if necessary	Yes
1	2–3	Take two pills as soon as possible Finish the pill pack	No
1	4	Skip placebo pills Finish the pill pack	No
2–4	1	Take two pills as soon as possible ^a Finish the pill pack Use emergency contraception if necessary	Yes
2–4	2	Take two pills as soon as possible ^a Finish the pill pack Use emergency contraception if necessary	Yes
2–4	3	Start a new pill pack ^a	No
2–4	4	Skip placebo pills Finish the pill pack	No
5	Any	Take two pills as soon as possible Start a new pill pack Use emergency contraception if necessary	Yes

^aAlternative recommendation is to take one of the missed pills every 12 hours until caught up, then continue the rest of the pill pack.

Data from Hatcher et al.^{3,4} and Dickey.⁵

Transdermal Contraceptives ① ② A CHC is available as a transdermal patch (Ortho Evra), which includes 0.75 mg of EE and 6 mg of norelgestromin, the active metabolite of norgestimate.^{3–5} Comparative trials have shown the transdermal patch to be as effective as combined OCs in patients weighing less than 90 kg (198 pounds). Of the 15 pregnancies reported in the clinical trials, five were among women weighing more than 198 lb (90 kg); therefore, this product is not recommended as a first-line option for these women.^{3,4,26} Some patients experience application-site reactions, but other side effects are similar to those experienced with OCs (e.g., breast discomfort, headache, and nausea).

③ A warning from the manufacturer states that women using the patch are exposed to approximately 60% more estrogen than from a typical OC containing 35 mcg of EE, due to the transdermal system eliminating first-pass metabolism. Whether this increased estrogen exposure leads to increased cardiovascular or thromboembolic events is unclear. The Ortho Evra package insert provides preliminary data indicating a higher incidence of thromboembolic events with the patch.²⁶ Another case-control study compared the patch to a 35-mcg norgestimate-containing OC and found no significant difference in thromboembolism occurrence.²⁷ Currently, the Food and Drug Administration (FDA) is monitoring this risk because more consistent data are needed.

The patch should be applied to the abdomen, buttocks, upper torso, or upper arm at the beginning of the menstrual cycle and replaced every week for 3 weeks (the fourth week is patch-free).^{3,4} The patch releases estrogen and progestin for 9 days. If the woman forgets to change her patch or restarts the active patches after the ninth day, a backup method should be used for 7 days. Approximately 5% of patches will need to be replaced because they become partly detached or fall off altogether, so single replacements are available. If the patch is detached for more than 24 hours, a new 4-week cycle should be restarted and backup method used for 7 days.^{3,4} Users have demonstrated greater compliance with the patch than with an OC, but whether this results in reduced pregnancy rates remains to be seen.²⁸ The benefits of compliance must be weighed against the risk of increased estrogen exposure and possibility of thromboembolic events.

Vaginal Rings ① ② The vaginal ring containing EE and etonogestrel (NuvaRing) currently is the only product available using vaginal delivery for hormonal contraception.²⁹ It is a 54-mm flexible ring, 4 mm in thickness.³ Over a 3-week period, the ring releases approximately 15 mcg/day of EE and 120 mcg/day of etonogestrel. Comparative trials have shown the vaginal ring to be as effective as combined OCs. On the first cycle of use, the ring should be inserted on or before the fifth day of the menstrual cycle, remain in place for 3 weeks, then removed for 1 week to allow for withdrawal bleeding. The new ring should be inserted on the same day of the week as it was during the last cycle, similar to starting a new OC pack on the same day of the week. A second method of contraception should be used if the ring has been expelled accidentally for more than 3 hours.^{3,29}

③ Side effects, precautions, and contraindications for use of the hormonal ring are similar to those for all CHCs. The most commonly reported reasons for discontinuation of use were device-related issues, such as foreign-body sensation, device expulsion, and vaginal symptoms. Cycle control with the vaginal ring appears to be as good as or better than with combined OCs, with a low incidence of breakthrough bleeding and spotting after the second cycle of use, presumably due to increased compliance and release of steady levels of estrogen and progestin.^{29,30} Patient acceptability of the delivery system has been studied, and the majority of women do not complain of discomfort in general or during intercourse.³¹

The ring should be inserted vaginally. In contrast to diaphragms and cervical caps, precise placement is not an issue because the estrogen and progestin are absorbed anywhere in the vagina.

Women should be in a comfortable position, and compress the ring between the thumb and index finger and push it into the vagina. There is no danger of inserting the ring too far because the cervix will prevent it from traveling up the genital tract. Removal of the ring is performed in a similar manner; pulling it out with the thumb and index finger, and discarding into the foil patch (the ring should not be flushed down the toilet).²⁹ Patients should be discouraged from douching, but other vaginal products, including antifungal creams and spermicides, can be used.^{3,4,29}

Long-Acting Injectable and Implantable Contraceptives Steroid hormones provide long-term contraception when injected or implanted into the skin. Progestins are used in existing injectable and implantable contraceptives.^{3–5} Sustained progestin exposure blocks the LH surge, thus preventing ovulation. Should ovulation occur, progestins reduce ovum motility in the fallopian tubes. Even if fertilization occurs, progestins thin the endometrium, reducing the chance of implantation. Progestins also thicken the cervical mucus, producing a barrier to sperm penetration. These long-acting methods of contraception do not provide any protection from STDs.

① ② Women who particularly benefit from progestin-only methods are those who are breast-feeding, those who are intolerant to estrogens (i.e., have a history of estrogen-related headache, breast tenderness, or nausea), and those with concomitant medical conditions in which estrogen is not recommended (Table 82–3). Additionally, injectable and implantable contraceptives are beneficial for women with compliance issues. Pregnancy failure rates with long-acting progestin contraceptives are comparable to the rates with female sterilization.^{3–5} Reports have stated an increased risk of ectopic pregnancies while using progestin-only methods, but no evidence supports this finding with use of recent injectable and implantable products.

Injectable Progestins. ① ② Medroxyprogesterone acetate is similar in structure to naturally occurring progesterone. DMPA 150 mg (Depo-Provera) is administered by deep intramuscular injection in the gluteal or deltoid muscle within 5 days of onset of menstrual bleeding and inhibits ovulation for more than 3 months.³² Additionally, a new formulation approved by the FDA contains 104 mg of DMPA (Depo-SubQ Provera 104), which is injected subcutaneously into the abdomen or thigh.³³ With perfect use, the efficacy of DMPA is more than 99%; however, with typical use, 3% of women experience unintended pregnancy.⁴ Although these injections may inhibit ovulation for up to 14 weeks, the dose should be repeated every 3 months (12 weeks) to ensure continuous contraception. The manufacturer recommends excluding pregnancy in women with a lapse of 13 or more weeks between injections for the intramuscular formulation or 14 or more weeks between injections for the subcutaneous formulation. Depo-Provera is available as a 150 mg/mL injection vial or prefilled syringe and Depo-SubQ Provera 104 is available as a prefilled syringe.^{32,33}

Although no adverse effects have been documented in infants exposed to DMPA through breast milk, the manufacturer recommends not initiating DMPA until 6 weeks postpartum in breast-feeding women. Women who are not breast-feeding but require contraception can receive DMPA immediately postpartum.^{13,32} Women with sickle cell disease are good candidates for DMPA, as studies have demonstrated a reduction in sickle cell pain crises in women using DMPA.¹³ In addition, women with seizure disorders may experience fewer seizures when taking DMPA for contraception.⁴ The subcutaneous DMPA formulation has been FDA approved for treatment of endometriosis-associated pain.³³ The incidence of *Candida* vulvovaginitis, ectopic pregnancy, and pelvic inflammatory disease, as well as endometrial and ovarian cancer, is decreased in women using DMPA for contraception compared with women using no contraception.^{3,32}

Because return of fertility may be delayed after discontinuation of DMPA, it should not be recommended to women desiring pregnancy in the near future. The median time to conception from the first omitted dose is 10 months. Sixty-eight percent of women will be able to conceive within 12 months, 83% within 15 months, and 93% within 18 months of the last injection.^{32,33}

③ Menstrual irregularities, including irregular, unpredictable spotting or, more rarely, continuous heavy bleeding, are the most frequent adverse effects of both formulations of DMPA. In some cases, bleeding is severe enough to cause a significant drop in hemoglobin. Women who cannot tolerate prolonged bleeding may benefit from a short course of estrogen (e.g., 7 days of 2-mg estradiol or 1.25-mg conjugated estrogen given orally).^{3,4} The incidence of irregular bleeding decreases from 30% in the first year to 10% thereafter. After 12 months of therapy with either formulation, 55% of women report amenorrhea, with the incidence increasing to 68% after 2 years.^{32,33} Bleeding patterns after 1 year of the subcutaneous formulation have not been established.^{33,34}

Other adverse effects, including breast tenderness, weight gain, and depression, occur less commonly (<5%). However, data suggest that DMPA may actually improve depression, and use of DMPA in women with depression may be appropriate with close monitoring.¹³ Weight gain averages 1 kg annually and may not resolve until 6 to 8 months after the last injection.^{32,33}

CLINICAL CONTROVERSY

Both formulations of DMPA have a black box warning that addresses the association between DMPA use and decreased BMD, specifically in adolescent and young women. The clinical significance of this finding is unknown, and current evidence suggests osteoporosis or fractures do not occur more frequently in women who use DMPA. Many clinicians have adopted the policy, recommended by the manufacturer, of dual-energy x-ray absorptiometry (DXA) studies to monitor BMD. In contrast, WHO and ACOG guidelines recommend against the use of DXA in short- and long-term DMPA users due to the limited clinical utility of monitoring BMD in this population.

Concern has been raised over DMPA use and the development of osteoporosis because DMPA suppresses ovarian production of estradiol and has been associated with a reduction in BMD.^{4,17} However, DMPA has not been associated with the development of osteoporosis or fractures, and discontinuation of DMPA results in return to baseline BMD values within 12 to 30 months. In 2004, the FDA added a black box warning to DMPA, recommending continued use of more than 2 years only if other contraceptive methods were inappropriate.^{17,32,33} However, current data do not provide a clear rationale for this time limit, as evidence suggests the rate of BMD loss may slow after 1 to 2 years of DMPA use.³⁵

Many clinicians have adopted the policy, recommended by the manufacturer, of DXA studies to monitor BMD in DMPA users. Bone loss with DMPA can be prevented by providing supplemental estrogen (0.625-mg conjugated equine estrogen daily or 5-mg intramuscular estradiol cypionate), but because reductions in BMD have not been linked to the development of osteoporosis, the utility of this finding is questionable. In addition, most women use DMPA because they are unable to use estrogen-containing contraceptives, or adolescents use DMPA because of compliance issues. The WHO does not recommend a restriction on the use of DMPA in women aged 18 to 45 years and states that the benefits of use outweigh the potential risks.³⁶ Appropriate counseling regarding prevention of osteoporosis should be provided for women using DMPA, including the use of 1,200 to 1,500 mg of elemental calcium plus 400

international units of vitamin D and a regular regimen of weight-bearing exercise.³

Subdermal Progestin Implants. ① ② Norplant, developed by the Population Council, was the first subdermal progestin implant approved for use in the United States in 1990.⁴ The Norplant contraceptive system was a set of six implantable, nonbiodegradable, soft silicone rubber capsules, each filled with 36-mg crystalline levonorgestrel, that provided continuous contraception for up to 5 years. Although extremely effective, Norplant was removed from the U.S. market in 2003 due to difficulty with insertion and removal.

Implanon is the progestin implant currently available in the United States.³⁷ Implanon is a single 4-cm-long implant, containing 68 mg of etonogestrel, that is placed under the skin of the upper arm using a preloaded inserter.^{37,38} Implanon releases etonogestrel at a rate of 60 mcg daily for the first month, then decreases to an average of 30 mcg daily at the end of the 3 years of recommended use. Etonogestrel suppresses ovulation in 97% of cycles. When ovulation is not suppressed, etonogestrel still is effective as the progestin thickens the cervical mucus and produces an atrophic endometrium. With perfect use, efficacy approaches 100% but may be reduced in women weighing more than 130% of their ideal body weight. Because only one rod is used, the difficulties experienced with insertion and removal of Norplant hopefully will be avoided.

④ The etonogestrel implant should be inserted between days 1 and 5 of the menstrual cycle in women who have not previously used hormonal contraception.^{37,38} Women currently taking OCs can have the implant inserted within 7 days after taking the last active OC tablet. Women currently taking progestin-only pills should have the implant inserted without skipping any days, on the same day that the progestin-only IUD is removed, or on the day that the DMPA injection is due. After removal, fertility returns within 30 days.

③ The major adverse effect associated with Implanon is irregular menstrual bleeding, which led to discontinuation of the implant in 11% of patients in clinical trials.^{37,38} Like the bleeding pattern seen with other progestins, some women (22%) became amenorrheic with continued use, but many continued to have prolonged bleeding and spotting (18%) and frequent bleeding (7%). Other adverse effects include headache, vaginitis, weight gain, acne, and breast and abdominal pain. Implanon does not appear to affect BMD. Concomitant administration of drugs that induce hepatic enzymes (Table 82–6) may decrease the efficacy of etonogestrel, necessitating use of a different method of contraception while these potentially interacting drugs are used. Implanon is contraindicated in women who are pregnant or have active liver disease, a history of thromboembolic events, or a history of breast cancer.

Implanon is a unique implantable contraceptive agent that provides enhanced compliance and prolonged efficacy. Therefore, it may be a good choice for women with a history of noncompliance, who do not plan to have children for at least 3 years, and who have estrogen-related adverse effects or contraindications. Because fertility returns soon after removal and Implanon does not affect bone health, it may be preferred over DMPA. Women should be counseled about the risk of irregular bleeding patterns so that patients will not request early removal of Implanon.

Intrauterine Devices

① ② The low-grade intrauterine inflammation and increased prostaglandin formation caused by IUDs and endometrial suppression caused specifically by the progestin-releasing IUD appear to be primarily spermicidal, although interference with implantation is a backup mechanism.^{3,4,39} Efficacy rates with IUDs are greater than 99% with both perfect and typical use.⁴ Although increasing in popularity, the IUD still has several contraindications. The risk of pelvic inflammatory disease among IUD users ranges from 1% to

2.5%. Because the increased risk of infection appears to be related to introduction of bacteria into the genital tract during IUD insertion, the risk is highest during the first 20 days after the procedure.⁴⁰ Ideal patients for IUD use include nulligravid women who are monogamous and are not at risk for STDs or pelvic inflammatory disease. Two IUDs currently are marketed in the United States; all are T-shaped and are medicated, one with copper (ParaGard) and one with levonorgestrel (Mirena).^{3,4}

③ ParaGard provides better contraceptive effectiveness than previous copper devices and can be left in place for 10 years.^{3,4} A disadvantage of ParaGard is increased menstrual blood flow and dysmenorrhea; average monthly blood loss among users increased by 35% in clinical trials. Initially, Mirena releases 20 mcg of levonorgestrel daily, but release decreases to 10 mcg daily over the 5 years of use.^{3,4,39} Systemically absorbed levonorgestrel is minimal and considerably less than with OCs. However, the levonorgestrel IUD produces its effects locally via suppression of the endometrium, causing a reduction in menstrual blood loss. In contrast to the copper IUD, menstrual flow in users of the levonorgestrel IUD is decreased, and development of amenorrhea has been observed in 20% of users in the first year and 60% in the fifth year. A disadvantage of the levonorgestrel IUD is increased spotting in the first 6 months of use, and women should be counseled that the spotting will decline gradually over time.^{3,4,39}

IUDs should be considered because they require no compliance once inserted and result in immediate return of fertility once removed. The levonorgestrel IUD is a good choice for women with menorrhagia or dysmenorrhea because of its benefits with regard to menstrual blood loss. IUDs, in general, are an alternative for women who cannot tolerate estrogen-containing contraceptive agents.

CLINICAL CONTROVERSY

Pharmacists who refuse to fill valid prescriptions for emergency contraception have been highly publicized in the media. Position statements published by the American Pharmaceutical Association and American College of Clinical Pharmacy support pharmacists' rights to decline filling a valid prescription if doing so conflicts with moral, ethical, or religious beliefs. However, it is the pharmacists' professional responsibility to refer the patient to another pharmacist who will fill the prescription in a timely, confidential, and nonjudgmental manner so that no harm is caused to the patient.

Emergency Contraception

⑤ EC is used to prevent unwanted pregnancy after unprotected sexual intercourse (e.g., condom breakage, diaphragm dislodging, or sexual assault). Higher doses of combined estrogen and progestin or progestin-only containing products can be used.^{3–5} Insertion of copper IUD is an option, although it is not an FDA approved or a widely used method of EC. Exact mechanisms of action of oral EC are being studied and vary according to the product used. EC may prevent the fertilized egg from implanting into the endometrium; however, studies contradict this potential mechanism. Additional mechanisms include impaired sperm transport and corpus luteum function. Pregnancy occurs when the fertilized egg is implanted into the endometrial lining. After intercourse, implantation of the fertilized egg typically takes approximately 5 days. Oral EC will not disrupt the fertilized egg after implantation has occurred.^{40,41} Currently, one progestin-containing pill is approved and marketed specifically for EC in the United States. Commercially available OCs in specific dosages can be used as an alternative.^{3–5,41}

Plan B is the only product specifically approved for EC and is the regimen of choice. It contains two white tablets, each containing

0.75 mg of levonorgestrel. The first dose is taken within 72 hours of unprotected intercourse (although the sooner, the more effective); the second dose is taken 12 hours later.^{3-5,41-43} One study found that 1.5 mg of levonorgestrel (two tablets of Plan B) taken as a single dose was as effective as taking the doses 12 hours apart and did not cause an increased incidence of adverse effects. Although this single-dose regimen is not FDA approved, it is a reasonable option, especially in women who may not be compliant with the two-dose regimen.^{41,44} Plan B was approved by the FDA in 2006 for OTC sales to women 18 years of age or older. A prescription is required for patients aged 17 years and younger. It is sold only in pharmacies and must be stocked behind the counter. Patients must provide proof of age prior to purchasing the product. The manufacturer is continuing its efforts in gaining OTC status for provision to minors.⁴⁵

Despite the availability of Plan B, use of regular combined contraceptives for EC (i.e., Yuzpe method) still is permissible, although some studies suggest that they may not be as effective and may be associated with more adverse effects.^{41,42} Specifically, the FDA has declared the following regimens containing the progestins norgestrel and levonorgestrel safe and effective methods of EC: Ovral (two tablets per dose); Nordette, Levlen, Levora, Lo/Ovral, Triphasil, Tri-Levlen, or Trivora (four tablets per dose); and Alesse or Levlite (five tablets per dose).^{3-5,41} Additionally, regular progestin-only pills can be used as EC, but many tablets must be taken (i.e., Ovrette, 20 tablets per dose).^{3,4,41} Patients should be counseled to take the appropriate number of tablets as soon as possible after unprotected sexual intercourse and to repeat the dose in 12 hours.

The efficacy of all EC regimens declines if they begin more than 72 hours after intercourse.^{3,4,41} However, one study suggests that EC may still be effective when used up to 120 hours after intercourse and should be considered in some women when use is delayed.^{41,46} It is recommended that women have an advanced prescription on hand to maximize the effectiveness of EC.

Common adverse effects include nausea, vomiting, and irregular bleeding. Nausea and vomiting occur significantly less when Plan B is administered. If the Yuzpe method is prescribed, antiemetics given 1 hour before the dose is taken may be warranted. Many women will experience irregular bleeding regardless of which EC method is used, with the menstrual period usually occurring 1 week before or after the expected time. No current data regarding the safety of repeated use EC are available, but current consensus suggests the risks are low, and women can receive multiple regimens if warranted. Pharmacists have a key role in providing patient counseling regarding EC. Appropriate counseling should be provided regarding timing of the dose, common adverse effects, and use of a regular contraceptive method (backup barrier methods should be used after EC for at least 7 days).⁴¹

PHARMACOECONOMIC CONSIDERATIONS

More than half of all pregnancies in the United States are unintended.⁴ Not all unintended pregnancies are unwanted; many are just “mistimed.” Nevertheless, the United States has a higher rate of induced abortions than most other industrialized western nations. Whatever method is used, preventing unintended pregnancy is highly cost effective. With regard to the acquisition cost of reversible contraception, spermicides alone are the least expensive method, followed by use of spermicides with condoms. The diaphragm and cervical cap (with spermicide) are midrange in cost; the female condom is slightly more expensive than the other female barrier methods. Injectable and implantable methods (Depo-Provera, Implanon, ParaGard, Mirena) carry a higher initial cost that can be prohibitive for some women, and the annual cost is greater if the products are removed prior to their expiration. OCs, the contraceptive patch, and the vaginal ring are the most expensive forms of

reversible contraception. These cost estimates are based on the assumption of 100 acts of intercourse annually. However, with regard to direct medical costs (e.g., method use, side effects, and unintended pregnancies) over 5 years, IUDs, vasectomy, Depo-Provera, and now Implanon are the most cost effective. OCs are more cost effective than methods with high failure rates (e.g., barrier methods, spermicides, withdrawal, and periodic abstinence), but even these methods are more cost effective than no method.⁴⁷

EVALUATION OF THERAPEUTIC OUTCOMES

4 Patients should receive both verbal and written instructions on the chosen method of contraception. Followup appointments can increase compliance, allow time for the patient to ask questions, and provide opportunities to address other health maintenance issues (e.g., self-breast examination, Pap smears, human papillomavirus vaccines, STD risk).⁴

At least annual blood pressure monitoring is recommended for all users of CHC. When a patient with a history of glucose intolerance or overt diabetes mellitus begins or discontinues the use of CHC, glucose levels must be monitored closely for deterioration of the condition. Contraceptive users should receive at least annual (more frequent if they are at risk for STDs) cytologic screening. Women should undergo annual examination for clinical problems possibly relating to the CHC (e.g., breakthrough bleeding, amenorrhea, weight gain, and acne).

Women using Implanon should be monitored annually for menstrual cycle disturbances, weight gain, local inflammation or infection at the implant site, acne, breast tenderness, headaches, and hair loss. Women using DMPA should be asked at 3-month followup visits about weight gain, menstrual cycle disturbances, and STD risks. Patients taking DMPA should be weighed, undergo blood pressure checks, and receive annual examinations as indicated based on the patient's age.

Choosing a contraceptive method most suited to the patient's needs will reduce significantly the chance of unintended pregnancy. A medical and sexual history and a thorough physical examination are essential when evaluating the various methods available. Understanding the risks and precautions associated with the methods available is essential for both patients and clinicians.

ABBREVIATIONS

KEY CONCEPTS

- 1 Unrecognized pregnancy is the most common cause of amenorrhea. A urine pregnancy test should be one of the first steps in evaluating this disorder.
- 2 For hypoestrogenic conditions associated with primary and secondary amenorrhea, estrogen (along with a progestin) is provided.
- 3 Causes of menorrhagia can be divided into systemic disorders and specific uterine abnormalities.
- 4 Pregnancy, including intrauterine pregnancy, ectopic pregnancy, and miscarriage, must be at the top of the differential diagnosis for any woman presenting with heavy menses.
- 5 The reduction in menorrhagia-related blood loss with use of nonsteroidal antiinflammatory drugs and oral contraceptives is directly proportional to the amount of pretreatment blood loss.
- 6 Intrauterine devices (IUDs) are considered therapeutic options in a variety of menstruation-related disorders. Guidelines from the American College of Obstetricians and Gynecologists indicate that both nulliparous and multiparous women at low risk of sexually transmitted diseases are good candidates for IUD use.
- 7 Anovulatory bleeding is the standard terminology used to describe bleeding from the uterine endometrium as a result of a dysfunctioning menstrual system, specifically excluding an anatomic lesion of the uterus.
- 8 Polycystic ovarian syndrome can present as a variety of menstruation disorders, including amenorrhea, menorrhagia, and anovulatory bleeding. Although its definition continues to evolve, it is generally considered to be a disorder of androgen excess that often includes polycystic ovarian morphology and ovulatory dysfunction.
- 9 Use of metformin and the thiazolidinediones for anovulatory bleeding associated with polycystic ovarian syndrome is beneficial not only for anovulatory bleeding and fertility but also for improving glucose tolerance and decreasing overall, long-term cardiovascular risk.
- 10 The selective serotonin reuptake inhibitors are first-line pharmacologic treatment options for premenstrual dysphoric disorder.

Problems related to the menstrual cycle are exceedingly common in women of reproductive age. This chapter discusses the most frequently encountered menstruation-related difficulties: amenorrhea, menorrhagia, anovulatory bleeding, dysmenorrhea, premenstrual syndrome (PMS), and premenstrual dysphoric disorder (PMDD). The need for effective treatments of these disorders stems from their impact on any or all of the following: a reduced quality of life, negative effects on reproductive health, and potential for long-term detrimental health effects, such as osteoporosis in the case of amenorrhea and cardiovascular disease in the case of polycystic ovarian syndrome (PCOS).

AMENORRHEA

Amenorrhea is traditionally described as either primary or secondary in nature. Primary amenorrhea is the absence of menses by age 16 years in the presence of normal secondary sexual development or the absence of menses by age 14 in the absence of normal secondary sexual development. Secondary amenorrhea is the absence of menses for three cycles or for 6 months in a previously menstruating woman. In clinical practice there is a significant amount of overlap between the two. The initial evaluation of amenorrhea often is the same, regardless of age of onset, except in unusual clinical situations.¹

EPIDEMIOLOGY

The incidence of primary amenorrhea is less than 0.1% in the general population. Secondary amenorrhea, on the other hand, has an incidence of 0.7% to 4% in the general population and occurs more frequently in women younger than 25 years with a history of menstrual irregularities.²

ETIOLOGY

1 Unrecognized pregnancy is the most common cause of amenorrhea. A urine pregnancy test should be one of the first steps in evaluating this disorder. In organizing an approach to diagnosis and treatment, it is helpful to consider the organs involved in the menstrual cycle, which include the uterus, ovaries, anterior pituitary, and hypothalamus.

After excluding pregnancy, the five most common causes of secondary amenorrhea, in descending order of prevalence, are hypothalamic suppression (33%), chronic anovulation (28%), hyperprolactinemia (14%), ovarian failure (12%), and uterine disorders (7%).³

PATHOPHYSIOLOGY

Each organ in the hypothalamic–pituitary–ovarian–uterine axis must be considered in determining the etiology and pathophysiology of amenorrhea. Beginning with the uterus/outflow tract and pro-

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

TABLE 83-1 Pathophysiology of Selected Menstrual Bleeding Disorders		
Organ System	Condition	Pathophysiology/Laboratory Findings
Amenorrhea		
Uterus	Asherman's syndrome Congenital uterine abnormalities	Postcurettage/postsurgical uterine adhesions Abnormal uterine development
Ovaries	Turner's syndrome Gonadal dysgenesis Premature ovarian failure Chemotherapy/radiation	Lack of ovarian follicles Other genetic abnormalities Early loss of follicles Gonadal toxins
Anterior pituitary	Pituitary prolactin-secreting adenoma Hypothyroidism	↑ Prolactin suppresses HPO axis TRH causes ↑ prolactin, other abnormalities
Hypothalamus	Medication (antipsychotics, verapamil) "Functional" hypothalamic amenorrhea Eating disorder Exercise Anovulation/PCOS	↑ Prolactin suppresses HPO axis ↓ Pulsatile GnRH secretion in the absence of other abnormalities ↓ Pulsatile GnRH secretion, ↓ FSH and LH secondary to weight loss ↓ Pulsatile GnRH secretion, ↓ FSH and LH secondary to low body fat Asynchronous gonadotropin and estrogen production, abnormal endometrial growth
Anovulatory bleeding		
Physiologic causes	Adolescence Perimenopause	Immaturity of the HPO axis: no LH surge Declining ovarian function
Pathologic causes	Hyperandrogenic anovulation (PCOS) Hypothalamic dysfunction (physical or emotional stress, exercise, weight loss) Hyperprolactinemia (pituitary gland tumor, psychiatric medications) Hypothyroidism Premature ovarian failure	Hyperandrogenism: high testosterone, high LH, hyperinsulinemia, and insulin resistance Suppression of pulsatile GnRH secretion and estrogen deficiency: low LH, low FSH High prolactin High TSH High FSH
Menorrhagia		
Hematologic	von Willebrand's disease Idiopathic thrombocytopenic purpura	Factor VII defect causing impaired platelet adhesion and increased bleeding time Decrease in circulating platelets, can be acute or chronic
Hepatic	Cirrhosis	Decreased estrogen metabolism, underlying coagulopathy
Endocrine	Hypothyroidism	Alterations in HPO axis
Uterine	Fibroids Adenomyosis Endometrial polyps Gynecologic cancers	Alteration of endometrium, changes in uterine contractility Alteration of endometrium, changes in uterine contractility Alteration of endometrium Various dysplastic alterations of endometrium, uterus, cervix

FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; HPO, hypothalamic–pituitary–ovarian axis; LH, luteinizing hormone; PCOS, polycystic ovary disease; TSH, thyroid stimulating hormone; TRH, thyrotropin-releasing hormone.
Data from references 1, 2, 4, and 5.

gressing caudally will result in a comprehensive differential diagnosis. Table 83–1 lists the pathophysiology of amenorrhea relative to the organ system(s) involved as well as the specific condition(s) that results in amenorrhea.

Uterus/Outflow Tract

For menstruation to occur, a uterus, functional endometrium, and patent vagina must be present. Several anatomic abnormalities of the female genital tract may cause amenorrhea. If primary amenorrhea is the presenting symptom, a congenital anomaly such as imperforate hymen or uterine agenesis may be present and often can be determined by physical examination. In the case of secondary amenorrhea, an acquired condition of the genital tract, such as Asherman's syndrome or cervical stenosis, is more likely.

Ovaries

Normal ovarian function is critical for menstruation to occur. The ovaries must respond appropriately to follicle-stimulating hormone (FSH) and luteinizing hormone (LH) by secreting estrogen and progesterone in proper sequence to influence growth and shedding of the endometrium (Fig. 83–1).

Premature ovarian failure occurs when no viable follicles remain in the ovaries. As in menopause, estrogen will not be produced in sufficient quantity to stimulate endometrial growth in the absence of follicles. In a woman younger than 30 years, amenorrhea due to premature ovarian failure may be the result of genetic anomalies.¹

The ovaries may play a role in amenorrhea through anovulation. Ovulation is required for the follicle (an estrogen-secreting body) to become a corpus luteum (a progesterone-secreting body). Without ovulation, the proper sequence of estrogen production, progesterone production, and estrogen/progesterone withdrawal will not occur. This can result in amenorrhea. Anovulation can occur secondary to thyroid disease, androgen excess (PCOS), or chronic illness.

FIGURE 83-1. Hormonal fluctuations with the normal menstrual cycle. (Courtesy of Hatcher RA, Nelson AL, Ziemann M, et al. *A Pocket Guide to Managing Contraception*. Tiger GA: Bridging the Gap Foundation, 2003:1-146. This figure may be reproduced at no cost to the reader.)

Pituitary Gland

The anterior pituitary gland secretes FSH and LH in sequential fashion in response to stimulation by the hypothalamus and a complex feedback mechanism from the ovaries. Normal secretion of FSH and LH can be altered by several endocrinologic and iatrogenic conditions, including thyroid disease, hyperprolactinemia, and dopaminergic drug administration.

Hypothalamus

The hypothalamus secretes cyclic gonadotropin-releasing hormone (GnRH), which causes the pituitary to produce FSH and LH. A disruption of this cyclic excretion will interrupt the hormonal cascade that results in normal menstruation. Anorexia nervosa, bulimia, intense exercise, and stress may cause hypothalamic amenorrhea.

CLINICAL PRESENTATION OF AMENORRHEA

General

- Although patients may be concerned about cessation of menses and implications for fertility, patients are generally not in acute distress.

Symptoms

- Patient will note cessation of menses.
- Patients may complain of infertility, vaginal dryness, or decreased libido.

Signs

- Cessation of menses for more than 6 months in women with established menstruation, absence of menses by age 16 in the presence of normal secondary sexual development, or absence of menses by age 14 in the absence of normal secondary sexual development
- Recent significant weight loss or weight gain
- Presence of acne, hirsutism, hair loss, or acanthosis nigrans may suggest androgen excess

Laboratory Tests

- Pregnancy test
- Thyroid-stimulating hormone
- Prolactin
- If PCOS is suspected, consider free or total testosterone, 17-hydroxyprogesterone, fasting glucose, fasting lipid panel.
- If suspect premature ovarian failure, consider FSH, LH.

Other Diagnostic Tests

- Progesterone challenge
- Pelvic ultrasound to evaluate for polycystic ovaries

TREATMENT

Just as the causes of amenorrhea are varied, so are the nonpharmacologic and pharmacologic treatment options.

Desired Outcome

Therapeutic modalities for amenorrhea are used to restore the normal menstrual cycle. Treatment goals include preservation of bone density, prevention of bone loss, and restoration of ovulation, thus improving fertility as desired. Amenorrhea resulting from hypoestrogenism may affect quality of life via induction of hot flashes (premature ovarian failure), dyspareunia, and, in prepubertal females, lack of secondary sexual characteristics and absence of menarche. Treatment of these patients would be targeted at reversing these effects.

General Approach to Treatment

The overall success of any intervention to treat amenorrhea is dependent on proper identification of the underlying cause(s) of the disorder. Once the cause is identified, the appropriate intervention(s) can be made. For patients experiencing amenorrhea secondary to hypoestrogenic states, a diet rich in calcium and vitamin D is essential to avoid negative impact on bone health.

Nonpharmacologic Therapy

Nonpharmacologic therapy for amenorrhea varies depending upon the underlying cause. Amenorrhea secondary to anorexia may respond to weight gain. In young women for whom excessive exercise is an underlying cause, a reduction in exercise is recommended.

Pharmacologic Therapy

2 For hypoestrogenic conditions associated with primary or secondary amenorrhea, estrogen (along with a progestin) is provided. It can be administered in the form of an oral contraceptive (OC), conjugated equine estrogen, or estradiol patch. The purpose of estrogen therapy in this patient population is twofold: to reduce the risk of osteoporosis and to improve quality of life.^{7,8} Table 83–2 lists a variety of therapeutic agents for treatment of amenorrhea, including recommended doses. Figure 83–2 illustrates a treatment algorithm for management of amenorrhea.

If hyperprolactinemia is identified as the cause of amenorrhea, use of bromocriptine or cabergoline, dopamine agonists, results in a reduction in prolactin concentrations and the resumption of menses. Bromocriptine requires multiple doses per day, but cabergoline is dosed twice weekly. Bromocriptine has been observed in head-to-head clinical trials to be less effective in normalizing prolactin levels and has a higher incidence of adverse events leading to treatment discontinuation compared to cabergoline.^{15,16}

Amenorrhea related to anovulation resulting from PCOS may respond to agents that reduce insulin resistance. Metformin and the thiazolidinediones for this purpose are discussed in the section on anovulatory bleeding.

Progestins have long been used to induce withdrawal bleeding in women with secondary amenorrhea. Several factors predict the efficacy of progesterone for this purpose.¹⁰ These factors include estrogen concentrations ≥ 35 pg/mL and endometrial thickness (the greater the thickness, the greater the amount of withdrawal bleeding).

The efficacy of progestins for secondary amenorrhea varies depending upon the formulation used. Progesterone in oil administered intramuscularly results in withdrawal bleeding in 70% of treated patients, whereas oral medroxyprogesterone acetate (MPA) induces withdrawal bleeding in 95% of treated patients.¹⁰ Table 83–2 identifies the types and doses of progestinones used for treatment of secondary amenorrhea. Figure 83–2 illustrates when to consider progesterone use for amenorrhea treatment.

Special Populations Amenorrhea in the adolescent population is of particular concern because this is the time in the female life cycle when peak bone mass is achieved. The cause of amenorrhea, whether primary or secondary, must be promptly identified in this population, as amenorrhea and its related hypoestrogenism contribute negatively to bone development. In addition to treating or eliminating the underlying cause of the amenorrhea, ensuring that the patient is receiving adequate amounts of calcium and vitamin D is imperative. Estrogen replacement, typically via an OC, is important.

Drug class information Table 83–3 identifies the significant pharmacologic properties, common adverse events, and clinically significant drug–drug and drug–food interactions of the agents used for management of amenorrhea.

TABLE 83-2 Therapeutic Agents for Selected Menstrual Disorders

Specific Menstrual Disorder(s)	Agent(s)	Dose Recommended
Amenorrhea (primary or secondary)	CEE Ethinyl estradiol patch Combination OC	0.625–1.25 mg by mouth daily on days 1–25 of the cycle ⁸ 50 mcg/24 hours ¹⁰ 30–40 mcg formulations ⁷
Amenorrhea (secondary)	Oral MPA	5–10 mg by mouth on days 14–25 of the cycle ⁸
Amenorrhea related to hyperprolactinemia	Bromocriptine ^{15,16} Cabergoline ^{15,16}	2.5 mg by mouth 2–3 times daily 0.25 mg by mouth 2 times weekly (maximum 1 mg by mouth 2 times weekly)
Anovulatory bleeding	Combination OC	Optimal dose unknown ⁵
Dysmenorrhea	Combination OC Depo MPA Levonorgestrel IUD ¹² NSAIDs (any are acceptable); the most commonly studied/ cited are included in this table	Less than 35 mcg formulations + norgestrel or levonorgestrel ¹¹ ; use of extended-cycle formulations is beneficial for this indication 150 mg intramuscularly every 12 weeks 20 mcg released daily Diclofenac 50 mg by mouth 3 times daily; ibuprofen 800 mg by mouth 3 times daily; mefenamic acid 500 mg by mouth as a loading dose, then 250 mg by mouth up to 4 times daily as needed ⁹ Naproxen 550-mg loading dose by mouth started 1–2 days prior to menses followed by 275 mg by mouth every 6–12 hours as needed ¹¹ Treatment should begin 1–2 days prior to the suspected onset of menses ⁹ Optimal dose unknown 20 mcg released daily 5–10 mg by mouth on days 5–26 of the cycle or during the luteal phase ¹² Doses as recommended for dysmenorrhea may be used; therapy should be initiated with the onset of menses ¹²
Menorrhagia	Combination OC Levonorgestrel IUD Oral MPA NSAIDs	50 mg by mouth daily for 5 days starting 3–5 days after the start of menses; dose can be increased in 50 mg increments to a maximum dose of 250 mg daily 150 mg intramuscularly every 12 weeks 10 mg by mouth for 10 days ⁵ 1,500–2,000 mg by mouth daily ¹⁵
PCOS-related amenorrhea and/or anovulatory bleeding	Clomiphene ⁵ Depo MPA Oral MPA Metformin Thiazolidinediones (pioglitazone, rosiglitazone) ⁵	Pioglitazone 15–45 mg by mouth daily; rosiglitazone 4–8 mg by mouth daily 25–75 mg by mouth daily taken either continuously or only during the luteal phase 3 mg (+ 30 mcg ethinyl estradiol) by mouth on days 1–21 of the menstrual cycle ¹³ 3.75 mg intramuscularly ¹⁴
PMDD	Clomipramine ¹⁴ Drospirenone Leuprolide SSRIs (citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, sertraline)	Citalopram 10–30 mg; escitalopram 10–20 mg ⁵⁹ ; fluoxetine 10–20 mg; fluvoxamine 50 mg; paroxetine 10–30 mg; sertraline 25–150 mg; all agents are given by mouth daily and can be dosed either continuously or during the luteal phase only ¹⁴

CEE, conjugated equine estrogen; IUD, intrauterine device; MPA, medroxyprogesterone acetate; NSAID, nonsteroidal antiinflammatory drug; OC, oral contraceptive; PCOS, polycystic ovarian syndrome; PMDD, premenstrual dysphoric disorder; SSRI, selective serotonin reuptake inhibitors.

Data from references 5 and 7–16.

PHARMACOECONOMIC CONSIDERATIONS

The largest price gap among agents used for management of amenorrhea occurs when comparing the dopamine agonists bromocriptine and cabergoline in the treatment of hyperprolactinemia. Cabergoline is slightly more effective, with fewer side effects and less frequent dosing, but its monthly cost is significantly greater than that of bromocriptine. Given this, it is reasonable to reserve its use for patients who do not achieve treatment success with bromocriptine or for whom the side effects of bromocriptine are responsible for drug discontinuation.

EVALUATION OF THERAPEUTIC OUTCOMES

Table 83–4 lists the expected outcomes and specific monitoring parameters for treatment modalities used in the management of amenorrhea.

MENORRHAGIA

The traditional definition of menorrhagia is menstrual blood loss greater than 80 mL per cycle. This definition has been questioned because of several factors, including difficulty quantifying men-

strual loss in clinical practice. Additionally, many women with “heavy menses” but blood loss less than 80 mL merit treatment consideration because of problems with flow containment, unpredictably heavy flow days, or other associated symptoms.^{21,28}

EPIDEMIOLOGY

Rates of menorrhagia in healthy women range from 9% to 14%.⁴

ETIOLOGY

③ Causes of menorrhagia can be divided into systemic disorders and specific uterine abnormalities. ④ Pregnancy, including intrauterine pregnancy, ectopic pregnancy, and miscarriage, must be at the top of the differential diagnosis for any woman presenting with heavy menses. In several studies of adolescents with acute menorrhagia, underlying bleeding disorders accounted for 3% to 13% of emergency room presentations. Although von Willebrand’s disease has an incidence of 1% in the general population,²⁹ its prevalence in women with menorrhagia may be as high as 20%.³⁰ It initially may present as heavy menses in the adolescent.²⁹ Hypothyroidism also may be associated with heavy menses. Specific uterine causes of menorrhagia are more common in older childbearing women and include fibroids, adenomyosis, endometrial polyps, and gynecologic malignancies.

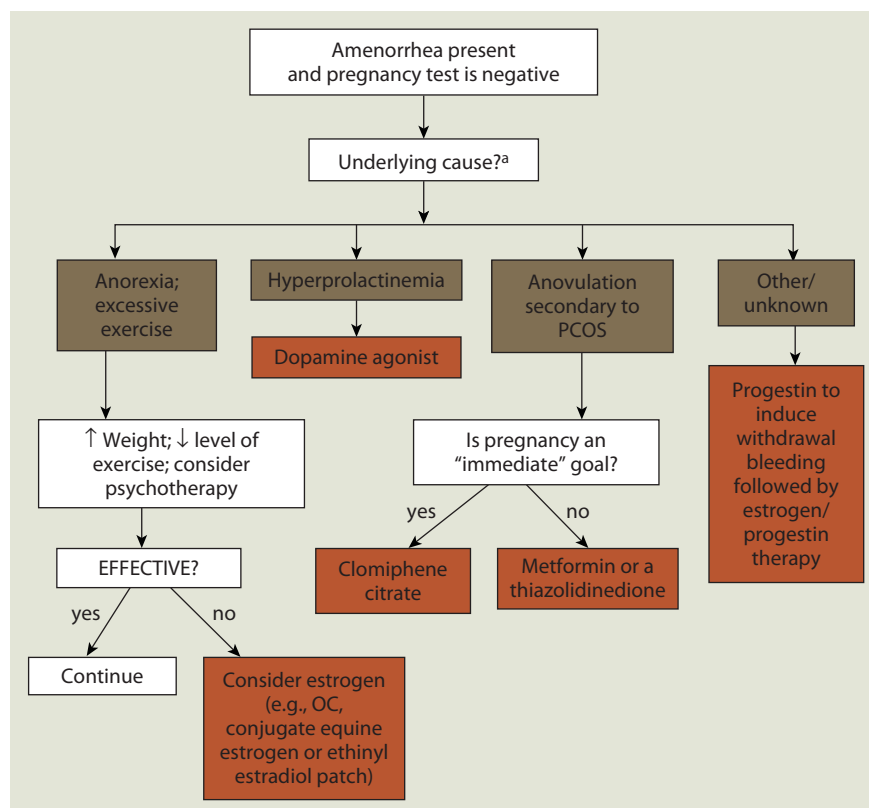

FIGURE 83-2. Treatment algorithm for amenorrhea. ^aRegardless of cause, adequate calcium and vitamin D intake must be ensured. (OC, oral contraceptive; PCOS, polycystic ovarian syndrome.)

PATHOPHYSIOLOGY

Table 83-1 lists the pathophysiology of menorrhagia relative to the organ system(s) involved and the specific conditions that result in menorrhagia.

CLINICAL PRESENTATION OF MENORRHAGIA

General

- Patient may or may not be in acute distress.

Symptoms

- Patients may complain of heavy/prolonged menstrual flow. They also may have signs of fatigue and lightheadedness in cases of severe blood loss. These symptoms may or may not occur with dysmenorrhea.

Signs

- Orthostasis, tachycardia, and pallor may be noted, especially in cases of significant acute blood loss.

Laboratory Tests

- Complete blood count and ferritin levels; hemoglobin and hematocrit results may be low.
- If the history dictates, testing may be performed to identify coagulation disorder(s) as a cause.

Other Diagnostic Tests

- Pelvic ultrasound
- Pelvic magnetic resonance imaging
- Papanicolaou (Pap) smear
- Endometrial biopsy
- Hysteroscopy
- Sonohysterogram

TREATMENT

Initial treatment choice for menorrhagia is influenced by whether or not the woman desires to become pregnant.

Desired Outcome

Menorrhagia therapy should reduce menstrual blood flow, improve the patient's quality of life, and defer the need for surgical intervention. Table 83-2 lists the various agents and their recommended dosing for management of menorrhagia. Figure 83-3 illustrates how to decide which treatment(s) to use and when.

General Approach to Treatment

Several treatment options exist for menorrhagia. The initial and, if needed, subsequent treatment options should be thoughtfully chosen in an effort to avoid the need for surgery.

Nonpharmacologic Therapy

Nonpharmacologic interventions for menorrhagia include surgical interventions that are generally reserved for patients who do not respond to pharmacologic treatment. These interventions may vary from conservative endometrial ablation to hysterectomy.³¹

Pharmacologic Therapy

Among the agents used to treat menorrhagia, the nonsteroidal antiinflammatory drugs (NSAIDs) have the advantage of being taken only during menses. NSAID use is associated with a 20% to 50% reduction in blood loss in 75% of treated women.¹² In some patients, as much as an 80% reduction in blood loss has been observed.¹²

For women who wish to avoid pregnancy, use of OCs is beneficial for menorrhagia and can be considered. A 43% to 53% reduction in menstrual blood loss has been observed in 68% of menorrhagia patients treated with OCs containing ≥35 mcg of estradiol.¹² **5** The reduction in

TABLE 83-3 Significant Pharmacologic Properties and Significant Drug–Drug and Drug–Food Interactions of Therapeutic Agents for Selected Menstrual Disorders

Therapeutic Agent/ Drug Class	Mechanism of Action/Role in Particular Menstrual Disorders	Significant Side Effects	Significant Drug–Drug, Drug–Food, Drug–Disease Interactions
Clomiphene	Estrogen receptor antagonist that contributes to a compensatory ↑ in FSH and LH to induce ovulation	Hot flashes, ovarian enlargement, thromboembolism, blurred vision, breast discomfort	
Clomipramine	Exact mechanism in PMDD unknown	Dry mouth, fatigue, vertigo, sweating	
Combination OCs	Exogenous estrogen and progesterone that suppresses FSH and LH production and thus inhibits ovulation Can be used to reduce menstrual flow (menorrhagia, dysmenorrhea), and control menstrual cycle (anovulatory bleeding secondary to hypoestrogenism)	Thromboembolism, breast enlargement, breast tenderness, bloating, nausea, gastrointestinal upset, headache, peripheral edema	St. John's wort contributes to altered menstrual bleeding Rifampin induces estrogen metabolism, possibly contributing to treatment failure Sulfa-containing drugs may contribute to increased photosensitivity
CEE	Estrogen replacement for hypoestrogenic states leading to anovulatory bleeding	As noted for combination OC	Same as OCs
Dopamine agonists (bromocriptine, cabergoline)	Suppresses prolactin production from pituitary tumors such that resumption of normal FSH and LH production occurs	Hypotension, nausea, constipation, anorexia, Raynaud's phenomenon	Inhibit CYP3A4 and are metabolized by CYP3A4 ¹⁷ St. John's wort induces CYP3A4; coadministration may lead to treatment failure
Drospirenone-containing OCs	Progesterone with antimineralocorticoid and antiandrogenic properties; decreases emotional lability associated with PMDD	As noted for combination OC; increased risk of hyperkalemia	Same as OCs Coadministration of potassium-sparing diuretics or diets high in potassium may contribute to increased serum potassium concentrations, particularly in women with renal dysfunction
Ethinyl estradiol transdermal patch	Same as combination OCs and CEE	As noted for combination OC; however, lesser effects on serum cholesterol concentrations because patch avoids first-pass metabolism	Same as OCs
Leuprolide	GnRH agent that contributes to suppression of FSH and LH and ultimately a reduction in estrogen and progesterone, inhibiting the normal menstrual cycle/hormonal fluctuations	Hot flashes, night sweats, headache, nausea	
Levonorgestrel-containing IUD	Suppresses FSH and LH and ultimately estrogen and progesterone, inhibiting the usual growth of the endometrium	Irregular menses, amenorrhea	
MPA (oral and depot)	Suppresses FSH and LH and ultimately estrogen and progesterone, inhibiting the usual growth of the endometrium	Edema, anorexia, depression, insomnia, weight gain or loss, increase in serum total and LDL cholesterol, may reduce HDL cholesterol	
Metformin	Inhibits hepatic glucose production and increases sensitivity of tissues to insulin, thus reducing insulin resistance	Anorexia, nausea, vomiting, diarrhea, flatulence, lactic acidosis (rare)	IV contrast dye may increase the risk of lactic acidosis; stop metformin 1 day prior and restart when renal function is normal and stabilized following the IV dye
NSAIDs	Inhibits prostaglandin release that occurs with menses, thus reducing inflammatory response contributing to dysmenorrhea	Gastrointestinal upset, stomach ulcer, nausea, vomiting, heartburn, indigestion, rash, dizziness	
SSRIs	Exact mechanism in PMDD unknown	Sexual dysfunction (reduced libido, anorgasmia), insomnia, sedation, hypersomnia, nausea, diarrhea	
Thiazolidinediones	Increases peripheral tissue sensitivity to insulin, thus reducing insulin resistance	Weight gain, increase in total, LDL, and HDL cholesterol, edema, headache, fatigue, hepatic injury (rare)	
Venlafaxine	Exact mechanism in PMDD unknown		

CEE, conjugated equine estrogen; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; HDL, high-density lipoprotein; IUD, intrauterine device; LDL, low-density lipoprotein; LH, luteinizing hormone; MPA, medroxyprogesterone acetate; NSAID, nonsteroidal antiinflammatory drug; OC, oral contraceptive; PMDD, premenstrual dysphoric disorder; SSRI, selective serotonin reuptake inhibitor.

Data from references 7, 9, 12, 14, 15, and 17–20.

menorrhagia-related blood loss with use of NSAIDs and OCs is directly proportional to the amount of pretreatment blood loss.¹²

Menorrhagia also can be treated with the levonorgestrel-releasing intrauterine device (IUD). This is a very effective treatment that has consistently reduced menstrual flow by at least 90%.^{12,32} In particular, a reduction in blood loss by as much as 86% has been observed after 3 months of use and as much as 97% after 12 months.³³ Its use has also resulted in the postponement or cancellation of scheduled

endometrial resection surgery or hysterectomy. Specifically, 60% of treated patients have been able to avoid hysterectomy.^{32,34,35}

Progesterone therapy either during the luteal phase of the menstrual cycle or for 21 days, starting on day 5 after onset of menses, results in a 32% to 50% reduction in menstrual blood loss.¹² However, progesterone use has not been shown to be superior to other medical treatments, including the NSAIDs.¹² Progesterone use is not associated with any contraceptive benefit.²⁶

TABLE 83-4 Expected Outcome Measures for Select Menstrual Bleeding Disorders

Menstrual Disorder	Expected Outcome Measures: Specific Monitoring Parameters and Frequency of Monitoring
Amenorrhea	<p>Patient should return after one month of treatment to evaluate whether menses has resumed. Menses should resume within 1–2 months of therapy. If amenorrhea has been long-standing and secondary to a hypoestrogenic condition, preservation/improvement of BMD is warranted. A baseline BMD test may be desirable; repeat test no sooner than 1–2 years.</p> <p>If amenorrhea is secondary to high prolactin levels, serum prolactin levels should be measured at baseline and weekly with dosage increases until response (resumption of menses) is observed; consider discontinuation of therapy after 6–12 months of menses and serum prolactin concentrations have normalized.</p> <p>In young women who have primary amenorrhea, normal breast development should occur over a time frame of several months of therapy.</p>
Menorrhagia	<p>Amount of blood lost with menses should be reduced (monitor decline in number of times feminine hygiene products such as pads and tampons require changing during menses) as observed within 1–2 menstrual cycles of therapy. Patient should return for evaluation after one full menstrual cycle of therapy. Hemoglobin/hematocrit should be measured at baseline and within 3 months of beginning therapy.</p> <p>Annual gynecologic examination should be performed in women receiving hormonal agents for treatment of menorrhagia. Serum lipid concentrations should be measured within 3–6 months of starting the hormonal regimen and repeated per national lipid guidelines as appropriate. Blood pressure should be measured at baseline and within 4–6 weeks of beginning any hormonal agents; repeat blood pressure measurements per national hypertension guidelines as appropriate.</p>
Anovulatory bleeding	<p>Patients should return for follow up within 1 week to evaluate alleviation of acute bleeding when present. Acute severe bleeding should decline within 10 days of therapy onset. Ovulation, if desired, can be measured via daily basal body temperature evaluation, use of home ovulation predictor kits, and serum FSH/LH measurements at the time of suspected ovulation. If ovulation has not occurred after 2–3 months of initial clomiphene dosing, the dose can be increased in 50 mg increments. If resumption of ovulation is desired by women receiving metformin, the same monitoring parameters as noted for clomiphene can be used. Metformin may contribute to resumption of ovulation after 3–6 months of therapy. In women with PCOS, baseline and repeat measurements of blood pressure, serum lipids, and blood glucose should be taken per national guidelines to monitor for the development, presence, or progression of hypertension, hyperlipidemia, and diabetes.</p> <p>When OCs are used for control of abnormal uterine bleeding, improvement in the pattern of abnormal bleeding should occur within 1–2 menstrual cycles of therapy. Annual gynecologic examinations should be performed; serum lipid concentrations should be measured within 3–6 months of starting the OC and repeated per national lipid guidelines. Blood pressure should be measured at baseline and within 4–6 weeks of beginning any hormonal agents; repeat blood pressure measurements per national hypertension guidelines as appropriate.</p>
Dysmenorrhea	<p>Patient should return for evaluation of reduction in or absence of pelvic pain related to menses after 1–2 menstrual cycles of therapy. In addition, reduction in time lost from work/school and improved quality of life should be observed after a full 1–3 menstrual cycles of OC therapy. If NSAIDs are used, improvement in pain should be observed within hours of the dose.</p>
PMDD	<p>Reduction in or absence of initial symptoms and improved quality of life may be observed within 1–3 menstrual cycles of therapy. SSRIs have resulted in significant improvement after one cycle of treatment. If an OC containing drospirenone is used, serum potassium should be monitored within the first month of use if the woman is also receiving agents that predispose her to increased serum potassium concentrations. An annual gynecologic examination should be performed; serum lipid concentrations should be measured within 3–6 months of starting the OC and repeated per national lipid guidelines as appropriate. Blood pressure should be measured at baseline and within 4–6 weeks of beginning any hormonal agents; repeat blood pressure measurements per national hypertension guidelines as appropriate.</p>

BMD, bone mineral density; FSH, follicle-stimulating hormone; LH, luteinizing hormone; NSAID, nonsteroidal antiinflammatory drug; OC, oral contraceptive; PCOS, polycystic ovary syndrome; PMDD, premenstrual dysphoric disorder; SSRI, selective serotonin reuptake inhibitor.

Data from references 4, 5, 18, and 21–27.

Drug Treatments of First Choice For women who have menorrhagia associated with ovulatory cycles and do not desire hormonal therapy and/or contraception, NSAIDs during menses is a reasonable choice, in the absence of any contraindications or gastrointestinal illnesses such as peptic ulcer disease or gastroesophageal reflux disease. This choice is convenient (only taken during menses) and comparatively inexpensive. For women who do desire contraception, it would be reasonable to start with either an OC or the levonorgestrel-releasing IUD. Either choice is acceptable for both nulligravid and multiparous women who desire a long-term reversible form of contraception.³² Given cost-effectiveness data, the levonorgestrel-releasing IUD would be the best first-line choice for women desiring contraception.³⁶ Clinical trial data illustrate a higher failure rate with the OCs as the primary treatment method (62.5%) compared to the levonorgestrel-releasing IUD as the primary treatment method (34%).³⁶

Alternative Drug Treatments Given their side effects, reduced efficacy compared to the first-line agents, and/or cost, use of oral progesterone and depot medroxyprogesterone acetate should be reserved. Tranexamic acid may be considered, in particular, as a treatment option for women with identified coagulopathies. In comparison to luteal phase oral progesterone, tranexamic acid results in a significantly greater reduction in menstrual blood loss and greater relief of patient-reported symptoms.¹²

Special Populations Although in the past it was believed that IUD use should be avoided in nulliparous women, the American College of Obstetricians and Gynecologists (ACOG) currently sup-

ports its use in such women who are at low risk for developing sexually transmitted diseases (see Clinical Controversy).³² As such, any of the treatment options discussed could be used in any female presenting with menorrhagia.

Drug Class Information Table 83–3 identifies the significant pharmacologic properties, common adverse events, and clinically significant drug–drug and drug–food interactions of the agents used for management of menorrhagia.

PHARMACOECONOMIC CONSIDERATIONS

Use of the levonorgestrel-releasing IUD was observed to be the most cost effective compared to both surgical management and OCs in women who were naïve to OCs and women who had received OCs with or without a response.³⁶

CLINICAL CONTROVERSY

Fear of pelvic inflammatory disease and subsequent infertility has been the primary reason why use of IUDs in nulliparous women has been considered controversial. ACOG guidelines state that any woman at low risk for contracting sexually transmitted diseases is a good candidate for IUD use.³² ACOG specifically recommends the levonorgestrel IUD as a treatment option for idiopathic amenorrhea.³³ 6 IUDs are considered therapeutic options for a variety of menstruation-related disorders.

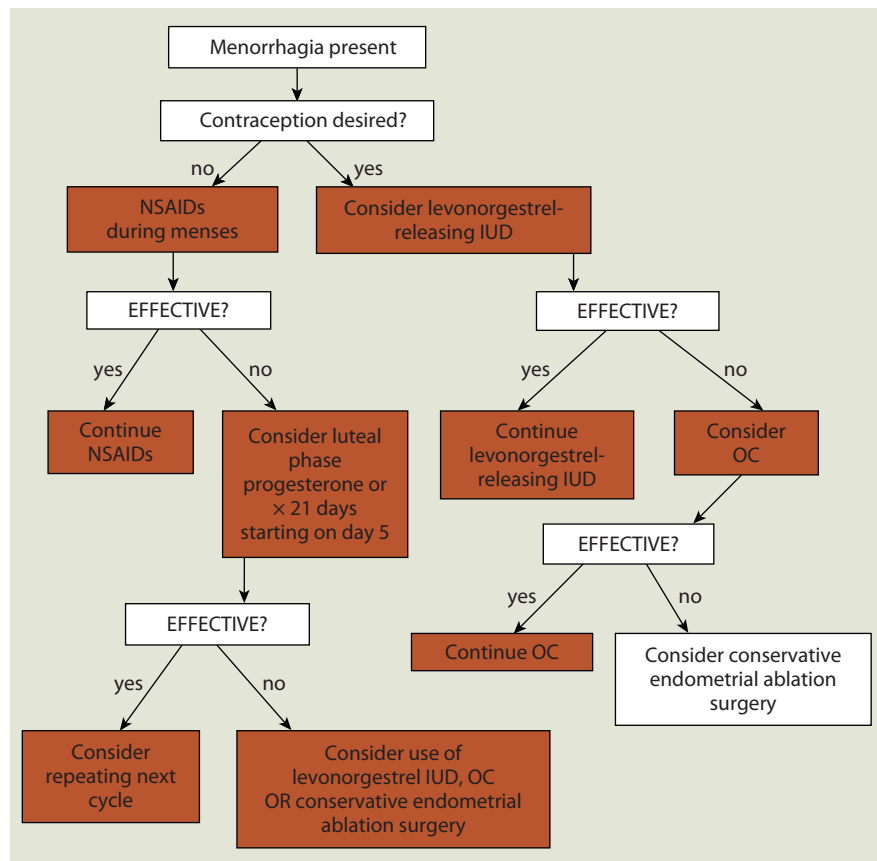

FIGURE 83-3. Treatment algorithm for menorrhagia. (IUD, intrauterine device; NSAIDs, nonsteroidal antiinflammatory drugs; OC, oral contraceptive.)

EVALUATION OF THERAPEUTIC OUTCOMES

Table 83-4 illustrates the expected outcomes and specific monitoring parameters for the treatment modalities used in the management of menorrhagia.

ANOVULATORY BLEEDING

7 Anovulatory bleeding is the standard terminology used to describe bleeding from the uterine endometrium as a result of a dysfunctional menstrual system, specifically excluding an anatomic lesion of the uterus.^{1,22} Anovulatory bleeding also is referred to as *dysfunctional* or *irregular uterine bleeding*.

EPIDEMIOLOGY

Anovulatory bleeding is the most common form of noncyclic uterine bleeding.²² PCOS is by far the most common cause, with prevalence rates ranging from 4% to 8% in various reports, depending on the diagnostic criteria used (e.g., PCOS-NIH³⁷ or PCOS-Rotterdam³⁸).^{1,5,39,40} In fact, PCOS is the most common endocrine abnormality among U.S. women of reproductive age.⁴¹ **8** PCOS can present as a variety of menstruation disorders, including amenorrhea, menorrhagia, and anovulatory bleeding. Although its definition continues to evolve, it is generally considered to be a disorder of androgen excess that often includes polycystic ovarian morphology and ovulatory dysfunction. It is a significant risk factor for the metabolic syndrome, type 2 diabetes, dyslipidemia, hypertension, and possibly cardiovascular disease.⁴² Approximately 70% of ovulatory dysfunction cases in adult women are secondary to PCOS.⁴⁰ Other common causes in adult women include hyperprolactinemia (approximately 10% of cases), hypothalamic amenorrhea, also

known as hypogonadotropic hypogonadism (approximately 10% of cases), and premature ovarian failure (approximately 10% of cases).⁴⁰ Thyroid disease can contribute to anovulation, and approximately 23% of hypothyroidism cases and 21% of hyperthyroidism cases are associated with menstrual irregularities.⁴³

ETIOLOGY

When considering the etiology of anovulatory bleeding, it is helpful to consider the patient's age. All patients who present with abnormal bleeding should be evaluated for pregnancy. Most adolescents will experience physiologic anovulatory cycles in the first few years following menarche because their hypothalamic-pituitary-gonadal axis is still maturing. However, if an adolescent has not developed regular menstrual cycles within 5 years of menarche, further evaluation for the cause, such as PCOS, should be considered.⁴⁴ Anovulatory cycles may “unmask” an underlying bleeding disorder. When irregular menses is associated with significant bleeding, it is important to consider an inherited bleeding disorder as the cause, especially in adolescence.^{22,45} Women who experience anovulation in their reproductive years should be evaluated for pathologic causes, including PCOS, thyroid dysfunction, hyperprolactinemia, primary pituitary disease, premature ovarian failure, hypothalamic dysfunction, disordered eating, adrenal disease, and androgen-producing tumors. Women in their perimenopausal years may experience “physiologic” anovulatory cycles because of intermittently declining estrogen levels. Regardless of age, evaluation for endometrial hyperplasia and/or endometrial cancer should be considered any time a woman experiences excessive bleeding with anovulatory cycles. When considering the etiology of anovulation, it is not unusual for several conditions to coexist (e.g., PCOS and hypothyroidism), each contributing to the woman's constellation of symptoms. All common etiologies should be considered when beginning an evaluation for anovulation.¹

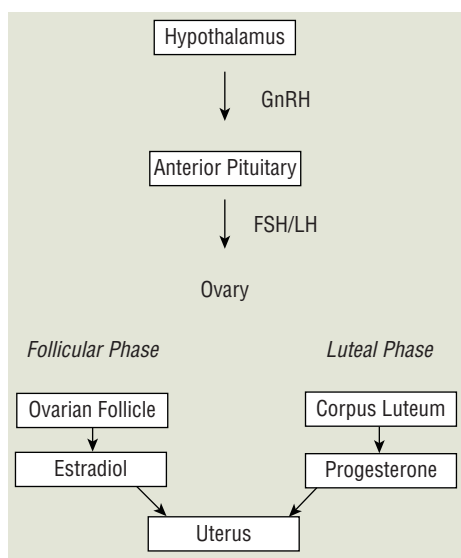

FIGURE 83-4. Summary of the normal menstrual cycle. (FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.)

PATHOPHYSIOLOGY

Normal menstrual cycles occur through a complex interaction of the hypothalamus, pituitary gland, ovaries, and endometrium (Fig. 83-4). In an ovulatory cycle, the ovary produces a mature, estrogen-secreting follicle in response to FSH release from the pituitary. The endometrium proliferates under the influence of this estrogen production. At a critical level of estrogen concentration, the pituitary is induced to produce an “LH surge,” which creates a cascade of events in the ovaries, culminating in ovulation. Upon release of the oocyte, the follicle becomes a progesterone-producing corpus luteum. The endometrium “organizes” into secretory endometrium in the presence of adequate progesterone. If conception and implantation do not occur, involution of the corpus luteum causes a decline in estrogen and progesterone leading to predictable, organized menstrual flow as the endometrium sloughs.

If ovulation does not occur, progesterone will not be produced, and the endometrium will continue to proliferate in an “unorganized” fashion under the influence of continued estrogen production. Eventually the endometrium will become so thick that it cannot be supported by continued estrogen production. This results in unorganized, sporadic sloughing of the endometrium, characteristic of the unpredictable and heavy bleeding of anovulation. Anovulation can be caused by several etiologies. In adolescence, hypothalamic–pituitary axis immaturity contributes to the absence of the LH surge required for ovulation. In the anorexic patient, the hypothalamus loses much of its pulsatile GnRH release, leading to production of low levels of FSH and LH, enough for estrogen production but not enough to induce ovulation.

CLINICAL PRESENTATION OF ANOVULATORY BLEEDING

General

- Patients may or may not be in acute distress.

Symptoms

- Irregular, heavy, or prolonged vaginal bleeding, perimenopausal symptoms (hot flashes, night sweats, vaginal dryness.)

Signs

- Acne, hirsutism, obesity

Laboratory Tests

- If PCOS is suspected, consider free or total testosterone, fasting glucose, fasting lipid panel.
- If perimenopause is suspected, measure FSH.
- Thyroid-stimulating hormone

Other Diagnostic Tests

- If the patient is older than 35 years, endometrial biopsy
- Pelvic ultrasound to evaluate for polycystic ovaries
- If perimenopause is suspected, measure FSH.

TREATMENT

The optimal treatment choice for anovulatory bleeding depends on accurate identification of the cause(s). As such, the treatment options for anovulatory bleeding are wide and varied.

Desired Outcome

The need to control excessive bleeding in the short term is paramount. The long-term goals of therapy include preventing future episodes of noncyclic bleeding, decreasing the complications of anovulation (e.g., osteopenia, infertility), and improving overall quality of life.²² Table 83-2 identifies the agents used to manage anovulatory bleeding and their recommended doses.

General Approach to Treatment

Although the appropriate primary treatment choice for anovulatory bleeding depends on the accurate diagnosis of its cause and identification of desired outcomes, additional treatment may be necessary to manage other signs and symptoms. In addition to initiating treatment to resolve the anovulatory bleeding, underlying menorrhagia may need to be addressed.

Nonpharmacologic Therapy

Nonpharmacologic treatment options for anovulatory bleeding depend on the underlying cause. In a woman of reproductive age with PCOS, weight loss may be beneficial. In women who have completed childbearing or who have not responded to medical management, endometrial ablation or resection and hysterectomy are surgical options. The choice of procedure should be based on shared decision making with the patient. In the short term, ablation appears to result in less morbidity and shorter recovery periods. However, a significant number of women eventually undergo hysterectomy in the subsequent 5 years.²²

Pharmacologic Therapy

Estrogen is the recommended treatment for managing acute severe bleeding episodes because it promotes endometrial stabilization.²² Following initial use of estrogen for controlling acute bleeding episodes, continuation of therapy may be necessary to prevent future occurrences. OC use fulfills this role and contributes to predictable menstrual cycles.

The OCs help to prevent recurrent anovulatory bleeding by providing a progestin and by suppressing ovarian hormones and adrenal androgen production. They also, indirectly, increase sex hormone-binding globulin (SHBG). SHBG binds to androgens and reduces their circulating concentrations. For women with high androgen levels and its related signs (e.g., hirsutism), OCs containing ≤35 mcg of ethinyl estradiol are the treatment of choice.²² Theoretically, use of an OC with a progesterone that has a larger impact on increasing SHBG can be considered, but to date there is no best contraceptive choice for these women (e.g., those with PCOS).⁵

In women with contraindication(s) to estrogen or in whom the side effects are unacceptable, progesterone-only products may be considered. They should be strongly considered for women experiencing menorrhagia associated with anovulatory bleeding.⁴⁶ In women with PCOS, use of depot and intermittent oral MPA suppresses pituitary gonadotropins and circulating androgens.⁵ Use of cyclic progesterone may benefit women older than 40 years in whom anovulatory bleeding occurs.²² In particular, if pregnancy is not a desired outcome of treatment, another progesterone option is placement of a levonorgestrel-containing IUD.⁴⁶

Use of metformin and the thiazolidinediones, including pioglitazone, results in improved insulin sensitivity. In patients with PCOS, this is associated with reduced circulating androgen concentrations, increased ovulation rates,^{5,47,48} and improved glucose tolerance.⁵ These improvements can be attributed to the SHBG increase that occurs via increased insulin sensitivity. 9 Metformin and thiazolidinedione use for anovulatory bleeding associated with PCOS is beneficial not only for anovulatory bleeding and fertility but also for improving glucose tolerance and decreasing overall long-term cardiovascular risk.⁵ For women who have pregnancy as a desired outcome, metformin is pregnancy category B, and pioglitazone and rosiglitazone are category C.

If the goal of treatment is to improve fertility via ovulation induction, then clomiphene citrate is an option. Treatment with 50 mg/day for 5 days can be initiated between days 3 and 5 of the menstrual cycle. This often occurs after induction of withdrawal bleeding with a progesterone such as MPA 10 mg daily orally for 10 days. If ovulation does not occur with this dose of clomiphene, the dose may need to be increased to 100 mg/day. In rare instances, it may be increased in 50 mg increments up to 250 mg/day.

Drug Treatments of First Choice As with many menstruation-related disorders, there is not one universal treatment option of first choice for anovulatory bleeding. Rather, the treatment(s) chosen depends on accurate diagnosis of the etiology as well as identification of the desired treatment outcome(s).

ACOG recommends OCs as the first-choice treatment in women with anovulatory bleeding.²² Based on consensus and expert opinion, the ACOG recommends the temporary use of conjugated equine estrogen not for anovulatory bleeding per se but for its efficacy in controlling severe abnormal uterine bleeding.²²

Relative to anovulation in women with PCOS, the ACOG recommends using insulin-sensitizing agents including metformin and the thiazolidinediones to improve ovulatory frequency. The ACOG also recommends clomiphene because it frequently results in pregnancy in these patients.⁵

More recent data appear to support even further the use of metformin compared to the use of clomiphene for ovulation induction.^{47,48} Its use for ovulation induction⁴⁷ as well as its use throughout pregnancy⁴⁹ in women with PCOS has been associated with reduced miscarriage rates in this population of patients (see Clinical Controversy).

Special Populations Anovulatory cycles are not unusual in the perimenarchal reproductive years. Ovulation typically is established 1 year or more following menarche. Anovulatory bleeding that occurs in this population may be excessive. If excessive bleeding occurs, the patient should be evaluated for bleeding disorders. The prevalence of bleeding disorders, including von Willebrand's disease, prothrombin deficiency, and idiopathic thrombocytopenia purpura, in this population ranges from 5% to 20%.²²

In the adolescent population, specific bleeding disorders should be treated. Acute severe bleeding can be managed with high-dose estrogen. OCs containing ≤ 35 mcg of ethinyl estradiol are the treatment of choice in adolescents with chronic anovulation.²²

Drug Class Information Table 83–3 identifies the significant pharmacologic properties, common adverse events, and clinically significant drug–drug and drug–food interactions of the agents used to treat anovulatory bleeding.

CLINICAL CONTROVERSY

The overall role of metformin in treating PCOS, particularly its duration of therapy, remains controversial. Relative to its use for ovulation induction, data illustrate that metformin is highly effective in both clomiphene citrate-resistant patients and in patients using it as initial therapy.^{47,48} Its use throughout pregnancy has been associated with a reduction in early pregnancy loss rates.⁴⁹ The presence of dyslipidemia and hyperinsulinemia in women with PCOS increases their long-term risk for developing cardiovascular disease. Current research indicates that metformin use should be considered as prophylactic therapy to reduce cardiovascular risk in these women.⁵⁰ More research is needed to definitively identify the role(s) of metformin in PCOS.

EVALUATION OF THERAPEUTIC OUTCOMES

Table 83–4 lists the expected outcomes and specific monitoring parameters for the treatment modalities used to manage anovulatory bleeding.

DYSMENORRHEA

Dysmenorrhea is one of the most commonly encountered gynecologic complaints. It is defined as crampy pelvic pain occurring with or just prior to menses. Primary dysmenorrhea implies pain in the setting of normal pelvic anatomy and physiology. Secondary dysmenorrhea is associated with underlying pelvic pathology.⁹

EPIDEMIOLOGY

Rates of dysmenorrhea range from 20% to 90%.^{9,23,51} Its presence may be associated with significant interference in work and school attendance. Risk factors include young age, heavy menses, nulliparity, early menarche, and cigarette smoking.^{9,11}

ETIOLOGY

For most patients, dysmenorrhea is associated with normal ovulatory cycles and normal pelvic anatomy. This is referred to as *primary*, or *functional*, *dysmenorrhea*. However, in approximately 10% of the adolescents and young adults who present with painful menses, an underlying anatomic or physiologic cause is found.¹¹

PATHOPHYSIOLOGY

The most significant mechanism for primary dysmenorrhea is the release of prostaglandins and leukotrienes into the menstrual fluid, initiating an inflammatory response and possibly vasopressin-mediated vasoconstriction.^{9,11,29} Causes of secondary dysmenorrhea include cervical stenosis, endometriosis, pelvic infections, pelvic congestion syndrome, uterine or cervical polyps, uterine fibroids, genital outflow tract obstructions, and pelvic adhesions.^{11,24} Pregnancy and miscarriage must be considered in the presentation of dysmenorrhea.

CLINICAL PRESENTATION OF DYSMENORRHEA

General

- Patient may or may not be in acute distress, depending on the level of menstrual pain experienced.

Symptoms

- Patients complain of crampy pelvic pain beginning shortly before or at the onset of menses. Symptoms typically last from 1 to 3 days.

Laboratory Tests

- Pelvic examination should be performed to screen for sexually transmitted diseases as a cause of the pain in sexually active females.
- Gonorrhea, *Chlamydia* cultures or polymerase chain reaction, wet mount

Other Diagnostic Tests

- Pelvic ultrasound can be used to identify potential anatomic abnormalities such as masses/lesions or to detect ovarian cysts and endometriomas.

TREATMENT

Initial choice of treatment is influenced by whether or not the woman desires to become pregnant. Nonpharmacologic options have been studied and observed to be as effective as some existing pharmacologic options.

Desired Outcome

Medical management of dysmenorrhea should relieve the related pelvic pain and, as applicable, should result in reducing lost school and work days. Table 83–2 identifies the agents used to manage dysmenorrhea and their recommended doses. Figure 83–5 shows a treatment algorithm for the management of dysmenorrhea.

General Approach to Treatment

There are several effective treatment options for dysmenorrhea. They include nonhormonal and hormonal pharmacologic options and

other noninvasive nonpharmacologic options. Treatment choice may be influenced by the desire for contraception, the patient's level of sexual activity, potential for adverse effects, and cost.

Nonpharmacologic Therapy

Several nonpharmacologic interventions are used for managing dysmenorrhea. Among these, topical heat therapy, exercise, and a low-fat vegetarian diet all have been shown to reduce the intensity of dysmenorrhea.^{9,11} Dietary changes may shorten the duration of dysmenorrhea. Application of topical heat via an abdominal patch for 12 consecutive hours/day has been proven to be as effective as 400 mg of ibuprofen dosed three times daily.⁵² Because topical heat, exercise, and dietary changes do not impart any systemic effects, they are associated with little to no risk compared to the available pharmacologic options. Other nonpharmacologic options that are reserved for use following a failed trial of pharmacologic interventions include transcutaneous electric nerve stimulation, acupressure, and acupuncture.⁹

Pharmacologic Therapy

Given the role of prostaglandins in the pathophysiology of dysmenorrhea, NSAIDs are the initial treatment of choice. These agents do appear to be different in terms of efficacy. The most commonly used agents are naproxen and ibuprofen.

All NSAIDs have a propensity for causing gastrointestinal distress and ulceration, so they should be taken with food or milk to minimize these effects. Choice of one agent over another may be based on cost, convenience, and patient preference.⁹ It has been suggested that a loading dose (twice the usual single dose) of the NSAID be used, followed by the usually recommended dose until symptoms resolve.¹¹ An alternate recommendation is to begin the NSAID at the onset of menses or perhaps even the day before and continue treatment around the clock instead of waiting until symptom onset. For patients in whom NSAID use is contraindicated, hormonal agents should be considered. Acetaminophen is inferior to NSAID in treatment of this disorder.⁹

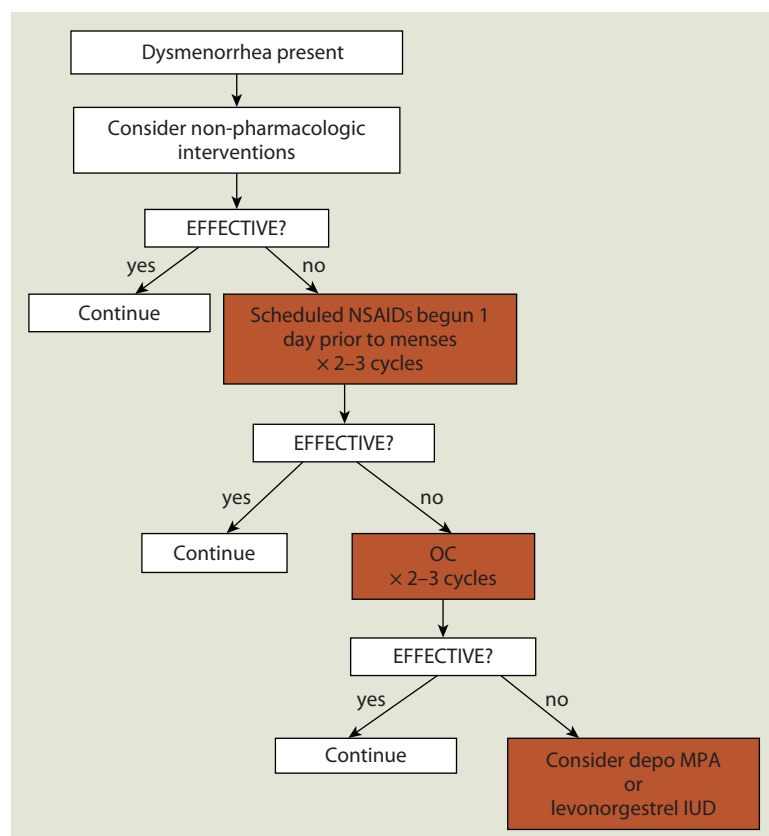

FIGURE 83-5. Treatment algorithm for dysmenorrhea. (IUD, intrauterine device; MPA, medroxyprogesterone acetate; NSAIDs, nonsteroidal antiinflammatory drugs; OC, oral contraceptive.)

OCs are effective in improving dysmenorrhea by inhibiting endometrial tissue proliferation. This reduction in tissue contributes to a reduction in endometrial-derived prostaglandins that cause the pelvic pain.¹¹ A trial of 2 to 3 months of OC dosing is required to establish whether the patient will respond to therapy.²⁷ Significant improvements in mild, moderate, and severe dysmenorrhea have been noted with the use of OCs. These agents have other benefits, such as prevention of pregnancy, improving acne, and reducing ovarian cancer risk. Although monophasic formulations may be more efficacious for this indication, the supporting evidence is limited.⁹

Depot MPA can be considered for dysmenorrhea treatment. Its efficacy is secondary to its ability to render most patients amenorrheic within 1 year of use.⁹ Because the pelvic pain of dysmenorrhea is related to the prostaglandins released during menses, in the setting of amenorrhea the underlying cause of dysmenorrhea is removed.

Another progesterone product to be considered in managing dysmenorrhea is the levonorgestrel-releasing IUD. Observational data indicate its ability to reduce dysmenorrhea from 60% to 29% after 3 years of use.⁹ As observed with depot MPA, this reduction likely is secondary to its effect in reducing menstrual flow.

Drug Treatments of First Choice Several factors influence the first-line treatment option chosen to treat dysmenorrhea. If contraception is desired, then a hormonal option may be considered using the same rationale for choosing it as would be used for choosing contraception (cost, adherence issues, side effects). If contraception is not desired, then a scheduled-dose NSAID started 1 day before menses would be desirable from both cost and convenience standpoints. If NSAIDs are contraindicated or the patient has a history of gastrointestinal disorders that would preclude their use, topical heat should be recommended.

Special Populations Dysmenorrhea is common in adolescent females. Any of the treatment measures used for adult patients would be appropriate in the adolescent population. Although NSAIDs, topical heat, and OCs are among the top choices, use of the levonorgestrel IUD is also an option.³²

Drug Class Information Table 83–3 identifies the pharmacology, pharmacokinetics, common adverse events, and clinically significant drug–drug and drug–food interactions of the agents used to treat dysmenorrhea.

PHARMACOECONOMIC CONSIDERATIONS

For women with third-party coverage for prescriptions, the costs of OCs and the higher doses of NSAIDs used for dysmenorrhea would be covered. For women without such coverage, the OC cost may be prohibitive. Generic forms of NSAIDs in over-the-counter strengths can be considered and are less expensive than marketed topical heat products, such as Therma Care. Topical heat can be administered inexpensively via a reusable heating pad or hot water bottle. However, these products are generally not convenient to use.

EVALUATION OF THERAPEUTIC OUTCOMES

Table 83–4 lists the expected outcomes and specific monitoring parameters for the treatment modalities used in the management of dysmenorrhea.

PREMENSTRUAL SYNDROME AND PREMENSTRUAL DYSPHORIC DISORDER

PMS is a constellation of symptoms including mild mood disturbance and physical symptoms that occur prior to menses and resolve with initiation of menses. It is distinct from PMDD.

EPIDEMIOLOGY

It is estimated that up to 75% of menstruating women experience symptoms of PMS.⁵³ However, a spectrum of premenstrual mood disturbances exists, and the most severe is PMDD. Approximately 3% to 8% of women have PMDD.⁵³

ETIOLOGY AND PATHOPHYSIOLOGY

PMDD is a complex psychiatric disorder with multiple biological, psychological, and sociocultural determinants.⁵⁴ Although cyclic hormonal changes are in some way related to PMS and PMDD, the association is neither linear nor simple. When ovulation is suppressed medically or surgically, symptoms improve. Some evidence suggests that PMS and PMDD symptoms are related to low levels of the centrally active progesterone metabolite allopregnanolone in the luteal phase and/or lower cortical γ -aminobutyric acid levels in the follicular phase.⁵⁴ Women with PMS and PMDD may have enhanced sensitivity to progesterone.²⁵ Studies of the relationship between PMS and PMDD and testosterone levels are conflicting.⁵⁴ A number of studies suggest a link between PMS and PMDD and low serotonin levels.^{25,54} A study suggests that, despite similar affective symptoms, hypothalamic–pituitary–adrenal (HPA) axis function in PMS and PMDD is distinct from that seen in major depressive disorder. Specifically, women with PMS show a decrease in stimulated HPA axis response, whereas this response is increased in women with major depressive disorder.⁵⁵ Although several cross-cultural studies suggest that the physical symptoms of PMS are consistent across cultures, the negative affective symptoms are part of the negative “menstrual socialization” in western culture.^{1,54}

CLINICAL PRESENTATION OF PMDD

A summary of the American Psychiatric Association’s criteria for PMDD is as follows^{1,54}:

- Symptoms are temporally associated with the last week of the luteal phase and remit with onset of menses.
- At least five of the following symptoms are present: markedly depressed mood, marked anxiety, marked affective lability, marked anger or irritability, decreased interest in activities, fatigue, difficulty concentrating, changes in appetite, sleep disturbance, feelings of being overwhelmed, and physical symptoms, such as breast tenderness or bloating.
- One of the symptoms must be markedly depressed mood, anxiety, irritability, or affective lability.
- Symptoms interfere significantly with work and/or social relationships.
- Symptoms are not an exacerbation of another underlying psychiatric disorder.
- The criteria are confirmed prospectively by daily ratings over two menstrual cycles.

TREATMENT

Women who experience symptoms of PMS and PMDD have been observed to miss significantly more work and school than do controls. They also report significant impairment of their ability to participate in social activities and hobbies and in their relationships with others.⁵⁶ Given this finding, the need for effective treatment modalities is clear.

Desired Outcome

Interventions for managing PMS and PMDD should aim to alleviate the presenting symptoms and subsequently improve quality of life.

Table 83–2 lists the various agents used in the management of this disorder and their recommended dosing.

General Approach to Treatment

As with any disorder or disease state, a treatment modality that is minimally invasive or without systemic effects is desired for initial therapy. Key to the successful choice of pharmacologic therapy for PMS and PMDD is having the patient chart her specific symptoms for at least 2 months.

Nonpharmacologic Therapy

Lifestyle interventions should be started and followed for 2 months while the patient charts her symptoms. Although these interventions lack significant supporting clinical trial data, anecdotal efficacy reports exist. Some lifestyle changes for women with mild-to-moderate premenstrual symptoms include minimizing intake of caffeine, refined sugar, and sodium and increasing exercise.^{14,53} Vitamin and mineral supplements, such as vitamin B₆ (50–100 mg daily) and calcium carbonate (1,200 mg daily), have been observed to help reduce the physical symptoms associated with PMS.^{14,53} A review of clinical trials concludes that the following options lack efficacy and safety data and therefore should not be recommended: herbal medicines, homeopathic remedies, dietary supplements, relaxation, massage therapy, reflexology, chiropractic treatments, and biofeedback.⁵⁷

Pharmacologic Therapy

If symptoms persist after 2 months of symptom charting and lifestyle modifications, pharmacologic therapy can be considered for PMDD management. Over the past decade, use of the selective serotonin reuptake inhibitors (SSRIs) for this disorder has been studied significantly.^{58–63} Studies have revealed very positive results relative to most of the symptoms associated with PMDD. Other agents that have been studied and are alternatives include the selective serotonin–norepinephrine reuptake inhibitor venlafaxine, as well as OCs, tricyclic antidepressants, and GnRH agonists.

Drug Treatments of First Choice ⑩ The first-line pharmacologic treatment options for PMDD are the SSRIs.⁵³ Among this class of agents, data support the use of citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline. They can be given either continuously or only during the luteal phase of the menstrual cycle. The ideal time for initiating therapy is unknown (see Clinical Controversy), and new evidence suggests efficacy when they are started at the onset of symptoms.

The SSRIs are efficacious in more than half of the treated patients compared to less than 30% of those receiving placebo.^{14,58,61–63} Several studies report 50% or greater symptom reduction with SSRI treatment compared to baseline.^{14,59,60} Improvement is noted to occur during the first cycle of use.¹⁴

Alternative Drug Treatments The tricyclic antidepressant clomipramine has been studied for treatment of PMDD. In placebo-controlled trials, both continuous daily dosing and luteal phase administration proved effective.¹⁴ Compared to the SSRIs, however, clomipramine has a less desirable side-effect profile with low tolerability. Venlafaxine has been studied on a continuous daily basis⁶⁴ and during the luteal phase.⁶⁵ Both venlafaxine regimens resulted in significant symptom improvement (compared to placebo) in more than 60% of the women treated.

If treatment with an SSRI or another antidepressant such as clomipramine is not successful, hormonal treatment with a GnRH agonist, such as leuprolide, can be considered.¹⁴ Leuprolide improves premenstrual emotional symptoms as well as some physical symptoms, such as bloating and breast tenderness. However, its cost, the need for intra-

muscular administration, and its hypoestrogenism side effects (e.g., vaginal dryness and hot flashes) limit its use.

A randomized, double-blind, placebo-controlled trial evaluating the use of a monophasic OC containing 30 mcg of ethinyl estradiol and 3 mg of drospirenone, a progesterone with antiandrogenic effects, showed improvement in the treatment arm compared to placebo.¹³ In particular, appetite, food cravings, and acne improved. However, active treatment was not associated with a statistically significant improvement in the overall outcome measure, the Calendar of Premenstrual Experiences (COPE) scale, perhaps because of the small sample size (n = 82).

Drug Class Information Table 83–3 lists the pharmacology, pharmacokinetics, common adverse events, and clinically significant drug–drug and drug–food interactions of the agents used to treat PMDD.

PHARMACOECONOMIC CONSIDERATIONS

The SSRIs as first-line treatment options for PMDD management are comparably priced overall; however, a generic formulation of fluoxetine is available. Emerging data on the most appropriate dosing regimens (see Clinical Controversy) may contribute even further to a reduction in the cost of managing this disorder.

CLINICAL CONTROVERSY

Current evidence supports SSRI use, either dosed continuously or during the luteal phase, as first-line treatment of PMDD. Some evidence suggests that dosing at symptom onset also may be effective.⁶³ The bulk of studies evaluating the SSRIs include women over the age of 18 years and had durations not longer than 3 to 6 months.⁵³ The most effective dosing strategy (continuous, luteal phase, or symptom onset), the most efficacious treatments in the adolescent and perimenopausal populations, and the optimal duration of treatment all warrant further investigation.

EVALUATION OF THERAPEUTIC OUTCOMES

Table 83–4 lists the expected outcomes and specific monitoring parameters for the treatment modalities used in the management of PMDD.

CONCLUSIONS

Treatment success for the various menstruation-related disorders can be measured by the degree to which the care plan (1) relieves or reverses symptoms of the disorder, (2) prevents or reverses the complications of the disorder (e.g., osteoporosis, anemia, and infertility as noted with amenorrhea, menorrhagia, and anovulatory bleeding, respectively), and (3) minimizes side effects. The return of a regular menstrual cycle with minimal premenstrual symptoms or symptoms of dysmenorrhea is desirable. Depending on the desire for conception and subsequent therapy, this cycle may be ovulatory or anovulatory.

Once optimal therapy has been identified, the regimen can be continued as long as is deemed necessary. In amenorrhea, discontinuation of therapy may be warranted once menses resumes. In anovulatory bleeding, therapy may be discontinued once ovulatory menstrual cycles return. In menorrhagia, dysmenorrhea, and PMDD, optimal therapy may be continued for years or until other health factors affect its continuation. For example, a woman taking OCs for menorrhagia or dysmenorrhea may discontinue them when she is trying to become pregnant.

Symptom relief in dysmenorrhea should occur within hours of starting an NSAID or within the next menstrual cycle/menses if using OCs. Evaluate the patient for improvement of symptoms associated with amenorrhea, menorrhagia, anovulatory bleeding, or PMDD within one to two menstrual cycles. Ask patients at this visit about the type, frequency, and severity of current symptoms compared to their initial presenting symptoms. Refer patients with persistent symptoms for further medical evaluation to identify other underlying issues or complications.

Assess the effectiveness of therapy in resuming normal menstrual cycles with minimal related pain after an appropriate treatment interval (1–2 months). Assess improvement in quality of life measures such as physical, psychological, and social functioning and well-being. Evaluate the patient for adverse drug reactions, drug allergies, and drug interactions. Table 83–3 lists the common side effects that may occur and the monitoring required. Table 83–4 lists the specific expected outcome measures for each of the menstruation-related disorders discussed in this chapter.

ABBREVIATIONS

COPE: Calendar of Premenstrual Experiences

FSH: follicle-stimulating hormone

GnRH: gonadotropin-releasing hormone

HPA: hypothalamic–pituitary axis

IUD: intrauterine device

LH: luteinizing hormone

MPA: medroxyprogesterone acetate

NSAID: nonsteroidal antiinflammatory drug

OC: oral contraceptive

PCOS: polycystic ovarian syndrome

PID: pelvic inflammatory disease

PMDD: premenstrual dysphoric disorder

PMS: premenstrual syndrome

SHBG: sex hormone–binding globulin

SSRI: selective serotonin reuptake inhibitor

DEBORAH A. STURPE

KEY CONCEPTS

- 1 The etiology of endometriosis likely is due to multiple factors, with no single theory satisfactory to explain all cases.
- 2 Endometriosis should be suspected in any woman of reproductive age, including adolescents, with recurring cyclic or acyclic pelvic pain and/or subfertility.
- 3 No physical examination findings or laboratory tests are considered diagnostic for endometriosis. A definitive diagnosis can be made only via surgical visualization of lesions. Confirmation of diagnosis is not necessary in all cases.
- 4 Treatment goals of endometriosis include improvement of painful symptoms and maintenance or improvement of fertility. Therapy is considered successful based on resolution of the patient's symptoms or achievement of pregnancy.
- 5 All medical therapies are equally efficacious in treating endometriosis-related pain based on available evidence. Choice among agents is determined primarily by side-effect profile, cost, and individual patient response.
- 6 Endometriosis-related pain can be treated by medical or surgical therapy. Empirical medical therapy likely is more cost effective and is recommended based on consensus guidelines.
- 7 Recurrence rates of endometriosis-related pain are high after both medical and surgical therapies. Extended use of medical therapy or postoperative use of medical therapy may be needed to maintain efficacy.
- 8 Endometriosis-related infertility is unresponsive to medical therapy. Conservative surgical therapy is the preferred treatment.

Endometriosis is a common cause of chronic pelvic pain in women and is associated with infertility. Characterized by the presence of endometrial tissue outside the uterus, endometriosis is a chronic, recurring disease. Therapy is targeted at relieving symptoms and improving fertility.

EPIDEMIOLOGY

Prevalence of endometriosis in the general population is estimated at approximately 6% to 10% of women.^{1,2} An estimated 35% to 50% of women presenting with chronic pelvic pain have endometriosis, and

approximately 38% of women with infertility have the disorder.^{1,2} The disease typically presents during the reproductive years but has been documented over a wide age range from 8 to 76 years, with some cases occurring prior to menarche.^{3,4} A genetic predisposition for endometriosis has been noted, as evidenced by disease rates that are six times higher in primary relatives of affected women compared to the general population.²

ETIOLOGY

- 1 The etiology of endometriosis is unknown. Multiple mechanisms for development of lesions are likely, including theories of retrograde menstrual flow, coelomic metaplasia, lymphatic and vascular spread, and immunologic abnormalities.^{1,2,5,6} Although retrograde menstruation is the most popular theory of endometriosis development, the low percentage of women with this disorder who develop endometriosis along with rare occurrence of disease in prepubertal girls supports other mechanisms of pathogenesis.³ Involvement of immune system factors in the development and progression of endometriosis is recognized. Findings of abnormal B- and T-cell function, decreased apoptosis, and altered levels of prostanoids, cytokines, growth factors, and interleukins in endometrial lesions and peritoneal fluid of affected women support this theory.^{6,7} Based on these findings, it has been hypothesized that an underlying immunologic disorder is responsible for development of endometriosis in most women.⁶

PATHOPHYSIOLOGY

Endometriosis-associated pain is secondary to structural and/or inflammatory causes. Endometrial lesions may cause pain or dyspareunia by direct compression of nerve fibers or increased pressure within endometriomas (cysts within the ovary).^{6,8} Endometrial lesions also generate local inflammation, resulting in prostaglandin release and development of adhesions.^{6,8} Endometrial lesions contain estrogen and progesterone receptors; thus, symptoms may correlate with the cyclic release of hormones during the menstrual cycle. In severe endometriosis, infertility may result from distortion of the pelvic structure secondary to endometrial lesions, inflammation, and adhesions.^{6,8,9} In milder disease, the cause-and-effect relationship is more controversial. Decreased oocyte viability and/or production resulting from the altered uterine environment may be a contributing factor.⁸

CLINICAL PRESENTATION

Symptoms

- The patient may be asymptomatic or complain of symptoms such as dyspareunia, chronic pelvic pain (cyclic or acyclic), premenstrual spotting, gastrointestinal disturbances, urinary disturbances (dysuria, hematuria), low back pain, painful defecation, or infertility.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

Signs

- Findings on physical examination may include cul-de-sac or uterosacral ligament tenderness, adnexal enlargement or tenderness, or a pelvic mass.
- Findings on laparoscopic examination may include red “flame” lesions (early disease), blue/brown/gray “powder burn” lesions, “white lesions” (healed or inactive disease), or “chocolate cysts” (endometriomas containing blood).

Data from Valle⁶ and Child and Tan.⁸

2 **3** Endometriosis should be suspected in women, including adolescents, with subfertility, dysmenorrhea, dyspareunia, or chronic pelvic pain. A definitive diagnosis can be made only by direct surgical visualization of endometrial lesions; however, most treatment guidelines allow for nondefinitive diagnosis in patients presenting with chronic pelvic pain provided that other causes of pain are ruled out and pain responds to first-line empiric therapies.^{3,10–12} Severity of disease can be classified according to the American Association of Reproductive Medicine staging system (stage I = mild to stage IV = severe), but this staging system is not useful in clinical practice because the size, location, and number of lesions do not correlate with painful symptoms, nor does the staging system predict pregnancy rates.^{1,6} In addition, disease severity may be underestimated.¹⁰

TREATMENT

The treatment of endometriosis varies depending on presenting symptoms, patient age, and desired outcome.

DESIRED OUTCOME

4 Treatment goals for endometriosis depend on the patient's presentation. Only women with active symptoms (pelvic pain, infertility, or both) require therapy. Depending on the primary complaint, goals of endometriosis treatment include (1) minimization or removal of endometrial deposits, (2) prevention of disease progression, (3) minimization of associated pain, and (4) prevention or correction of associated infertility.

GENERAL APPROACH TO TREATMENT

5 The treatment of an asymptomatic patient with endometriosis consists of expectant management (watchful waiting) only because therapy is not indicated unless symptoms develop. For symptomatic patients, the foundation of therapy includes medical treatment, surgical treatment, or both. To date, no studies have directly compared medical and surgical treatment as first-line therapy. Furthermore, determining the optimal medical or surgical approach is difficult secondary to a paucity of well-designed, randomized, controlled trials. All commonly prescribed medical therapies relieve endometriosis-related pain by regressing lesions via induction of a pseudopregnancy or pseudomenopausal state but do not eradicate lesions or improve fertility. Therefore, choice of initial therapy depends on multiple factors such as the patient's primary complaint, location and extent of disease, desire for future fertility, cost of therapy, contraindications to therapy, and potential side effects or complications of therapy.

6 Guidelines recommend empirical treatment of chronic pelvic pain suspected to be secondary to endometriosis with nonsteroidal antiinflammatory drugs (NSAIDs) and/or combined hormonal contraceptives (CHCs) for 3 months.^{3,10–12} If symptoms fail to improve with such therapy, empiric therapy with a gonadotropin-releasing hormone (GnRH) agonist can be considered. Other pharmacologic

agents (e.g., danazol, progestins) also can be considered for use in selected patients. Conservative surgical therapy is recommended for treatment of painful symptoms in women who do not respond to, or have contraindications to, medical therapy or patients with other compelling reasons for surgery. Of note, **7** 30% to 75% of women will experience recurrence of pain within 6 to 24 months after initial treatment with either medical or surgical means, and extended use of medical therapy or postoperative adjunctive medical therapy may be necessary.^{2,6,13} Definitive treatment for endometriosis involves non-conservative surgical therapy via bilateral salpingo-oophorectomy, with or without hysterectomy. This therapy should be reserved for women not desiring future fertility who accept the potential complications of surgically induced menopause. A general treatment algorithm for endometriosis-related pain is shown in Fig. 84–1.

8 For women presenting with infertility as a primary complaint, first-line therapy involves surgical resection of endometrial lesions to restore normal anatomy, followed by watchful waiting.^{10,11,14} Medical therapy is ineffective for endometriosis-related infertility and should be avoided.^{8,10,11,14–17} For women in whom surgical intervention does not result in pregnancy within 6 months, controlled ovarian stimulation with intrauterine insemination or in vitro fertilization is commonly used.¹⁸ Pretreatment with a GnRH agonist prior to in vitro fertilization cycles may increase success rates.^{18,19} No clear guidelines or recommendations exist to guide the choice of one therapy or technique over another.

NONPHARMACOLOGIC THERAPY: SURGERY

8 Surgical intervention in endometriosis can be used as both a diagnostic and a therapeutic tool. Laparoscopic procedures are highly effective in treating endometriosis pain and are preferred over laparotomy because of lower complication rates, lower incidence of postoperative adhesions, and more rapid patient recovery.^{1,6,20} Unfortunately, up to 44% of women will experience recurrence of painful symptoms at 1 year, so use of adjunctive medical therapy postoperatively is sometimes recommended in order to extend the pain-free interval.^{1,6,13,19} Current data best support use of danazol or a GnRH agonist for this purpose.¹⁰ Conservative surgical therapy is also primary treatment of endometriosis-associated infertility, and patients with advanced disease causing distortion of the pelvic structure may benefit most from surgical intervention.

PHARMACOLOGIC THERAPY

Typically, pharmacologic therapy is the first choice for treatment of endometriosis-related pain in order to minimize risks from surgery. However, drug therapy will not treat endometriosis-related infertility.

Drug Treatments of First Choice

5 First-line therapy for endometriosis-associated pain includes NSAIDs or CHCs.^{3,10–12} These two drug classes are considered as effective as, and less costly than, other endometriosis treatments. Choice of agent depends on patient characteristics, such as desire for contraception, pain patterns, and contraindications. Long-term maintenance therapy with these agents may be considered for women achieving a good therapeutic response.

Efficacy of NSAIDs in patients with endometriosis has not been evaluated in a large number of controlled trials. However, NSAIDs have proven efficacy in treating primary dysmenorrhea and likely have benefit in endometriosis as well.^{10–12}

Use of CHCs for treatment of endometriosis pain is desirable because of the potential for long-term use without significant side effects. A low-dose combined oral contraceptive administered cyclically was compared with a GnRH agonist in a randomized trial.²¹ Both groups showed overall improvement in dyspareunia, nonmen-

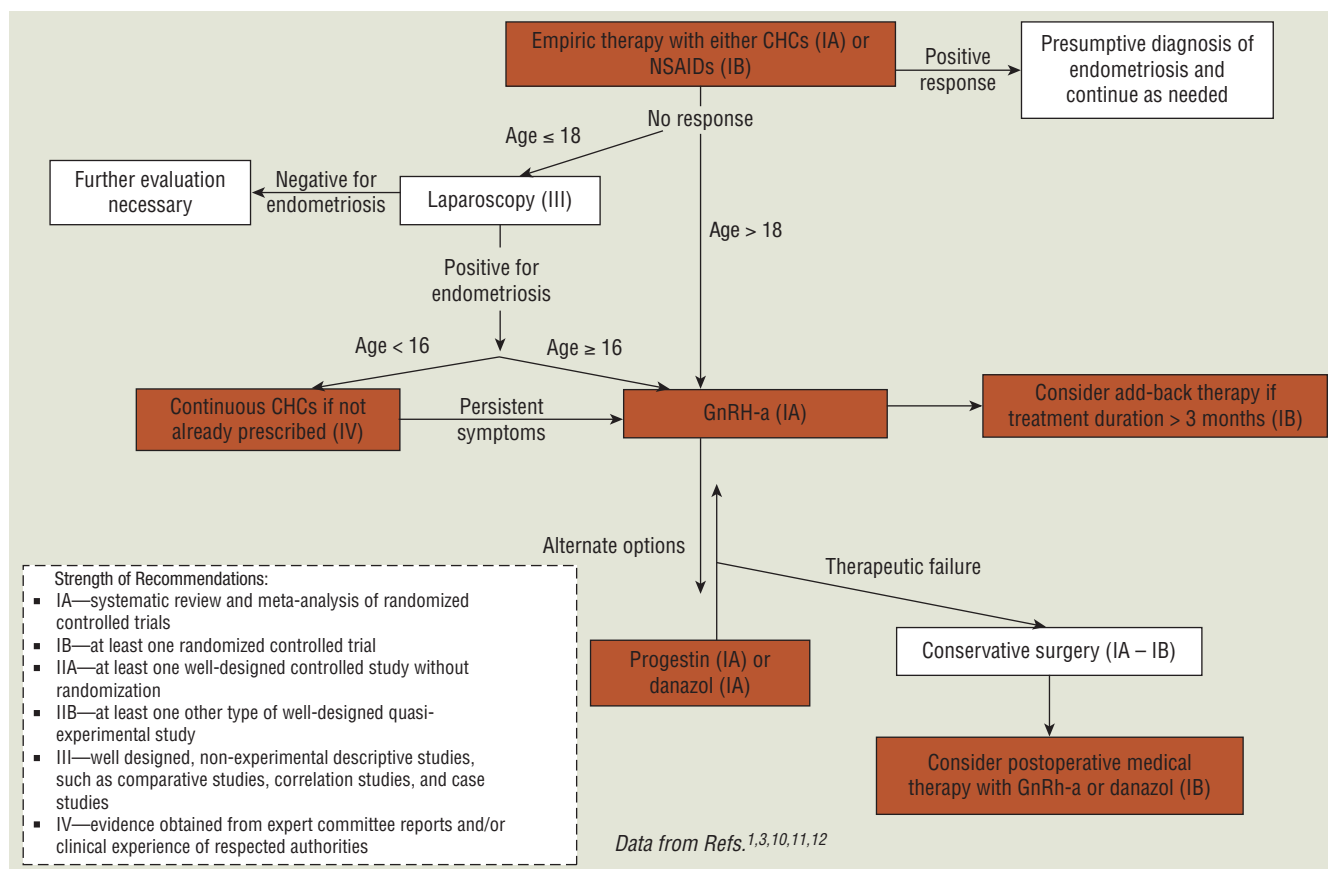

FIGURE 84-1. Treatment algorithm for cyclic/acyclic chronic pelvic pain and suspected endometriosis. (CHC, combined hormonal contraceptive; GnRH-a, gonadotropin-releasing hormone agonist.)

strual pain, and dysmenorrhea at 6 months. The rate of recurrent symptoms 6 months after cessation of therapy was equal between groups. Combined oral contraceptives can be administered on a continuous basis if desired. Studies on the efficacy of other formulations of CHCs (vaginal ring and transdermal patch) for treatment of endometriosis pain have not been conducted; however, use of these agents in endometriosis is reasonable.

Alternative Drug Treatments

Adolescents (age less than 18 years) experiencing chronic pelvic pain despite therapy with NSAIDs or CHCs should undergo evaluative laparoscopy prior to initiation of additional pharmacotherapy.³

In adolescents with endometriosis diagnosed by laparoscopy or in adults with chronic pelvic pain unresponsive to NSAIDs or CHCs, advanced medical therapy for endometriosis pain may be considered.^{3,10–12} Agents that can be used as advanced medical therapy include progestins, danazol, or GnRH agonists. Systematic reviews have concluded that all three classes are effective choices, and no class has been proven superior to another.^{19,22–24} The primary difference between treatments is the side-effect profile and available dosage forms; therefore, choice of agent depends on patient age, preference, and tolerance of side effects. A 2-month trial of the agent should be used, and treatment should be continued for a minimum of 6 months if relief is obtained.¹² For women treated with a GnRH agonist, add-back therapy with estrogens or progestins should be considered to minimize vasomotor side effects and bone mineral density loss.^{3,10–12}

Surgical therapy for endometriosis pain should be considered for women who do not respond to advanced medical therapy, women with contraindications to medical therapy, and women unable to tolerate side effects caused by medical therapy.¹²

Special Populations: Adolescents

4 Treatment goals for endometriosis in adolescent patients include pain control, minimization of disease progression, and preservation of fertility.³ Medical therapy is preferred over surgical therapy in this population in order to minimize adhesion development from repeated surgeries.²⁵ A treatment algorithm that includes therapy for adolescent patients is shown in Fig. 84–1.

The effect of drugs on bone mineral density is of particular concern in young women who have not achieved peak bone mass; thus, add-back therapy should be considered for all adolescents receiving GnRH agonist therapy.^{3,4,25} Although progestins are likely to be well tolerated by the adolescent population, efficacy has not been clearly established, and concerns regarding long-term effects on bone mineral density and lipid profile are not clearly defined.^{3,25} Danazol is not likely to be well tolerated by the adolescent population and generally is not recommended for use.^{3,4,25}

Drug Class Information

When selecting therapy for endometriosis related pain, choice of drug within a class often depends on strength of evidence for efficacy in endometriosis or specific patient factors.

Nonsteroidal Antiinflammatory Drugs NSAIDs treat the painful symptoms of endometriosis by interfering with prostaglandin production but do not directly affect the structure of endometrial lesions.⁶ Long-term use of these agents may be limited by gastrointestinal or renal toxicity. They also may aggravate reactive airway disease and should be used with caution in such patients. The NSAIDs most commonly used for treatment of gynecologic pain are ibuprofen and naproxen.¹³ Dosing may be intermittent or

TABLE 84-1 Pharmacologic Therapy for Endometriosis-Associated Pain

Drug	Dose	Comments
CHCs		
Combined oral contraceptives (various)	1 orally daily	Continuous administration may lessen dysmenorrhea Contraindicated in women with history of thromboembolism; avoid in women >35 years old who smoke
Contraceptive patch (Ortho-Evra)	1 patch weekly	Continuous administration may lessen dysmenorrhea Contraceptive efficacy may be diminished in women >90 kg (198 lb) Contraindicated in women with history of thromboembolism; avoid in women >35 years old who smoke
Contraceptive vaginal ring (NuvaRing)	1 ring monthly	Continuous administration may lessen dysmenorrhea Contraindicated in women with history of thromboembolism; avoid in women >35 years old who smoke
NSAIDs		
Ibuprofen	400 mg orally every 4–6 hours	Use with caution in women with reactive airways disease, renal disease, or history of gastrointestinal ulcer
Naproxen	250 mg orally every 6–8 hours	Use with caution in women with reactive airways disease, renal disease, or history of gastrointestinal ulcer
Progestins		
MPA	150 mg IM every 3 months	Generally well tolerated and less costly than GnRH-a or danazol Black box warning to limit therapy to no more than 2 years May delay return of fertility
	120 mg SC every 3 months	Generally well tolerated and less costly than GnRH-a or danazol Black box warning to limit therapy to no more than 2 years May delay return of fertility
GnRH-a		
Leuprolide	11.25 mg IM every 3 months	Vasomotor symptoms and bone loss may limit use Add-back therapy improves side effects and reduces bone loss Not preferred in younger adolescent patients secondary to bone loss
Goserelin	3.6 mg SC monthly	Vasomotor symptoms and bone loss may limit use Add-back therapy improves side effects and reduces bone loss Not preferred in younger adolescent patients secondary to bone loss
Nafarelin	200 mcg (one spray) intranasally twice daily	Vasomotor symptoms and bone loss may limit use Add-back therapy improves side effects and reduces bone loss Not preferred in younger adolescent patients secondary to bone loss
Other		
Danazol	600–800 mg orally daily in divided doses	Androgenic side effects limit use; not preferred in adolescent patients secondary to side-effect profile

CHC, combined hormonal contraceptive; MPA, medroxyprogesterone acetate; IM, intramuscular; GnRH-a, gonadotropin-releasing hormone agonists; SC, subcutaneous; NSAID, nonsteroidal antiinflammatory drug. Data from references 1, 3, 10, 11, 12, 43, and 44.

continuous, depending on whether the pain is cyclic or acyclic.¹² Specific dosing information is listed in Table 84–1.

Combined Hormonal Contraceptives CHCs treat the pain of endometriosis by decreasing menstrual flow and regressing endometrial implants through induction of an anovulatory and/or hypoestrogenic state.^{3,26} Continuous therapy also can be used to suppress menstruation and induce a “pseudopregnancy”-like state.³ Studies suggest that combined oral contraceptives likely are equal in efficacy to GnRH agonists and medroxyprogesterone for relieving endometrial pain.²⁷ Combined oral contraceptives also are effective in preventing recurrence of pain after surgical intervention for endometriosis.²⁸ No evidence suggests that one combined oral contraceptive is superior to another. Additionally, although no specific studies have examined the efficacy of the contraceptive patch or vaginal ring in endometriosis, effects of these agents likely are similar to those of the oral formulations.³ Thus, choice between CHCs should be guided by patient preference, likelihood of adherence, and cost.

Side effects of CHCs typically are mild and may include nausea, bloating, headache, and breakthrough bleeding. However, all CHCs can increase risk of thromboembolism, so they should not be used in women with a history of thromboembolism or in smokers over age 35 years.

Administration of CHCs may be cyclic (includes a placebo or non-drug week) or continuous. Although no studies have directly compared the two methods, continuous administration is more likely to induce amenorrhea and, therefore, may be more beneficial in treating dysmenorrhea.^{3,13,19}

Progestins Multiple progestins have been studied for the treatment of endometriosis. Agents available in the United States include oral medroxyprogesterone, depot medroxyprogesterone (both subcutaneous and intramuscular), megestrol, norethindrone, and the levonorgestrel-releasing intrauterine device (IUD). The progestins treat endometriosis via atrophy and decidualization of endometrial tissue. They tend to be less expensive and better tolerated than other advanced medical endometriosis treatments.

Despite a paucity of well-designed, controlled trials examining use of progestins in endometriosis, a systematic review concluded that continuous therapy with progestins is no more or less effective than other therapies for treatment of endometriosis-associated pain.²⁴ More recent studies have examined the use of the subcutaneous form of depot medroxyprogesterone for treatment of endometriosis-associated pain.^{29,30} Both studies compared subcutaneous medroxyprogesterone to the GnRH agonist leuprolide, and in each study the progestin showed statistically equivalent improvement in symptoms. Studies examining the use of the levonorgestrel-releasing IUD also suggest some efficacy in the treatment of endometriosis-associated pain.^{31–33}

Common side effects of systemic progestins include breakthrough bleeding, weight gain, fluid retention, and mood swings. For women desiring immediate future fertility after cessation of therapy, progestins may not be optimal secondary to prolonged amenorrhea and anovulation. Also of concern are unknown long-term effects on bone mineral density associated with these agents. Both depot medroxyprogesterone products carry black box warnings against use for more than 2 years.^{34,35} However, in the studies that directly compared the

subcutaneous form of depot medroxyprogesterone to leuprolide over a treatment period of 6 months, the extent and degree of bone loss were less severe with the progestin.^{29,30} Specific progestin dosing information is given in Table 84–1.

Gonadotropin-Releasing Hormone Agonists GnRH agonists create a functional oophorectomy via inhibition of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) secretion. This, in turn, diminishes endometrial implants. When first initiated, GnRH agonists create an initial gonadotropin flare prior to receptor down-regulation that may cause a temporary increase in pain. Initiating therapy during the midluteal phase may minimize such effects.

Therapy with a GnRH agonist is superior to placebo and comparable with danazol for relief of endometriosis-associated pain.²³ Response rates are approximately 85% to 100% after 6 months of therapy, but recurrence rates at 5 years are 53%.^{1,19,23,27} Although a GnRH agonist typically is taken for 6 months, one comparative study has shown equivalent efficacy and recurrence rates between 3 and 6 months of GnRH agonist therapy.³⁶ Therapy may be extended beyond 6 months to maintain efficacy, although data regarding such extended usage are limited.

The three GnRH agonists currently available in the United States are goserelin, leuprolide, and nafarelin. These agents differ primarily by route of administration; therefore, choice of therapy depends on patient preference. Specific dosing information for the GnRH agonists is given in Table 84–1.

Side effects are the primary limitation of GnRH agonist use. The pharmacologically induced hypoestrogenic environment results in bone loss and vasomotor symptoms such as hot flashes, vaginal dryness, and insomnia. Loss of bone mineral density is estimated at 4% to 6% over 6 months of GnRH agonist therapy and occurs at both the hip and spine, but this loss is partially to fully recoverable upon cessation of the drug.³⁷ Bone loss is progressive as use of the drugs is extended beyond 6 months, and whether reversibility is maintained after such longer treatment periods is unknown.³⁸ Add-back therapy with estrogens, progestins, or bisphosphonates has been studied for treatment of vasomotor symptoms and prevention of bone loss while maintaining drug efficacy.^{3,10,11}

Women receiving GnRH agonist therapy should be encouraged to take supplemental calcium and to exercise. One small study suggests that women who exercise (walking and aerobic sessions) during 6 months of GnRH agonist therapy sustain similar bone mineral loss during therapy but have better recovery of bone mineral density after cessation of therapy compared to women who do not exercise.³⁹

CLINICAL CONTROVERSY

Add-back therapy alleviates the vasomotor symptoms and bone density loss associated with GnRH agonist therapy. Controversy exists as to when to initiate such therapy. Some practitioners believe that add-back therapy should be prescribed only after 6 months of GnRH agonist treatment because bone loss until this point is believed to be reversible. However, recent data suggest that this may not be entirely true. Consequently, some clinicians recommend immediate use of add-back therapy to minimize side effects and improve adherence, especially because some evidence suggests that use of immediate add-back therapy can completely eliminate bone mineral density loss. Consideration for use of immediate add-back therapy may be of particular importance in women younger than 30 years because bone mineral density is still building.

Danazol Danazol is a synthetic steroid analog of 17-ethinyl testosterone. It induces anovulation, amenorrhea, and endometrial atrophy through pituitary suppression of the midcycle LH and FSH surge and

induction of a high-androgen, low-estrogen environment. The drug also has immunosuppressive activity that may contribute to its efficacy. Formerly the “gold standard” of endometriosis treatment, the popularity of danazol has decreased with the development of agents with more favorable side-effect profiles.

Danazol has proven effective as empirical therapy as well as postoperative therapy. Symptomatic improvement has been reported in up to 80% to 90% of women using the drug, with the best results seen in women achieving amenorrhea.¹³ A systematic review concluded that 6 months of danazol therapy is superior to placebo in relieving painful symptoms.²² Therapy for only 3 months has not been as successful, especially when used postoperatively.^{1,12,13}

The primary limitation of danazol therapy is the high occurrence of androgenic side effects, including weight gain, acne, hot flashes, decreased breast size, hirsutism, and increased low-density lipoprotein cholesterol. Lowering the dose of danazol may alleviate some of these side effects, but drug efficacy is compromised.¹³ Danazol should not be initiated in women with hyperlipidemia or liver disease. Danazol is teratogenic, and barrier forms of contraception must be used. The dose of danazol ranges from 200 to 800 mg/day; most studies have used doses of 600 to 800 mg. Specific dosing information is given in Table 84–1.

PHARMACOECONOMIC CONSIDERATIONS

Several cost considerations must be made when choosing endometriosis therapy. Cost of medical therapy must be weighed against the cost of surgical therapy, and the costs of each type of medical therapy must be weighed against another.

6 Two studies have determined that empirical pain therapy with a GnRH agonist is less expensive than empirical surgical therapy by laparotomy. Cost savings estimates from these studies range from \$1,000 to \$2,500 per treated patient, although the results of these studies are limited by the lack of consideration of the cost of add-back therapy and/or postoperative medical therapy.^{40–42} Because the rate of recurrence of symptoms is high for both conservative surgical therapy and medical therapy, empirical medical therapy appears to be the most reasonable option. Generally, GnRH agonists are the most expensive agents and CHCs and progestins are the least expensive.

CLINICAL CONTROVERSY

Several of the drug therapies used for treatment of endometriosis may lead to decreases in bone mineral density. Unfortunately, the role of routine bone mineral density testing as a monitoring parameter for these drug therapies is not yet determined. Some clinicians choose to routinely measure bone mineral density in order to follow changes over time. However, the accuracy of bone mineral density results in predicting fracture risk in younger patients has not been well established, nor has a threshold of loss been established for discontinuation of therapy. Thus, some clinicians may decide that the cost of routine testing is not justified.

EVALUATION OF THERAPEUTIC OUTCOMES

4 Monitoring of endometriosis therapy is focused on subjective relief of symptoms.^{12,13} Although objective confirmation of lesion regression by laparotomy is feasible, the results typically are misleading because the number and size of lesions do not correlate well with patient symptoms.¹³

Endometriosis-related pain should be relieved within 2 months of initiating medical therapy. If symptoms persist, consideration should be given to different medical and/or surgical therapy. For endometriosis-related infertility, most experts recommend 6 months of watch-

ful waiting after surgical intervention. If pregnancy is not achieved within that time, assisted reproductive techniques can be considered.

Careful monitoring of the patient for side effects to recommended drug therapy is important. Most of the monitoring can be accomplished by eliciting any subjective complaints from the patient at routine followup visits. However, certain drug therapies may require additional objective monitoring, such as fasting lipid profile and blood pressure measurements.

ABBREVIATIONS

CHCs: combined hormonal contraceptives

FSH: follicle-stimulating hormone

GnRH: gonadotropin-releasing hormone

IUD: intrauterine device

LH: leuteinizing hormone

NSAID: nonsteroidal antiinflammatory drug

KEY CONCEPTS

- 1 Estrogen-based postmenopausal hormone therapy should be used for treatment of menopausal symptoms (e.g., vasomotor and urogenital symptoms) and, when specifically indicated, for osteopenia and osteoporosis prevention.
- 2 A progestogen should be added for endometrial protection when estrogen therapy is prescribed. Thus, women with an intact uterus should not receive unopposed estrogen, whereas women who have undergone hysterectomy always should receive estrogen alone.
- 3 Lower doses of hormone therapy than previously used should be considered as standard initial therapy. Clinicians should prescribe hormone therapy at the lowest effective dose for the shortest duration, carefully and individually weighing treatment goals and risks for each woman.
- 4 The major indication for estrogen-containing hormone therapy is the relief of menopausal symptoms. The benefits of short-term perimenopausal and postmenopausal hormone therapy for the relief of severe menopausal symptoms outweigh the risks in many women.
- 5 Osteoporosis prevention remains an approved indication for estrogen-based hormone therapy, but alternative strategies are available and should be considered as first-line agents for asymptomatic women. Vitamin D deficiency should be excluded before any other treatment is prescribed for the prevention or treatment of bone loss, and adequate calcium intake should be ensured.
- 6 Postmenopausal hormone treatment with oral combined estrogen plus progestogen has no benefit for cardiovascular disease prevention and increases the risk of breast cancer, coronary heart disease events, stroke, and venous thromboembolic events. However, it reduces the rates of hip fracture.
- 7 Hormone therapy improves mood and well-being primarily in women with hot flashes, night sweats, and sleep disturbance, but it does not improve gross quality-of-life measures in postmenopausal women who do not experience vasomotor symptoms.
- 8 Evaluation of each individual woman is essential in determining the appropriateness of perimenopausal and postmenopausal hormone therapy, and collaboration between a woman

and her primary care provider in the decision-making process is essential. The benefits and risks of hormone therapy should be reassessed annually.

- 9 Results from randomized trials of hormone therapy in postmenopausal women cannot be extrapolated to premenopausal women with ovarian dysfunction. Women with premature ovarian failure (i.e., those younger than 40 years) need exogenous sex steroids to compensate for the decreased production by their ovaries.

Menopause is the permanent cessation of menses following the loss of ovarian follicular activity.¹ By definition, it is a physiologic event that occurs after 12 consecutive months of amenorrhea, so the time of the final menses is determined retrospectively. Women who have undergone hysterectomy must rely on their symptoms to estimate the actual time of menopause.

Many women seek therapy for alleviation of symptoms that arise from loss of ovarian function at the time of menopause. However, since 2002, use of hormone therapy (estrogen with or without progestogen) for the prevention of diseases of aging has attracted considerable public attention as a result of the premature termination of the estrogen–progestogen arm of the Women's Health Initiative (WHI) trial due to increased risk of coronary heart disease and breast cancer.² The estrogen-alone arm of the trial also was discontinued after 7 years of followup because the study found that estrogen alone did not affect (either increase or decrease) heart disease.³ Breast cancer risk was not increased during the study period.³

The median age at the onset of menopause in the United States is 51 years, whereas the average life expectancy for women is 81 years. Thus, American women can expect to be postmenopausal for more than one third of their lives.

Although the age at menarche has declined steadily throughout the centuries, probably as a result of improved nutrition, the age at menopause onset appears to be relatively stable. However, on average, cigarette smokers experience menopause 2 years earlier than do nonsmokers. Women who have undergone hysterectomy also are more likely to have an earlier menopause despite preservation of their ovaries.

Since the publication of the WHI trial results, many women have either stopped or become reluctant to use hormone therapy.⁴ The WHI trial was a chronic disease prevention trial designed to evaluate the role of hormone therapy in reducing the risks of cardiovascular disease in older women and at the same time to investigate the effects on the risk of breast cancer.^{2,3} The trial was conducted in a total of 16,607 mainly asymptomatic women who were an average 12 to 13 years postmenopausal (mean age 63 ± 7.11 years).^{2,3} No randomized controlled clinical trials of the population of women normally targeted for hormone therapy (i.e., symptomatic perimenopausal or early postmenopausal women) have been reported. Although hor-

Learning objectives, review questions,
and other resources can be found at
www.pharmacotherapyonline.com.

hormone therapy is not indicated for prevention of chronic diseases of aging, it remains the most effective treatment for vasomotor symptoms, impaired sleep quality, and urogenital symptoms of menopause. Regulatory authorities expressed major concerns about hormone therapy use following the results of the WHI trial.^{5,6}

Approved indications of postmenopausal hormone therapy include treatment of menopausal symptoms (e.g., hot flashes, night sweats, and urogenital atrophy) and osteoporosis prevention.⁵ Although it has been proposed that hormone therapy should be prescribed at the lowest possible dose for the shortest possible time,⁵ evidence that new low-dose regimens are safer than traditionally prescribed doses is lacking. Weighing the risks and benefits, the Food and Drug Administration (FDA) mandated the addition of new safety warnings to the labels of all systemic estrogens (regardless of route or dosage form), including estrogen-only and combined estrogen-progestogen products.⁶ The labels now caution that use of estrogen-containing hormone therapy regimens by postmenopausal women may be associated with an increased risk of myocardial infarction, stroke, breast cancer, and thromboembolism.⁶

MENOPAUSE AND PERIMENOPAUSAL AND POSTMENOPAUSAL HORMONE THERAPY

PHYSIOLOGY

Characteristics of the human menstrual cycle throughout reproductive life are well described.⁷ A woman is born with approximately two million primordial follicles in her ovaries. During a normal reproductive life span, she ovulates fewer than 500 times. The vast majority of follicles undergo atresia.

The hypothalamic-pituitary-ovarian axis dynamically controls reproductive physiology throughout the reproductive years. The pituitary is regulated by pulsatile secretion of gonadotropin-releasing hormone (GnRH) from the hypothalamus. Follicle-stimulating hormone (FSH) and luteinizing hormone (LH), produced by the pituitary in response to GnRH, regulate ovarian function. These gonadotropins also are influenced by negative feedback from estradiol and progesterone. Ovarian follicular activity is reflected by the circulating concentrations of sex steroids and by peptide hormones (e.g., inhibin and activin). The sex steroids include estradiol, produced by the dominant follicle; progesterone, produced by the corpus luteum after maturation of the dominant ovarian follicle; and androgens, primarily testosterone and androstenedione, secreted by the ovarian stroma. Sex steroids are important for the healthy functioning of many organs, including the bones, brain, skin, and reproductive and urogenital tracts. They act primarily by regulating gene expression.

Pathophysiologic changes associated with menopause are caused by loss of ovarian follicular activity.¹ Ovarian primordial follicle numbers decrease with advancing age, and at the time of the menopause, few follicles remain in the ovary. Hence the postmenopausal ovary is no longer the primary site of estradiol or progesterone synthesis. The postmenopausal ovary secretes primarily androstenedione and testosterone. In contrast to the acute fall in circulating estrogen at the time of menopause, the decline in circulating androgens commences in the decade leading up to the average age of natural menopause and closely parallels increasing age.⁸ Androgens are secreted by both the ovaries and the adrenal glands. Following menopause, direct ovarian androgen secretion appears to account for as much as 50% of testosterone production, with the adrenal gland being a less important source. Hypertrophy of the ovarian stroma may develop after menopause, probably secondary to high LH concentrations, thereby resulting in increased ovarian testosterone production. Alternatively, the ovaries may become fibrotic and a poor source of sex steroids.

No endocrine event clearly signals the time just prior to final menses.⁹ Nonetheless, as women age, a progressive rise in circulating FSH¹⁰ and a concomitant decline in ovarian inhibin⁹ are observed. In women who continue to experience menstrual bleeding, FSH determinations on day 2 or 3 of the menstrual cycle are considered elevated when concentrations exceed 10 to 12 international units/L, an indication of diminished ovarian reserve. Clear elevations in serum FSH are seen in women at age approximately 40 years.⁹ When ovarian function has ceased, serum FSH concentrations are greater than 40 international units/L.

The perimenopause is the period immediately prior to the menopause and the first year after menopause. The menopausal transition is the period of time when the endocrinologic, biologic, and clinical features of the approaching menopause commence.⁹ The menopausal transition usually begins approximately 4 years prior to menopause and is characterized by menstrual cycle irregularity caused by increased frequency of anovulatory cycles. Vasomotor symptoms (hot flashes and night sweats), psychological symptoms (anxiety, mood swings, and depression), and disturbances of sexuality are increased markedly in the perimenopause. Menopause is characterized by a 10- to 15-fold increase in circulating FSH concentrations compared with concentrations of FSH in the follicular phase of the cycle, a fourfold to fivefold increase in LH, and a greater than 90% decrease in circulating estradiol concentrations.⁹ During the perimenopause, FSH concentrations may rise to the postmenopausal range during some cycles but return to premenopausal levels during subsequent cycles. Thus, high concentrations of FSH should not be used to diagnose menopause in perimenopausal women. However, vasomotor symptoms in perimenopausal women may require treatment despite the presence of menstrual bleeding. Abnormal thyroid function and other conditions that may cause similar symptomatology should be excluded first. Dysfunctional uterine bleeding may occur during the perimenopausal years because of anovulatory cycles, but other gynecologic causes also should be considered. Treatment options for dysfunctional uterine bleeding include progestogens or low-dose oral contraceptives.

An observational study of more than 9,000 postmenopausal women examined the relationship between endogenous estrogens and bone mineral density, bone loss, fractures, and breast cancer.^{11–14} Women with detectable serum estradiol concentrations (5–25 pg/mL) had a 6% to 7% higher bone mineral density at the total hip and spine compared with women with undetectable levels (less than 5 pg/mL).¹¹ They also had significantly less bone loss at the hip than women with undetectable levels.¹² Women with undetectable serum estradiol concentrations had a relative risk of 2.5 for subsequent hip and vertebral fractures.¹³ However, women with the highest estradiol serum concentrations had the greatest risk of developing breast cancer.¹⁴

CLINICAL PRESENTATION OF PERIMENOPAUSE AND MENOPAUSE

Symptoms

- Vasomotor symptoms (hot flashes and night sweats)
- Sleep disturbances
- Mood changes
- Sexual dysfunction
- Problems with concentration and memory
- Vaginal dryness and dyspareunia

Signs

- *Perimenopause:* Dysfunctional uterine bleeding as a result of anovulatory cycles (other gynecologic disorders should be excluded)
- *Menopause:* Signs of urogenital atrophy

Laboratory Tests

- *Perimenopause*: FSH on day 2 or 3 of the menstrual cycle greater than 10–12 international units/L
- *Menopause*: FSH greater than 40 international units/L

Other Relevant Diagnostic Tests

- Thyroid function tests
- Iron stores

CLINICAL PRESENTATION OF MENOPAUSE

Vasomotor symptoms, hot flashes, and night sweats are common symptoms of estrogen withdrawal. Hot flashes are the classic sign of menopause and the major clinical complaint of American women during the perimenopausal and early menopausal years. Hot flashes are a sensation of warmth, frequently accompanied by skin flushing and perspiration. A chill may follow as the core body temperature drops. Hot flashes may occur in women of any age who experience acute estrogen withdrawal. They can be occasional or frequent, can last from seconds to 1 hour, and are characterized by symptoms ranging from mild warmth to profuse sweating. For some women, hot flashes are a minor nuisance, but for other women, they are a disturbing symptom that disrupts their sense of well-being and causes problems in their social and professional lives. They usually occur spontaneously but often are increased in frequency or severity in hot or humid weather or after ingestion of caffeine, alcohol, or spicy foods. The prevalence of hot flashes is higher in the first 2 postmenopausal years. Women who have undergone surgical menopause tend to have more intense menopausal symptoms than those who experience a natural menopause.

Vaginal dryness is directly related to estrogen insufficiency, but some women can find adequate relief from nonestrogenic vaginal creams. Most women with significant vaginal dryness require local or systemic estrogen therapy to replenish moisture. Vaginal dryness should be differentiated from lack of lubrication during sexual stimulation. The latter is an impaired arousal response and may not improve with simple vaginal estrogen therapy.

Although some accept a range of other symptoms to be typical of estrogen deficiency (e.g., mood swings, tiredness, poor concentration, depression, insomnia, migraines, formication, arthralgia, myalgia, and urinary frequency), the relationship between these symptoms and the absolute decline in estrogen is more controversial. Many women, nonetheless, experience relief of such symptoms with estrogen therapy.

TREATMENT**Menopause**

Postmenopausal hormone therapy is a subject of major interest in the field of women's health. In some women, menopausal symptoms can be managed effectively with lifestyle modifications, including exercise, weight control, smoking cessation, and a healthful diet. More recently, however, dietary supplements and nonpharmacologic therapies have been promoted as “complementary medicine” alternatives to hormone therapy. To date, little evidence supports the use of such nonprescription products, which include various herbal remedies and soy-based supplements.

PHYTOESTROGENS

Phytoestrogens have physiologic effects in humans.¹⁵ They are plant compounds with estrogen-like biologic activity and relatively weak estrogen receptor-binding properties. Epidemiologic studies suggest

that consumption of a phytoestrogen-rich diet, which is common in traditional Asian societies, is associated with a lower risk of breast cancer.¹⁶

The biologic potencies of phytoestrogens vary. Most of these compounds are nonsteroidal and are less potent than synthetic estrogens. The three main classes of phytoestrogens are isoflavones, lignans, and coumestans, all of which are found in plants or their seeds.¹⁵ The most commonly studied phytoestrogen is the isoflavone class. Genistein and daidzein are the most abundant active components of isoflavones. The concentration of isoflavones per gram of soy protein varies considerably among preparations. Also, a single plant often contains more than one class of phytoestrogen. Common food sources of phytoestrogens include soybeans (isoflavones), cereals, oilseeds such as flaxseed (lignans), and alfalfa sprouts (coumestans).

Mild estrogenic effects have been seen in postmenopausal women,¹⁵ but current data suggest that phytoestrogen supplementation is no more effective than placebo in relieving hot flashes or other symptoms of menopause in postmenopausal women.¹⁷

Phytoestrogens decrease low-density lipoprotein (LDL) cholesterol and triglyceride concentrations with no significant change in high-density lipoprotein (HDL) cholesterol concentrations.¹⁸ Furthermore, phytoestrogens have the ability to inhibit LDL oxidation and normalize vascular reactivity in estrogen-deprived primates.¹⁸ In addition, bone density may be improved by phytoestrogens.¹⁵ Common adverse effects include constipation, bloating, and nausea.¹⁹

Larger, long-term studies are needed to document the effects of phytoestrogens on the breast, bone, and endometrium. Furthermore, differences among classes of phytoestrogens must be identified clearly, including dosing and biologic activity, before phytoestrogens can be considered an alternative to conventional hormone therapy in postmenopausal women.

Black cohosh (*Cimicifuga racemosa*), a widely used herbal supplement, may not offer substantial benefits for relief of vasomotor symptoms as suggested by earlier trials.²⁰ This substance does not appear to have strong intrinsic estrogenic properties but may act through the serotonergic system. Long-term effects of black cohosh are unknown.

HORMONAL REGIMENS

Approved indications of hormone therapy include treatment of menopausal symptoms and osteoporosis prevention. Therapy directed at menopausal symptoms, such as hot flashes, often is short term. However, therapy directed at prevention of osteoporosis should be long term. For osteoporosis prevention, the advantages of hormone therapy must be weighed against the risks, including thrombosis and the increased incidence of cardiovascular disease and breast cancer,² and consideration should be given to approved nonestrogen alternatives.

In women with an intact uterus, hormone therapy consists of an estrogen plus a progestogen. In women who have undergone hysterectomy, estrogen therapy is given unopposed by a progestogen.

The WHI randomized controlled trial was a chronic disease prevention trial designed to evaluate the role of hormone therapy in diseases of aging.^{2,3} The continuous combined oral estrogen-progestogen arm of the WHI trial was terminated prematurely. This arm included 16,608 relatively healthy postmenopausal women aged 50 to 79 years at enrollment (mean age 63.2 years). The primary outcome was coronary heart disease events, defined as nonfatal myocardial infarction and coronary artery disease death, with invasive breast cancer as the primary adverse outcome.² The study also examined secondary outcomes, including stroke, thromboembolic disease, fractures, colon cancer, and endometrial cancer.² After a mean followup of 5.2 years (planned duration 8.5 years), the Data and Safety Monitoring Board recommended stopping this arm of the trial because of the occurrence of a prespecified level of invasive breast

cancer. That is, women who received the active drug had an increased risk of invasive breast cancer (hazard ratio [HR] 1.26, 95% confidence interval [CI] 1–1.59), and the overall risks exceeded benefits.² The study also found increased coronary disease events (HR 1.29, 95% CI 1.02–1.63), stroke (HR 1.41, 95% CI 1.07–1.85), and pulmonary embolism (HR 2.13, 95% CI 1.39–3.25). Beneficial effects included decreases in hip fracture (HR 0.66, 95% CI 0.45–0.98) and colorectal cancer (HR 0.63, 95% CI 0.43–0.92).² Results from this study indicated that short-term use (<1 year) has risks for coronary heart disease and thromboembolic disease events. The number of deaths was similar among the groups.

After a mean followup of 7 years, the Data and Safety Monitoring Board also recommended stopping the oral estrogen-alone arm of the study. This arm consisted of 10,739 women who had undergone hysterectomy. Estrogen-only therapy had no effect on coronary heart disease risk and was not associated with increased breast cancer risk.³

Among women in the estrogen–progestogen arm, one serious adverse event occurred in every 100 women treated for 5 years. Specifically, the study suggested that for every 10,000 women taking combined hormone therapy, there would be eight more cases of breast cancer, seven more cases of myocardial infarctions, eight more cases of stroke, and eight more cases of pulmonary embolism. However, six fewer colorectal cancers and five fewer hip fractures would be expected.² For the majority of women who had never used hormone therapy before enrolling in the study (6,280 treated with estrogen–progestogen and 6,024 treated with placebo), the HR for breast cancer was 1.06 (95% CI 0.81–1.38), indicating that the burden of risk for breast cancer resulted from use of hormone therapy for more than 5 years. Subsequently, a large epidemiologic study reported a greater risk estimate for combined estrogen–progestogen use as well as increased risk for estrogen-only therapy and tibolone.²¹ However, interpretation of these findings is limited by selection bias because the risk profiles of women who used hormone therapy were significantly different from the those of nonusers.²¹ Whether the type of estrogen compound or the dose, route, or administration method could be at least partly responsible for the risks observed in the WHI trial is unclear.

■ ESTROGEN AND PROGESTOGEN TREATMENT

Estrogens

① The primary accepted indication for estrogen-based hormone therapy is the relief of vasomotor symptoms, and the initial dose

should be the lowest effective dose for symptom control. Estrogens are naturally occurring hormones or synthetic steroidal or nonsteroidal compounds with estrogenic activity. Various systemically administered estrogens (typically oral and transdermal) are suitable for replacement therapy (Table 85–1). Estrogens can be administered orally, transdermally (patches and other topical products), intravaginally (creams, tablets, or rings), intranasally, intramuscularly, and even subcutaneously in the form of implanted pellets. The choice of estrogen delivery (product, route, and method) should be determined in consultation with the patient to ensure acceptability and enhance compliance. In general, the oral and transdermal routes are used most frequently, with oral conjugated equine estrogens (CEE) particularly popular in the United States. No evidence indicates that one estrogen compound is more effective than another in relieving menopausal symptoms or preventing osteoporosis.

Oral Estrogen Oral CEE has been available for more than 50 years. CEE is prepared from the urine of pregnant mares and is composed of estrone sulfate (50%–60%) and multiple other equine estrogens such as equilin and 17 α -dihydroequilin.²²

Estradiol is the predominant and most active form of endogenous estrogens. A micronized form of estradiol (produced by a technique that yields extremely small particles of the pure hormone) is readily absorbed from the small intestines.²² When given orally, estradiol is metabolized by the intestinal mucosa and the liver during the first hepatic passage, and only 10% reaches the circulation as free estradiol. Metabolism of estrogen is partly mediated by the cytochrome P450 3A4 isoenzyme. Gut and liver metabolism converts a large proportion of estradiol to the less potent estrone. Thus, measurement of serum estradiol is not useful for monitoring oral estrogen replacement. The principal metabolites of micronized estradiol are estrone and estrone sulfate. Administration of estradiol via the oral route results in estrone concentrations that are three to six times those of estradiol. Ethinyl estradiol is a highly potent semisynthetic estrogen that has similar activity following administration by the oral or parenteral route.

Orally administered estrogens stimulate the synthesis of hepatic proteins and increase the circulating concentrations of sex hormone-binding globulin, which, in turn, may compromise the bioavailability of androgens and estrogens.

Other Routes Parenteral estrogens (including transdermal, intranasal, and vaginal) bypass the gastrointestinal tract and thereby avoid first-pass liver metabolism. Parenteral routes of estrogen delivery result in a more physiologic estradiol-to-estrone ratio (estradiol con-

TABLE 85-1 Selected Systemic Estrogen Products^{a,b}

Estrogen	Dosage Strength	Comments
Oral estrogens		
Conjugated equine estrogens	0.3, 0.45, 0.625, 0.9, 1.25 mg	Orally administered estrogens stimulate synthesis of hepatic proteins and increase circulating concentrations of sex hormone-binding globulin, which, in turn, may compromise the bioavailability of androgens and estrogens
Synthetic conjugated estrogens	0.3, 0.45, 0.625, 0.9, 1.25 mg	
Esterified estrogens	0.3, 0.625, 1.25, 2.5 mg	
Estropipate (piperazine estrone sulfate)	0.625, 1.25, 2.5, 5 mg	
Micronized estradiol	0.5, 1, 1.5, 2 mg	
Estradiol acetate	0.45, 0.9, 1.8 mg	
Parenteral estrogens		
Transdermal 17β-estradiol (patch)	14, 25, 37.5, 50, 60, 75, 100 mcg per 24 h	Women with elevated triglyceride concentrations or significant liver function abnormalities may benefit from parenteral therapy
Estradiol vaginal ring	0.05, 0.1 mg per 24 h (replaced every 3 months)	Single approved dose is 8.7 mg of estradiol hemihydrate per day (two pouches)
Estradiol topical emulsion	4.35 mg of estradiol hemihydrate per foil-laminated pouch	Apply to skin once daily
Estradiol topical gel	0.25 to 1 mg of estradiol per dose	Spray on inner surface of forearm once daily
Estradiol topical solution	1.53 mg of estradiol per spray	
Intranasal estradiol ^c	One spray per nostril delivers 150 mcg	

^aSystemic oral and transdermal estrogen and progestogen combination products are available in the United States.

^bSystemic oral estrogen and androgen combination products are available in the United States.

^cNot available in the United States.

TABLE 85-2 Estrogen for Treatment of Menopausal Symptoms and Osteoporosis Prevention

Regimen	Standard Dose	Low Dose	Route	Frequency
Conjugated equine estrogens	0.625 mg	0.3 or 0.45 mg	Oral	Once daily
Synthetic conjugated estrogens	0.625 mg	0.3 mg	Oral	Once daily
Esterified estrogens	0.625 mg	0.3 mg	Oral	Once daily
Estropipate (piperazine estrone sulfate)	1.5 mg	0.625 mg	Oral	Once daily
Ethinyl estradiol	5 mcg	2.5 mcg	Oral	Once daily
Micronized 17 β -estradiol	1–2 mg	0.25–0.5 mg	Oral	Once daily
Transdermal 17 β -estradiol	50 mcg	25 mcg	Transdermal (patch)	Once or twice weekly
Intranasal 17 β -estradiol ^a	150 mcg per nostril	—	Intranasally	Once daily
Implanted 17 β -estradiol	50–100 mcg pellets	25-mg pellets	Pellets implanted subcutaneously	Every 6 months
Percutaneous 17 β -estradiol	0.04 mg (gel) 0.05 mg (emulsion)		Transdermal (emulsion, gel)	Once daily

^aNot available in the United States.

centrations greater than estrone concentrations), as seen in the normal premenopausal state. Parenteral estrogen therapy also is less likely to affect sex hormone-binding globulin compared with oral therapy. Parenteral regimens produce little or no change in circulating lipids, coagulation parameters, or C-reactive protein levels.²³

Transdermal estrogens share the advantages of other parenteral estrogen routes. Transdermal systems have the added advantage of delivering estradiol to the general venous circulation at a continuous rate. Reactions at the application site occur in approximately 10% of women who use reservoir (alcohol-based) patches. The newer matrix systems (estrogen in adhesive) generally are better tolerated, and fewer than 5% of women experience skin reactions.²⁴ The incidence of skin irritation diminishes when the application site is rotated. Topical antiinflammatory products can be applied for managing the rashes, and switching to another transdermal patch is often a viable option.

Percutaneous preparations (gels, creams, and emulsions) are convenient, but variability in drug absorption is common. This form of estrogen is used for systemic therapy. Topical emulsion and gel formulations are approved for use in the United States.

Estradiol pellets (implants) containing pure crystalline 17 β -estradiol have been available for more than 50 years. They are inserted subcutaneously into the anterior abdominal wall or buttock. Pellets are difficult to remove and may continue to release estradiol for a long time after insertion. Implantation should not be repeated until serum estradiol concentrations have fallen to values similar to those at the midfollicular phase of the menstrual cycle. Estradiol pellets have not gained popularity in the United States.

Intranasal 17 β -estradiol spray, which enables single-daily or twice-daily dosing, has been shown to have clinical therapeutic equivalence to oral and transdermal estradiol and is associated with significantly lower reports of mastalgia.²⁵

Vaginal creams, tablets, and rings are used for treatment of urogenital (vulval and vaginal) atrophy. However, this route of administration can have more than just a local effect. Systemic estrogen absorption is lower with the vaginal tablets and rings (specifically Estring) compared with the vaginal creams. Nonetheless, local application of the cream at low doses can reverse atrophic vaginal changes and avoid significant systemic exposure. Nonestrogen vaginal moisturizers and lubricants also may provide local symptom relief. These products can be used alone or in combination with locally acting vaginal estrogens. Vaginal rings are a sustained-release delivery system composed of a biologically inert liquid polymer matrix with pure crystalline estradiol that can maintain adequate estradiol concentrations. One such vaginal ring product (Femring) is designed to achieve systemic concentrations of estrogen and is indicated for treatment of moderate-to-severe vasomotor symptoms.

The standard dose of estrogen previously believed to be effective in alleviating vasomotor symptoms is equivalent to 0.625 mg CEE,²⁶ but new evidence indicates that lower doses of estrogen also are

effective in controlling postmenopausal symptoms and reducing bone loss (Table 85–2).^{27–30} Even ultralow doses of 17 β -estradiol delivered by a vaginal ring (Estring) improved serum lipid profiles and prevented bone loss in elderly women.³¹ In general, if adverse effects such as breast tenderness occur with initial doses, lowering the dose may resolve the problem and improve patient compliance. Alternatively, if vasomotor symptoms are not controlled adequately with a lower-dose regimen, increasing the estrogen dose may be a reasonable option.

Adverse Effects Common adverse effects of estrogen include nausea, headache, breast tenderness, and heavy bleeding. More serious adverse effects include increased risk for coronary heart disease, stroke, venous thromboembolism, breast cancer, and gallbladder disease.

Initiating therapy with low doses of estrogen often will minimize breast tenderness, unscheduled bleeding, and potentially other adverse effects. Transdermal estrogen is less likely than oral estrogen to cause nausea and headache. Also, transdermal estrogen is associated with a lower incidence of breast tenderness and deep-vein thrombosis than is oral estrogen.^{32,33} In many cases changing from one estrogen regimen to another can alleviate certain adverse effects.

Progestogens

2 Because of the increased risk of endometrial hyperplasia and endometrial cancer with estrogen monotherapy (unopposed estrogen), women who have not undergone hysterectomy should be treated concurrently with a progestogen in addition to the estrogen.³⁴ Progestogens reduce nuclear estradiol receptor concentrations, suppress DNA synthesis, and decrease estrogen bioavailability by increasing the activity of endometrial 17-hydroxysteroid dehydrogenase, an enzyme responsible for converting estradiol to estrone.³⁵

Several progestogen regimens designed to prevent endometrial hyperplasia are available (Table 85–3). Progestogens must be taken for a sufficient period of time during each cycle. A minimum of 12 to 14 days of progestogen therapy each month is required for complete protection against estrogen-induced endometrial hyper-

TABLE 85-3 Progestogen Doses for Endometrial Protection (Oral Cyclic Administration)

Progestogen	Dose
Dydrogesterone ^a	10–20 mg for 12–14 days per calendar month
Medroxyprogesterone acetate	5–10 mg for 12–14 days per calendar month
Micronized progesterone	200 mg for 12–14 days per calendar month
Norethisterone ^a	0.7–1 mg for 12–14 days per calendar month
Norethindrone acetate	5 mg for 12–14 days per calendar month
Norgestrel ^a	0.15 mg for 12–14 days per calendar month
Levonorgestrel ^a	150 mcg for 12–14 days per calendar month

^aNot available in a progestogen-only oral dosage form in the United States.

plasia.³⁶ Of note, use of even low-dose estrogen, including some vaginal preparations, requires progestogen coadministration for endometrial protection in women with an intact uterus.³⁷ However, rarely is progestogen administration needed in women who have undergone hysterectomy.

Four combination estrogen and progestogen regimens currently in use are continuous-cyclic (sequential), continuous-combined, continuous long-cycle (or cyclic withdrawal), and intermittent-combined (or continuous-pulsed) hormone therapy.³⁸ The latter two were introduced during the past decade. Sequential hormone therapy results in scheduled vaginal withdrawal bleeding but often is scant or completely absent in older women. For many women, the scheduled withdrawal bleeding is one of the main reasons for avoiding or discontinuing hormone therapy. Because there is no physiologic need for bleeding, new hormone therapy regimens that reduce monthly bleeding (e.g., continuous long-cycle regimens) or prevent monthly bleeding (e.g., continuous-combined and intermittent-combined regimens) have been developed. Various hormone therapy regimens that combine an estrogen and a progestogen are available (Table 85-4).

The first generation of progestogens included the C-19 androgenic progestogens norethisterone, norgestrel, and levonorgestrel. More recent preparations have included the C-21 progestogens dydrogesterone and medroxyprogesterone acetate, which are less androgenic. Drospirenone, a synthetic progestogen analog of the potassium-sparing diuretic spironolactone, has both antiandrogenic and antialdosterone properties. Micronized progesterone also has become available for use in postmenopausal women. The most commonly used oral progestogens are medroxyprogesterone acetate, micronized progesterone, and norethisterone acetate. The latter now can be administered transdermally in the form of a combined estrogen-progestogen patch.

Adverse Effects Common adverse effects of progestogens include irritability, depression, and headache. Changing from a cyclic to a continuous-combined regimen or changing from one progestogen to another may decrease the incidence or severity of untoward effects. Adverse effects of progestogens are difficult to evaluate and can vary with the agent administered. Some women experience “premenstrual-like” symptoms, such as mood swings, bloating, fluid reten-

tion, and sleep disturbance. New methods and routes of progestogen delivery (e.g., parenterally by an intranasal spray or locally by an intrauterine device that releases levonorgestrel or a progesterone-containing bioadhesive vaginal gel) may be associated with fewer adverse effects. Women who are unable to tolerate a progestogen may be given unopposed estrogen if they are informed of the significant increased risk for endometrial cancer and have endometrial biopsy annually or whenever breakthrough vaginal bleeding occurs.

Methods of Estrogen and Progestogen Administration

Continuous Cyclic Estrogen/Progestogen (Sequential) Treatment

Estrogen typically is administered continuously (daily). A progestogen is coadministered with the estrogen for at least 12 to 14 days of a 28-day cycle.³⁶ The progestogen causes scheduled withdrawal bleeding in approximately 90% of women. With this regimen, bleeding usually begins 1 to 2 days after the last progestogen dose. Occasionally, bleeding begins during the latter phase of progestogen administration.

Continuous Combined Estrogen-Progestogen Treatment

Continuous-combined estrogen-progestogen administration results in endometrial atrophy and the absence of vaginal bleeding. However, initially it causes unpredictable spotting or bleeding, which usually resolves within 6 to 12 months. Decreasing the estrogen dose or increasing the progestogen dose usually decreases or stops the spotting. Occasionally, a drug-free period of 1 or 2 weeks is useful to stop the bleeding.

Women who recently have undergone menopause have a higher risk for excessive, unpredictable bleeding while receiving continuous therapy; thus, this regimen is best reserved for women who are at least 2 years postmenopause. Continuous-combined hormone therapy is more acceptable than traditional cyclic therapy.

Continuous Long-Cycle Estrogen-Progestogen Treatment

To decrease the incidence of uterine bleeding, a modified sequential regimen has been developed.³⁸ In the continuous long-cycle (or cyclic-withdrawal) estrogen-progestogen regimen, estrogen is given daily, and progestogen is given six times per year, every other month for 12 to 14 days, resulting in six periods per year. Bleeding episodes may be heavier and last for more days than withdrawal bleeding with continuous-cyclic regimens. The effect of continuous long-cycle estrogen-progestogen treatment on endometrial protection is unclear.

Intermittent Combined Estrogen-Progestogen Treatment

The intermittent combined estrogen-progestogen regimen, also called *continuous-pulsed estrogen-progestogen* or *pulsed-progestogen*, consists of 3 days of estrogen therapy alone, followed by 3 days of combined estrogen and progestogen, which is then repeated without interruption.³⁸ This regimen is designed to lower the incidence of uterine bleeding. It is based on the assumption that pulsed-progestogen administration will prevent downregulation of progesterone receptors that can be produced by continuous-combined regimens. The lower progestogen dose induces fewer side effects and can be better tolerated. The long-term effect of intermittent-combined regimens in endometrial protection is undetermined.

TABLE 85-4 Common Combination Postmenopausal Hormone Therapy Regimens

Regimen	Doses
Oral continuous-cyclic regimens	
CEE + MPA ^a	0.625 mg + 5 mg; 0.625 mg + 10 mg
Oral continuous-combined regimens	
CEE + MPA	0.625 mg + 2.5 mg; 0.625 mg + 5 mg; 0.45 mg + 2.5 mg; 0.3 mg + 1.5 mg/day
17β-Estradiol + NETA	1 mg + 0.1 mg; 1 mg + 0.25 mg; 1 mg + 0.5 mg/day
Ethinyl estradiol + NETA	1 mcg + 0.2 mg; 2.5 mcg + 0.5 mg; 5 mcg + 1 mg; 10 mcg + 1 mg/day
Transdermal continuous-cyclic regimens	
17β-Estradiol + NETA ^a	50 mcg + 0.14 mg; 50 mcg + 0.25 mg
Transdermal continuous-combined regimens	
17β-Estradiol + NETA	50 mcg + 0.14 mg; 50 mcg + 0.25 mg; 25 mcg + 0.125 mg

CEE, conjugated equine estrogens; MPA, medroxyprogesterone acetate; NETA, norethindrone acetate.

Other oral (drospirenone and norgestimate) and transdermal (levonorgestrel) progestogens also are available in combination with an estrogen.

^aEstrogen alone for days 1–14, followed by estrogen-progestogen on days 15–28.

CLINICAL CONTROVERSY

Although some clinicians believe that estrogen can be used safely at lower doses to treat postmenopausal women with severe and protracted vasomotor symptoms, others caution that such long-term therapy, even with lower doses of estrogen, may be associated with unacceptable risks.

Low-Dose Hormone Therapy

③ Increasingly, it has become recognized that use of hormone therapy at doses lower than prescribed historically is effective in the management of menopausal symptoms (see Table 85–2). The Women's Health, Osteoporosis, Progestin, Estrogen (HOPE) trial demonstrated equivalent symptom relief and bone density preservation without an increase in endometrial hyperplasia using lower doses of hormone therapy (CEE 0.45 mg/day and medroxyprogesterone acetate 1.5 mg/day).^{27–31} Whether lower doses of estrogen will be safer (lower incidence of venous thromboembolism and breast cancer) remains to be proven. Nonetheless, evidence of harm associated with a standard dose of hormone therapy^{2,3} has prompted many patients to either discontinue such therapy or taper to lower doses.

■ ANDROGENS

Pathophysiologic states affecting ovarian and adrenal function, along with aging, have been associated with androgen deficiency in women.³⁹ Therapeutic use of testosterone in women, although controversial, is becoming more widespread despite the lack of accurate clinical or biochemical findings of androgen deficiency.³⁹ Androgens have important biologic effects in women, acting both directly via androgen receptors in tissues, such as bone, skin fibroblasts, hair follicles, and sebaceous glands, and indirectly via the aromatization of testosterone to estrogen in the ovaries, bone, brain, adipose tissue, and other tissues.

A cluster of symptoms that characterizes androgen insufficiency in women, manifested as diminished sense of well-being, persistent or unexplained fatigue, and sexual function changes such as decreased libido, decreased sexual receptivity, and decreased pleasure, has been reported.³⁹ However, studies designed to evaluate this have shown no relationships between serum total and free testosterone levels and either sexual function⁴⁰ or well-being⁴¹ in women. Thus, as data supporting an androgen deficiency syndrome are lacking, in 2006 the American Endocrine Society recommended against making a diagnosis of androgen deficiency in women at the present time.⁴⁰ Evidence of short-term efficacy of testosterone is seen in selected populations, such as surgically menopausal women.⁴² Studies with adequate followup are necessary to assess long-term safety and efficacy of androgen therapy in women.

Absolute contraindications to androgen therapy include pregnancy or lactation and known or suspected androgen-dependent neoplasia. Relative contraindications include concurrent use of CEEs (for parenteral testosterone therapy), low sex hormone-binding globulin level, moderate-to-severe acne, clinical hirsutism, and androgenic alopecia.

Adverse effects from excessive dosage include virilization, fluid retention, and potentially adverse lipoprotein lipid effects, which are more likely with oral administration.

Testosterone is available as oral methyltestosterone in the United States and as testosterone implants in the United Kingdom. Of the available oral preparations, methyltestosterone in combination with esterified estrogen (either 0.625 mg esterified estrogen plus 1.25 mg methyltestosterone or 1.25 mg esterified estrogen plus 2.5 mg methyltestosterone) is the most widely studied.

Testosterone replacement for women is available in a variety of formulations (Table 85–5). Most of the earlier studies showing clinical improvement with testosterone therapy reported supraphysiologic levels. More recent studies using transdermal patch therapy have shown efficacy with free testosterone levels in the upper normal range for young women. The availability of testosterone regimens specifically designed for women has the potential to maintain testosterone levels within the normal range and help to clarify whether the apparent beneficial effects of testosterone therapy are physiologic or pharmacologic.^{42,43} In general, testosterone treatment should not be administered to postmenopausal women who are not receiving concurrent estrogen therapy until completion of studies on the use of testosterone without estrogen. At present, generalized use of testosterone is not recommended because the indications are inadequate, and evidence from long-term studies evaluating safety is lacking.⁴⁴

■ SELECTIVE ESTROGEN RECEPTOR MODULATORS

Selective estrogen receptor modulators (SERMs) are a group of nonsteroidal compounds that are chemically distinct from estradiol. They act as estrogen agonists in some tissues, such as bone, and as estrogen antagonists in other tissues, such as breast, through specific, high-affinity binding to the estrogen receptor.

The ideal SERM would protect against osteoporosis and decrease the incidence of breast, endometrial, and colorectal cancer and coronary heart disease without exacerbating menopausal symptoms or increasing the risk of venous thromboembolism or gallbladder disease. To date, no SERM meets these ideals. Tamoxifen, the first-generation SERM (a nonsteroidal triphenylethylene derivative), has estrogen antagonist activity on the breast and estrogen-like agonist activity on bone and endometrium. The second generation of SERMs, most notably raloxifene (a nonsteroidal benzothiophene derivative), has become available for prevention of osteoporosis. Raloxifene does not alleviate, and may even exacerbate, vasomotor symptoms.

Raloxifene decreases bone loss in recently menopausal women without affecting the endometrium and has estrogen-like actions on lipid metabolism.⁴⁵ Raloxifene generally is well tolerated. Its adverse effects include leg cramps and hot flashes.

The Multiple Outcomes of Raloxifene Evaluation (MORE), a multicenter randomized, blinded, placebo-controlled trial, showed that raloxifene increases bone mineral density in the spine and femoral neck and reduces the risk of vertebral fractures.⁴⁵ More important, the same study⁴⁶ and the Continuing Outcomes Relevant to Evista (CORE) trial⁴⁷ suggest that raloxifene use is associated with a significantly lower incidence of breast cancer compared with placebo. This benefit is primarily due to a reduced risk of estrogen receptor-positive invasive breast cancers.^{47,48} A prospective randomized study (Raloxifene Use for the Heart [RUTH]) of 10,101 postmenopausal women (mean age 67.5 years) with coronary heart disease or multiple risk factors for coronary heart disease showed that raloxifene did not significantly affect the risk of coronary heart disease.⁴⁸ Nonetheless, raloxifene use increases the risk of venous thromboembolism^{45–48} and stroke⁴⁸ to a degree similar to that of oral estrogen.

TABLE 85-5 Androgen Regimens Used for Women

Regimen	Dose	Frequency	Route
Methyltestosterone in combination with esterified estrogen	1.25–2.5 mg	Daily	Oral
Mixed testosterone esters	50–100 mg	Every 4–6 weeks	Intramuscular
Testosterone pellets	50 mg	Every 6 months	Subcutaneous (implanted)
Transdermal testosterone system ^a	150–300 mcg/day	Every 3–4 days	Transdermal patch
Nandrolone decanoate	50 mg	Every 8–12 weeks	Intramuscular

^aUndergoing clinical trials in the United States.

■ TIBOLONE

Tibolone is a gonadomimetic synthetic steroid in the norpregnane family with combined estrogenic, progestogenic, and androgenic activity.⁴⁹ Tibolone has been used for almost 2 decades in Europe for treatment of menopausal symptoms and prevention of osteoporosis. The hormonal effects of this synthetic steroid depend on its metabolism and activation in peripheral tissues. The parent compound has been described as a prodrug that is metabolized quickly in the gastrointestinal tract. It has several active metabolites, including a $\Delta 4$ -isomer and 3α -OH and 3β -OH compounds.⁴⁹ The $\Delta 4$ -isomer metabolite confers significant progestogenic and androgenic properties. Tibolone has beneficial effects on mood and libido and improves menopausal symptoms and vaginal atrophy. Tibolone protects against bone loss and reduces the risk of vertebral fractures in postmenopausal women with osteoporosis.⁵⁰ Tibolone use in elderly women has been reported to be associated with an increased risk of stroke.⁵⁰

Tibolone reduces concentrations of total cholesterol, triglycerides, and lipoprotein (a) but significantly decreases HDL cholesterol and thus may increase overall cardiovascular risk.²² Long-term safety data are lacking. The Million Women Study, a cohort study, suggested that current users of tibolone may be at increased risk for breast cancer (adjusted relative risk 1.45, 95% CI 1.25–1.68).²¹ This study had multiple limitations, including biased prescribing of tibolone in the community to women at greater risk for breast cancer. The Million Women Study also indicated a greater risk of endometrial cancer (adjusted relative risk 1.79, 95% CI 1.43–2.25).⁵¹ However, other controlled studies contradict this finding and suggest that tibolone has an endometrial safety profile similar to continuous-combined CEE and medroxyprogesterone acetate.⁵²

The major adverse effects of tibolone include weight gain and bloating. Additional studies are necessary to identify the true risk-to-benefit ratio of tibolone with respect to its overall effect on coronary artery disease and breast cancer.

■ TREATMENT CONSIDERATIONS

In the absence of contraindications, hormone therapy is appropriate mainly for women with hot flashes and vulvar or vaginal atrophy.⁵³ It is contraindicated in women with endometrial cancer, breast cancer, undiagnosed vaginal bleeding, coronary heart disease, thromboembolism (including recent spontaneous thrombosis or in the presence of a thrombophilia), stroke or transient ischemic attack, and active liver disease.⁵³ Relative contraindications include uterine leiomyoma, migraine headaches, and seizure disorder. In addition, oral estrogen should be avoided in women with hypertriglyceridemia, liver disease, and gallbladder disease. For these women, transdermal administration is a safer approach. The main reasons for discontinuing hormone therapy are side effects such as bleeding, breast tenderness, bloating, and “premenstrual-like symptoms.” Reducing the dose or changing the regimen or the route of administration can minimize these effects.

Pretreatment Assessment

The initial visit of a perimenopausal or postmenopausal woman is the most appropriate time to obtain a complete medical history, perform a physical examination, and educate the patient. Medical history should include a personal or family history of coronary heart disease and thrombotic problems. The physical examination should include a complete cardiovascular examination, clinical assessment of thyroid status, and breast and pelvic examinations. Papanicolaou cervical cytologic examination and screening mammography negative for malignancy are required before initiating hormone therapy. Thyroid function tests and lipoprotein lipid profile also are performed at the discretion of the clinician.

Each patient should be evaluated for the presence of indications (i.e., menopausal symptoms such as hot flashes or vaginal dryness) and possible contraindications. The risks and benefits of hormone therapy should be discussed with the patient so that she can weigh the risks and benefits versus alternatives and make a rational decision about whether to use hormone therapy.

■ BENEFITS OF HORMONE THERAPY

Relief of Menopausal Symptoms

Vasomotor Symptoms ⁴ The major indication for postmenopausal hormone therapy is management of vasomotor symptoms. Most women with vasomotor symptoms require hormone treatment for fewer than 5 years, so the risk appears to be small.

Fewer than 25% of women experience a menopausal transition without symptoms, whereas more than 25% suffer severe menopausal symptoms, most commonly hot flashes and night sweats.⁵⁴

Without treatment, hot flashes in most women typically disappear within 1 to 2 years, but in some untreated women hot flashes continue for more than 20 years.³² Women with mild vasomotor symptoms often experience relief by lifestyle modification (e.g., wearing layered clothing that can be removed or added as necessary); reduction in intake of hot spicy foods, caffeine, and hot beverages; exercise; and other good general health practices. At least 25% of women in clinical trials reported significant improvement of vasomotor symptoms when taking placebo. However, no therapy has been shown to be as effective as estrogen therapy in alleviating significant vasomotor symptoms. Estrogens diminish hot flashes in most women, and all types and routes of administration of estrogen are equally effective.⁵⁵ A dose-dependent relationship between estrogen administration and suppression of hot flashes is well established. Some women, especially younger women, may require a higher than average dose of estrogen to suppress symptoms. On the other hand, many women with hot flashes at the time of menopause require lower dose of estrogen.⁵⁵ Hormone therapy for menopausal symptoms can be stopped about 2 or 3 years after starting. If treatment can be tapered and stopped within 5 years, no evidence of increased risk of breast cancer is seen.²

Alternatives to estrogen for treatment of hot flashes include tibolone, selective serotonin reuptake inhibitors (e.g., paroxetine, fluoxetine), dual serotonin and noradrenaline reuptake inhibitors (e.g., venlafaxine), medroxyprogesterone acetate, megestrol acetate, clonidine, and gabapentin (Table 85–6).⁵⁶ Progestogens alone may be an option for some women (e.g., those with a history of breast cancer or venous thrombosis), but weight gain, vaginal bleeding, and other adverse effects often limit their use. Tibolone and progestogens cannot be considered nonhormonal agents for treatment of hot flashes in women for whom hormone therapy is contraindicated. For this group of patients, selective serotonin reuptake inhibitors and venlafaxine are considered by some to be a first-line therapy.^{56,57} However, the efficacy of venlafaxine for treatment of hot flashes has not been shown to extend beyond 12 weeks.⁵⁸ Furthermore, in breast cancer patients, evidence suggests that selective serotonin reuptake inhibitors could interfere with metabolism of endocrine therapies, such as tamoxifen.⁵⁹ Clonidine often is effective for symptom control but is not always well tolerated by women.

Randomized, placebo-controlled trials of nonhormonal therapies have been equivocal and have not established the safety and efficacy of herbal remedies, homeopathic treatments, or acupuncture for prevention or treatment of hot flashes.

Vaginal Atrophy Estrogen receptors have been demonstrated in the lower genitourinary tract, and at least 50% of postmenopausal women suffer symptoms of urogenital atrophy caused by estrogen deficiency.⁶⁰ Atrophy of the vaginal mucosa results in vaginal dryness

TABLE 85-6 Alternatives to Estrogen for Treatment of Hot Flashes

Drug	Dose (Oral)	Interval	Comments
Tibolone	2.5–5 mg	Once daily	Tibolone is not recommended during the perimenopause because it may cause irregular bleeding
Venlafaxine	37.5–150 mg	Once daily	Side effects include dry mouth, decreased appetite, nausea, and constipation
Paroxetine	12.5–25 mg	Once daily	12.5 mg is an adequate, well-tolerated starting dose for most women; adverse effects include headache, nausea, and insomnia
Fluoxetine	20 mg	Once daily	Modest improvement seen in hot flashes
Megestrol acetate	20–40 mg	Once daily	Progesterone may be linked to breast cancer etiology; also, there is concern regarding the safety of progestational agents in women with preexisting breast cancer
Clonidine	0.1 mg	Once daily	Can be administered orally or transdermally; drowsiness and dry mouth can occur, especially with higher doses
Gabapentin	900 mg	Divided in three daily doses	Adverse effects include somnolence and dizziness; these symptoms often can be obviated with a gradual increase in dosing

and dyspareunia. Lower urinary tract symptoms include urethritis, recurrent urinary tract infection, urinary urgency, and frequency. Most women with significant vaginal dryness because of vaginal atrophy require local or systemic estrogen therapy for symptom relief. Such treatment also reduces the risk of recurrent urinary tract infections, possibly by modifying the vaginal flora.⁶¹ Vaginal dryness and dyspareunia can be treated with a topical estrogen cream, tablet, or vaginal ring. In clinical trials, topical estrogen appears to be better than systemic estrogen for relieving these symptoms and avoids high levels of circulating estrogen. Concomitant progestogen therapy generally is unnecessary if women are using low-dose micronized 17 β -estradiol. However, regular use of CEE vaginal creams and other products that potentially promote endometrial proliferation in women with an intact uterus requires intermittent progestogen challenges (i.e., for 10 days every 12 weeks). This is an important caveat because vaginal atrophy requires long-term estrogen treatment.⁶¹

Urinary incontinence, which becomes more prevalent with increasing age, usually is not improved by estrogen therapy. In one large clinical trial, estrogen–progestogen therapy actually increased incontinence.⁶²

Osteoporosis Prevention

5 Postmenopausal osteoporosis is a serious age-related disease that affects millions of women throughout the world. The WHI randomized trial was the first study to demonstrate that hormone therapy reduces the risk of fractures at the hip, spine, and wrist.^{2,63} Hip and clinical vertebral fractures are reduced by 34%, and total osteoporotic fractures are reduced by 24%.⁶³ These findings are in agreement with observational data and several meta-analyses of the efficacy of hormone therapy for reducing fractures in postmenopausal women.⁶⁴

Menopause is accompanied by accelerated bone loss, and the central role of estrogen deficiency in postmenopausal osteoporosis is

well established. Osteoporosis is characterized by reduced bone mass associated with architectural deterioration of the skeleton and increased risk for fracture.⁶⁵ Estrogen deficiency results in bone loss through its actions in accelerating bone turnover and uncoupling bone formation from resorption. Annual decrements in bone mass of 3% to 5% are common in the years soon after the menopause, and decrements of 0.5% to 1% are seen after age 65 years.⁶⁶ Estrogen therapy reduces bone turnover and increases bone density in postmenopausal women of all ages. Nonetheless, the protective effect persists as long as the treatment is maintained. With cessation of therapy, postmenopausal bone loss resumes at the same rate as in untreated women. The standard bone-sparing daily estrogen dose is equivalent to 0.625 mg CEE²⁶ (see Table 85–2). Even low doses of estrogen may increase bone mass when they are supplemented with adequate calcium intake.²⁶

Osteoporosis prevention remains an indicated use of estrogen products; however, nonestrogen products, such as raloxifene and bisphosphonates, are as effective as hormone therapy for preventing osteoporosis (Table 85–7). The FDA has withdrawn the “osteoporosis treatment” indication from estrogen products.

Raloxifene decreases the risk of vertebral fracture by 30% to 50%, although it has not been shown to decrease the risk of hip fracture.⁴⁶ The bisphosphonates reduce the risk of both hip and vertebral fractures by 30% to 50%.⁶⁵ Bisphosphonates are analogs of pyrophosphate that inhibit bone resorption. Drugs in this class include alendronate, etidronate, pamidronate, risedronate, tiludronate, and zoledronate. Bisphosphonates have no known impact on the incidence of cardiovascular disease or breast or endometrial cancer. Adverse effects include upper gastrointestinal side effects, especially if not taken properly. A few trials have shown improved bone density over single therapy when a bisphosphonate is combined with estrogen or raloxifene, but no fracture data are available.⁶⁷

Tibolone can prevent bone loss and vertebral fractures in postmenopausal women with osteoporosis.⁵⁰

TABLE 85-7 Alternatives to Hormone Therapy for Osteoporosis Prevention

Drug	Dose	Comments
Raloxifene	60 mg/day	Raloxifene reduces the risk of vertebral fractures. Adverse effects include hot flashes and leg cramps. Slowly increasing the dose of raloxifene may help reduce the incidence and severity of hot flashes.
Tibolone	1.25 mg or 2.5 mg/day	Tibolone prevents bone loss. No data regarding fracture rates are available.
Alendronate	5 mg/day or 35 mg/wk	A 50% reduction in the risk of fractures is observed in women with osteoporosis. In younger postmenopausal women without osteoporosis, therapy with alendronate protected all women from bone loss for up to 4 years. Side effects include upper gastrointestinal symptoms, especially if the drug is not taken as directed.
Risedronate	5 mg/day or 35 mg/wk	A 40% reduction in vertebral and nonvertebral fractures is observed in women with osteoporosis. In postmenopausal women without osteoporosis, risedronate increases bone mineral density over 2 years. Significant side effects were not observed.
Etidronate	Intermittent administration of 400 mg/day (in 2-wk cycles); dose repeated every 3 months	Calcium is taken between the cycles of etidronate. Continuous daily use may cause abnormalities in bone mineralization. A 37% reduction is observed in the risk of vertebral fractures (but not nonvertebral fractures) in women with osteoporosis. Therapy in women without osteoporosis prevents bone loss over 2 years. Side effects include diarrhea and nausea.
Zoledronic acid	4 mg as a single intravenous infusion once yearly	Effects on bone turnover and bone density were similar to those with daily oral bisphosphonates. Adverse effects include myalgia and pyrexia.

General protective measures, such as adequate calcium intake (1,200 mg/day),⁶⁸ regular weight-bearing exercise, and avoidance of detrimental lifestyle habits such as smoking and alcohol abuse, are appropriate for all women. Most women require calcium supplementation to their dietary intake. Adequate exposure to sunlight is believed to protect against vitamin D deficiency, but many western women are deficient in this vitamin. The current recommended dietary intake for vitamin D is 400 international units/day for women aged 51 to 70 years and 600 international units/day for women older than 70 years.⁶⁸

Low bone density is the most important risk factor for osteoporosis. According to the World Health Organization, a woman with a bone mineral density >2.5 SD below the mean peak density has osteoporosis.⁶⁵ The rates of osteoporosis vary with ethnicity; it is more common in whites and those of Asian descent and less common in blacks.⁶⁵ In the United States, approximately 20% of white women 50 years and older have osteoporosis.⁶⁵

Bone mass measurement accurately determines the bone density in the spine and hip. The current “gold standard” method of bone density testing is dual-energy x-ray absorptiometry (DEXA).⁶⁵ In the United States, bone density testing is recommended for all women with medical causes of bone loss and for all women 65 years or older. Bone density testing should be assessed in conjunction with clinical risk profile evaluation. For women at high risk for fracture (i.e., T-score <2, previous nonspine fracture, family history of hip or spine fracture, and low body weight), bisphosphonates are the treatment of choice because of demonstrated fracture protection.⁶⁵ There are no clear indications for treating women at low risk for fracture (T-score >2), but raloxifene, tibolone, and bisphosphonates can be used. Long-term hormone therapy is no longer an appropriate first-choice option for osteoporosis prevention because of the risks associated with its long-term use. Therefore, hormone therapy should be considered for osteoporosis prevention only in women at significant risk for osteoporosis who cannot take nonestrogen regimens.

Colon Cancer Risk Reduction

Colorectal cancer is the fourth most common cancer and the second leading cause of cancer death in the United States (see Chapter 133). The estrogen-progestogen arm of the WHI study was the first randomized, controlled trial to confirm that combined estrogen-progestogen therapy reduces colon cancer risk. Compared with placebo, six fewer colorectal cancers are reported per year in every 10,000 women taking hormone therapy.²

Other

Diabetes In healthy postmenopausal women, hormone therapy appears to have a beneficial effect on fasting glucose levels in women with elevated fasting insulin concentrations.⁶⁹ Also, in women with coronary artery disease, hormone therapy reduces the incidence of diabetes by 35%.⁷⁰ These findings provide important insights into the metabolic effects of hormone therapy but are insufficient to recommend the long-term use of hormone therapy in women with diabetes.

Body Weight A meta-analysis of randomized controlled trials showed that unopposed estrogen or estrogen combined with a progestogen has no effect on body weight, suggesting that hormone therapy does not cause weight gain in excess of that normally observed at the time of menopause.⁷¹

■ RISKS OF HORMONE THERAPY

Cardiovascular Disease

6 Cardiovascular disease, including coronary artery disease, stroke, and peripheral vascular disease, is the leading cause of death among women. The American Heart Association recommends that post-

menopausal hormone therapy should not be used for reducing the risk of coronary heart disease.⁷²

In the last decade, an expectation of coronary benefit had been a major reason for use of postmenopausal hormone because observational studies indicated that women who use hormone therapy have a 35% to 50% lower risk of coronary heart disease than do nonusers.⁷³ In addition, previous studies have shown that estrogen exerts protective effects on the cardiovascular system, including lipid-lowering,⁷⁴ antioxidant,⁷⁵ and vasodilating effects.⁷⁶ Nevertheless, recent randomized clinical trials have provided no evidence of cardiovascular disease protection and even some evidence of harm with hormone therapy.^{2,77–80}

The primary findings of the estrogen-progestogen arm of the WHI trial showed an overall increase in the risk of coronary heart disease (HR 1.24, 95% CI 1–1.54) among healthy postmenopausal women 50 to 79 years old receiving combined estrogen-progestogen hormone therapy compared with those receiving placebo.^{2,80} The primary findings of the estrogen-only arm of the WHI trial show no effect (either increase or decrease) on the risk of coronary heart disease in women taking estrogen alone.³ However, recent analysis revealed that women in this cohort who initiated hormone therapy closer to the time of menopause tended to have decreased coronary heart disease risk compared to the increased risk noted among women who were more distant from menopause when estrogen therapy was initiated.^{81,82}

In the estrogen-progestogen arm of the WHI trial, the elevation in coronary heart disease risk was most apparent at 1 year (HR 1.81, 95% CI 1.09–3.01). The increased risk for stroke and venous thromboembolism continued throughout the 5 years of therapy.² Increased risk was observed only for ischemic stroke and not for hemorrhagic stroke.⁸³ In the estrogen-alone arm of the study, a similar increased risk for stroke was observed.³ Recent evidence suggests that hormone therapy has different effects on coronary heart disease risk in women when initiated in the early menopausal years (50–59 years of age) versus long after the menopause (i.e., menopausal for more than a decade), emphasizing the importance of timing of hormone therapy initiation.^{81,82,84}

Raloxifene therapy does not significantly affect the risk for coronary heart disease.⁴⁸

In the WHI trial, it is unclear whether the cardiovascular effects of hormone therapy during the perimenopause/early menopause and late menopause differ. There is a need for a long-term randomized controlled study of low-dose hormone therapy started around the time of menopause.⁸⁵ Hormone therapy should not be initiated or continued for the prevention of cardiovascular disease. Adherence to a healthful lifestyle (cessation of smoking, regular exercise, healthy diet, and body mass index <25) may prevent the onset of cardiovascular disease in postmenopausal women.^{86,87}

Breast Cancer

The WHI trial found that combined estrogen-progestogen therapy has an increased risk of invasive breast cancer (HR 1.26, 95% CI 1.0–1.59) and a trend toward increasing risk with increasing duration of therapy.² The estrogen-only arm of the WHI trial found no increased risk for breast cancer during the 7-year followup period.³ In the estrogen-progestogen arm, the increased breast cancer risk did not appear until after 3 years of study participation.² The breast cancers diagnosed in women in the hormone therapy group had similar histology and grade but were more likely to be in an advanced stage compared with women in the placebo group.⁸⁸ In an unselected postmenopausal population, the Million Women Study found that current use of hormone therapy increased breast cancer risk and breast cancer mortality (relative risk 1.66 and 1.22, respectively). Increased incidence was observed for estrogen-only use (relative risk 1.30), for estrogen-progestogen (relative risk 2), and for tibolone (relative risk 1.45).²¹

The lifetime risk of developing breast cancer in the United States is approximately one in eight women,⁸⁹ and the greatest incidence occurs in women older than 60 years (see Chapter 131). In a collaborative reanalysis of data from 51 studies evaluating more than 52,000 women with breast cancer and 108,000 controls, less than 5 years of therapy with estrogen combined with progestogen was associated with a 15% increase in the risk of breast cancer, and the increase was greater with longer duration (relative risk 1.53 after ≥ 5 of use).⁹⁰ However, 5 years after discontinuation of hormone replacement therapy, the risk of breast cancer was no longer increased.⁹⁰

Addition of progestogens to estrogen may increase breast cancer risk beyond that observed with estrogen alone.⁹¹ The Iowa Women's Health Study showed that exposure to hormone therapy is associated with an increased risk of breast cancer that has a favorable prognosis.⁹² These findings have been attributed to an increased breast cancer screening in women taking hormone therapy. A study of the effects of hormone therapy in women with a family history of breast cancer found that those who currently were receiving hormone therapy had approximately the same increased relative risk compared with those who did not have a family history.⁹³ The overall mortality for women with a family history of breast cancer from all causes was reduced significantly among hormone therapy users.⁹³ These data suggest that hormone therapy use in women with a family history of breast cancer is not associated with a significantly increased incidence of the disease.

Sex steroid deficiency during menopause results in lipomatous involution of the breast, which is seen as decreased mammographic breast density and markedly improved radiotransparency of breast tissue. Thus, mammographic changes indicating breast cancer can be recognized more easily and earlier after the menopause. Conversely, combination hormone therapy results in increased mammographic breast density, and increased density on mammography has been associated with higher breast cancer risk.⁹⁴ Of note, increased mammographic density is not observed with estrogen-only therapy.⁹⁵

Although raloxifene is not approved for prevention or treatment of breast cancer, a 4-year trial of raloxifene in women with osteoporosis (who were not at increased risk for breast cancer) showed a 76% risk reduction for estrogen receptor–positive breast cancer⁴⁶ (relative risk 0.24, 95% CI 0.13–0.44). Furthermore, the CORE trial, a study evaluating the efficacy of an additional 4 years of raloxifene therapy in women with osteoporosis, showed that the reduction in incidence of estrogen receptor–positive breast cancer continues for up to 8 years (HR 0.24, 95% CI 0.15–0.40).⁴⁷ Importantly, a prospective randomized double-blinded trial of 19,747 women at high risk for breast cancer (Study of Tamoxifen and Raloxifene [STAR]) showed that raloxifene is as effective as tamoxifen in reducing the risk of invasive breast cancer and has a lower risk of thromboembolic events.⁹⁶

Endometrial Cancer

The WHI trial suggests that combined hormone therapy does not increase endometrial cancer risk compared with placebo (HR 0.81, 95% CI 0.48–1.36).⁹⁷ Estrogen alone given to women with an intact uterus significantly increases uterine cancer risk.³⁵ With unopposed estrogen therapy, the risk of endometrial cancer increases within 2 years.³⁵ The excess risk increases with dose and duration of estrogen (10 years of unopposed estrogen increases the risk 10-fold), is apparent within 2 years of the start of treatment, and persists for many years after estrogen replacement is discontinued. Estrogen-induced endometrial cancer usually is of a low stage and grade at the time of diagnosis,³² and it can be prevented almost entirely by progestogen coadministration. The sequential addition of progestogen to estrogen for at least 10 days of the treatment cycle or continuous combined estrogen–progestogen does not increase the risk of endometrial cancer.⁹⁸

Lower doses of estrogen may be associated with a lower risk of endometrial hyperplasia.⁹⁹ Raloxifene does not result in endome-

trial hyperplasia, has no effect on endometrial thickness, is not associated with polyp formation, and has virtually no proliferative effect on the endometrium.¹⁰⁰ A 4-year trial of raloxifene in women with osteoporosis showed no increased risk of endometrial cancer.⁴⁸

Ovarian Cancer

Lifetime risk of ovarian cancer is low (1.7%). The WHI trial suggests that combined hormone therapy may increase the risk of ovarian cancer (HR 1.58, 95% CI 0.77–3.24).⁹⁷ However, a study reported an increased risk of ovarian cancer in women taking postmenopausal estrogen therapy for more than 10 years (relative risk 1.8, 95% CI 1.1–3.0) but no increased risk of ovarian cancer among women receiving combination estrogen–progestogen therapy.¹⁰¹ Additional large, controlled studies are needed to confirm these findings.

Venous Thromboembolism

Venous thromboembolism, including thrombosis of the deep veins of the legs and embolism to the pulmonary arteries, is uncommon in the general population. The absolute risk of venous thromboembolism in nonhormone therapy users is approximately 1 in 10,000 women.¹⁰² Women taking combined estrogen–progestogen hormone therapy have a twofold increased risk for thromboembolic events, with the highest risk occurring in the first year of use.¹⁰³ The absolute increase in risk is small, with 1.5 venous thromboembolic events per 10,000 women in 1 year.¹⁰³ Lower doses of estrogen are associated with a decreased risk for thromboembolism as compared with higher doses.¹⁰² Oral administration of estrogen increases the risk of venous thromboembolism compared to the transdermal route.¹⁰⁴ Also, the norpregnane progestogens, unlike micronized progesterone and pregnane derivatives (e.g., medroxyprogesterone acetate), appear to be thrombogenic.

Currently, there is no indication for thrombophilia screening before initiating hormone therapy. However, hormone therapy should be avoided in women at high risk for thromboembolic events.

Gallbladder Disease

Gallbladder disease is a commonly cited complication of oral estrogen use. A randomized trial showed an increased risk for cholecystitis, cholelithiasis, and cholecystectomy among women taking oral estrogen or estrogen–progestogen therapy.¹⁰⁵ Transdermal estrogen is an alternative to oral therapy for women at high risk for cholelithiasis.

CLINICAL CONTROVERSY

Some clinicians believe that hormone therapy improves well-being and quality of life of postmenopausal women, whereas others believe that hormone therapy, at best, has no effect. Hormone therapy improves mood and well-being mainly in women with vasomotor symptoms and sleep disturbance.

OTHER EFFECTS OF HORMONE THERAPY

Quality of Life, Mood, Cognition, and Dementia

7 Hormone therapy improves depressive symptoms in symptomatic menopausal women, most probably by relieving flushing and improving sleep.¹⁰⁶ Women with vasomotor symptoms receiving hormone therapy have improved mental health and fewer depressive symptoms compared with women receiving placebo; however, hormone therapy may worsen quality of life in women without flushes.¹⁰⁷

There is no evidence that hormone therapy improves quality of life or cognition in older, asymptomatic women.^{106–110}

More than 33% of women 65 years and older will develop dementia during their lifetime.¹¹¹ Several observational studies have suggested that estrogen therapy may be protective against Alzheimer's disease (see Chapter 67). The WHI Memory Study (an ancillary study of WHI trial) evaluated the effect of combined hormone therapy on dementia and cognition in 4,532 women 65 years and older.¹¹⁰ The study found that postmenopausal women 65 years and older taking estrogen plus progestogen therapy had twice the rate of dementia, including Alzheimer's disease, than women taking placebo (HR 2.05, 95% CI 1.21–3.48).¹¹⁰ In addition, estrogen plus progestogen therapy in these women did not prevent mild cognitive impairment, a cognitive and functional state between normal aging and dementia that frequently progresses to dementia.¹¹⁰ The estrogen-alone arm of the WHI trial showed similar findings.^{112,113}

Raloxifene does not have a significant effect on cognitive function; however, there is a trend toward a smaller decline in verbal memory and attention scores among women receiving raloxifene.¹¹⁴

Hormone therapy does not improve quality of life in postmenopausal women who do not have vasomotor symptoms. Hormone therapy does not improve cognitive function compared with placebo and, more importantly, produces an increased risk (albeit small) of clinically meaningful cognitive decline among women 65 years and older taking hormone therapy.^{107–110,112,113}

■ INDIVIDUALIZING HORMONE THERAPY

8 Menopause is a natural life event, not a disease. The decision to take hormone therapy must be individualized and based on several parameters, including menopausal symptoms, osteoporosis risk, coronary artery disease risk, breast cancer risk, and thromboembolism risk. Recommendations should be specific to each woman and her background (Table 85–8). Thus, menopausal treatment should be based on each woman's clinical profile and concerns. Approved indications of hormone therapy include treatment of vasomotor symptoms and urogenital atrophy and prevention of osteoporosis. Weighing risks and benefits, the FDA determined that the indication for vasomotor symptoms (hot flashes and night sweats) should remain unchanged, but the other two indications for hormone therapy should be revised. For treatment of vasomotor symptoms, systemic hormone therapy remains the most effective pharmacologic intervention (Fig. 85–1). For symptoms of urogenital atrophy, such as vaginal dryness, topical products should be considered. In addition, although prevention of postmenopausal osteoporosis remains an indicated use of hormone therapy, consideration should be given to approved nonestrogen products, such as raloxifene and bisphosphonates (Fig. 85–1). Clinicians should prescribe the lowest effective dose of hormone therapy for the shortest duration, weighing the potential benefits and risks for the individual woman. Measures to reduce the risks of cardiovascular disease (e.g., treating hypertension and avoiding smoking) and osteoporosis (e.g., taking calcium supplements and vitamin D, changing diet, and performing weight-bearing exercise) should be addressed.

EVALUATION OF THERAPEUTIC OUTCOMES

After the menopausal woman begins hormone therapy, a brief followup visit 6 weeks later may be useful to discuss patient concerns about hormone therapy and to evaluate the patient for symptom relief, adverse effects, and patterns of withdrawal bleeding. The FDA recommends that women who choose estrogen-based therapy should have yearly breast examinations, perform monthly breast self-examinations, and receive periodic mammograms (scheduled based on their age and risk factors). Also, women receiving hormone therapy should undergo annual monitoring, including a medical history, physical examination, pelvic examination, blood pressure measurement, and routine endometrial cancer surveillance, as indi-

TABLE 85-8 Evidence-Based Hormone Therapy Guidelines for Menopausal Symptom Management

Recommendation	Recommendation Grade ^a
In the absence of contraindications, estrogen-based postmenopausal hormone therapy should be used for treatment of moderate-to-severe vasomotor symptoms	A1
Systemic or vaginal estrogen therapy should be used for treatment of urogenital symptoms and vaginal atrophy	A1
Hormone therapy should be prescribed at the lowest effective dose and for the shortest duration	B2
Postmenopausal women taking estrogen-based therapy should be followed-up every year, taking into account findings from new clinical trials	A1
Postmenopausal women taking estrogen-based therapy for longer than 5 years should be informed about potential risks	A1
Safety and tolerability may vary substantially with the type and regimen of hormone therapy	B2
Breast cancer risk increases after use of continuous combined hormone therapy for longer than 5 years	A1
Breast cancer risk does not increase after long-term estrogen-only therapy (6.8 years) in postmenopausal women with hysterectomy	A1
Hormone therapy should not be used for primary or secondary prevention of coronary heart disease	A1
Oral hormone therapy increases risk of venous thromboembolism	A1
Parenteral hormone therapy may be safer for postmenopausal women at risk for venous thromboembolism who choose to take hormone therapy	B2
Oral hormone therapy increases risk of ischemic stroke	A1
Although hormone therapy decreases risk of osteoporotic fractures, it cannot be recommended as a first-line therapy for the treatment of osteoporosis	A1
Potential harm (cardiovascular disease, breast cancer, and thromboembolism) from long-term hormone therapy (use greater than 5 years) outweighs potential benefits	A1
Young women with premature ovarian failure have severe menopausal symptoms and increased risk for osteoporosis and cardiovascular disease. Decisions on whether and how these young women must be treated should not be based on studies of hormone therapy in women older than 50 years	B3

Quality of evidence: 1 = evidence from more than one properly randomized, controlled trial; 2 = evidence from more than one well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple time series; or dramatic results from uncontrolled experiments; 3 = evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

^aStrength of recommendations: A, B, C = good, moderate, and poor evidence to support recommendation, respectively.

cated. Additional followup is determined based on the patient's initial response to therapy and the need for any modification of the regimen. Endometrial biopsy should be considered in women taking cyclic hormone therapy if vaginal bleeding occurs at any time other than the expected time of withdrawal bleeding or when heavier or more prolonged withdrawal bleeding occurs. In women taking continuous combined hormone therapy, endometrial evaluation should be considered when irregular bleeding persists for more than 6 months after initiating therapy. Endovaginal ultrasonography also has been used for evaluation of abnormal uterine bleeding in women receiving hormone therapy. However, there is no universal agreement that endovaginal ultrasonography is adequate for excluding endometrial pathology.

The main indication for hormone therapy is relief of menopausal symptoms, and hormone therapy should be used only as long as symptom control is necessary (typically 2–3 years). When hormone

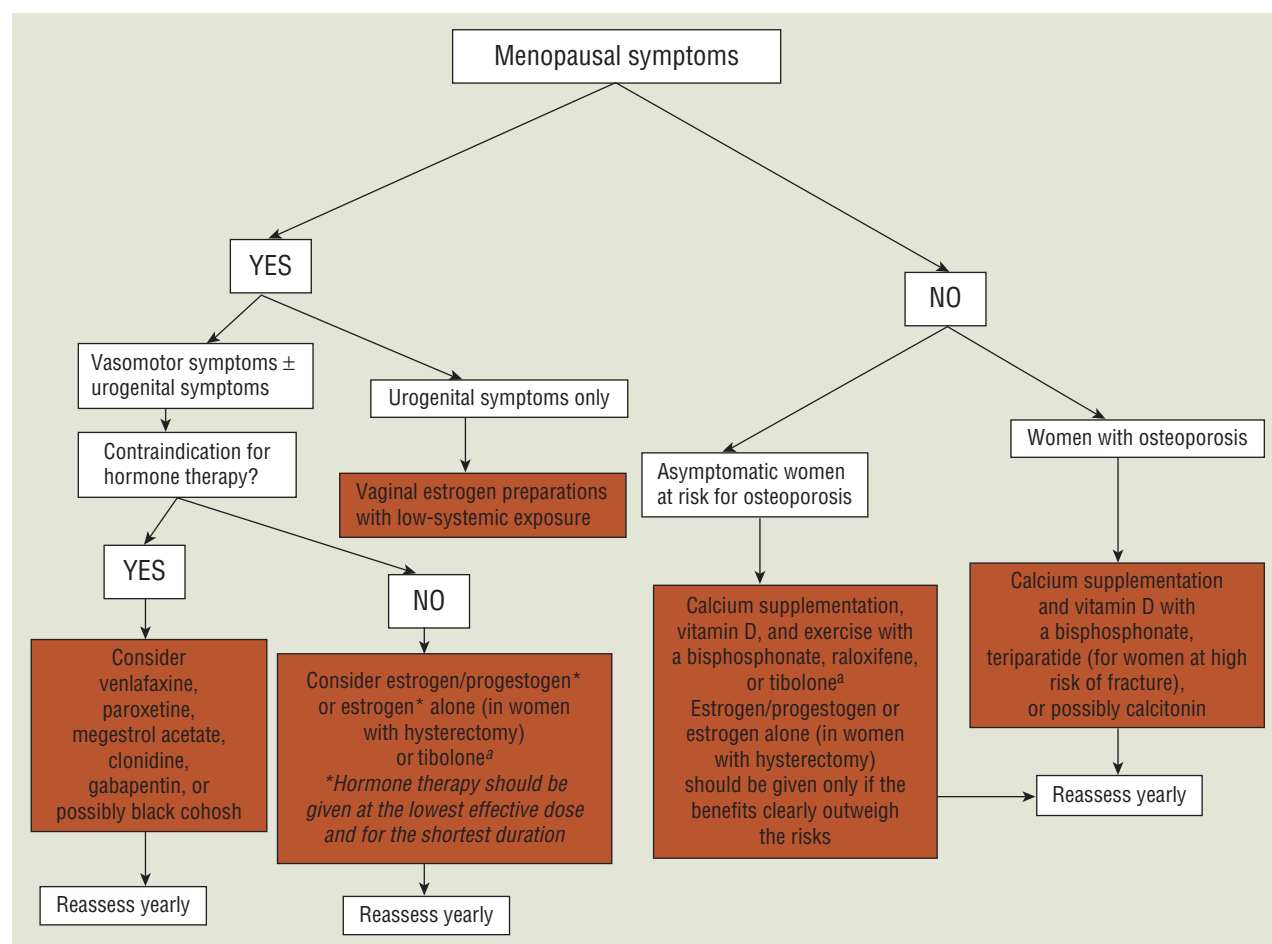

FIGURE 85-1. Algorithm for management of postmenopausal women. ^aTibolone is currently not approved for use in the United States.

therapy is used under such conditions, the absolute risk of harm to an individual woman is very small.²

Many women have no difficulty abruptly stopping hormone therapy; others develop vasomotor symptoms after discontinuation. Although these symptoms usually are mild and resolve over a few months, in some women the symptoms are severe and intolerable. Few studies have addressed the appropriate method for discontinuing use of hormone therapy. There is no evidence that gradual discontinuation of hormone therapy reduces the recurrence of hot flashes compared with sudden discontinuation. Studies determining effective ways to reduce symptoms of estrogen withdrawal are needed.

Bone mineral density should be measured in women older than 65 years and in women younger than 65 years with risk factors for osteoporosis. Although bone densitometry has been shown to predict fractures, at present there are no guidelines for followup bone mineral density testing. However, in women with significant bone loss, repeat testing should be performed as clinically indicated.

PHARMACOECONOMIC CONSIDERATIONS

Estrogens and progestogens used for postmenopausal hormone therapy still are prescribed commonly in the United States, especially for the management of menopausal vasomotor symptoms. Even before publication of the WHI trial findings, only a fraction of women filled their hormone therapy prescriptions, and only 25% to 40% continued to take postmenopausal hormone therapy for more than 1 year.¹¹⁵ This may be due to women's attitudes toward hormone therapy or a result of fear about adverse effects and

associated risks. Hormone therapy use in the United States declined substantially after dissemination of the WHI trial results.¹¹⁶

Use of hormone therapy for the management of vasomotor symptoms is cost effective, and data supporting the use of nonhormonal alternatives are limited. The cost of hormone therapy varies depending on the route and method of delivery. Transdermal preparations are about twice as expensive as their equivalent oral preparations.¹¹⁷ Women who have undergone hysterectomy use hormone therapy more frequently than do women with an intact uterus (58.7% vs 19.6%).⁵

Raloxifene adversely affects hot flashes, but it is likely to be used for osteoporosis prevention. For women with a history of breast cancer or thromboembolic disease, alternative means of reducing the risk of osteoporosis, such as bisphosphonates, should be considered.

The results of randomized trials suggest that hormone therapy should not be used for cardiovascular disease prevention. Women with coronary disease risk factors (e.g., hypertension, lipid abnormalities) can benefit from reduction of these risk factors through interventions such as weight loss, lipid-lowering therapy, use of aspirin, use of antioxidants, and physical activity.

CONCLUSIONS

During the past decade, postmenopausal hormone therapy became one of the most frequently prescribed therapies in the United States. Menopause is a natural life event, not a disease. Therefore, the decision to use hormone therapy must be individualized based on the severity of menopausal symptoms, risk of osteoporosis, and

consideration of factors such as coronary artery disease, breast cancer, and thromboembolism.

Large prospective, randomized trials have shown that postmenopausal hormone therapy prescribed for disease prevention may cause more harm than good.^{2,77} The WHI trial reported increased risk of cardiovascular disease, breast cancer, stroke, and thromboembolic disease among women using continuous-combined therapy with CEE plus medroxyprogesterone acetate compared with placebo.² In the estrogen-alone arm of the study, CEE had no effect on cardiovascular disease or breast cancer risk compared to placebo, but an increased risk of stroke and thromboembolic disease was noted in those who received estrogen.³ The WHI trial also demonstrated that quality of life¹⁰⁹ and cognition^{110,112,113} were no better in the group receiving hormone therapy than in the placebo group.

Postmenopausal symptoms, such as hot flashes and vaginal dryness, remain a valid indication for hormone therapy in the absence of contraindications. For short-term use of hormone therapy for the relief of menopausal symptoms, the benefits for many women generally outweigh the risks. For symptoms of genital atrophy alone, local estrogen and/or nonhormonal lubricants should be considered.

Long-term use of hormone therapy cannot be recommended routinely for osteoporosis prevention given the availability of alternative therapies, such as raloxifene and the bisphosphonates. For long-term hormone therapy use, the potential harm (cardiovascular disease, breast cancer, and thromboembolism) outweighs the potential benefits.

PREMATURE OVARIAN FAILURE AND PREMENOPAUSAL HORMONE REPLACEMENT

PATHOPHYSIOLOGY

Premature ovarian failure is a condition characterized by sex-steroid deficiency, amenorrhea, and infertility in women younger than 40 years.¹¹⁸ It affects 1% of women by age 40 years.¹¹⁹ Premature ovarian failure once was considered irreversible and was described as “premature menopause.” Premature ovarian failure is not an early natural menopause. Normal menopause results from ovarian follicle depletion, whereas premature ovarian failure is characterized by intermittent ovarian function in half of affected women.¹¹⁸ For this reason, the term “primary ovarian insufficiency” may be a more accurate term to describe this condition. These women produce estrogen intermittently and may ovulate despite the presence of high gonadotropin concentrations. Pregnancies have occurred in 5% to 10% of women after the diagnosis of premature ovarian failure, even in women with no follicles observed on ovarian biopsy.

Premature ovarian failure may occur as a result of ovarian follicle dysfunction or ovarian follicle depletion and may present as either primary amenorrhea (absence of menses in a girl who has reached age 16 years) or secondary amenorrhea (cessation of menses in a woman previously menstruating for at least 6 months).

In most cases, the etiology cannot be identified (Table 85–9). In the majority of patients, ovarian failure develops after the establishment of regular menses. Young women with premature ovarian failure who develop ovarian dysfunction before they achieve peak adult bone mass sustain sex steroid deficiency for more years than do naturally menopausal women. This deficiency can result in a significantly higher risk for osteoporosis¹²⁰ and cardiovascular disease.^{121,122} Importantly, a survey of more than 19,000 women between the ages of 25 and 100 years suggests that ovarian failure occurring before age 40 years is associated with significantly increased mortality, with an age-adjusted odds ratio for all-cause mortality of 2.14 (95% CI 1.15–3.99).¹²³

CLINICAL PRESENTATION OF PREMATURE OVARIAN FAILURE

Symptoms

- *Primary amenorrhea*: No symptoms of estrogen deficiency
- *Secondary amenorrhea*: Vasomotor symptoms (hot flashes and night sweats), sleep disturbances, mood changes, sexual dysfunction, problems with concentration and memory, vaginal dryness, dyspareunia

Signs

- *Primary amenorrhea*: Incomplete development of secondary sex characteristics
- *Secondary amenorrhea*: Normal development of secondary sex characteristics, signs of urogenital atrophy

Laboratory Tests

- FSH >40 international units/L
- Other relevant diagnostic tests (e.g., bone mineral density, ultrasound of the ovaries)
- Thyroid function tests, fasting glucose level, and adrenocorticotrophic hormone stimulation test

CLINICAL PRESENTATION

No characteristic menstrual pattern or history precedes premature ovarian failure. Approximately 50% of patients with this condition have a history of oligomenorrhea or dysfunctional uterine bleeding (prodromal premature ovarian failure), and approximately 25% develop amenorrhea acutely. Some patients develop amenorrhea postpartum, whereas others experience amenorrhea after discontinuing oral contraceptives. Primary amenorrhea is not associated with symptoms of estrogen deficiency. In cases of secondary amenorrhea, symptoms may include hot flashes, night sweats, fatigue, and mood changes. Prodromal premature ovarian failure may present with hot flashes even in women who menstruate regularly. Incomplete development of secondary sex characteristics may occur in women with primary amenorrhea, whereas these characteristics typically are normal in women with secondary amenorrhea. In general, women with premature ovarian failure have normal fertility before the disorder develops.

Approximately 50% of women with premature ovarian failure have documented ovarian follicle function.¹¹⁸

Premature ovarian failure is defined by the presence of at least 4 months of amenorrhea and at least two serum FSH concentrations measuring >40 international units/L (obtained at least 1 month apart) in women younger than 40 years. A complete history should be taken, considering other factors that can affect ovarian function such as prior ovarian surgery, chemotherapy, radiation, and autoimmune disorders. In patients with primary amenorrhea, particular

TABLE 85-9 Etiology of Premature Ovarian Failure

Idiopathic: <i>Karyotypically normal spontaneous premature ovarian failure</i>
Autoimmunity: (A) isolated autoimmune premature ovarian failure or (B) as a component of an autoimmune polyglandular syndrome in association with Addison's disease, hypothyroidism, hypoparathyroidism, or mucocutaneous candidiasis
Iatrogenic: <i>Chemotherapy, radiation, extensive ovarian surgery</i>
X-chromosome abnormalities
Gonadotropin and gonadotropin-receptor abnormalities: Signal defects
Enzyme deficiencies: Cholesterol desmolase, 17 α -hydroxylase, 17, 20-desmolase
Galactosemia
Blepharophimosis, ptosis, and epicanthus inversus syndrome type 1: Rare autosomal dominant syndrome in which premature ovarian failure is the predominant syndrome
Perrault's syndrome: Familial autosomal recessive premature ovarian failure in association with deafness

attention should be paid to breast and pubic hair development according to Tanner stages. Short stature, stigmata of Turner's syndrome, and other dysmorphic features of gonadal dysgenesis should be considered. Ideally, a pelvic examination is performed but is not always clinically appropriate. Alternatively, transabdominal ultrasonography can be performed in patients with primary amenorrhea to confirm the presence of normal anatomic structures. In the majority of cases, physical examination is completely normal. A karyotype should be performed in all patients experiencing premature ovarian failure. Women with ovarian failure and a karyotype containing a Y chromosome should undergo bilateral gonadectomy because of substantial risk for gonadal germ cell neoplasia.¹²⁴ Ovarian biopsy and antiovarian antibody testing are investigational procedures with no proven clinical benefit in premature ovarian failure. As clinically indicated, the workup should include tests for the diagnosis of other possible associated autoimmune disorders, such as hypothyroidism, diabetes mellitus, and Addison disease.

Young women find the diagnosis of premature ovarian failure particularly traumatic and frequently need extensive emotional and psychological support. Although most of these women will, in fact, be infertile, it is important to emphasize that premature ovarian failure can be transient and that spontaneous pregnancies have occurred even years after diagnosis.

TREATMENT

Premature Ovarian Failure

9 Postmenopausal women who take hormone therapy prolong their exposure to estrogen beyond the average age of completion of their reproductive phase. In contrast, women with premature ovarian failure need exogenous sex steroids to compensate for the decreased production by their ovaries. Importantly, 47% of young women with premature ovarian failure have significantly reduced bone mineral density within 1.5 years of their diagnosis despite taking standard hormone therapy.¹²⁰

The goal of therapy in young women with premature ovarian failure is to provide a hormone replacement regimen that maintains sex steroid status as effectively as the normal, functioning ovary.

■ PHARMACOLOGIC THERAPY: HORMONAL REGIMENS

Optimal hormone therapy depends on whether the patient has primary or secondary amenorrhea. Young women with primary amenorrhea in whom secondary sex characteristics have failed to develop initially should be given very low doses of estrogen in an attempt to mimic the gradual pubertal maturation process. A typical regimen is 0.3 mg CEE unopposed (i.e., no progestogen) daily for 6 months, with incremental dose increases at 6-month intervals until the required maintenance dose is achieved. Gradual dose escalation often results in optimal breast development and allows time for the young woman to adjust psychologically to her physical maturation. Cyclic progestogen therapy, given 12 to 14 days per month, should be instituted toward the end of the second year of treatment.

Women with secondary amenorrhea who have been estrogen deficient for 12 months or longer also should be given low-dose estrogen replacement initially to avoid adverse effects such as mastalgia and nausea. However, the dose can be titrated up to maintenance levels over a 6-month period, and progestogen therapy can be instituted with the initiation of estrogen therapy. Women with a brief history of secondary amenorrhea are less likely to experience undesired effects from hormone therapy if they are given a reduced dose for the first month of therapy, followed by a full dose from the second month onward.

TABLE 85-10 Premenopausal Hormone Replacement Therapy for Young Women with Premature Ovarian Failure

Regimen	Dose	Frequency	Route
Estrogen therapy			
Conjugated equine estrogen	1.25 mg	Daily	Oral
Piperazine estrone sulfate	2.5 mg	Daily	Oral
Micronized 17 β -estradiol	4 mg	Daily	Oral
Transdermal estrogen system	100 mcg/24 h	Once or twice weekly	Transdermal patch
Progestogen therapy			
Medroxyprogesterone acetate	10 mg	12–14 days ^a	Oral
Dydrogesterone ^b	20 mg	12–14 days ^a	Oral
Norethindrone acetate	10 mg	12–14 days ^a	Oral
Norethisterone ^b	1 mg	12–14 days ^a	Oral
Micronized progesterone	200 mg	12–14 days ^a	Oral
Transdermal norethindrone ^c	250 mcg/24 h	Twice weekly for 14 days per calendar month	Transdermal patch

^aPer calendar month.

^bNot available in a progestogen-only oral dosage form in the United States.

^cAvailable only in combination with estradiol.

An estrogen dose equivalent to at least 1.25 mg CEE (or 100 mcg transdermal estradiol) is needed to achieve adequate estrogen replacement in young women. A progestogen should be given for 12 to 14 days per calendar month to prevent endometrial hyperplasia (Table 85–10). Estrogens given in usual replacement doses do not suppress spontaneous follicular activity or ovulation. Because women with premature ovarian failure can have spontaneous pregnancies, hormone therapy should produce regular, predictable menstrual flow patterns (i.e., only cyclic regimens should be used). Patients who miss an expected menses should be tested for pregnancy and should discontinue hormone therapy. Because most young women negatively associate hormone therapy with menopause in older women, some clinicians prefer to prescribe oral contraceptives for hormone replacement in premenopausal women with hypogonadism. However, oral contraceptives may not inhibit ovulation or effectively prevent pregnancy in young women with elevated gonadotropin levels.

Women with premature ovarian failure have testosterone deficiency.¹²⁵ In these young women, testosterone replacement, in addition to estrogen, may be important.⁴³ However, preliminary analysis of a prospective study at the National Institutes of Health suggests that long-term “physiologic” testosterone supplementation (150 mcg/day), in addition to standard hormone replacement, did not significantly improve bone density and sexual function in these young women.^{126,127}

Importantly, all women with premature ovarian failure should understand that hormone therapy generally should be continued until the average age of natural menopause and that long-term follow up is necessary.

■ EVALUATION OF THERAPEUTIC OUTCOMES

Young women with premature ovarian failure should be monitored annually for their response to treatment, and their compliance with hormone therapy should be assessed regularly. Patients should be evaluated continuously for the presence of signs and symptoms of associated autoimmune endocrine disorders, such as hypothyroidism, adrenal insufficiency, and diabetes mellitus. Baseline bone mineral density testing should be performed in all women with premature ovarian failure. Mammography should be performed annually after age 40 years in accordance with accepted guidelines. Additional mammography screening in premenopausal women younger than 40 years who are receiving physiologic hormone therapy is not warranted. Other tests should be performed as clinically indicated.

CONCLUSIONS

Approximately 1% of women spontaneously develop ovarian failure before age 40 years.⁵ Premature ovarian failure is not an early natural menopause. Most affected women produce estrogen intermittently and may ovulate despite the presence of high gonadotropin concentrations. However, these women sustain sex steroid deficiency for more years than do naturally menopausal women, resulting in a significantly higher risk for osteoporosis¹²⁰ and cardiovascular disease.^{121,122}

Women with premature ovarian failure need exogenous sex steroids to compensate for the decreased production by their ovaries. Thus, premenopausal hormone therapy is required at least until these women reach the age of "natural menopause."

The goal of therapy is to provide a hormone replacement regimen that maintains sex steroid status as effectively as the normal, functioning ovary. This usually requires the administration of estrogen at a dose greater than the standard dose given to older women experiencing natural menopause.

Because women with premature ovarian failure can have spontaneous pregnancies, hormone therapy should produce regular, predictable menstrual flow patterns. Patients who miss an expected menses should be tested for pregnancy and promptly discontinue the hormone treatment.

Annual followup should include assessment of adherence with the prescribed hormone therapy regimen and evaluation for signs and symptoms of associated endocrine disorders.¹¹⁸

SECTION 10

UROLOGIC DISORDERS

CHAPTER

86

Erectile Dysfunction

MARY LEE

KEY CONCEPTS

- 1 The incidence of erectile dysfunction is low in men younger than 40 years. The incidence increases as men age, likely as a result of concurrent medical conditions that impair the vascular, neurologic, psychogenic, and hormonal systems necessary for a normal penile erection.
- 2 Many commonly used drugs have sympatholytic, anticholinergic, sedative, or antiandrogenic effects that may exacerbate or contribute to the development of erectile dysfunction. Clinicians should be familiar with these agents and be prepared to make adjustments in drug regimens to minimize adverse effects of these drugs on a patient's erectile function.
- 3 The first step in clinical management of erectile dysfunction is to identify and, if possible, reverse the underlying causes. Risk factors for erectile dysfunction, including hypertension, diabetes mellitus, smoking, and chronic ethanol abuse, should be addressed and minimized.
- 4 Specific treatments for erectile dysfunction include vacuum erection devices, pharmacologic treatments, psychotherapy, and surgery.
- 5 The ideal treatment of erectile dysfunction should have a fast onset, be effective, be convenient to administer, be cost effective, have a low incidence of serious adverse effects, and be free of serious drug interactions.
- 6 Specific treatment is first initiated with the least invasive forms of treatment, including vacuum erection devices or oral phosphodiesterase inhibitors, followed by intracavernosal injections or intraurethral inserts, and finally by surgical insertion of a penile prosthesis.
- 7 Vacuum erection devices can have a slow onset of action (30 minutes) and are not discreet; therefore, they are most effective for a couple in a stable relationship.
- 8 Although phosphodiesterase inhibitors are convenient and effective regardless of the etiology of erectile dysfunction, they fail in 30% to 40% of patients. Also, phosphodiesterase inhibitors are contraindicated in patients taking any dosage formulation of nitrate.
- 9 Testosterone supplementation should be reserved for patients with primary or secondary hypogonadism who have erectile dysfunction as a consequence of a decreased libido. Testosterone supplementation should not be used by patients with erectile dysfunction who have normal serum testosterone levels.
- 10 Although intracavernosal injections and intraurethral pellets of alprostadil are effective independent of the etiology of erectile dysfunction, they fail in one third of patients. To self-administer medication by these routes, patients require training to minimize administration-related adverse effects.

The National Institutes of Health Consensus Development Panel on Impotence defines erectile dysfunction as the failure to achieve a penile erection to allow for satisfactory sexual intercourse.¹ Patients may refer to it as impotence.

Erectile dysfunction must be distinguished from disorders of libido, ejaculatory disorders, and infertility, which are caused by different pathophysiologic mechanisms and are treated with alternative agents (Table 86–1). A patient may suffer from one or more disorders of sexual dysfunction. For example, an elderly man with primary hypogonadism may suffer from decreased libido and erectile dysfunction. Diagnosis of the type of sexual disorder that a patient has is a key to initiating the most appropriate treatment.

EPIDEMIOLOGY

- 1 The incidence of erectile dysfunction is low in men younger than 40 years but increases as men age.^{2–4} The Massachusetts Male Aging Study, a cross-sectional survey of a random sample of 1,290 men in the Boston area, was conducted during the period from 1987 to 1989. The study reported an overall prevalence of 52% for any degree of erectile dysfunction in men aged 40 to 70 years, with an age-related increase in incidence ranging from 12.4% in men aged 40 to 49 years, up to 46.4% in men aged 60 to 69 years.^{1,2} In the most

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

TABLE 86-1 Types of Sexual Dysfunction in Men	
Type of Dysfunction	Definition
Decreased libido	Decreased sexual drive or desire
Increased libido	Precocious puberty; inappropriate and excessive sexual drive or desire
Erectile dysfunction (impotence)	Failure to achieve a penile erection suitable for satisfactory sexual intercourse
Delayed ejaculation	Commonly referred to as “dry sex”; ejaculation is delayed or absent
Retrograde ejaculation	Ejaculate passes retrograde into the bladder, instead of toward the anterior urethra (antegrade) and out of the penis
Infertility	Sperm are insufficient in number or have inadequate motility and fail to fertilize the ovum

recent Health Professional Follow-Up Study of more than 31,000 male health professionals aged 53 to 90 years, the prevalence of erectile dysfunction was 33%.³

Although erectile dysfunction is sometimes assumed to be a symptom of the aging process in men, it likely results from concurrent medical conditions of the patient (e.g., hypertension, arteriosclerosis, hyperlipidemia, diabetes mellitus, or psychiatric disorders) or from medications that patients may be taking for these diseases.²⁻⁵ For example, up to 50% of patients with diabetes mellitus develop erectile dysfunction, and medications such as β -blockers are associated with a high incidence of erectile dysfunction.

PHYSIOLOGY OF A NORMAL PENILE ERECTION

A normal penile erection requires full functioning of several physiologic systems: vascular, nervous, and hormonal. The patient also must be psychologically receptive to sexual stimuli.

VASCULAR SYSTEM

The penis comprises two corpora cavernosa on the dorsal side and one corpus spongiosum on the ventral side. The corpus spongiosum surrounds the urethra and forms the glans penis. The corpora are composed of multiple interconnected sinuses, which can fill with blood to produce an erection. The corpora are encased by the tunica albuginea, a fibrous tissue membrane, which has limited distensibility. In the flaccid state, arterial flow into and venous outflow from the corpora are balanced. During the erectile phase, arterial blood flow increases and blood fills the sinusoids within the corpora, which causes penile swelling and elongation. The erection is prolonged by a decrease in venous outflow from the corpora, which is caused by compression of subtunical venules against the tunica albuginea by the swollen corpora (Fig. 86-1).

Arterial flow into the corpora is enhanced by acetylcholine-mediated vasodilation. Acetylcholine does not directly enhance arterial flow to the corpora or increase sinusoidal filling of the corporal tissue. Rather, acetylcholine is a coneurotransmitter, which works along with other nonpeptidergic intracellular neurotransmitters—

FIGURE 86-1. Microanatomy of and vascular changes in the penis in flaccid and erect states. In the flaccid state, arterial flow into and venous outflow from the corpora are balanced. During the erectile phase, arterial blood flow increases and blood fills the sinusoids within the corpora, causing penile swelling and elongation. The erection is prolonged by a decrease in venous outflow from the corpora, which is caused by compression of subtunical venules by the swollen corpora. (From Walsh PC, ed. *Campbell's Urology*, 8th ed. Philadelphia: WB Saunders, 2002: 1595 and 1697.)

including cyclic guanosine monophosphate (cGMP), cyclic adenosine monophosphate (cAMP), or vasoactive intestinal polypeptide—to produce vasodilation. In effect, cGMP and cAMP are secondary messengers that direct desired effects in target tissues.⁶

Acetylcholine produces an erection probably through two different pathways. Through one pathway, in the presence of sexual stimulation to genital tissue, acetylcholine enhances the production of nitric oxide by endothelial cells and nonadrenergic–noncholinergic neurons. Nitric oxide enhances the activity of guanylate cyclase, which increases the conversion of cyclic guanosine triphosphate to cGMP. cGMP decreases intracellular calcium concentrations in smooth muscle cells of penile arteries and cavernosal sinuses. As a result, smooth muscle relaxation occurs, which enhances arterial blood flow to and blood filling of the corpora.⁵ An erection results.

In an alternative pathway, acetylcholine stimulates a smooth muscle cell membrane receptor to enhance the activity of adenylyl cyclase. Adenylyl cyclase increases the conversion of cyclic adenosine triphosphate to cAMP, a potent muscle relaxant. Similarly to cGMP, cAMP decreases intracellular calcium concentrations to produce smooth muscle relaxation in cells of the arteries and cavernosal sinuses. Arterial blood flow to and blood filling of the corpora are enhanced, and a penile erection results.⁵

NERVOUS SYSTEM AND PSYCHOGENIC STIMULI

Some erections are mediated by a sacral nerve reflex arc (e.g., erections can occur while the patient is sleeping). However, in the conscious patient, sensory sexual stimulation mediates erections via the central nervous system. That is, when a patient sees an attractive partner, hears sweet words, smells a particular scent, or tastes or touches a pleasant object, these situations can result in an erection. In this case, the patient's brain processes this information and the nervous impulse is carried down the spinal cord to peripheral cholinergic nerves that innervate the vascular supply to the corpora, resulting in an erection.

The medial preoptic area of the hypothalamus is thought to be that portion of the brain responsible for integrating external stimuli. Here dopamine exerts a proerectogenic effect, whereas, α_2 -adrenergic stimulation causes the penis to become and/or remain flaccid. After moving down the spinal cord, nerve impulses travel to the penis by efferent peripheral nerves, including inhibitory sympathetic neurons (T11 through L2), proerectogenic parasympathetic neurons (S2 through S4), and proerectogenic somatic neurons (S2 through S4).

In summary, acetylcholine produces an erection by working along with other coneurotransmitters, including cGMP and cAMP. Thus, an erection is initiated by the action of nerves, maintained by arterial blood filling of the corpora, and sustained by occlusion of venous outflow from the corpora.

Detumescence, or the progression of an erect penis to a flaccid state, results from the actions of norepinephrine, which contracts vascular smooth muscle to decrease arterial inflow to the corpora and contracts sinusoidal tissue in the corpora. As a result, venous outflow from the corpora increases.

HORMONAL SYSTEM

Testosterone stimulates libido or sexual drive in males. Within the normal physiologic serum concentration range (normal 300–1,100 ng/dL), sexual drive is normal. Approximately one third of men older than 50 years have hypogonadism, which is characterized by subphysiologic serum testosterone levels. Patients complain of loss of energy, loss of muscle strength, depressive mood, and decreased libido.

When libido is decreased, a patient may not develop erections. Thus, erectile dysfunction is considered secondary to a decreased libido. The relationship between erectile dysfunction and serum

testosterone levels is complicated. Patients with normal serum testosterone levels may have erectile dysfunction, and patients with subnormal serum testosterone levels may have normal sexual function.⁵

PATHOPHYSIOLOGY

Erectile dysfunction can result from any single abnormality or combination of abnormalities of the four systems necessary for a normal penile erection. Vascular, neurologic, or hormonal etiologies of erectile dysfunction are collectively referred to as *organic erectile dysfunction*. Approximately 80% of patients with erectile dysfunction have the organic type. Patients who do not respond to psychogenic stimuli have *psychogenic erectile dysfunction*.

Diseases that compromise vascular flow to the corpora cavernosum (e.g., peripheral vascular disease, arteriosclerosis, and essential hypertension) are associated with an increased incidence of erectile dysfunction. Diseases that impair nerve conduction to the brain (e.g., spinal cord injury or stroke) or conditions that impair peripheral nerve conduction to the penile vasculature (e.g., diabetes mellitus) can result in erectile dysfunction.

Diseases associated with hypogonadism, primary or secondary, result in subphysiologic levels of testosterone, which cause diminished sexual drive (decreased libido) and secondary erectile dysfunction. Primary hypogonadism can be associated with the normal aging process in men or surgical removal of the testes for treatment of prostate or testicular cancer. Secondary hypogonadism may result from hypothalamic or pituitary disorders of luteinizing hormone–releasing hormone or luteinizing hormone, respectively; or elevated prolactin levels, which can result from pituitary tumors or can occur in patients with chronic renal failure.

Patients must be in the proper mental frame of mind to be receptive to sexual stimuli. Patients who suffer from malaise, have reactive depression or performance anxiety, are sedated, have Alzheimer's disease, have hypothyroidism, or have mental disorders, commonly complain of erectile dysfunction. In most studies, patients with psychogenic erectile dysfunction generally exhibit a higher response rate to various interventions than do patients with organic erectile dysfunction because the former have less severe disease.

Social habits of patients have been linked to erectile dysfunction. The vasoconstrictor effect of cigarette smoking may compromise blood flow to the corpora and decrease cavernosal filling. Excessive ethanol intake may lead to androgen deficiency, peripheral neuropathy, or chronic liver disease, all of which can contribute to erectile dysfunction.

② Medications may cause erectile dysfunction through similar pathophysiologic mechanisms (Table 86–2).^{7,8} Medications are estimated to be responsible for approximately 10% to 25% of cases of erectile dysfunction.

CLINICAL PRESENTATION: ERECTILE DYSFUNCTION

General

- Men are affected emotionally in many different ways
- Depression
- Performance anxiety
- Marital difficulties and avoidance of sexual intimacy (patients are often brought to a physician by their partners)
- Nonadherence to medications patient believes are causing erectile dysfunction

Symptoms

- Impotence or inability to have sexual intercourse

TABLE 86-2 Medication Classes That Can Cause Erectile Dysfunction

Drug Class	Proposed Mechanism by Which Drug Causes Erectile Dysfunction	Special Notes
Anticholinergic agents (antihistamines, antiparkinsonian agents, tricyclic antidepressants, phenothiazines)	Anticholinergic activity	<ul style="list-style-type: none"> Second-generation nonsedating antihistamines (e.g., loratadine) are not associated with erectile dysfunction Selective serotonin reuptake inhibitor antidepressants can be substituted for tricyclic antidepressants if erectile dysfunction is a problem Phenothiazines with less anticholinergic effect (e.g., chlorpromazine) can be substituted in some patients if erectile dysfunction is a problem
Dopamine agonists (e.g., metoclopramide, phenothiazines)	Inhibit prolactin inhibitory factor, thereby increasing prolactin levels	<ul style="list-style-type: none"> Increased prolactin levels are associated with blocking testosterone production from the testes; depressed libido results
Estrogens, antiandrogens (e.g., luteinizing hormone–releasing hormone superagonists, digoxin, spironolactone, ketoconazole, cimetidine)	Suppress testosterone-mediated stimulation of libido	<ul style="list-style-type: none"> In the face of a decreased libido, a secondary erectile dysfunction develops
Central nervous system depressants (e.g., barbiturates, narcotics, benzodiazepines, short-term use of large doses of alcohol)	Suppress perception of psychogenic stimuli	
Agents that decrease penile blood flow (e.g., diuretics, peripheral β -adrenergic antagonists, or central sympatholytics [methyl-dopa, clonidine, guanethidine])	Reduce arteriolar flow to corpora	<ul style="list-style-type: none"> Any diuretic that produces a significant decrease in intravascular volume can decrease penile arteriolar flow Safer antihypertensives include angiotensin-converting enzyme inhibitors, postsynaptic α_1-adrenergic antagonists (terazosin, doxazosin), calcium channel blockers, and angiotensin II receptor antagonists

From Thomas et al.⁷ and Lee and Sharifi.⁸

Signs

- If completing an International Index of Erectile Dysfunction survey, results are consistent with low satisfaction with the quality of erectile function.
- Medical history may identify concurrent medical illnesses, past surgical procedures that interfere with good vascular flow to the penis or damage nerve function to the corpora, or mental disorders associated with decreased reception of sexual stimuli.
- Medication history may reveal prescription or nonprescription medications that could cause erectile dysfunction.
- Physical examination may reveal signs of hypogonadism (e.g., gynecomastia, small testicles, decreased body hair, decreased muscle mass), which may contribute to erectile dysfunction. The patient may have signs of an abnormally curved penis when erect, decreased pulses in the pelvic region (suggesting impaired vascular flow to the penis), or decreased anal sphincter tone (suggesting impaired nerve function to the corpora). Men older than 50 years should undergo a digital rectal examination to determine whether an enlarged prostate is contributing to the patient's erectile dysfunction.

Laboratory Tests

- If patient has signs of hypogonadism and complains of decreased libido, a serum testosterone concentration may be below the normal, which would be consistent with the disorder.
- If the patient has an enlarged prostate noted on digital rectal examination, a blood sample for prostate specific antigen should be obtained. If elevated, the patient should be evaluated for a prostate disorder, which could contribute to erectile dysfunction.

DIAGNOSIS

With the availability in the late 1990s of effective medications for erectile dysfunction independent of the etiology, diagnostic evalua-

tion of erectile dysfunction became streamlined.^{9,10} Key assessments include a description of the severity of erectile dysfunction, complete medical and surgical histories, review of concurrent medications, physical examination, and selected clinical laboratory tests.¹⁰

To assess the severity of erectile dysfunction, the patient should be asked about the quality of sexual intercourse for the last 4 weeks to 6 months. A self-administered standardized questionnaire, such as the International Index of Erectile Dysfunction (IIEF), is often used. It is administered before initiation of any treatment and repeated at regular intervals during treatment. It includes 15 questions about the quality of erectile function and satisfactoriness of sexual intercourse.¹¹ Questions include the following: How often were you able to maintain an erection? How difficult was it to sustain an erection? How satisfied are you with your sexual life? The physician should carefully assess the expectations for erectile function of the patient and the partner to ensure that the expectations are reasonable. Shorter versions of the IIEF and other self-reporting questionnaires are also used in clinical practice.

A medical history should be obtained to identify concurrent medical illnesses or surgical procedures that are risk factors for or are associated with organic or psychogenic erectile dysfunction. Underlying diseases that do not optimally respond to treatment should be addressed before specific treatment for erectile dysfunction is initiated. If the patient smokes cigarettes, drinks excessive amounts of ethanol, or uses recreational drugs, these social habits should be discontinued before specific treatment for erectile dysfunction is started.

A complete listing of the patient's prescription and nonprescription medications and dietary supplements should be reviewed by the clinician, who should identify drugs that may be contributing to erectile dysfunction. If possible, causative agents should be discontinued or the dose should be reduced.

A physical examination of the patient should include a check for hypogonadism (i.e., signs of gynecomastia, small testicles, and decreased body hair). The penis should be evaluated for diseases associated with abnormal penile curvature (e.g., Peyronie's disease), which are associated with erectile dysfunction. Femoral and lower extremity pulses should be assessed to provide an indication of

vascular supply to the genitals. Anal sphincter tone and other genital reflexes should be checked for the integrity of the nerve supply to the penis. A digital rectal examination in patients 50 years or more is needed to rule out benign prostatic hyperplasia, which may contribute to erectile dysfunction.

Selected laboratory tests should be obtained to identify the presence of underlying diseases that could cause erectile dysfunction. They include a fasting serum blood glucose and lipid profile. Serum testosterone levels should be checked in patients older than 50 years and in younger patients who complain of decreased libido. Serum testosterone levels follow a circadian pattern of secretion, with the highest levels occurring during the morning hours. To interpret serum testosterone levels properly, serum samples should be obtained in the mornings. At least two serial serum testosterone levels are needed to confirm the presence of hypogonadism.¹²

Finally, erectile dysfunction is a potential marker for arteriosclerosis. Therefore, patients who present with erectile dysfunction should undergo a cardiovascular risk assessment to identify treatable medical conditions.¹³

TREATMENT

Erectile Dysfunction

■ DESIRED OUTCOMES

The goal of treatment is improvement in the quantity and quality of penile erections suitable for satisfactory intercourse. Simple as this may sound, healthcare providers must ensure that patients and their partners have reasonable expectations for any therapies that are initiated. Furthermore, only patients with erectile dysfunction should be treated. Patients who have normal sexual function should not seek—or be encouraged to seek—treatment in an effort to enhance sexual function or enable increased activity.¹⁴

■ GENERAL APPROACH TO TREATMENT

3 The Second Princeton Consensus Conference is a widely accepted multidisciplinary approach to managing erectile dysfunction that maps out a stepwise treatment plan.^{15–17} The first step in clinical management of erectile dysfunction is to identify and, if possible, reverse underlying causes. Risk factors for erectile dysfunction, including hypertension, diabetes mellitus, smoking, or chronic ethanol abuse, should be addressed and minimized. Patients should follow a heart-healthy lifestyle, which includes physical fitness, weight loss to achieve a normal body mass index, low-cholesterol diets, no excessive ethanol intake, and no smoking.^{18,19} In some cases, these types of interventions are sufficient to restore erectile function. However, if erectile dysfunction does not respond to these measures, specific treatment is indicated.

For patients with psychogenic erectile dysfunction, psychotherapy can be used as monotherapy or as an adjunct to specific treatments for the disorder. To enhance the relevance of psychotherapy, both the patient and the partner should be included in the counseling sessions. Treatment should be individualized and should address immediate factors that may be causing performance anxiety or depression, rather than the remote, deep-seated reasons for psychological disorders.²⁰ The effectiveness of psychotherapy is generally low, and long-term psychotherapy is often necessary.

4 5 6 Specific treatments of erectile dysfunction include vacuum erection devices (VEDs), pharmacologic treatments, and surgery. The ideal treatment of this disorder should have a fast onset, be effective, be convenient to administer, be cost effective, have a low incidence of serious adverse effects, and be free of serious drug interactions (Table 86–3). Generally, when choosing from among treatment approaches, those that are least invasive are selected first; more invasive therapies are reserved for patients who do not respond to first-line agents. A sample algorithm that guides selection of treatment is shown in Fig. 86–2.

TABLE 86-3 Dosing Regimens for Selected Drug Treatments for Erectile Dysfunction

Route of Administration	Generic Name (Brand Name)	Dosage Form	Common Dosing Regimen
Oral	Yohimbine (Aphrodyne, Yocon, Yohimex)	5.4-mg tablet or capsule	5.4 mg three times per day
	Sildenafil (Viagra)	25-mg, 50-mg, 100-mg tablet	25–100 mg 1 hour before intercourse
	Apomorphine (Uprima) ^a	10-mg sublingual tablet, 25-mg tablet and capsule	10–40 mg daily
	Fluoxymesterone (Halotestin)	2-mg, 5-mg, 10-mg, 50-mg tablet	5–20 mg daily
	Trazodone (Desyrel)	100-mg, 150-mg, 300-mg tablet	50–150 mg daily
Topical	Vardenafil (Levitra)	2.5-mg, 5-mg, 10-mg, 20-mg tablet	5–10 mg 1 hour before intercourse
	Tadalafil (Cialis)	5-mg, 10-mg, 20-mg tablet	5–20 mg before intercourse
	Testosterone patch (Testoderm)	4 mg/patch, 6 mg/patch	4–6 mg/day; apply to scrotum
	Testosterone patch (Testoderm TTS)	4 mg/patch, 6 mg/patch	4–6 mg/day; apply to arm, buttock, back
	Testosterone patch (Androderm)	2.5 mg/patch	2.5–5 mg/day; apply to arm, back, abdomen, thigh
Intramuscular	Testosterone gel (AndroGel 1%)	5 g/pkt, 10 g/pkt	5–10 g/day; apply to shoulders, upper arms, abdomen
	Testosterone cypionate (Depo-Testosterone)	100 mg/mL, 200 mg/mL	200–400 mg every 2–4 weeks
	Testosterone enanthate (Delatestryl)	100 mg/mL, 200 mg/mL	200–400 mg every 2–4 weeks
Subcutaneous implant	Testosterone (Testopel)	75-mg pellet	150–450 mg every 3–4 months
Intraurethral	Alprostadil (MUSE)	125-mcg, 250-mcg, 500-mcg, 1,000-mcg pellet	125–1,000 mcg 5–10 minutes before intercourse
Intracavernosal	Alprostadil (Caverject)	5-mcg, 10-mcg, 20-mcg injection	2.5–60 mcg 5–10 minutes before intercourse
	Alprostadil (Edex)	5-mcg, 20-mcg, 40-mcg injection	2.5–60 mcg 5–10 minutes before intercourse
	Papaverine ^b	30 mg/mL injection	Variable, usually used in combination with alprostadil and phentolamine
	Phentolamine ^b	2.5 mg/mL injection	Variable, usually used in combination with alprostadil and papaverine

^aNot commercially available in the United States as a sublingual formulation; only available in United States as subcutaneous injection that is FDA approved for Parkinson's disease.

^bNot FDA approved for this use.

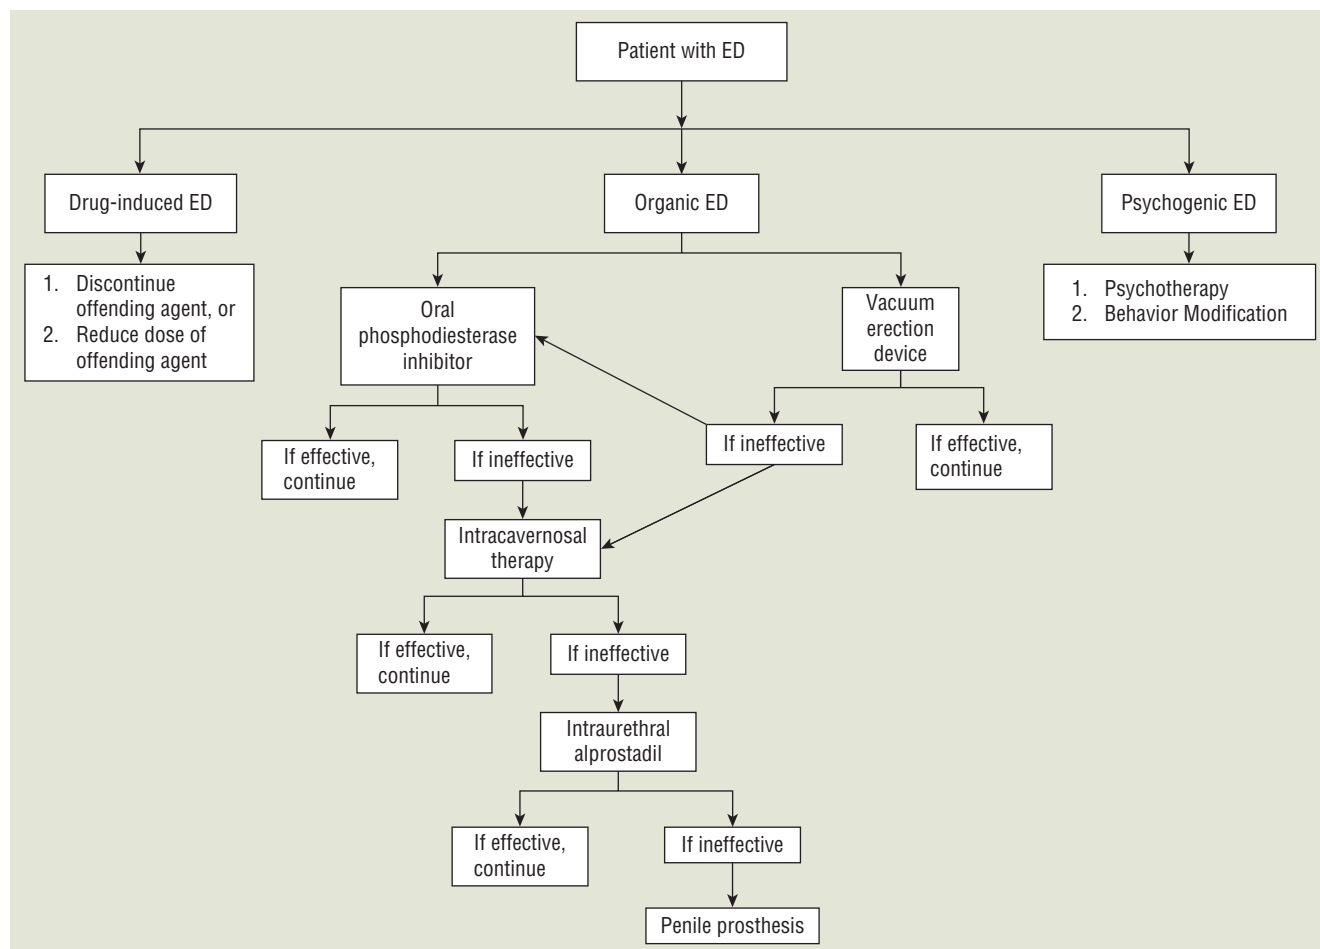

FIGURE 86-2. Algorithm for selecting treatment for erectile dysfunction. For organic erectile dysfunction (ED), oral agents are first-line therapy for younger patients, and vacuum erection devices are generally used first in older patients who are married or otherwise have a stable sexual relationship. These two approaches are sometimes used together in an effort to avoid surgical implantation of penile prostheses.

■ VACUUM ERECTION DEVICE

A VED has three parts: a pump, which generates a negative vacuum pressure; a cylinder, which is closed at one end and into which the penis is inserted; and tubing, which connects the pump to the cylinder. The patient inserts his penis into the open end of the cylinder, which is then pushed up flush against his lower abdomen to create a vacuum chamber. Then the patient activates the pump to produce a vacuum pressure, which draws arteriolar blood into the corpora cavernosa. To prolong the erection, the patient can use constriction bands or tension rings, which are placed at the base of the penis, to keep the arteriolar blood in and to reduce venous outflow from the penis. With the assistance of loading cones to protect the glans, these bands or rings can be rolled over the glans penis and up the erect penile shaft. Alternatively, they can be first threaded onto the plastic cylinder before the penis is inserted. Once the penis is erect, the band or ring can be rolled off the cylinder onto the base of the penis (Fig. 86-3).

7 The onset of action of the VED is comparatively slow (30 minutes), which requires patience from both the patient and the sexual partner. VEDs are not discreet. That is, a patient's use of a VED is evident to the partner. For this reason, VEDs appear to work best in older patients who are married or have stable sexual relationships. In this group, VEDs are considered first-line therapy, and the overall satisfaction rate is 60% to 80%.^{5,14} However, 6% to 11% of partners complain that the penis is cool to the touch or is discolored (bluish) in appearance, particularly when constriction bands are used.

VEDs may be used as second-line therapy in patients who do not respond to oral or injectable drug treatments for erectile dysfunction. The combination of a VED with intracavernosal or intraurethral alprostadil is associated with a higher efficacy rate than use of the VED alone. As a result, combination therapy sometimes is attempted before penile prosthesis surgery is considered in the patient who fails VED monotherapy.

VEDs are available with manual or battery-operated pumps. The latter offer greater convenience, particularly in patients with arthritis of the hands, who find the manual pumps too difficult and tiring to operate. The American Urological Association recommends the use of commercially available VEDs by prescription only.²¹

Pain or injury from VEDs most often is caused by the constriction bands used to sustain an erection. Because these rings trap blood in the corpora and reduce arteriolar flow into the penis, the penile shaft may feel cold and numb. If the constriction bands are applied for longer than 30 to 60 minutes, the penile shaft may turn blue and hurt. Patients may complain that a hinge-like erection is produced in that the penis pivots on the rubber ring or tension band. Patients sometimes fail to ejaculate.

VEDs are contraindicated in patients with sickle cell disease. These patients are prone to priapism, which can be exacerbated by the use of constriction bands with VEDs. The devices also should be used cautiously by patients taking oral anticoagulants because warfarin, through a poorly understood and idiosyncratic mechanism, can cause priapism.

FIGURE 86-3. Technique for using a vacuum erection device with tension band or rubber constriction ring. The patient inserts his penis into the cylinder, which is then pushed up flush against his lower abdomen to create a vacuum chamber. The patient activates the pump to produce a vacuum pressure, which draws arteriolar blood into the corpora cavernosa. To prolong the erection, the patient can use constriction bands or tension rings, which are placed at the base of the penis, to keep the arteriolar blood in and reduce venous outflow from the penis. (From <http://kidney.niddk.nih.gov/kudiseases/pubs/impotence>.)

■ PHOSPHODIESTERASE INHIBITORS

Mechanism

In the presence of sexual stimulation, nitric oxide is released by neurons or endothelial cells in penile tissue, thereby enhancing the activity of guanylate cyclase, the enzyme responsible for conversion of guanylate triphosphate to cGMP (Fig. 86-4).²² cGMP is a vasodilatory secondary messenger that enhances arterial flow to the corpora cavernosa and enhances blood filling of cavernosal sinuses. Catabolism of cGMP is mediated by phosphodiesterase.

Three selective inhibitors of the phosphodiesterase isoenzyme type 5 found in genital tissue are marketed for erectile dysfunction in the United States (Table 86-4). They act by decreasing catabolism of cGMP. However, phosphodiesterase isoenzyme type 5 is also found in peripheral vascular tissue, tracheal smooth muscle, and platelets. Inhibition of phosphodiesterase in these nongenital tissues can produce unwanted effects.

The three marketed phosphodiesterase inhibitors differ in their degree of selectivity in inhibiting other phosphodiesterase isoen-

zymes, pharmacokinetic profiles, drug-food interactions, and adverse effects (see Table 86-4).

Efficacy

Because of their apparent effectiveness, convenient route of administration, and comparatively low incidence of serious adverse effects, phosphodiesterase inhibitors are considered first-line therapy for erectile dysfunction, particularly in younger patients. They allow for discreet use. All three commercially available phosphodiesterase inhibitors are equally effective.^{23,24}

In the presence of sexual stimulation and in doses of 25 to 100 mg, sildenafil produces satisfactory erections in 56% to 82% of patients, independent of the etiology of erectile dysfunction. Similar results are documented in the product labeling for the other two agents in this class (65%–80% for vardenafil and 62%–77% for tadalafil). Response rates in the lower range for phosphodiesterase inhibitors have been documented in patients with diabetes mellitus or in patients after radical prostatectomy, probably due to postoperative nerve damage.^{22,25} The effectiveness of the drugs appears to be dose related.

8 Approximately 30% to 40% of patients do not respond to phosphodiesterase inhibitors.¹³ At least half of nonresponders can benefit from education on proper use of the drugs, and this likely will prove true for the other agents used for erectile dysfunction. Education of patients should include the following points: (1) patients must engage in sexual stimulation (foreplay) for the best response; (2) sildenafil should be taken on an empty stomach, at least 2 hours before meals, for the fastest response, but the other two agents can be taken without regard to meals; (3) taking sildenafil or vardenafil with a fatty meal can decrease the absorption rate, but the absorption rate of tadalafil is not affected²⁶; (4) patients who do not respond to the first dose should continue with the phosphodiesterase inhibitor for at least five to eight doses before failure is declared, as increasing success rates are reported with sequential dose administration²⁷; and (5) some patients require dosage titration up to 100 mg sildenafil, 20 mg vardenafil, or 20 mg tadalafil for a response.^{27–29}

The effectiveness of switching from one phosphodiesterase inhibitor to another when the patient does not respond to an initial agent is controversial. In two small studies, vardenafil was beneficial in patients who did not respond to sildenafil.^{26,30} However, controlled clinical trials in larger patient groups are needed before this strategy is used as routine treatment.

The phosphodiesterase inhibitors should not be used by patients with normal erectile function. Also, according to Food and Drug

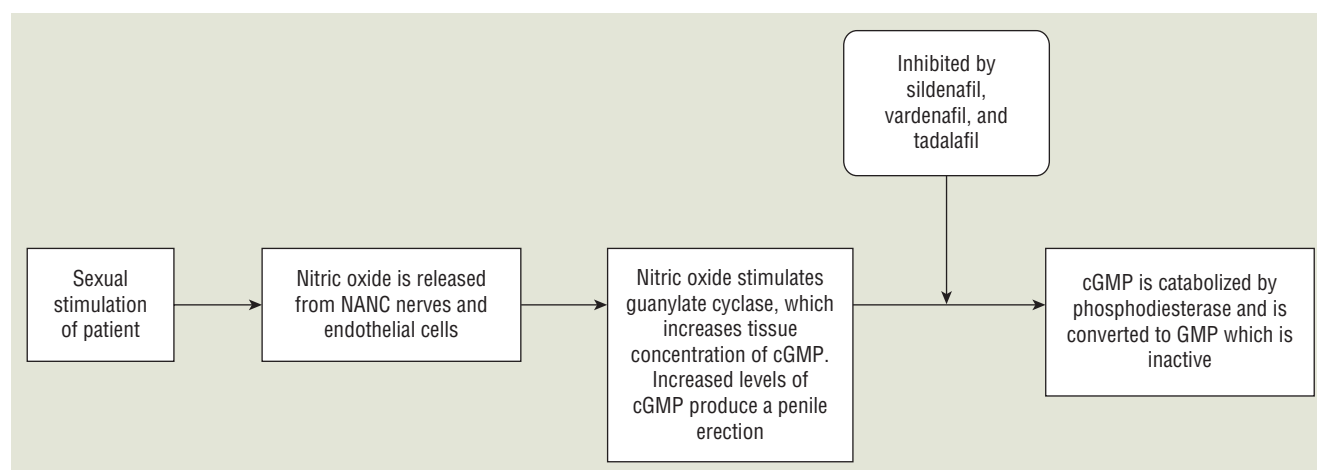

FIGURE 86-4. Mechanism of action of phosphodiesterase inhibitors. All inhibit catabolism of cGMP, a vasodilatory secondary messenger. (cGMP, cyclic guanosine monophosphate; NANC, nonadrenergic noncholinergic.)

TABLE 86-4 Pharmacodynamics and Pharmacokinetics of Phosphodiesterase Inhibitors

	Sildenafil (Viagra) ^a	Vardenafil (Levitra) ^a	Tadalafil (Cialis) ^a
Inhibits PDE-5	Yes	Yes	Yes
Inhibits PDE-6	Yes	Minimally	No
Inhibits PDE-11	No	No	Yes

Daily dose in mild hepatic impairment (mg)	25–100	5–20	10
Daily dose in moderate hepatic impairment (mg)	25–100	5–10	10
Daily dose in severe hepatic impairment (mg)	25	Not evaluated	Not recommended
Dose in patients taking cytochrome P450 3A4 inhibitors ^a	25 mg daily	2.5–5 mg every 24–72 hours	10 mg every 72 hours

^aSildenafil doses should be decreased when any potent cytochrome P450 3A4 inhibitor (e.g., cimetidine, erythromycin, clarithromycin, ketoconazole, itraconazole, ritonavir, and saquinavir) is used. Vardenafil doses vary according to the agent used (2.5 mg every 72 hours for ritonavir; 2.5 mg every 24 hours for indinavir, ketoconazole 400 mg daily, and itraconazole 400 mg daily; and 5 mg every 24 hours for ketoconazole 200 mg daily, itraconazole 200 mg daily, and erythromycin). Tadalafil doses are reduced only when the drug is used with the most potent cytochrome P450 3A4 inhibitors (e.g., ketoconazole, ritonavir).

PDE, phosphodiesterase.

Administration (FDA)-approved labeling, the drugs should not be used in combination with other forms of therapy for erectile dysfunction because prolonged erections may result.³¹

■ SELECTIVITY OF OTHER PHOSPHODIESTERASE ISOENZYMES

More than 25 different phosphodiesterase isoenzymes have been identified; however, the physiologic effects of stimulation and inhibition of some of these isoenzymes remain to be elucidated. Of note, phosphodiesterase isoenzyme type 6 is localized to the rods and cones of the eye. Inhibition of this isoenzyme has been associated with blurred vision and cyanopsia. Sildenafil is the most potent inhibitor of phosphodiesterase isoenzyme type 6, vardenafil is an intermediate inhibitor, and tadalafil is the least potent inhibitor.²⁶ Likewise, phosphodiesterase isoenzyme type 11 is localized to striated muscle. Inhibition of this isoenzyme has been associated with myalgia and muscle pain. Tadalafil exerts the greatest inhibitory activity against phosphodiesterase type 11.⁶

Pharmacokinetics and Drug–Food Interactions

Pharmacokinetic parameters of the phosphodiesterase inhibitors are listed in Table 86–4.

Vardenafil and sildenafil have similar pharmacokinetic profiles. Both drugs have a 1-hour onset of action, short duration of action, and oral absorption that is significantly delayed when the drug is taken within 2 hours of a fatty meal. In contrast, tadalafil has a delayed onset of action of 2 hours, has a prolonged duration of action up to 36 hours, and food does not affect its rate of absorption. Thus, tadalafil offers greater spontaneity for patients, as one dose can last through an entire weekend and allow for multiple acts of sexual intercourse over multiple days with a single dose.^{32–35}

The onset of action of these agents has undergone reexamination to assess how soon after drug administration patients can expect to have an erection suitable for intercourse. Although up to 50% of patients may develop an erection within 20 to 30 minutes of sildenafil 100 mg, vardenafil 20 mg, or tadalafil 20 mg, the rest of the patients may require a full hour to achieve an adequate erectile response.^{26,36} Therefore, patients should be instructed to allow adequate time for the drug to work.

Concomitant ingestion of ethanol with phosphodiesterase inhibitors can result in orthostatic hypotension. Therefore, the manufacturer recommends that patients avoid ethanol when taking these medications.

All three phosphodiesterase inhibitors are hepatically catabolized by the cytochrome P450 3A4 microsomal isoenzyme as well as by other P450 isoenzymes (minor routes) and/or other hepatic enzymes. The drugs and their metabolites (some of which are active) are excreted primarily in the feces, but also in the urine to varying degrees (see Table 86–4).

Dosing

The usual oral doses of the phosphodiesterase inhibitors are listed in Table 86–4. Sildenafil and vardenafil should be taken on demand or at least 30 to 60 minutes before sexual intercourse. Tadalafil should be taken at least 2 hours before sexual intercourse. The durations of action for sildenafil and vardenafil are 4 to 5 hours, whereas the effects of tadalafil last for 36 hours. The agents vary as to whether doses must be adjusted for patients 65 years and older and those with compromised hepatic or renal function. Patients should be advised to take no more than the amount prescribed and to use only one dose per day (or less often in the case of some patients taking tadalafil). Doses greater than those recommended have not consistently produced improved erectile responses.

For patients who do not respond to an adequate course of on-demand phosphodiesterase inhibitors for erectile dysfunction, regular daily dosing of these agents may improve endothelial function in cavernosal tissue. That is, regular use of phosphodiesterase inhibitors may increase local concentrations of cGMP, which may lead to increased oxygen tension, improved blood flow, and reduced endothelial damage. A preliminary clinical trial of daily use of tadalafil showed a 58% frequency of successful sexual intercourse compared with conventional on-demand use of tadalafil, which produced a 21% frequency of success.^{13,36} However, more extensive clinical study is needed to evaluate the benefit of regular daily use of phosphodiesterase inhibitors before the approach can be recommended.

Adverse Effects

Most adverse effects of the phosphodiesterase inhibitors are mild or moderate and are self-limited, and patients often become tolerant to

them with continued use.³⁷ The rates of drug discontinuation caused by adverse effects are low, ranging from 2.1% to 2.5%, and are similar for all three agents. In usual doses the most common adverse effects are headache (11%), facial flushing (12%), dyspepsia (5%), nasal congestion (3.4%), and dizziness (3%),²² all of which result from vasodilation or smooth muscle relaxation secondary to inhibition of phosphodiesterase isoenzyme type 5 in extragenital tissues.¹⁴

Sildenafil and vardenafil produce an 8- to 10-mm Hg decrease in systolic and a 5- to 6-mm Hg decrease in diastolic blood pressure starting approximately 1 hour after a dose is taken and lasting for 4 hours. Most patients are asymptomatic as a result of these blood pressure changes, but some patients, particularly those taking multiple antihypertensives or nitrates or those with baseline hypotension, may develop clinical symptoms as a consequence of these peripheral vascular effects. Tadalafil does not produce decreases in blood pressure, but it must be used with caution in patients with cardiovascular disease because of the cardiac risk inherent to sexual activity. A management approach for such patients, developed based on an analysis of deaths in men who were using sildenafil and commonly referred to as the recommendations of the Princeton Consensus Guideline Conference II,¹⁵ should be applied to all the phosphodiesterase inhibitors (Table 86–5).

Sildenafil and vardenafil cause increased sensitivity to light, blurred vision, or loss of blue–green color discrimination in 2% to 3% of patients. These effects result from inhibition of phosphodiesterase type 6 in the photoreceptor cells of in retinal rods and cones, particularly at doses larger than 100 mg.³⁹ Visual adverse effects commonly occur at the time of peak serum concentrations. Although visual adverse effects are mild and reversible, caution regarding use is recommended for airplane pilots, who rely on green and blue lights for landing planes. Tadalafil has minimal to no inhibitory activity against type 6 phosphodiesterase, and no visual adverse effects have been reported. Nevertheless, according to current product labeling, all phosphodiesterase inhibitors should be used cautiously in patients at risk for retinitis pigmentosa, a genetic disease associated with retinal phosphodiesterase deficiency.⁴⁰

Isolated cases of nonarteritic anterior ischemic optic neuropathy (NAION) have been associated with phosphodiesterase inhibitor use.⁴¹ Although a cause-and-effect relationship has not been definitively established, the blood pressure–lowering effects of these medications may decrease blood flow to the optic nerve and lead to

sudden unilateral decrease in vision. Because NAION may lead to permanent vision loss, the FDA has required inclusion of warnings on the product labeling of phosphodiesterase inhibitors. Specifically, before receiving these agents, patients at risk for NAION should be evaluated by an ophthalmologist. Patients at risk include those with glaucoma, macular degeneration, and diabetic retinopathy, and those who have undergone eye surgery or have experienced eye trauma. A patient who experiences sudden vision loss while taking a phosphodiesterase inhibitor should be evaluated for NAION before continuing treatment.

Tadalafil inhibits type 11 phosphodiesterase, which is found in skeletal muscle. This may explain the symptoms of lower back and limb muscle pain, which occur in a dose-related fashion in 7% to 30% of patients treated with doses of 10 to 100 mg.³²

Sildenafil inhibits phosphodiesterase isoenzyme type 5 in platelets, which theoretically could inhibit platelet aggregation. However, in vitro and in vivo studies show no significant effect of sildenafil on platelets.³⁶

Priapism is a rare adverse effect of phosphodiesterase inhibitors, particularly sildenafil and vardenafil, which have shorter plasma half-lives than tadalafil. Priapism has been associated with excessive doses of the phosphodiesterase inhibitor or concomitant therapy involving other erectogenic drugs.

Drug Interactions

Patients taking organic nitrates may develop severe hypotension if they are taken with phosphodiesterase inhibitors as a result of two major factors: (1) organic nitrates on their own produce hypotension, and (2) organic nitrates are nitric oxide donors, which can stimulate the activity of guanylate cyclase and increase tissue levels of cGMP. For this reason, use of the three phosphodiesterase inhibitors is contraindicated in patients taking nitrates given by any route at scheduled times or intermittently.^{15,42} Furthermore, nitrates should be withheld for 24 hours after sildenafil or vardenafil administration and for 48 hours after tadalafil administration.⁴² Finally, if a patient who has taken a phosphodiesterase inhibitor requires medical treatment of angina, non–nitrate-containing agents (e.g., calcium channel blocker, β -adrenergic antagonist, morphine) should be used.

If severe hypotension occurs after exposure to nitrates and a phosphodiesterase inhibitor, the patient should be placed in a

TABLE 86-5 Recommendations of the Second Princeton Consensus Conference for Cardiovascular Risk Stratification of Patients Being Considered for Phosphodiesterase Inhibitor Therapy

Risk Category	Description of Patient's Condition	Management Approach
Low risk	Has asymptomatic cardiovascular disease with <3 risk factors for cardiovascular disease Has well-controlled hypertension Has mild, stable angina Has mild congestive heart failure (NYHA class I) Has mild valvular heart disease Had a myocardial infarction >6 weeks ago	Patient can be started on phosphodiesterase inhibitor
Intermediate risk	Has ≥ 3 risk factors for cardiovascular disease Has moderate, stable angina Had a recent myocardial infarction or stroke within the past 6 weeks Has moderate congestive heart failure (NYHA class II)	Patient should undergo complete cardiovascular workup and treadmill stress test to determine tolerance to increased myocardial energy consumption associated with increased sexual activity
High risk	Has unstable or symptomatic angina, despite treatment Has uncontrolled hypertension Has severe congestive heart failure (NYHA class III or IV) Had a recent myocardial infarction or stroke within past 2 weeks Has moderate or severe valvular heart disease Has high-risk cardiac arrhythmias Has obstructive hypertrophic cardiomyopathy	Phosphodiesterase inhibitor is contraindicated; sexual intercourse should be deferred

NYHA, New York Heart Association.
From Rosen et al.¹⁵ and Kostis et al.¹⁷

Trendelenburg position and aggressive fluid administration initiated. If severe hypotension continues, parenteral α -adrenergic agonists (e.g., dopamine) should be administered cautiously.

Interestingly, dietary sources of nitrates, nitrites, or L-arginine (a precursor for nitrates) do not interact with the phosphodiesterase inhibitors. This is because dietary sources do not increase circulating levels of nitric oxide in humans.

Sildenafil does not appear to interact with antihypertensive medications. In retrospective analyses of patients taking sildenafil in combination with α -adrenergic antagonists, β -adrenergic antagonists, diuretics, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, or calcium channel blockers, the incidence of hypotension was similar to that reported in patients taking sildenafil alone.^{43,44} This finding was confirmed by a retrospective analysis of pooled data on more than 4,800 patients in 35 clinical trials.³¹

Small decreases in blood pressure with clinically symptomatic hypotension have been described in some patients taking sildenafil and tadalafil and immediate-release formulations of terazosin and doxazosin.⁴⁵ In contrast, concurrent administration of extended-release alfuzosin or tamsulosin, which produce lower peak serum concentrations than immediate-release formulations after administration, show no decrease in blood pressure.^{46,47} Until more data become available, manufacturers of phosphodiesterase inhibitors recommend a 4-hour interval between doses of phosphodiesterase inhibitors and α -adrenergic antagonists when these drugs are prescribed concomitantly in the same patient.

Hepatic metabolism of all three phosphodiesterase inhibitors can be inhibited by cytochrome P450 hepatic microsomal enzyme inhibitors of CYP 3A4, including cimetidine, erythromycin, clarithromycin, ketoconazole, itraconazole, ritonavir, and saquinavir.⁴⁸ Lower starting doses should be used in these patients (see Table 86–4).

CLINICAL CONTROVERSY

Some clinicians believe that tachyphylaxis may develop with continuous use of sildenafil, but others believe that a lack of responsiveness may be due to worsening of underlying diseases that may contribute to the development of erectile dysfunction.¹⁴ Positive treatment response despite continuous use of these agents for up to 6 years suggests that tachyphylaxis does not occur.^{26,38,49}

■ TESTOSTERONE REPLACEMENT REGIMENS

Mechanism

9 Testosterone replacement regimens supply exogenous testosterone and restore serum testosterone levels to the normal range (300–1,100 ng/dL). In so doing, testosterone replacement regimens correct symptoms of hypogonadism, which include malaise, loss of muscle strength, depressed mood, and decreased libido. Testosterone can directly stimulate androgen receptors in the central nervous system and is thought to be responsible for maintaining normal sexual drive. In addition, testosterone may stimulate nitric oxide synthase, thereby increasing cavernosal concentrations of nitric oxide,^{13,50,51} or enhance the effects of phosphodiesterase type 5 in cavernosal tissue.⁵²

Indications

Testosterone replacement regimens are indicated in symptomatic patients with primary or secondary hypogonadism, as confirmed by the presence of a decreased libido and low serum concentrations of testosterone.¹⁴ Serum testosterone concentrations typically are measured in the early morning because the secretion pattern of this hormone follows a circadian pattern, with highest serum concentrations in the morning hours. Simultaneous serum luteinizing hor-

mone levels help to distinguish patients with primary hypogonadism, who have elevated luteinizing hormone levels, from those with secondary hypogonadism, who have decreased luteinizing hormone levels. Primary hypogonadism can be a characteristic of aging men who undergo andropause, in which the Leydig cells of the testes slowly and progressively decrease testosterone production.⁵⁰

Testosterone replacement regimens should never be administered to men with normal serum testosterone levels.

Efficacy

Testosterone replacement regimens restore muscle strength and sexual drive and improve mood in patients with hypogonadism. Improvements are generally observed within days or weeks of the start of testosterone replacement. Administration of testosterone will correct the serum testosterone level to the normal range. No additional benefit has been demonstrated for large doses of testosterone, which increase the serum testosterone level from the low end to the upper end of the normal range or to the above-normal range.⁷ Testosterone replacement regimens do not directly correct erectile dysfunction; instead, they improve libido, thereby correcting secondary erectile dysfunction.

Testosterone replacement regimens can be administered orally, parenterally, or transdermally (Table 86–6). Injectable testosterone replacement regimens are the preferred treatment for symptomatic patients with primary or secondary hypogonadism because they are effective, inexpensive, and not associated with the bioavailability problems or hepatotoxic adverse effects of oral androgens.^{5,50} Although convenient for the patient, testosterone patches and gels are much more expensive than other forms of androgen replacement; therefore, they should be reserved for patients who refuse injectable testosterone.

In the ideal testosterone replacement regimen, the medication would mimic the normal circadian pattern of serum testosterone concentrations such that peak and trough concentrations occur in the early morning and late afternoon, respectively; produces serum concentrations in the normal range; produces serum concentrations of dihydrotestosterone and estradiol, which are metabolites of testosterone that mimic the normal physiologic pattern; and produces minimal adverse effects.⁵⁰ Table 86–6 compares commercially available testosterone replacement regimens for these characteristics and shows that an ideal regimen has yet to be identified.

Pharmacokinetics

Natural testosterone has poor oral bioavailability because of extensive first-pass hepatic metabolism; therefore, large doses must be taken. To improve oral bioavailability, alkylated derivatives were formulated. Of these derivative, methyltestosterone and fluoxymesterone are more resistant to hepatic catabolism and can be taken in smaller daily doses, which are potentially safer. However, oral alkylated derivatives of testosterone are associated with a higher incidence of serious hepatotoxicity and therefore are not preferred for management of hypogonadism.

An alternative to oral administration is the testosterone buccal system (Striant), which is applied to the gum above the upper incisor teeth twice per day. Over time it forms a gel from which testosterone is absorbed. One advantage of this route of administration is that the drug bypasses first-pass hepatic catabolism, which allows for increased bioavailability of testosterone.

Several testosterone esters have been formulated for intramuscular injection, with different durations of action (see Table 86–3). The shorter-acting testosterone propionate, which requires dosing three times per week, has largely been completely replaced with testosterone cypionate or enanthate, which can be dosed every 2, 4, or 6 weeks in most patients. An even longer-acting parenteral testoste-

TABLE 86-6 Comparison of Testosterone Replacement Regimens and Ideal Testosterone Replacement Regimen

	Achieves Serum Testosterone Concentrations in Normal Range?	Produces Normal Circadian Pattern of Serum Testosterone Concentrations?	Produces Normal Pattern of Serum Concentrations of Androgen Metabolites?	Adverse Effects
Oral testosterone	No	No	No	Hyperlipidemia Sodium retention
Oral alkylated androgens	Yes	No	No	Hyperlipidemia Sodium retention Hepatotoxicity
Intramuscular testosterone cypionate or enanthate	Yes	No; produces supraphysiologic serum concentrations for several days after injection	No, excess testosterone is converted to estradiol	Mood swings Gynecomastia Polycythemia Hyperlipidemia
Transdermal nonscrotal skin patch	Yes	Yes, provided the patch is placed at night	Yes	Dermatitis due to permeation enhancers in formulation
Transdermal scrotal skin patch	Yes	Yes provided the patch is applied in the morning	No; 5 α -reductase in scrotal skin metabolizes testosterone and increases serum concentrations of dihydrotestosterone	Dermatitis due to permeation enhancers in formulation
Transdermal gel	Yes	Yes	Yes	May be inadvertently transferred to others who rub up against the patient's skin treated area
Testosterone subcutaneous implant	Yes	No	No; produces elevated concentrations of dihydrotestosterone	Pellet may be extruded accidentally, resulting in loss of drug effect
Buccal system	Yes	No	Yes	Gum irritation, bitter taste

Data from Gore JL, Swerdloff RS, Rajfer J. Androgen deficiency in the etiology and treatment of erectile dysfunction. *Urol Clin N Am* 2005;32:457–468.

rone is available as a subcutaneous implant for dosing every 4 to 6 months. Although this schedule minimizes repeat visits to the clinician's office for repeated dosing, the implant must be administered by a physician, and the implanted pellet may be extruded after administration. This extrusion has been reported in up to 8.5% of treated patients and results in loss of drug effect. However, these testosterone formulations produce suprapharmacologic patterns of serum testosterone during the dosing interval, which have been linked to mood swings in some patients.

Topical testosterone replacement regimens can be delivered as once-daily patches or gel. Testosterone patches increase serum testosterone levels into the normal range in 2 to 6 hours. Serum testosterone levels return to baseline 24 hours after patch administration. However, unlike oral or injectable supplements, transdermal testosterone patches applied at bedtime or testosterone gel applied each morning produce physiologic patterns of serum testosterone levels throughout the day. The clinical importance of this biochemical effect is unknown.⁵⁰

The original Testoderm brand patch was formulated for scrotal application. Scrotal skin is thinner and has a richer vascular supply than does the skin on the arms or thighs. Therefore, application of Testoderm patches produces excellent absorption of the hormone. However, the patch can fall off when the scrotum becomes damp or moist, when the patient exercises, or if the scrotum is excessively hairy.

For improved convenience, Androderm and Testoderm TTS patches were formulated for application to the arms, buttocks, or back; Androderm can also be applied to the thighs. The addition of absorption enhancers and different adhesives has been linked to a higher incidence of contact dermatitis with Androderm patches compared with the original Testoderm scrotal patch.

Testosterone gel 1% formulation (AndroGel) is applied in much larger doses—5 or 10 g each day—to the skin of the shoulders, upper arms, or abdomen. The hormone is absorbed quickly, within 30 minutes, but several hours may be required for complete absorption of the dose. For this reason, the patient should be reminded to wait at least 5 to 6 hours after application before showering. To prevent inadvertent transfer of testosterone gel to others, the patient should thoroughly wash his hands with soap and water after administration of a dose.

Dosing

Table 86–3 lists the usual doses for testosterone replacement regimens. Two to three months is considered an adequate treatment trial with a particular dose. Thus, a dose should not be increased until the patient has used one particular dose for at least this time period.⁵²

Before initiating any testosterone replacement regimen in patients 40 years and older, patients should be screened for benign prostatic hyperplasia and prostate cancer. Both of these diseases are testosterone-dependent conditions and theoretically could be worsened by exogenous administration of testosterone. Prostate cancer is a contraindication to androgen supplementation. To screen for these conditions, a prostate-specific antigen serum concentration should be obtained and a digital rectal examination of the prostate performed. These tests are generally repeated at 1-year intervals after treatment is started.⁵⁰

Adverse Effects

Testosterone replacement regimens can cause sodium retention, which can cause weight gain, or exacerbate hypertension, congestive heart failure, and edema. Gynecomastia can occur as a result of conversion of testosterone to estrogen in peripheral tissues. This has been reported most often in patients with liver cirrhosis.

Deleterious serum lipoprotein changes have been reported, including decreasing high-density lipoprotein cholesterol levels. However, no cases of cardiovascular disease have been reported with testosterone replacement regimens.

Large doses of parenteral testosterone can produce adverse metabolic effects. Thus, patients on long-term testosterone replacement regimens must undergo clinical laboratory testing for a serum testosterone level, lipid profile, and hematocrit before starting treatment and every 6 to 12 months during treatment.⁵⁰ Repeated serum testosterone levels that exceed the normal range require a dosage reduction or increased interval between drug doses. An abnormal lipid profile may require lifestyle and dietary modification and, if necessary, antihyperlipidemic drug therapy. If the hematocrit exceeds 55%, the testosterone replacement regimen should be withheld to avoid polycythemia and its consequences.

Oral alkylated testosterone replacement regimens have caused hepatotoxicity, ranging from mild elevations of hepatic transami-

nases to serious liver diseases, including peliosis hepatis (hemorrhagic liver cysts), hepatocellular and intrahepatic cholestasis, and benign or malignant tumors. For this reason, parenteral testosterone replacement regimens are preferred.

Topical testosterone patches may cause contact dermatitis, which responds well to topical corticosteroids. This adverse effect has been associated with the presence of permeation enhancers, which are added to patch formulations. If the dermatitis becomes problematic, an alternative is testosterone gel formulations, which are associated with a lower incidence of contact dermatitis compared with patches.

■ ALPROSTADIL

Mechanism

Alprostadil, also known as prostaglandin E_1 , stimulates adenylyl cyclase, resulting in increased production of cAMP, a secondary messenger that causes smooth muscle relaxation of the arterial blood vessels and sinusoidal tissues in the corpora. This results in enhanced blood flow to, and blood filling of the corpora.

Alprostadil is commercially available as an intracavernosal injection (Caverject and Edex) and as an intraurethral insert (medicated urethral system for erection [MUSE]).

Indications

Both commercially available formulations of alprostadil are FDA approved as monotherapy for management of erectile dysfunction. Alprostadil is more effective by the intracavernosal route than the intraurethral route.

The enhanced efficacy of the intracavernosal injection may be related to the excellent bioavailability of the drug when injected directly into the corpora cavernosum. In contrast, intraurethral alprostadil doses generally are several hundred times larger than intracavernosal doses. This is because intraurethral alprostadil must be absorbed from the urethra, through the corpus spongiosum, and into the corpus cavernosum, where it exerts its full proerectogenic effect.

Although several other agents, including papaverine, phentolamine, and atropine, have been used off-label for intracavernosal therapy, alprostadil is preferentially prescribed. This is because intracavernosal alprostadil has been FDA approved for erectile dysfunction, it does not require extemporaneous compounding, and it has a low potential for causing prolonged erections and priapism.

Both formulations of alprostadil are considered more invasive than VEDs or phosphodiesterase inhibitors. For this reason, intracavernosal alprostadil is generally prescribed after patients do not respond to or cannot use the less invasive interventions. Intracavernosal alprostadil is preferred over intraurethral alprostadil because of its greater effectiveness. Intracavernosal alprostadil may be preferred in patients with diabetes mellitus, who are accustomed to injectable drug therapy and may suffer from peripheral neuropathies, which decrease the patient's perception of pain upon injection. Intraurethral alprostadil is generally reserved as a treatment of last resort for patients who do not respond to other less invasive and more effective forms of therapy and who refuse surgery.

Intracavernosal Alprostadil

Efficacy The overall efficacy of intracavernosal alprostadil is 70% to 90%.⁵ Three characteristics of intracavernosal alprostadil are the following:

1. The effectiveness of alprostadil is dose related over the range from 2.5 to 20 mcg. The mean duration of erection is directly related to the dose of alprostadil administered and ranges from 12 to 44 minutes.

2. A higher percentage of patients with psychogenic and neurogenic erectile dysfunction respond to alprostadil at a lower dose compared to patients with vasculogenic erectile dysfunction.
3. Tolerance does not appear to develop with continued use of intracavernosal alprostadil at home.

⑩ Although 70% to 75% of patients respond to intracavernosal alprostadil, a high proportion of patients elect to discontinue its use over time. Depending on the study and the length of observation, 30% to 50% of patients voluntarily discontinue therapy, usually during the first 6 to 12 months. Common reasons for discontinuation include lack of perceived effectiveness; inconvenience of administration; an unnatural, nonspontaneous erection; needle phobia; loss of interest; and cost of therapy.^{5,53}

Approximately one third of patients do not respond to usual doses of intracavernosal alprostadil. In these patients, intracavernosal alprostadil has been used successfully along with VEDs. Such combination therapy can be attempted by patients before transitioning to more invasive surgical procedures.^{54,55} Alternatively, intracavernosal injections of synergistic combinations of vasoactive agents that act by different mechanisms have been used.⁵⁴ Intracavernosal drug combinations typically produce an erection that lasts longer than an erection produced by any one of the agents in the mixture. In addition, because of the low dosage of each agent in the combination, fewer systemic and local fibrotic adverse effects develop compared with high-dose monotherapy. For example, when used in low-dose combination regimens, papaverine is less likely to induce hypotension and liver dysfunction, and phentolamine is less likely to induce tachycardia and hypotension.⁵⁵ However, as previously mentioned, such intracavernosal drug combinations are not commercially available and must be extemporaneously compounded.

Pharmacokinetics Intracavernosal injection should be administered into only one corpus cavernosum. From this injection site, the drug will reach the other corpus cavernosum through vascular communications between the two corpora. Alprostadil acts rapidly, with an onset in 5 to 15 minutes. The duration is directly related to the dose. Within the usual dosage range of 2.5 to 20 mcg, the duration of erection is no more than 1 hour. Higher doses are expected to exhibit a longer duration of action. Local enzymes in the corpora cavernosum quickly metabolize alprostadil. Any alprostadil that escapes into the systemic circulation is deactivated on first pass through the lungs.⁵ Hence, the plasma half-life of alprostadil is approximately 1 minute, and the potential for systemic adverse effects is negligible. Dose modification is not necessary in patients with renal or hepatic disease.

Dosing The usual dose of intracavernosal alprostadil is 10 to 20 mcg, with a maximum recommended dose of 60 mcg. Doses greater than 60 mcg have not produced any greater improvement in penile erection but may cause prolonged erections lasting more than 1 hour or systemic hypotension.⁵ The dose should be administered 5 to 10 minutes before intercourse. The manufacturer recommends that patients be slowly titrated up to the minimally effective dosage. Under a physician's supervision, patients should be started with a 1.25-mcg dose, which can be increased in increments of 1.25 to 2.50 mcg at 30-minute intervals up to the lowest dose that produces a firm erection for 1 hour and does not produce adverse effects. In clinical practice, this process is rarely done because it is time consuming. Thus, many physicians start the patient on 10 mcg and move quickly up the dosage range to identify the best dose for the patient. To avoid adverse effects, patients should receive no more than one injection per day and not more than three injections per week.

Intracavernosal injections should be performed using a 0.5-inch, 27- or 30-gauge needle. A tuberculin syringe or a syringe prefilled with diluent as supplied by the manufacturer should be used to

FIGURE 86-5. Technique for administration of intracavernosal injections. (From package insert for Caverject, Pharmacia & Upjohn company, Kalamazoo, MI. Revised October 2003. Data from http://pfizer.com/pfizer/do/medicines/mn_uspi.jsp. Web site accessed 3/27/2007.)

ensure precise measurement of doses. Patients with needle phobia, poor vision, or poor manual dexterity can use commercially available autoinjectors (e.g., PenInject) to facilitate administration of intracavernosal alprostadil.

Intracavernosal injections require that the patient or the sexual partner practice good aseptic technique (to avoid infection), have good manual skills and visual ability, and be comfortable with injection techniques. When practicing self-injection, the patient should use one hand to firmly hold the glans penis against his thigh to expose the lateral surface of the shaft. The injection should be made at right angles into one of the lateral surfaces of the proximal third of the penis. The injection should never be made into the dorsal or ventral surface of the penis. This will prevent inadvertent injection of the drug into arteries on the dorsal surface or the urethra on the ventral surface. After the injection, the penis should be massaged to help distribute the drug into the opposite corpus cavernosum. Injection sites should be rotated with each dose. Finally, manual pressure should be applied to the injection site for 5 minutes to reduce the likelihood of hematoma formation (Fig. 86-5).

Once the optimal dosage of intracavernosal alprostadil is established, the patient should return for routine medical followup every 3 to 6 months. Some patients subsequently require dosage adjustment, largely attributed to worsening of the underlying disease that is contributing to the erectile dysfunction.

Adverse Effects Intracavernosal alprostadil is most commonly associated with local adverse effects, which occur most often during the first year of therapy. However, improved administration technique with continued use is believed to account for the lower frequency of adverse effects during subsequent treatment periods.

Intracavernosal injections are associated with several local adverse effects. Cavernosal plaques or areas of fibrosis at injection sites form in approximately 2% to 12% of patients. When they occur, the patient should suspend further injections until the plaques resolve. These plaques may cause penile curvature, similar to Peyronie disease, which makes sexual intercourse difficult or impossible. The cause of corporal fibrosis and plaque formation is

unknown. This adverse effect may be caused by poor injection technique⁵⁶ or by alprostadil itself. Although patients have developed corporal fibrosis, alprostadil may be less likely to cause this adverse effect compared to other intracavernosal drug combinations, such as phentolamine or papaverine. Unlike cavernosal fibrosis associated with large doses and repeated administration of papaverine, penile scarring secondary to alprostadil appears to be unpredictable.

Alprostadil causes penile pain in approximately 10% to 44% of patients. The pain has been described as a burning discomfort or dull pain near the injection site or during the erection, which generally does not persist after the penis becomes flaccid. The pain usually is mild, generally does not require discontinuation of therapy, and often abates even with continued treatment. However, 2% to 5% of patients discontinue taking alprostadil because of severe pain. The pain can be managed by oral analgesics (e.g., acetaminophen), if necessary. One investigator has recommended adding procaine to intracavernosal alprostadil, but this may mask the signs of more serious adverse effects of the drug or of penile injury during intercourse and is not recommended.⁵⁸ The mechanism of this adverse reaction is poorly understood. Alprostadil may intrinsically produce pain. Also, the pain may be a result of the pH of the parenteral solution. Alprostadil is acidic, and the commercially available Caverject formulation is buffered with sodium citrate, a weak base, to reduce pain on injection.⁵

Priapism, a prolonged, painful erection lasting more than 1 hour, occurs in 1% to 15% of treated patients.⁵ It occurs most often during the dose titration period and is rare thereafter. Blood sludging in the corpora can lead to tissue hypoxia and cavernosal fibrosis and scarring. The risk for this complication is greatest for erections that persist beyond 4 hours. Patients are advised to seek medical attention immediately when drug-induced erections last more than 1 hour, as this is considered a urologic emergency. Its management includes supportive care, including analgesics for pain and sedatives for anxiety. In addition, needle aspiration of sludged blood in the corpora or intracavernosal injection of α -adrenergic agonists (e.g., phenylephrine) has been used.⁵ These procedures facilitate venous drainage of the corpora, allowing venous outflow to “catch up” with arterial inflow.

The likelihood of prolonged erections with intracavernosal alprostadil is dose related. Therefore, to prevent this adverse effect, the lowest effective dose should be used, and the dose should be titrated to ensure that the duration of the erection is no more than 1 hour.

Other local adverse effects include injection site hematomas and bruising. These effects are largely the result of unskillful injection technique. To minimize the risk of injection site hematomas, patients should be advised to apply pressure to the injection site for 5 minutes after each dose. Similarly, infection at the injection site has been reported. Meticulous aseptic technique is recommended to prevent this complication.

Intracavernosal alprostadil rarely causes systemic adverse effects, owing to the agent's localized injection and rapid catabolism. However, large doses greater than 20 mcg are associated with dizziness and hypotension in some patients and is one reason why such large doses are not commonly used.

Intracavernosal injection therapy should be used cautiously by patients at risk for priapism, including patients with sickle cell disease or lymphoproliferative disorders. It should be used cautiously by patients who may develop bleeding complications secondary to injections, including patients with thrombocytopenia or those taking anticoagulants. It also should be used cautiously by patients who use poor-quality injection technique, including patients with psychiatric disorders, obese patients (who may not be able to reach or see the penile injection site), patients who are blind, and patients with severe arthritis.

Intraurethral Alprostadil

Efficacy ¹⁰ Intraurethral alprostadil inserts are marketed as MUSE, which contains a medication pellet inside a prefilled urethral applicator. Multiple studies show this product has an overall effectiveness rate of 43% to 60%⁵ compared with 70% to 90% for intracavernosal alprostadil. Its decreased effectiveness and inconvenient administration method have resulted in this product being considered a third-line treatment option for patients with erectile dysfunction. However, some patients respond to intraurethral alprostadil even though they did not respond to intracavernosal alprostadil.⁵⁸

Intraurethral alprostadil has been combined with an adjustable penile constriction band to improve treatment response.⁵⁹

Pharmacokinetics Following intraurethral instillation, alprostadil is absorbed quickly through the urethra, into the corpus spongiosum, and then into the corpora cavernosum. As much as 90% of each dose is absorbed by the urethra and corpus spongiosum in less than 10 minutes, with peak absorption occurring in 20 to 25 minutes. An estimated 20% of each dose is delivered to the corpora cavernosum. As with intracavernosal injections of alprostadil, any drug absorbed into the systemic circulation is rapidly metabolized on first pass through the lungs.

The onset after intraurethral insertion is similar to that of intracavernosal injection, 5 to 10 minutes.

Dosing The usual dose of intraurethral alprostadil is 125 to 1000 mcg. The dose should be administered 5 to 10 minutes before sexual intercourse. No more than two doses per day are recommended. Before administration, the patient should be advised to empty his bladder, voiding completely.

Similar to intracavernosal injection treatments, intraurethral insertion of alprostadil requires good manual and visual skills to minimize the risk of urethral injuries. Intraurethral alprostadil is supplied in a prefilled intraurethral applicator. The patient should void first. With one hand the patient holds the glans penis, and with the other hand the patient inserts the intraurethral applicator 0.5 inch into the urethra. The drug pellet is then pushed into the urethra. The penis should be massaged to enhance drug dissolution in the urethral fluids and drug absorption (Fig. 86–6).

Adverse Effects The urethra can be injured because of improper administration technique. Injuries can lead to urethral stricture and difficulty voiding. Patients should receive complete education about optimal administration procedures before starting treatment.

Urethral pain has been reported in 24% to 32% of patients. Usually it is mild and does not require discontinuation of treatment. Female sexual partners may experience vaginal burning, itching, or pain, which probably is related to transfer of alprostadil from the man's urethra to the woman's vagina during intercourse. However, the resumption of sexual intercourse also could produce such symptoms.

Prolonged painful erections (priapism) have been rarely reported.⁵

Syncope and dizziness have been reported rarely (only 2% to 3% of patients) and likely are related to use of excessively large doses.

CLINICAL CONTROVERSY

Although combinations of proerectogenic drugs (e.g., sildenafil plus alprostadil intracavernosal injection) may be used by some patients,¹³ such combinations are not recommended by the FDA and may lead to prolonged erections and priapism.

■ UNAPPROVED AGENTS

A variety of other commercially available and investigational agents have been used for management of erectile dysfunction. Although it

FIGURE 86-6. Technique for administration of intraurethral alprostadil with a medicated urethral system for erection applicator. (From package insert for Muse, Vivus, Inc., Mountain View, CA. Data from <http://www.vivus.com>. Web site accessed 3/27/2007.)

is beyond the scope of this chapter to discuss all of them, some of the more commonly used agents are discussed here.

Trazodone

The mechanism by which trazodone produces an erection is not clear. It likely acts peripherally to antagonize α -adrenergic receptors. As a result, a predominant cholinergic effect results, which causes peripheral arteriolar vasodilation and relaxation of cavernosal tissues, enhancing blood filling of the corpora. Intracavernosal injection of trazodone in experimental studies supports this likely mechanism.⁶⁰

Although some clinical trials suggested that trazodone 50 to 200 mg daily by mouth might be effective in the management of erectile dysfunction, these trials were generally poorly controlled, were non-

randomized, included small samples treated for short time periods, and did not include validated objective parameters of response.^{60,61}

The adverse effects of trazodone, when used for erectile dysfunction, are similar to those reported with trazodone when used to treat depression and include dry mouth, sedation, and dizziness.

Yohimbine

Yohimbine, a tree-bark derivative also known as *yohimbe*, is widely used as an aphrodisiac. Yohimbine is a central α_2 -adrenergic antagonist that increases catecholamines and improves mood. Some investigators believe that yohimbine has peripheral proerectogenic effects. Yohimbine may reduce peripheral α -adrenergic tone, thereby permitting a predominant cholinergic tone, which could result in a vasodilatory response.^{5,62} The usual oral dose is 5.4 mg three times per day.

A controlled clinical trial has shown that high-dose yohimbine (100 mg daily) is no more effective than placebo.⁶³ Based on a meta-analysis of published studies that came to the same conclusion, the American Urological Association has cautioned against the use of yohimbine.²¹ In addition, yohimbine can cause many systemic adverse effects, including anxiety, insomnia, tachycardia, and hypertension. In a 2004 article on “12 supplements you should avoid,” *Consumer Reports* called yohimbine “likely hazardous” and reported that deaths and cardiovascular adverse effects had been associated with its use.

Papaverine

Papaverine is a nonspecific phosphodiesterase inhibitor that decreases metabolic catabolism of cAMP in cavernosal tissue. As a result of enhanced tissue levels of cAMP, smooth muscle relaxation occurs. Cavernosal sinusoids fill with blood, and a penile erection results.⁵

Papaverine is not FDA approved for erectile dysfunction. Intracavernosal papaverine alone is not commonly used for management of erectile dysfunction because the large doses required produce dose-related adverse effects, such as priapism, corporal fibrosis, hypotension, and hepatotoxicity.^{55,64} Papaverine is more often administered in lower doses combined with phentolamine and/or alprostadil. A variety of formulas have been used, but no one mixture has been proven better than other mixtures (see Table 86–6). Combination formulations are considered safer and are associated with the potential for fewer serious adverse effects than high doses of any one of these agents.

A portion of each papaverine dose is systemically absorbed, and its prolonged plasma half-life of 1 hour contributes to adverse effects. The usual dose of papaverine is 7.5 to 60 mg when used as a single agent for intracavernosal injection. When used in combination, the dose decreases to 0.5 to 20 mg.

If treated with papaverine, patients with a history of underlying liver disease or alcohol abuse should undergo liver function tests at baseline and every 6 to 12 months during continued treatment.

Phentolamine

Phentolamine is a competitive nonselective α -adrenergic blocking agent. It reduces peripheral adrenergic tone and enhances cholinergic tone. As a result, it improves cavernosal filling and is proerectogenic.

Phentolamine has most often been administered as an intracavernosal injection. Monotherapy is avoided because large doses are required for an erection, and at these large doses systemic hypotensive adverse effects would be prevalent. Most often, phentolamine has been used in combination with other vasoactive agents for intracavernosal administration. A ratio of 30 mg papaverine to 0.5 to 1 mg phentolamine is typical, and the usual dose ranges from 0.1 to 1 mL of the mixture. Such a mixture promotes local effects of phentolamine and minimizes systemic hypotensive adverse effects.⁵

Hypotension is the most common adverse effect of intracavernosal phentolamine. It is more common and more severe with large

FIGURE 86-7. Example of surgically implanted penile prosthesis. (a, activation mechanism; b, reservoir with fluid for inflating prosthesis; c, inflatable rods in corpora.) (From <http://kidney.niddk.nih.gov/kudiseases/pubs/impotence/>.)

doses or in patients with poor injection technique who have injected into a vein (rather than the cavernosa). Prolonged erections have been reported in patients who used excessive doses of combination intracavernosal therapy.

■ PENILE PROSTHESES

Surgical insertion of a penile prosthesis is the most invasive treatment of erectile dysfunction. It is reserved for patients who do not respond to or who are not candidates for less invasive oral or injectable treatments.

Prosthesis insertion requires anesthesia and skilled urologists. Two prostheses are widely used: malleable and inflatable. Malleable prostheses consist of two bendable rods that are inserted into the corpora cavernosa. The patient appears to have a permanent erection after the procedure; the patient is able to bend the penis into position at the time of intercourse.

The inflatable prosthesis has several mechanical parts. The inflatable prosthesis produces a more natural erection. The patient develops an erection only when the device is activated. Some newer advances in inflatable prosthesis technology have resulted in devices with fewer mechanical parts. These devices can be placed during shorter surgical procedures and are less likely to malfunction than are the original inflatable prostheses (Fig. 86–7).

Penile prostheses provide penile rigidity suitable for vaginal intercourse and are associated with a greater than 90% patient satisfaction rate, which is generally higher than that observed with any other drug treatment or VED.⁶⁵ The surgical success rate after insertion is 82% to 98%.⁵

Adverse effects of prosthesis insertion can occur early or late after the surgical procedure. The most common early complication is infection. Late complications include mechanical failure of the prosthesis, particularly when an inflatable prosthesis has been inserted. With improved technology, the mechanical failure rate has decreased to 5%.⁵ Other late complications include erosion of the rods through the penis or late-onset infection. Although some salvage procedures have been devised, in many cases the prosthesis requires removal.

EVALUATION OF THERAPEUTIC OUTCOMES

The primary therapeutic outcomes of specific treatments for erectile dysfunction include (1) improvement in the quantity and quality of

penile erections suitable for intercourse and (2) avoidance of adverse drug reactions and drug interactions.

At baseline and after the patient has completed a clinical trial period of 1 to 3 weeks with a specific treatment for erectile dysfunction, the physician should conduct assessments to determine whether the quality and quantity of penile erections has improved. A patient's level of satisfaction is highly individualized, depending on his lifestyle and expectations. Therefore, a patient who has successful intercourse once per week might be completely satisfied, whereas another patient might judge this to be unsatisfactory. Patients with unrealistic expectations in this regard must be identified and counseled by clinicians to avoid adverse effects of excessive use of erectogenic agents.

Failure to improve the quality and quantity of penile erections suitable for intercourse after an appropriate clinical trial period with a specific treatment for erectile dysfunction occurs in a significant percentage of patients. In this case, physicians generally take the following steps in order:

1. Ensure that the patient has been prescribed a maximum tolerated dose and has an adequate clinical trial of a specific treatment before discarding it as ineffective.
2. Switch to another drug, usually one with a greater potential for adverse effects and complications than the first drug initiated (see Fig. 86-4).
3. Reserve surgical treatment for patients who do not respond to drug treatment.

CONCLUSIONS

Erectile dysfunction is a common disorder of aging men. Its incidence is higher in patients with underlying medical disorders that compromise the vascular, neurologic, hormonal, or psychogenic systems necessary for a normal penile erection. Medications are common causes of erectile dysfunction. By correcting the underlying etiology, erectile dysfunction can often be reversed without the use of specific treatments.

When treatments of erectile dysfunction are needed, the least invasive forms of treatment should be used first because they produce the lowest incidence of serious adverse effects. VEDs or phosphodiesterase inhibitors are considered first-line treatments. If these treatments fail, intracavernosal alprostadil injection therapy can be initiated. If this treatment fails, the patient can attempt a combination of intracavernosal alprostadil plus VED, combination intracavernosal therapy, or intraurethral alprostadil. If this treatment fails, the patient may require insertion of a penile prosthesis.

Some insurance companies do not reimburse for drug treatments for erectile dysfunction, so cost is an important issue for some patients.

Clinicians should provide clear and simple advice. Patient confidentiality and privacy, which are extremely important to men with erectile dysfunction, should be maintained at all times.

Management of Benign Prostatic Hyperplasia

MARY LEE

KEY CONCEPTS

- 1 Although symptomatic benign prostatic hyperplasia (BPH) is rare in men younger than 50 years, it is very common in men 60 years and older as a result of androgen-driven growth in the size of the prostate. Symptoms commonly result from both static and dynamic factors.
- 2 BPH symptoms may be exacerbated by medications, including antihistamines, phenothiazines, tricyclic antidepressants, and anticholinergic agents. In these cases, discontinuing the causative agent can relieve symptoms.
- 3 Specific treatments for BPH include watchful waiting, drug therapy, and surgery.
- 4 For patients with mild disease who are asymptomatic or have mildly bothersome symptoms and no complications of BPH disease, no specific treatment is indicated. These patients can be managed with watchful waiting. Watchful waiting includes behavior modification and return visits to the physician at 12-month intervals for assessment of worsening symptoms or signs of BPH.
- 5 If symptoms progress to a moderate or severe level, drug therapy or surgery is indicated. Drug therapy with an α_1 -adrenergic antagonist is an interim measure that relieves voiding symptoms. In selected patients with prostates of at least 40 g, 5 α -reductase inhibitors delay symptom progression and reduce the incidence of BPH-related complications.
- 6 All α_1 -adrenergic antagonists are equally effective in relieving BPH symptoms. Older second-generation α_1 -adrenergic antagonists (e.g., terazosin, doxazosin) can cause adverse cardiovascular effects, mainly first-dose syncope, orthostatic hypotension, and dizziness. In patients who cannot tolerate hypotensive effects of the second-generation agents, the third-generation, pharmacologically uroselective agent tamsulosin is a good alternative. An extended-release formulation of alfuzosin, a second-generation functionally uroselective agent, has fewer cardiovascular adverse effects than terazosin or doxazosin; however, whether alfuzosin has the same cardiovascular safety profile as tamsulosin is unclear.
- 7 5 α -Reductase inhibitors are useful primarily in patients with large prostates greater than 40 g who wish to avoid surgery and

cannot tolerate the side effects of α_1 -adrenergic antagonists. 5 α -Reductase inhibitors have a slow onset of action, taking up to 6 months to exert maximal clinical effects, which is a disadvantage of their use. In addition, decreased libido, erectile dysfunction, and ejaculation disorders are common adverse effects, which may be troublesome problems in sexually active patients.

- 8 Surgery is indicated for moderate to severe symptoms of BPH in patients who do not respond to or do not tolerate drug therapy, or in patients with complications of BPH. It is the most effective mode of treatment in that it relieves symptoms in the greatest number of men with BPH. However, the two most widely used techniques, transurethral resection of the prostate and open prostatectomy, are associated with the highest rates of complications, including retrograde ejaculation and erectile dysfunction. Therefore, minimally invasive surgical procedures are often desired by patients. These relieve symptoms and are associated with a lower rate of adverse effects and a higher reoperation rate than the gold standard procedures.
- 9 Although widely used in Europe for treatment of BPH, phytotherapy should be avoided. Studies of these herbal medicines are inconclusive, and the purity of available products is questionable.

Benign prostatic hyperplasia (BPH) is the most common benign neoplasm of American men. A nearly ubiquitous condition among elderly men, BPH is of major societal concern, given the large number of men affected, the progressive nature of the condition, and the healthcare costs associated with it.

This chapter discusses BPH and its available treatments: watchful waiting, α_1 -adrenergic antagonists, 5 α -reductase inhibitors, and surgery. The limitations of phytotherapy are described.

EPIDEMIOLOGY

- 1 According to the results of autopsy studies, approximately 80% of elderly men develop microscopic evidence of BPH. About half of the patients with microscopic changes develop an enlarged prostate gland and as a result have difficulty emptying the contents of the urinary bladder. Approximately half of symptomatic patients eventually require treatment.

The peak incidence of clinical BPH occurs at 63 to 65 years of age. Symptomatic disease is uncommon in men younger than 50 years, but some urinary voiding symptoms are present by the time men turn 60 years of age. The Boston Area Normative Aging Study estimated that the cumulative incidence of clinical BPH was 78% in patients at age 80 years.¹ Similarly, the Baltimore Longitudinal Study of Aging projected that approximately 60% of men at least 60 years old develop clinical BPH.²

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

NORMAL PROSTATE PHYSIOLOGY

Located anterior to the rectum, the prostate is a small heart-shaped, chestnut-sized gland located below the urinary bladder. It surrounds the proximal urethra like a doughnut.

Round, soft, symmetric, and mobile on palpation, a normal prostate gland in an adult man weighs 4 to 20 g. Physical examination of the prostate must be done by digital rectal examination (i.e., the prostate is manually palpated by inserting a finger into the rectum). Thus, the prostate is examined through the rectal mucosa.

The prostate has two major functions: (a) to secrete fluids that make up a portion (20%–40%) of the ejaculate volume; and (b) to provide secretions with possible antibacterial effect related to its high concentration of zinc.²

At birth, the prostate is the size of a pea and weighs approximately 1 g. The prostate remains that size until the boy reaches puberty. At that time, the prostate undergoes its first growth spurt, growing to its normal adult size of 15 to 20 g by the time the young man is 25 to 30 years of age. The prostate remains this size until the patient reaches age 40 years, when a second growth spurt begins and continues until the man is 70 to 80 years. During this period, the prostate can quadruple in size or grow even larger.

The prostate gland comprises three types of tissue: epithelial tissue, stromal tissue, and the capsule. Epithelial tissue, also known as *glandular tissue*, produces prostatic secretions. These secretions are delivered into the urethra during ejaculation and contribute to the ultimate ejaculate volume. Androgens stimulate epithelial tissue growth. Stromal tissue, also known as *smooth muscle tissue*, is embedded with α_1 -adrenergic receptors. Stimulation of these receptors by norepinephrine causes smooth muscle contraction, which results in an extrinsic compression of the urethra, reduction of the urethral lumen, and decreased urinary bladder emptying. The normal prostate is composed of a higher amount of stromal tissue than epithelial tissue, as reflected by a stromal-to-epithelial tissue ratio of 2:1. This ratio is exaggerated to 5:1 in patients with BPH, which explains why α_1 -adrenergic antagonists are quickly effective in symptomatic management and why 5 α -reductase inhibitors reduce an enlarged prostate gland by only 25%.^{2,3} The capsule, or outer shell of the prostate, is composed of fibrous connective tissue and smooth muscle, which also is embedded with α_1 -adrenergic receptors. When stimulated with norepinephrine, the capsule contracts around the urethra (Fig. 87-1).

Testosterone is the principal testicular androgen in males, whereas androstenedione is the principal adrenal androgen. These two hormones are responsible for penile and scrotal enlargement, increased muscle mass, and maintenance of the normal male libido. These androgens are converted by 5 α -reductase in target cells to dihydrotestosterone (DHT), an active metabolite. Two types of 5 α -reductase exist. Type I enzyme is localized to hair follicles, sebaceous glands in the frontal scalp, liver, and skin. DHT produced at these target tissues causes acne, increased body and facial hair, and male pattern baldness. Type II enzyme is localized to the prostate, genital tissue, and scalp. In the prostate, DHT induces growth and enlargement of the gland.³

In prostate cells, DHT has greater affinity for intraprostatic androgen receptors than for testosterone, and DHT forms a more stable complex with the androgen receptor. Thus, DHT is considered a more potent androgen in the prostate than is testosterone. Of note, despite the decrease in testicular androgen production in the aging male, intracellular DHT levels in the prostate remain normal, probably due to increased activity of intraprostatic 5 α -reductase.

Estrogen, a product of peripheral metabolism of androgens, is believed to stimulate the growth of the stromal portion of the prostate gland. Estrogens are produced when testosterone and androstenedione are converted by aromatase enzymes in adipose tissues. In addition,

FIGURE 87-1. Representation of the anatomy of and α -adrenergic receptor distribution in the prostate, urethra, and bladder. (From the *Western Journal of Medicine* 1994;161:501. Reproduced with permission from the BMJ Publishing Group.)

estrogens may induce the androgen receptor.² As men age, the ratio of serum levels of testosterone to estrogen decreases as a result of a decline in testosterone production by the testes and increased adipose tissue conversion of androgen to estrogen.

PATHOPHYSIOLOGY

Although the precise pathophysiologic mechanisms causing BPH remain unclear, the role of intraprostatic DHT and type II 5 α -reductase in the development of BPH is evidenced by several observations:

- BPH does not develop in men who are castrated before puberty.
- Castration causes an enlarged prostate to shrink.
- Patients with type II 5 α -reductase enzyme deficiency do not develop BPH.
- Administration of testosterone to orchietomized dogs of advanced age produces BPH.

The pathogenesis of BPH is often described as resulting from both static and dynamic factors. Static factors relate to anatomic enlargement of the prostate gland, which produces a physical block at the bladder neck and thereby obstructs urinary outflow. Enlargement of the gland depends on androgen stimulation of epithelial tissue and estrogen stimulation of stromal tissue in the prostate. Dynamic factors relate to excessive α -adrenergic tone of the stromal component of the prostate gland, bladder neck, and posterior urethra, which results in contraction of the prostate gland around the urethra and narrowing of the urethral lumen.

Symptoms of BPH disease may result from static and/or dynamic factors, and this must be recognized when drug therapy is considered. For instance, some patients may present with obstructive

voiding symptoms but have prostates of normal size. In these patients, dynamic factors likely are responsible for the symptoms. However, in patients with enlarged prostate glands, static and dynamic factors likely are working in concert to produce the observed symptoms.

Static factors may be accentuated by environmental factors. Patients who are stressed or in pain may experience an exacerbation of voiding difficulty. In these situations, increased α -adrenergic tone may precipitate excessive contraction of prostatic stromal tissue. When the stressful event resolves, voiding symptoms often disappear.²

MEDICATION-RELATED SYMPTOMS

2 Medications in several pharmacologic categories should be avoided in patients with BPH because they may exacerbate symptoms. Testosterone replacement regimens, used to treat primary or secondary hypogonadism, deliver additional substrate that can be metabolized to DHT by the prostate. Although no cases of BPH have been reported as a result of exogenous testosterone administration, cautious use is advised in patients with prostatic enlargement. α -Adrenergic agonists, used as oral or intranasal decongestants (e.g., pseudoephedrine, ephedrine, or phenylephrine), can stimulate α -adrenergic receptors in the prostate, resulting in muscle contraction. By decreasing the caliber of the urethral lumen, bladder emptying may be compromised. Drugs with significant anticholinergic adverse effects (e.g., antihistamines, phenothiazines, tricyclic antidepressants, or anticholinergic drugs used as antispasmodics or to treat Parkinson's disease) may decrease contractility of the urinary bladder detrusor muscle. For patients with BPH who have a narrowed urethral lumen, loss of effective detrusor contraction could result in acute urinary retention, particularly in patients with significantly enlarged prostate glands. Diuretics, particularly in large doses, can produce polyuria, which may present as urinary frequency, similar to that experienced by patients with BPH.

CLINICAL PRESENTATION

Patients with BPH can present with a variety of symptoms and signs of disease. All symptoms of BPH can be divided into two categories: obstructive and irritative.

CLINICAL PRESENTATION OF BENIGN PROSTATIC HYPERPLASIA

General

- Patient is in no acute distress unless he has moderate to severe symptoms or complications of BPH

Symptoms

- Urinary frequency, urgency, intermittency, nocturia, decreased force of stream, hesitancy, and straining

Signs

- Digital rectal examination reveals an enlarged prostate (>20 g) with no nodules or area of induration; prostate is soft, symmetric, and mobile

Laboratory Tests

- Increased blood urea nitrogen (BUN) and serum creatinine, elevated prostate-specific antigen (PSA) level

Other Diagnostic Tests

- Increased American Urological Association (AUA) Symptom Score, decreased urinary flow rate (<10 mL/s), and increased postvoid residual (PVR) urine volume

Obstructive symptoms, also known as *prostatism* or *bladder outlet obstruction*, result when dynamic and/or static factors reduce bladder emptying. The force of the urinary stream becomes diminished, urinary flow rate decreases, and bladder emptying is incomplete and takes a long time. Patients report urinary hesitancy and straining and a weak urine stream. Urine dribbles out of the penis, and the urinary bladder always feels full, even after patients have voided. Some patients state that they need to press on their bladder to force out the urine. In severe cases, patients may go into urinary retention when bladder emptying is not possible. In these cases, suprapubic pain can result from bladder overdistension.

Approximately 50% to 80% of patients have irritative voiding symptoms, which typically occur late in the disease course. Irritative voiding symptoms result from long-standing obstruction at the bladder neck. To compensate, the bladder muscle undergoes hypertrophy so that it can generate a greater contractile force to empty urine past the anatomic obstruction at the bladder neck. Although initially helpful, decompensation eventually occurs, and the hypertrophied bladder muscle is no longer able to generate adequate contractile force as it becomes hypersensitive and ineffective in storing urine. As a result, small amounts of urine irritate the bladder and initiate a bladder emptying response. Patients complain of urinary frequency and urgency. Bedwetting or clothes wetting occurs. Patients report waking up every 1 to 2 hours at night to void (nocturia), which significantly reduces quality of life.

Symptoms of BPH vary over time. Symptoms may improve, remain stable, or worsen spontaneously. Thus, BPH is not necessarily a progressive disease; in fact, some patients experience symptom regression. Between one and two thirds of men with mild disease stabilize or improve without treatment over 2.5 to 5 years.² However, other patients experience a slow progression of disease.

Collectively, obstructive and irritative voiding symptoms and their impact on a patient's quality of life are referred to as *lower urinary tract symptoms* (LUTS). However, LUTS is not pathognomonic for BPH and may be caused by other diseases, such as neurogenic bladder and urinary tract infection.⁴

Another characteristic of BPH is silent prostatism. Patients have obstructive or irritative voiding symptoms but adapt to them and do not voluntarily complain about them. Such patients do not present for medical treatment until complications of BPH disease arise or a spouse brings in a symptomatic patient for medical care.

BPH can be a progressive disease, although the rate of progression is variable among patients.^{2,4} When BPH progresses, it can produce complications that include the following:

- Acute, painful urinary retention, which can lead to acute renal failure
- Persistent gross hematuria when tissue growth exceeds its blood supply
- Overflow urinary incontinence or unstable bladder
- Recurrent urinary tract infection that results from urinary stasis
- Bladder diverticula
- Bladder stones
- Chronic renal failure from long-standing bladder outlet obstruction

Approximately 17% to 20% of patients with symptomatic BPH require treatment because of disease complications.⁵ Older men with large prostates greater than 40 g were three times more likely to have severe symptoms or suffer from acute urinary retention and to require prostatectomy than patients with smaller prostates.⁶⁻⁸ Thus, a serum PSA level of 1.4 ng/mL has been used as a surrogate marker for an enlarged prostate gland to identify patients at risk for developing complications of BPH disease⁶ and has been used to guide selection of the most appropriate treatment modality in some patients.^{9,10}

DIAGNOSTIC EVALUATION

Because the common obstructive and irritative voiding symptoms associated with BPH are not unique to the disease and can be presenting symptoms of other genitourinary tract disorders, including prostate or bladder cancer, neurogenic bladder, prostatic calculi, or urinary tract infection, the patient presenting with signs and symptoms of BPH must be thoroughly evaluated.

A careful medical history should be taken to ensure that a complete listing of symptoms is collected as well as to identify concomitant disorders that may be contributing to voiding symptoms. The medical history should be followed by a thorough medication history, including all prescription and nonprescription medications and dietary supplements that the patient is taking. Any drugs that could be causing or exacerbating the patient's symptoms should be identified. If possible, the suspected drugs should be discontinued or the dosing regimen modified to ameliorate the voiding symptoms.

The patient should undergo a physical examination, including a digital rectal examination, although the size of the prostate gland does not correspond to symptoms. BPH usually presents as an enlarged, soft, smooth, symmetric gland, greater than 20 g in size. Some patients have only a slightly enlarged gland and yet have bothersome or even serious voiding difficulties, usually the result of dynamic factors. Other patients have an intravesical enlargement of the prostate gland (i.e., the gland grows into the urinary bladder and produces a ball-valve blockage of the bladder neck). This type of prostate enlargement is not palpable on manual examination.

The patient's perception of the severity of BPH symptoms guides selection of a particular treatment modality in a patient. To evaluate perceptions objectively, validated instruments, such as the AUA Symptom Score, are commonly used. Using the AUA index, the patient rates the "bothersomeness" of seven obstructive and irritative voiding symptoms.^{2,11} Each item is rated for severity on a scale from 0 to 5, such that 35 is the maximum score and is consistent with the most severe symptoms.

The only clinical laboratory test that must be performed is a urinalysis. Because many of the voiding symptoms of BPH could be caused by other urologic disorders, a urinalysis can help screen for hematuria due to bladder cancer, stones, and infection. Other clinical laboratory tests include BUN and serum creatinine to check for renal impairment as a result of bladder outlet obstruction and PSA to screen for prostate cancer, another common cause of glandular enlargement. The latter test should be performed only in patients with at least a 10-year life expectancy in whom the cost of the test will be outweighed by the potential benefit of diagnosing the disorder.¹²

Additional objective measures of bladder emptying should be performed if surgical treatment is being considered. Measures include peak and average urinary flow rate (normal is at least 10 mL/s). These measures are determined using a uroflowmeter, which checks the rate of urine flow out of the bladder. This is a quick noninvasive outpatient procedure in which the patient is instructed to drink water until his bladder feels full and then the patient's urinary flow is clocked during voiding. A low urinary flow rate (<12 mL/s) implies failure of bladder emptying, but the degree of bladder outlet obstruction correlates poorly with peak urinary flow rate.¹²

Another objective measure is PVR urine volume (normal is 0 mL). This is a simple outpatient procedure and is determined after the patient has attempted to empty his bladder. A straight catheter is inserted to drain any urine remaining in the bladder. A high PVR urine volume (>25–30 mL) implies failure of bladder emptying and a predisposition for urinary tract infections. Because of a weak correlation among voiding symptoms, prostate size, and urinary flow rate, most physicians use a combination of measures, including the patient's assessment of symptoms along with objective evalua-

tion of urinary outflow and presence of complications of BPH to determine the need for treatment.

Many other tests can be performed if additional information is needed to assess the severity of BPH disease and its complications, to assist in the preoperative assessment of the patient, or to distinguish prostate enlargement due to BPH from prostate cancer. Tests include a voiding cystometrogram, transrectal ultrasound of the prostate, intravenous pyelogram, renal ultrasound, and prostate biopsy.

TREATMENT

Benign Prostatic Hyperplasia

As a disease of symptoms, BPH is treated by relieving bothersome symptoms. Patients usually are stratified into three severity groups for the purposes of deciding a treatment modality (Table 87-1). However, literature about the natural history of BPH and the significant risk of disease complications suggests that physicians also should consider prevention of serious complications of BPH and decreasing the need for surgery as goals of treatment in selected patients. This is a controversial topic complicated by many issues, including the variable costs of treatment options, the inability to clearly distinguish patients who experience spontaneous regression or disease stabilization from those in whom symptoms progress, and the potential benefit that may occur in a comparatively small number of treated patients.

The AUA Guidelines on Management of Benign Prostatic Hyperplasia is the principal tool used in the United States,¹¹ and the AUA recommendations are similar to the European¹³ and Canadian Practice Guidelines (Fig. 87-2).¹⁴

③ Management options include watchful waiting, drug treatment, and surgical intervention. Although phytotherapy is used by some patients alone or along with conventional medications for BPH, head-to-head comparisons with FDA-approved treatments are lacking, so such herbals cannot be recommended at this time.

④ Patients with mild disease are asymptomatic or have mildly bothersome symptoms and have no complications of BPH disease. In these patients, no specific treatment is indicated. These patients can be managed with watchful waiting, which entails having the patient return for reassessment at yearly intervals. At each return visit, the patient should complete a standardized, validated survey tool to assess severity of symptoms. Watchful waiting should be accompanied by patient education about the disease and behavior modification to avoid practices that exacerbate voiding symptoms. Behavior modification includes fluid restriction close to bedtime, avoiding caffeine and alcohol intake, frequent emptying of the bladder during waking hours (to avoid overflow incontinence and urgency), and avoiding drugs that could exacerbate voiding symptoms.¹⁵ At each visit, physicians should assess the patient's risk of developing acute

TABLE 87-1 Categories of BPH Disease Severity Based on Symptoms and Signs

Disease Severity	AUA Symptom Score	Typical Symptoms and Signs
Mild	≤7	Asymptomatic Peak urinary flow rate <10 mL/s Postvoid residual urine volume >25–50 mL Increased BUN and serum creatinine
Moderate	8–19	All of the above signs plus obstructive voiding symptoms and irritative voiding symptoms (signs of detrusor instability)
Severe	≥20	All of the above plus one or more complications of BPH

AUA, American Urological Association; BPH, benign prostatic hyperplasia; BUN, blood urea nitrogen.

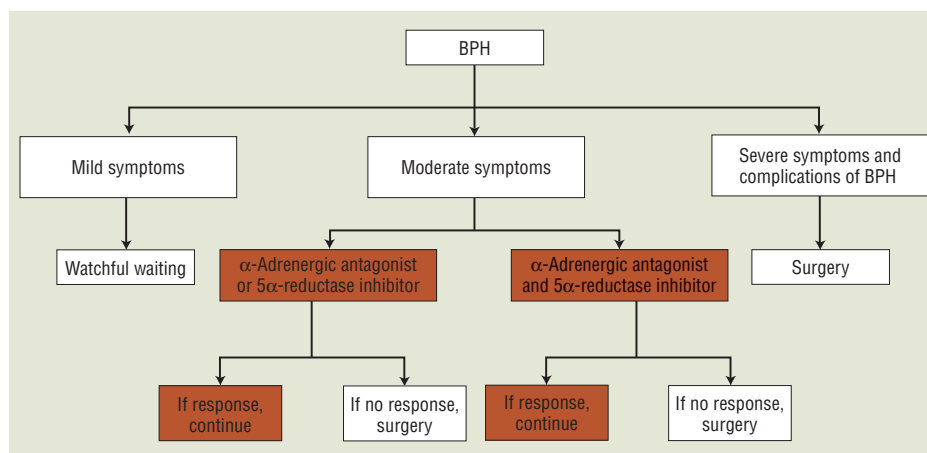

FIGURE 87-2. Management algorithm for benign prostatic hyperplasia (BPH).

urinary retention by evaluating the patient's prostate size or using PSA as a surrogate marker of prostate enlargement.¹²

5 If symptoms progress to the moderate or severe level or the patient perceives his symptoms to be bothersome, the patient should be offered specific treatment. In these patients, watchful waiting delays—but does not decrease—the need for prostatectomy. In symptomatic patients, watchful waiting can lead to intractable urinary retention, increased PVR urine volumes, and significant voiding symptoms.¹⁶ Recommended treatment options include drug therapy with an α_1 -adrenergic antagonist or 5 α -reductase inhibitor, a combination of an α_1 -adrenergic antagonist and a 5 α -reductase inhibitor, or surgery.

5 Patients with serious complications of BPH should be offered surgical correction (transurethral or open prostatectomy, or a minimally invasive surgical procedure). Drug therapy is considered an interim measure in such patients because it likely only delays worsening of complications and the need for surgical intervention.^{11,16}

■ PHARMACOLOGIC THERAPY

Drug therapy for BPH can be categorized into three types: agents that relax prostatic smooth muscle (reducing the dynamic factor), agents that interfere with testosterone's stimulatory effect on prostate gland enlargement (reducing the static factor), and combination therapy of an α_1 -adrenergic antagonist and a 5 α -reductase inhibitor (Table 87-2).^{17,18} Of the agents that relax prostatic smooth muscle, second- and third-generation α_1 -adrenergic antagonists have been most widely used. These agents relax the intrinsic urethral sphincter

and prostatic smooth muscle, thereby enhancing urinary outflow from the bladder. α_1 -Adrenergic antagonists do not reduce prostate size. Of the agents that interfere with testosterone's stimulatory effect on prostate gland size, the only agents approved by the U.S. Food and Drug Administration (FDA) are 5 α -reductase inhibitors (e.g., finasteride, dutasteride). Other agents that interfere with androgen stimulation of the prostate have not been popular in the United States because of the many adverse effects associated with their use. The luteinizing hormone-releasing hormone superagonists leuprolide and goserelin decrease libido and can cause erectile dysfunction, gynecomastia, and hot flashes. Antiandrogens (e.g., bicalutamide, flutamide) produce nausea, diarrhea, and hepatotoxicity.¹⁹

Selection of a medical treatment for a patient should be determined on a case-by-case basis after patient and provider discussion of risks, benefits, and costs of various treatments. With drug therapy for BPH, patients must understand that the benefits continue only as long as the medication is taken.^{11,19}

If possible, drug therapy should be initiated with a single agent, usually an α_1 -adrenergic antagonist, which is faster acting and more effective than a 5 α -reductase inhibitor. In addition, α_1 -adrenergic antagonists are effective in reducing LUTS independent of prostate size, have no effect on PSA, and are associated with less sexual dysfunction than are 5 α -reductase inhibitors. A 5 α -reductase inhibitor is a good first-choice agent in patients with a significantly enlarged prostate (>40 g) who cannot tolerate the cardiovascular adverse effects of α_1 -adrenergic antagonists. In patients at risk for developing complications of BPH, specifically patients with an enlarged prostate gland greater than 40 g^{5,11,20} and an elevated PSA ≥ 1.4 ng/mL, combination drug therapy with an α_1 -adrenergic antagonist and a 5 α -reductase inhibitor is more beneficial than single drug therapy. The pharmacologic rationale for such a combination is that using two drugs with different mechanisms of action can be more effective than either drug alone. The clinical benefit of combination therapy is that it delays disease progression and reduces the need for surgical intervention.

α -Adrenergic Antagonists

Three generations of α -adrenergic antagonists have been used to treat BPH. They all relax smooth muscle in the prostate and bladder neck. Because of their antagonism of presynaptic α_2 -adrenergic receptors that results in tachycardia and arrhythmias, first-generation agents such as phenoxybenzamine have been replaced by the second-generation postsynaptic α_1 -adrenergic antagonists and third-generation uroselective postsynaptic α_1 -adrenergic antagonists.

6 The second- and third-generation α_1 -adrenergic antagonists are considered equally effective for treatment of BPH.^{11,21,22} These agents generally improve AUA Symptom Score by 30% to 40%, increase urinary flow rate by 2 to 3 mL/s in 60% to 70% of treated patients,

TABLE 87-2 Summary of Medical Treatment Options for Benign Prostatic Hyperplasia

Category	Mechanism	Drug (Brand Name)
Reduces dynamic factor	Blocks α_1 -adrenergic receptors in prostatic stromal tissue	Prazosin (Minipress) Alfuzosin (Uroxatral) Terazosin (Hytrin) Doxazosin (Cardura)
	Blocks α_{1A} -receptors in the prostate	Tamsulosin (Flomax)
Reduces static factor	Blocks 5 α -reductase enzyme	Finasteride (Proscar) Dutasteride (Avodart)
	Blocks dihydrotestosterone at its intracellular receptor	Bicalutamide (Casodex) Flutamide (Eulexin)
	Blocks pituitary release of luteinizing hormone	Leuprolide (Lupron) Nafarelin
	Blocks pituitary release of luteinizing hormone and blocks androgen receptor	Megestrol acetate

and reduce PVR urine volume. They have no effect on decreasing prostate volume. Finally, α_1 -adrenergic antagonists do not reduce PSA levels, preserving the utility of this prostate cancer marker in this high-risk population.¹¹

Second-generation agents include prazosin, terazosin, doxazosin, and alfuzosin. At the usual doses used to treat BPH, prazosin, terazosin, and doxazosin antagonize peripheral vascular α_1 -adrenergic receptors in addition to those in the prostate. As a result, first-dose syncope, orthostatic hypotension, and dizziness are characteristic adverse effects. To improve tolerance to these adverse effects, therapy should start with a low dose of 1 mg daily and then should be slowly titrated up to a full therapeutic dose over several weeks. Additive blood pressure lowering effects commonly occur when these agents are used with antihypertensive agents, which limits use of these agents in some patients. These three agents differ in terms of duration of action and dosage formulation. Whereas prazosin requires dosing two to three times per day, terazosin, doxazosin, and alfuzosin offer more convenient once-daily dosing. Because prazosin requires twice-to thrice-daily dosing and has significant cardiovascular adverse effects, it is not recommended in the current AUA guidelines for treatment of BPH.¹¹ Extended-release dosage formulations are available for doxazosin and alfuzosin. These offer the convenience of once-daily dosing, treatment initiation with a full therapeutic dose, and decreased dose-related hypotension as the formulation produces lower peak serum concentrations than immediate-release products.^{6,23,24} An α_1 -adrenergic antagonist is not preferred as single-drug therapy for treatment of both BPH and hypertension in a patient. In the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) of 24,000 patients with hypertension, doxazosin produced more congestive heart failure than amlodipine, lisinopril, or chlorthalidone.²⁵ Thus, both the AUA and the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure²⁶ recommend that patients with BPH and hypertension be treated with separate and appropriate drug treatment initiated for each medical condition.²⁷

Alfuzosin is considered functionally and clinically uroselective in that usual doses used to treat BPH are less likely than other second-generation agents to cause cardiovascular adverse effects in animal or human models.²⁸ This clinical observation has been seen more often with the once-daily, extended-release formulation of alfuzosin, which is the only commercially available formulation in the United States, compared to the immediate-release formulation that is dosed three times per day, which is available in Europe.²⁹ It has been postulated to be due to higher concentrations of alfuzosin achieved in the prostate versus serum after usual doses,³⁰ decreased blood-brain barrier penetration of alfuzosin,¹⁹ absence of high peak serum levels with the extended-release formulation,³¹ and fixed dosing schedule of the extended-release formulation. Extended-release alfuzosin dosing is FDA approved for 10 mg daily, with no dose titration increase.^{29,32} This is convenient for physician prescribers and patients who are starting to take the medication.

Tamsulosin is the only third-generation α_1 -adrenergic antagonist available in the United States. It is an advance over second-generation agents in that it is selective for prostatic α_{1A} -adrenergic receptors, which compose approximately 70% of the adrenergic receptors in the prostate gland.³³ Blockade of these receptors results in smooth muscle relaxation of the prostate and bladder neck without causing peripheral vascular smooth muscle relaxation. Tamsulosin has low affinity for vascular α_{1B} -adrenergic receptors, which explains why hypotension is not a common adverse effect and why the agent has not been studied as a therapy for hypertension.

Tamsulosin's selectivity for α_{1A} -adrenergic receptors has multiple implications. Dose titration is minimal; therefore, patients can begin therapy with the lowest effective maintenance dose of 0.4 mg/day taken orally. Patients can be instructed to take the dose anytime during

the day, unlike terazosin and doxazosin, which should be taken at bedtime so that patients can sleep through the time when peak cardiovascular adverse effects are most likely to occur. However, for best oral absorption, tamsulosin should be taken on an empty stomach because food decreases the drug's bioavailability and reduces the peak serum concentration of drug after dosing. The onset of peak action is quick, in the range of 1 week, and only a minority of patients will require up-titration to a higher daily dose. No decreases in blood pressure or increases in heart rate have been reported in normotensive patients, the elderly, subgroups of patients with well-controlled hypertension, or those with uncontrolled hypertension.^{34,35} Thus, tamsulosin allows initiation of treatment with a therapeutic dose that is not limited by cardiovascular adverse effects, unlike immediate-release formulations of terazosin and doxazosin.³⁶ Finally, the addition of tamsulosin to selected antihypertensive regimens of patients does not result in potentiation of the hypotensive effect of furosemide, enalapril, nifedipine, and atenolol.^{35,37} Therefore, tamsulosin is a good choice, particularly for patients who cannot tolerate hypotension; have severe coronary artery disease, volume depletion, cardiac arrhythmias, severe orthostasis, or liver failure; are taking multiple antihypertensives; or when the titration would be too complicated for the patient or produce an unacceptable delay in onset for a particular patient.

The usual doses of α_1 -adrenergic antagonists are summarized in Table 87-3.

When using the second-generation α_1 -adrenergic antagonists terazosin and doxazosin, slow titration up to a therapeutic maintenance dose is necessary to minimize orthostatic hypotension and first-dose syncope. Conservatively, dosages should be increased in an orderly stepwise process, at 2- to 7-day intervals, depending on the patient's response to the medication. A faster titration schedule can be used as long as the patient does not develop orthostatic hypotension or dizziness. Two sample titration schedules for terazosin are as follows:

- **Schedule 1: Slow titration**

Days 4 to 14: 2 mg at bedtime

Weeks 2 to 6: 5 mg at bedtime

Weeks 7 and on: 10 mg at bedtime

- **Schedule 2: Quicker titration**

Days 1 to 3: 1 mg at bedtime

Days 4 to 14: 2 mg at bedtime

Weeks 2 to 3: 5 mg at bedtime

Weeks 4 and on: 10 mg at bedtime

TABLE 87-3 Dosing Schedule of α_1 -Adrenergic Antagonists in Patients with Benign Prostatic Hyperplasia

Drug	Half-Life (h)	Usual Daily Dosage	Time to Peak Effect on BPH Symptoms ^a
Prazosin (Minipress)	2–3	2–10 mg in two to three divided doses	2–6 weeks
Terazosin (Hytrin)	11–14	1–10 mg as a single dose; maximum 20 mg	2–6 weeks
Doxazosin (Cardura)	15–19	1–4 mg as a single dose; maximum 8 mg	2–6 weeks
Doxazosin GTS (Cardura XL)	15–19	4 or 8 mg as a single dose, maximum 8 mg	Several days
Alfuzosin (Uroxatral)		10 mg as a single dose	Several days
Tamsulosin (Flomax)	14–15	0.4 or 0.8 mg as a single dose	Several days

^aTime to peak effect on benign prostatic hyperplasia (BPH) symptoms is dependent on the titration period to achieve full therapeutic doses.

Patients should continue taking the drug as long as they continue to respond to it. Durable responses for 6 and 10 years have been reported for tamsulosin³⁸ and doxazosin,³⁹ respectively. If BPH symptoms worsen despite maximum tolerable drug doses, surgery should be considered.

No dosage adjustments are recommended for α_1 -adrenergic antagonists in patients with renal failure. Because these drugs are hepatically catabolized, the lowest effective dose should be used in patients with hepatic dysfunction, and patients should be monitored carefully for adverse effects. No specific dosing guidelines for this patient population are available.

Approximately 10% to 12% of patients discontinue taking second-generation α_1 -adrenergic antagonists because of adverse effects, especially those that affect the cardiovascular system (e.g., syncope, dizziness, hypotension).⁴⁰ Patients who tolerate hypotension poorly should avoid second-generation α_1 -adrenergic antagonists. This includes patients with poorly controlled angina, serious cardiac arrhythmias, patients with reduced circulating volume, and patients taking multiple antihypertensives.⁴⁰ These patients are candidates for tamsulosin or finasteride, if drug therapy is deemed necessary. Whether extended-release alfuzosin is a good choice remains to be elucidated in controlled comparison trials with tamsulosin.^{27,41}

Tiredness and asthenia, ejaculatory dysfunction, flu-like symptoms, and nasal congestion are the most common dose-related adverse effects of tamsulosin.⁴² These adverse effects are extensions of its α -adrenergic antagonist activity and are unavoidable, but with proper education patients likely will not discontinue treatment. Floppy iris syndrome has been associated with tamsulosin use. Tamsulosin blocks α_{1A} -receptors in the iris dilator muscles. As a result, during cataract surgery, papillary constriction occurs and the iris billows out (floppy iris), both of which complicate the procedure. Tamsulosin should be discontinued 1 week before elective cataract surgery.^{43–45} Patients with severe sulfa allergy should avoid tamsulosin.

Caution is needed when cimetidine or diltiazem is used with tamsulosin or other α_1 -adrenergic antagonists because a drug–drug interaction leads to decreased metabolism of the latter agents. In contrast, carbamazepine and phenytoin may increase hepatic catabolism of α_1 -adrenergic antagonists.

Phosphodiesterase inhibitors (e.g., sildenafil, vardenafil, tadalafil) may produce systemic hypotension if used in large doses along with α_1 -adrenergic antagonists. The mechanisms for this interaction are related to the intrinsic vasodilatory effects of phosphodiesterase inhibitors and the higher susceptibility of elderly patients to venous pooling because of autonomic incompetence.^{27,46} Therefore, package labeling for these drugs includes a warning to avoid α_1 -adrenergic antagonists for 4 hours after taking a dose of one of these phosphodiesterase inhibitors. The exception is tadalafil, which can be taken together with tamsulosin 0.4 mg.

CLINICAL CONTROVERSY

Among the α_1 -adrenergic antagonists, tamsulosin and extended-release alfuzosin have been associated with the highest and lowest incidences of ejaculatory dysfunction, respectively. Although some clinicians claim that this difference should be considered when selecting one agent over another, this adverse effect is of variable clinical significance. Some patients complain of decreased sexual satisfaction because of ejaculatory dysfunction, whereas other patients do not.

5 α -Reductase Inhibitors

7 Finasteride competitively inhibits type II 5 α -reductase, suppresses intraprostatic DHT by 80% to 90%, and decreases serum

DHT levels by 70%.⁴⁷ Dutasteride is a nonselective inhibitor of type I and II 5 α -reductase. It more quickly and completely suppresses intraprostatic DHT production and decreases serum DHT levels by 90%.⁴⁸ However, direct comparison clinical trials showed no advantages of these pharmacodynamic actions of dutasteride compared to finasteride.⁴⁹ These agents are indicated for management of moderate to severe BPH disease in patients with enlarged prostate glands of at least 40 g.⁴⁹ In such patients, 5 α -reductase inhibitors may slow disease progression and decrease the risk of disease complications, thereby decreasing the ultimate need for surgical intervention.⁵⁰ When taken continuously for 4 years, finasteride has been shown to decrease the risk of acute urinary retention and prostatectomy.⁵¹ In patients with severe disease, these agents generally can be used with a 6-month short course of an α_1 -adrenergic antagonist, which will provide fast symptom relief until the 5 α -reductase inhibitor starts to work. 5 α -Reductase inhibitors may be preferred in patients with BPH and an enlarged prostate gland who have uncontrolled arrhythmias, have poorly controlled angina, are taking multiple antihypertensive agents, or are unable to tolerate hypotensive adverse effects of second-generation α_1 -adrenergic antagonists.

5 α -Reductase inhibitors reduce prostate size by 25%, increase peak urinary flow rate by 1.6 to 2.0 mL/s, improve voiding symptoms in approximately 30% of treated patients, and produce few serious adverse effects. Compared to α_1 -antagonists, 5 α -reductase inhibitors have several disadvantages. 5 α -Reductase inhibitors have a delayed peak onset of clinical effect, which is undesirable in patients with bothersome symptoms, and an adequate clinical trial is 6 to 12 months. In addition, the percentage of patients who experience objective improvement is less with 5 α -reductase inhibitors than with α_1 -adrenergic antagonists. 5 α -Reductase inhibitors cause more sexual dysfunction than α_1 -adrenergic receptor antagonists; therefore, physicians consider 5 α -reductase inhibitors to be second-line agents for treatment of BPH (Table 87–4).¹¹

Patients with BPH who are concerned about developing prostate cancer can be prescribed finasteride, which has been shown to reduce the 7-year prevalence of prostate cancer by 25% in the Prostate Cancer Prevention Trial.^{42,50} However, in this study, finasteride use was associated with a small increased risk of developing a higher-grade prostate cancer, which has a greater potential for invasiveness. The ongoing Reduction by Dutasteride in Prostate Cancer Events (REDUCE) trial⁵¹ should provide additional information on the value of 5 α -reductase inhibitors in preventing prostate cancer.^{52–54}

TABLE 87-4 Comparison of α_1 -Adrenergic Antagonists and 5 α -Reductase Inhibitors

	α_1 -Adrenergic Antagonists	5 α -Reductase Inhibitors
Decreases prostate size	No	Yes
Halts disease progression	No	Yes
Peak onset	1–6 weeks	3–6 months
Efficacy	++	++ (in patients with enlarged prostates)
Frequency of dosing	1–2 times per day, depending on the agent	Once per day
Decreases prostate-specific antigen	No	Yes
Sexual dysfunction adverse effects	+	++
Cardiovascular adverse effects	Yes	No

CLINICAL CONTROVERSY

Dutasteride is a nonselective 5α -reductase inhibitor that more quickly and effectively lowers intraprostatic DHT production and lowers plasma DHT levels than finasteride. Whether these hormonal changes result in clinical advantages over finasteride remains to be elucidated.^{49,55}

Finasteride is well absorbed from the gastrointestinal tract (95%), and its absorption is unaffected by food. Peak serum concentrations are reached 1 to 2 hours after the dose. Finasteride is highly protein bound. The liver extensively metabolizes finasteride to inactive metabolites, which are largely excreted in stool. The plasma half-life is 4.7 to 7.1 hours, but its biologic half-life probably is longer, as decreased serum DHT levels persist for up to 2 weeks after finasteride dosing is stopped.⁴⁷

For BPH, finasteride is given in doses of 5 mg by mouth daily. The dose can be taken with meals or on an empty stomach. No dosage adjustment is needed in patients with renal dysfunction. Although no dosage reduction is recommended in patients with hepatic insufficiency, patients should be monitored carefully. Maximal reductions in prostate volume or symptom improvement may not be evident for 12 months, but noticeable changes from baseline should occur after 6 months of continuous treatment. No clinically relevant drug interactions have been reported with 5α -reductase inhibitors.

Patients must continue to take 5α -reductase inhibitors as long as they respond. Durable responses to finasteride and dutasteride have been reported with continued treatment for 6 years⁵² and 4 years,⁴⁹ respectively. Upon discontinuation of the drug, prostate size and voiding symptoms generally return to baseline.

5α -Reductase inhibitors can produce sexual dysfunction, and this has led to discontinuation of therapy in up to 12% of treated patients in one pooled analysis.²² Ejaculation disorders (dry sex or delayed ejaculation) have been reported in 3% to 8% of treated patients.⁵⁶ These disorders, which are possible results of decreased prostatic secretion, are reversible with drug discontinuation.

Erectile dysfunction has been reported in 3% to 16% of patients.^{19,22} It may be secondary to ejaculation disorders or may be due to drug-induced inhibition of nitric oxide synthase (which is needed to produce nitric oxide, a vasodilatory substance) in cavernosal tissue.⁵⁷ The role of 5α -reductase inhibitors in causing erectile dysfunction is not clear, as elderly men with BPH commonly develop erectile dysfunction as they age or have concurrent medical illnesses or concomitant drug therapies that may predispose to the development of sexual dysfunction.⁵⁶ Decreased libido has been reported in 2% to 10% of treated patients.^{19,22}

Other minor adverse effects include nausea, abdominal pain, asthenia, dizziness, flatulence, headache, rash, muscle weakness, and gynecomastia.

5α -Reductase inhibitors are in FDA pregnancy category X, which means that they are contraindicated in pregnant females. Exposure of the male fetus to finasteride may produce pseudohermaphroditic offspring with ambiguous genitalia, similar to those of patients with a rare genetic deficiency of type II 5α -reductase. Because of this teratogenic effect, women who are pregnant or seeking to become pregnant should not handle 5α -reductase inhibitor tablets and should not have contact with semen from men being treated with 5α -reductase inhibitors. Women pharmacists of childbearing age should handle this product with rubber gloves if there is any chance that they are pregnant.

Usual doses of 5α -reductase inhibitors reduce serum PSA levels by 50%. For this reason, PSA levels must be measured before treatment begins, and the patient should have a digital rectal examination. After 6 months of therapy, the patient should have a repeat PSA. If the level does not decline by 50% and the patient has

been adherent to the 5α -reductase inhibitor regimen, he should be evaluated for prostate cancer. Annually thereafter, the patient should have a PSA assay and digital rectal examination, and patients with any increase in PSA levels should be evaluated for prostate cancer or noncompliance to the prescribed regimen. To interpret a PSA level in a patient being treated with a 5α -reductase inhibitor, it is generally recommended that the actual measured level be doubled to get an estimate of the true level.^{11,58,59}

CLINICAL CONTROVERSY

5α -Reductase inhibitors have been shown to delay disease progression, which is linked to shrinkage of an enlarged prostate gland. This benefit of treatment remains to be demonstrated for α_1 -adrenergic antagonists.

Combination Therapy

Combination therapy with an α_1 -adrenergic antagonist and a 5α -reductase inhibitor is ideal in patients with severe symptoms, who also have an enlarged prostate gland of at least 40 g and PSA of at least 1.4 ng/mL.^{5,11,59} Such patients appear to be at high risk for disease progression, as evidenced by symptom worsening and development of disease complications.⁶ A regimen of finasteride and doxazosin for 5 years was shown to prevent symptom progression by 66%, decrease the risk of developing acute urinary retention by 81%, and decrease the need for prostate surgery by 67%.⁶ Although not proven by direct comparison trials, any combination of 5α -reductase inhibitor and α_1 -adrenergic antagonist probably is similarly effective in patients with the aforementioned characteristics.¹¹ The disadvantages of a combination regimen include increased medication cost to the patient and an increased incidence of adverse drug effects.

Use of Anticholinergic Agents in Patients with BPH

Treatment with an α_1 -adrenergic antagonist, 5α -reductase inhibitor, or surgery may improve urinary flow rate and bladder emptying; however, the patient may still complain of irritative voiding symptoms (e.g., urinary frequency, urgency). Oxybutynin and tolterodine have been used to relieve these symptoms. By blocking muscarinic receptors in the detrusor muscle, these agents can reduce uninhibited detrusor contractions, a sequela of prolonged bladder outlet obstruction from BPH. Thus, they can reduce urinary frequency and urgency. Because elderly patients are sensitive to the central nervous system adverse effects and dry mouth associated with anticholinergic agents, patients should be started on the lowest effective dose and then slowly titrated up.⁵⁹⁻⁶¹ Similarly in the presence of BPH, anticholinergic agents can cause acute urinary retention. Therefore, prescribing anticholinergic agents should be done cautiously and patients monitored closely.

SURGICAL INTERVENTION

8 The gold standard for treatment of patients with complications of BPH is prostatectomy performed either transurethral or suprapubically.¹⁶ Surgical intervention is also used in patients with moderate to severe symptoms, who are not responsive to drug therapy, who are noncompliant with drug therapy, or who prefer surgical intervention. Surgical removal of the prostate offers the highest rate of symptom improvement, but it also has the highest complication rate.

With transurethral resection of the prostate (TURP), an endoscopic resectoscope inserted through the urethra is used to remove the inside core of the prostate. This enlarges the urethral opening at the bladder neck. TURP is performed only in men with enlarged prostates that are less than 50 g so that the resection can be

completed in less than 1 hour. Often performed as outpatient surgery, this procedure produces on average a peak urinary flow rate increase of 125% and improvement of voiding symptoms by almost 90% in approximately 90% of patients.⁶ A common complication of TURP is retrograde ejaculation, occurring in up to 75% of patients. Significant bleeding, urinary incontinence, and erectile dysfunction occur in smaller but significant numbers of patients (2%–15%).^{62,63} Approximately 2% to 10% and 12% to 15% of patients require second surgeries within 5 and 8 years, respectively.⁶²

Men with larger prostates (>50 g) require an open surgical procedure (open prostatectomy), which can be performed retropubically or suprapubically. This necessitates hospitalization for at least a few days, anesthesia, and a longer recuperation time. Adverse effects of open prostatectomy include bleeding, urinary and soft-tissue infection, retrograde ejaculation in 77% of patients, erectile dysfunction in 16% to 33% of patients, and urinary incontinence in 2% of patients. The reoperation rate is 3% to 5% at 10 years.^{4,11}

Transurethral incision of the prostate (TUIP) is an alternative surgical procedure for patients with moderate to severe voiding symptoms who have an enlarged prostate gland less than 30 g in size. TUIP is as effective as TURP but requires less operation time, causes less blood loss, and produces fewer adverse effects.¹¹ TUIP involves using an endoscopic resectoscope to make two or three incisions at the bladder neck to widen the opening. Finally, transurethral vaporization of the prostate uses laser energy under direct visualization to ablate prostate tissue.¹¹

Minimally invasive surgical procedures are highly desirable by patients. The procedures are short (lasting minutes), have a lower potential to produce adverse effects, are less expensive than continuous drug therapy lasting years, and may be particularly useful in debilitated patients who are poor surgical candidates. The ideal candidates have moderate to severe voiding symptoms with smaller-sized prostate glands.¹² These procedures typically use heat energy from microwaves, water, or laser to destroy prostate tissue.⁶⁴ Commonly used procedures include transurethral needle ablation of the prostate and transurethral microwave thermotherapy of the prostate.^{4,65} A disadvantage of all minimally invasive surgical procedures is that a higher percentage of patients may develop acute urinary retention in the immediate postoperative period and may require reoperation after an initial improvement in symptoms than patients who undergo TURP or open prostatectomy.^{64,65}

■ PHYTOTHERAPY

9 Although phytotherapy is widely used in Europe for the management of BPH, the published data on herbal agents are largely inconclusive and conflicting. Studies often lack placebo controls, which are essential for assessing treatments of BPH because spontaneous regression of symptoms can occur. Furthermore, because these agents are marketed under the Dietary Supplements Health and Education Act, their efficacy, safety, and quality are not regulated by the FDA. For these reasons, herbal products—including saw palmetto berry (*Serenoa repens*), stinging nettle (*Urtica dioica*), South African stargrass (*Hypoxis rooperi*), pumpkin seed (*Cucurbita pepo*), and African plum (*Pygeum africanum*)—are not recommended for treatment of BPH.^{11,66–70} An excellent review on phytotherapy for BPH has been published.⁶⁹

EVALUATION OF THERAPEUTIC OUTCOMES

The primary therapeutic outcome of BPH therapy is improvement of voiding symptoms with minimal treatment-related adverse effects. As a disease for which therapy is directed at the voiding symptoms that the patient finds most bothersome, assessment of outcomes depends on the patient's perceptions of the effectiveness

of therapy. Use of a validated, standardized instrument, such as the AUA Symptom Score, for assessing patient's voiding symptoms is important in this process.^{2,11}

In patients being considered for surgical treatment, objective measures of bladder emptying are useful and include the urinary flow rate and PVR urine volume (see Diagnostic Evaluation above).

Because this patient population is at high risk for prostate cancer, PSA should be measured and a digital rectal examination performed annually if the patient has a life expectancy of at least 10 years. For patients taking 5 α -reductase inhibitors, a second PSA taken after 6 months of treatment should be compared with baseline measurements. If the patient is suspected to have developed renal impairment as a consequence of long-standing bladder outlet obstruction, then BUN and serum creatinine should be evaluated at regular intervals.

SUMMARY

A ubiquitous disease of aging men, symptomatic BPH requires medical attention to preserve the patient's quality of life and to prevent disease complications, many of which can be life threatening in this patient population. In men who have no or mildly bothersome symptoms, watchful waiting and behavior modification are the best treatment approach, as BPH remains stable or even regresses in approximately half of these men.

For patients with voiding symptoms that are moderate to severely bothersome, pharmacotherapy is indicated. An α_1 -adrenergic antagonist is the agent of first choice. Second-generation agents include terazosin, doxazosin, and alfuzosin, and a third-generation agent is tamsulosin. Terazosin and doxazosin cause more cardiovascular adverse effects than do extended-release alfuzosin and tamsulosin. Whether extended-release alfuzosin is as well tolerated as tamsulosin in patients at risk for hypotension or hypotension-related morbidity remains to be elucidated. 5 α -Reductase inhibitors are preferred drug treatment in patients with enlarged prostates who poorly tolerate the hypotensive adverse effects of α_1 -adrenergic antagonists. However, 5 α -reductase inhibitors have a slow onset of action. For patients who do not respond to monotherapy, combination drug therapy could be attempted. Such regimens have been found to be most effective in patients with enlarged prostates greater than 40 g. Alternatively, surgery is an option.

In patients who have complications of BPH, surgery is required. Although it has more adverse complications than does pharmacotherapy or watchful waiting, TURP is considered the gold standard.

ABBREVIATIONS

AUA: American Urological Association

BPH: benign prostatic hyperplasia

BUN: blood urea nitrogen

DHT: dihydrotestosterone

LUTS: lower urinary tract symptoms

PSA: prostate-specific antigen

PVR: postvoid residual

TUIP: transurethral incision of the prostate

TURP: transurethral resection of the prostate

KEY CONCEPTS

- 1 In evaluating urinary incontinence, drug-induced or drug-aggravated etiologies must be ruled out.
- 2 Accurate diagnosis and classification of urinary incontinence type are critical to the selection of appropriate pharmacotherapy.
- 3 Nonpharmacologic, nonsurgical therapy is the cornerstone of management of several types of urinary incontinence, often should be the first therapy initiated, and should be continued even when drug therapy is initiated.
- 4 Anticholinergic/antispasmodic agents are the pharmacologic therapies of choice for bladder overactivity (urge incontinence).
- 5 Duloxetine (not yet approved for treatment of urinary incontinence in the United States), α -adrenergic receptor agonists, and topical (vaginal) estrogens (alone or together) are the pharmacologic therapies of choice in urethral underactivity (stress incontinence).
- 6 Patient-specific treatment goals should be identified. They are not static and may change over time. Choice of therapy may be influenced by characteristics such as patient age, comorbidities, concurrent medications, and ability to adhere to the prescribed regimen. If therapeutic goals are not achieved with a given agent at optimal dosage, addition of a second agent or switching to an alternative single agent should be considered.

Urinary incontinence (UI) is defined as involuntary leakage of urine.¹ It is frequently accompanied by other bothersome lower urinary tract symptoms, such as urgency, increased daytime frequency, and nocturia. It is a common yet underdetected and underreported health problem that can significantly affect quality of life. Patients with UI may have depression as a result of the perceived lack of self-control, loss of independence, and lack of self-esteem, and they often curtail their activities for fear of an “accident.” UI also may have serious medical and economic ramifications for untreated or undertreated patients, including perineal dermatitis, worsening of pressure ulcers, urinary tract infections, and falls.

This chapter highlights the epidemiology, etiology, pathophysiology, and treatment of stress, urge, mixed, and overflow UI in men and women.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

EPIDEMIOLOGY

Determining the true prevalence of UI is difficult because of problems with definition, reporting bias, and other methodologic issues.² Epidemiologic studies have not historically used a standard definition of the condition or a standard methodology for data recording, with some studies including “postvoid dribbling,” while other studies specify “urinary leakage causing a social or hygienic problem.” Many people suffer from UI, and the impact of this condition is substantial, crossing all racial, ethnic, and geographic boundaries. Compared with continent controls, patients with UI have an overall poorer quality of life.³ Several studies have objectively shown that UI is associated with reduced levels of social and personal activities, increased psychological distress, and overall decreased quality of life as measured by numerous indices.^{4,5} The condition can affect people of all age groups, but the peak incidence of UI, at least in women, appears to occur around the age of menopause, with a slight decrease in the age group 55 to 60 years, and then a steadily increasing prevalence after age 65 years.

One of the earliest comprehensive epidemiologic studies on UI was conducted by Diokno et al.⁶ using a standardized survey questionnaire. The Medical, Epidemiologic, and Social Aspects of Aging survey found that the prevalence of UI in noninstitutionalized women 60 years of age and older was approximately 38%. Almost one third of those surveyed noted urine loss at least once weekly and 16% noted UI daily. A publication from a National Institutes of Health working group conference estimated the median level of UI prevalence to be approximately 20% to 30% during young adult life, with a broad peak around middle age (30%–40% prevalence) and an increase in the elderly (30%–50% prevalence).⁷

In the United States, chronic UI is one of the most common reasons cited for institutionalization of the elderly, and the condition is frequently encountered in the nursing home setting.⁸ Little is known about the basic differences in clinical and epidemiologic characteristics of incontinence across racial or ethnic groups. Some studies report a higher incidence of UI overall in white populations^{9,10} as compared with African Americans, but differences in access to healthcare as well as cultural attitudes and mores may contribute to these differences.

Consistent across all studies of unselected, noninstitutionalized populations is that UI is at least half as common in men as in women.^{11,12} Overall, the prevalence of UI in men has been estimated to be approximately 9%.¹³ Unlike in women, the prevalence of UI in men increases with age across most studies, with the highest prevalence recorded in the oldest patient cohorts.¹³

ETIOLOGY AND PATHOPHYSIOLOGY

ANATOMY

The lower urinary tract consists of the bladder, urethra, urinary or urethral sphincter, and surrounding musculofascial structures,

including connective tissue, nerves, and blood vessels. The urinary bladder is a hollow organ composed of smooth muscle and connective tissue located deep in the bony pelvis in men and women. The urethra is a hollow tube that acts as a conduit for urine flow out of the bladder. The interior surface of both the bladder and urethra is lined by an epithelial cell layer termed the *transitional epithelium*, which is in constant contact with urine. Previously considered inert and inactive, transitional epithelium may play an active role in the pathophysiology of many lower urinary tract disorders, including interstitial cystitis and UI. The urinary or urethral sphincter is a combination of smooth and striated muscle within and surrounding the most proximal portion of the urethra adjacent to the bladder in both men and women. This is a functional but not anatomic sphincter that includes a portion of the bladder neck or outlet as well as the proximal urethra.

URINARY CONTINENCE

To prevent incontinence during the bladder filling and storage phase of the micturition cycle, the urethra, or more accurately the urethral sphincter, must maintain adequate closure in order to resist the flow of urine from the bladder at all times until voluntary voiding is initiated. Urethral closure or resistance to flow is maintained to a large degree by the proximal (under involuntary control) and distal (under both voluntary and involuntary control) urinary sphincters, a combination of smooth and striated muscles within and external to the urethra. Variable contributions to urethral closure may also come from the urethral mucosa, submucosal spongy tissue, and the overall length of the urethra. During bladder filling and storage, the bladder accommodates increasing volumes of urine flowing in from the upper urinary tract without a significant increase in bladder (intravesical) pressure. The maintenance of a low intravesical pressure despite increasing volumes of urine is a unique property of the bladder and is termed *compliance*. In addition, bladder or detrusor smooth muscle activity normally is suppressed during the filling phase by centrally mediated neural reflexes. Normal bladder emptying occurs with opening of the urethra concomitant with a volitional bladder contraction. Bladder contraction occurs in a coordinated fashion, resulting in a rise in intravesical pressure. The rise in intravesical pressure is ideally of adequate magnitude and duration to empty the bladder to completion. Opening and funneling of the bladder outlet results in urine flow into the urethra until the bladder is emptied to near completion.

The primary motor input to the detrusor muscle of the bladder is along the pelvic nerves emanating from spinal cord segments S2 to S4. Parasympathetic impulses travel to the bladder along the efferent fibers of the pelvic nerves. The impulses pass through ganglia situated in the bladder wall before reaching their target. Acetylcholine appears to be the primary neurotransmitter at the neuromuscular junction in the human lower urinary tract. Both volitional and involuntary contractions of the detrusor muscle are mediated by activation of postsynaptic muscarinic receptors by acetylcholine. Of the five known subtypes of muscarinic receptors, the majority of bladder smooth muscle cholinergic receptors are of the M_2 variety. In humans, the ratio of M_2/M_3 receptor numbers is approximately 3:1. However, M_3 receptors are the subtype responsible for both emptying contraction of normal micturition as well as involuntary bladder contractions that may result in UI.¹⁴ Thus, most pharmacologic antimuscarinic therapy is primarily anti- M_3 based.

This description of the mechanisms of urinary continence is a bit simplistic. Many other neurohumoral pathways and mechanisms, both within and outside the urinary tract, may play substantial roles in urinary continence (and voiding dysfunction) and may be future therapeutic options for treatment of voiding dysfunction and UI. Examples include adrenergic, purinergic, serotonergic, and dopa-

minergic pathways, tachykinin receptor antagonists, and calcium and potassium channel modulators.¹⁴

The bladder and urethra normally operate in unison during the bladder filling and storage phase, as well as the bladder emptying phase of the micturition cycle. The smooth and striated muscles of the bladder and urethra are organized during the micturition cycle by a number of reflexes coordinated at the pontine micturition center in the midbrain. Disturbances in the neural regulation of micturition at any level (brain, spinal cord, or pelvic nerves) often lead to characteristic changes in lower urinary tract function that may result in UI.

Mechanisms of Urinary Incontinence

Simply stated, UI may occur only as a result of abnormalities of the urethra (including the bladder outlet and urinary sphincter), the bladder, or a combination of both.¹⁵ Abnormalities may result in either overfunction or underfunction of the bladder and/or urethra, with resulting development of UI. Although this simple classification scheme excludes extremely rare causes of UI such as congenital ectopic ureters and urinary fistulas, it is useful for gaining a working understanding of the condition.

Urethral Underactivity (Stress Urinary Incontinence) Some patients characteristically note UI during exertional activities such as exercise, running, lifting, coughing, and sneezing. This implies that the compromised urethral sphincter is no longer able to resist the flow of urine from the bladder during periods of physical activity. In essence, increases in intraabdominal pressure during physical activity are transmitted to the bladder (an intraabdominal organ), compressing it and forcing urine through the weakened sphincter.

This type of UI is known as *stress urinary incontinence* (SUI). Although the exact etiology of urethral underactivity and SUI in women is incompletely understood, clearly identifiable risk factors include pregnancy, childbirth, menopause, cognitive impairment, obesity, and age.^{16,17} The prevalence of SUI in women appears to peak during or after the onset of menopause. This implies that hormonal factors are important in maintaining continence.

In men, SUI is most commonly the result of prior lower urinary tract surgery or injury, with resulting compromise of the sphincter mechanism within and external to the urethra. Radical prostatectomy for treatment of adenocarcinoma of the prostate probably is the most common setting in which surgical manipulation leads to UI. Overall, SUI in the male is uncommon and, in the absence of prior prostate surgery, severe trauma, or neurologic illness, is extraordinarily rare. Transurethral resection of the prostate for benign prostatic hyperplasia (BPH; see Chap. 87) may lead to SUI in men.

Bladder Overactivity (Urge Urinary Incontinence) Bladder overactivity, including bladder filling and urinary storage characterized by involuntary bladder contractions, is termed *urge urinary incontinence* (UUI). Symptoms of bladder overactivity occur because the detrusor muscle is overactive and contracts inappropriately during the filling phase. The terms *overactive bladder* and *detrusor overactivity* are distinct and should not be used interchangeably, as they frequently are in the medical lexicon. The International Continence Society defines *overactive bladder* as a symptom syndrome characterized by urinary urgency, with frequency and nocturia, with or without associated UI in the absence of a known pathologic condition that may result in similar symptoms (e.g., urinary tract infection or bladder cancer).¹

Therefore, a diagnosis of overactive bladder does not require urodynamic testing for confirmation but is a diagnosis based on patient symptoms. Conversely, detrusor overactivity is a specific urodynamic diagnosis referring to the finding of involuntary detrusor contractions during the filling phase of a urodynamic study. Therefore, invasive urodynamic testing is required to make the

diagnosis. Up to 40% of patients with overactive bladder do not demonstrate detrusor overactivity on urodynamic testing. The clinical significance of this finding is unknown. However, the effectiveness of pharmacologic therapy appears to be independent of the presence or absence of detrusor overactivity. This distinction between overactive bladder (a symptom syndrome) and detrusor overactivity (a urodynamic diagnosis) is essential in fully understanding the patient population under study and the effects of pharmacologic therapy reported in the literature.

Symptoms characteristic of overactive bladder are urinary frequency and urgency, with or without urge incontinence. *Frequency* is defined as micturition more than eight times per day. *Urgency* is described as a sudden compelling desire to urinate that is difficult to delay. People suffering from overactive bladder typically have to empty their bladders frequently, and, when they experience a sensation of urgency, they may leak urine if they are unable to reach the toilet quickly or if the sensation of urgency is very strong. Many patients have associated nocturia (>1 micturition per night) and/or nocturnal incontinence (enuresis). Nocturia and enuresis are particularly disruptive to sleep. For patients with incontinence, the amount of urine lost may be large, as the bladder may empty completely.

Most patients with overactive bladder and UII have no identifiable underlying etiology. The most common cause of overactive bladder and UII is “idiopathic.” Clearly identifiable risk factors for UII include normal aging, neurologic disease (including stroke, Parkinson’s disease, multiple sclerosis, and spinal cord injury), and bladder outlet obstruction (e.g., due to BPH or prostate cancer).

The mechanism for overactive bladder and UII must be either neurogenic or myogenic. The neurogenic hypothesis ascribes the condition to disease-related changes within the central or peripheral nervous system.¹⁸ The myogenic hypothesis states that overactive bladder and UII result from changes within the smooth muscle of the bladder wall itself.¹⁹ Precipitating factors, such as bladder outlet obstruction, can cause partial denervation of smooth muscle, leading to a state of decreased responsiveness to activation of intrinsic nerves but supersensitivity to contractile agonists and direct electrical activation.²⁰ In practice, UII is difficult to categorize as either neurogenic or myogenic in origin, as these etiologies often seem to be interconnected and complementary.

Urethral Overactivity and/or Bladder Underactivity (Overflow Incontinence) Overflow incontinence, the result of urethral overactivity and/or bladder underactivity, is an important but uncommon type of UI in both men and women. Overflow incontinence results when the bladder is filled to capacity at all times but is unable to empty, causing urine to leak from a distended bladder past a normal or even overactive outlet and sphincter.

In the setting of urethral overactivity, resistance to the flow of urine during volitional voiding is increased, resulting in functional or anatomic obstruction and incomplete bladder emptying. Clinically and practically, the most common causes of urethral overactivity in men are anatomic urethral obstruction, including that due to BPH and prostate cancer. In women, urethral overactivity is rare but may result from cystocele formation (with resultant kinking or obstruction of the urethra) or surgical overcorrection (iatrogenic obstruction) following anti-SUI surgery. In both men and women, overflow UI may be associated with systemic neurologic dysfunction or diseases, such as spinal cord injury or multiple sclerosis.

Bladder underactivity may result in overflow incontinence. Under certain circumstances, the detrusor muscle of the bladder may become progressively weakened and eventually lose the ability to voluntarily contract. In the absence of adequate contractility, the bladder is unable to empty completely, and large volumes of residual urine are left after micturition. Both myogenic and neurogenic factors have been implicated in producing the impaired contractility

seen in this condition. Clinically, overflow incontinence is most commonly seen in the setting of long-term chronic bladder outlet obstruction in men, such as that due to BPH or prostate cancer, diabetes mellitus, or denervation due to radical pelvic surgery, such as abdominopelvic resection or radical hysterectomy.

Mixed Incontinence and Other Types of Urinary Incontinence Various types of UI may coexist in the same patient. The combination of bladder overactivity and urethral underactivity is termed *mixed incontinence*. The diagnosis often is difficult because of the confusing array of presenting symptoms. Bladder overactivity may also coexist with impaired bladder contractility. This occurs most commonly in the elderly and is termed *detrusor hyperactivity with impaired contractility*.²¹

Functional incontinence is not caused by bladder- or urethra-specific factors. Rather, in patients with conditions such as dementia or cognitive or mobility deficits, the UI is linked to the primary disease process more than any extrinsic or intrinsic deficit of the lower urinary tract. An example of functional incontinence occurs in the postoperative orthopedic surgery patient. Following extensive orthopedic reconstructions such as total hip arthroplasty, patients often are immobile secondary to pain or traction. Therefore, patients may be unable to access toileting facilities in a reasonable amount of time and may become incontinent as a result. Treatment of this type of UI may involve simple interventions such as placing a urinal or commode at the bedside that allows for uncomplicated access to toileting.

Many localized or systemic illnesses may result in UI because of their effects on the lower urinary tract or the surrounding structures:

- Dementia/delirium
- Depression
- Urinary tract infection (cystitis)
- Postmenopausal atrophic urethritis or vaginitis
- Diabetes mellitus
- Neurologic disease (e.g., stroke, Parkinson disease, multiple sclerosis, spinal cord injury)
- Pelvic malignancy
- Constipation
- Congenital malformations

① Many commonly used medications may precipitate or aggravate existing voiding dysfunction and UI (Table 88–1).

TABLE 88-1 Medications That Influence Lower Urinary Tract Function

Medication	Effect
Diuretics, acetylcholinesterase inhibitors	Polyuria, frequency, urgency
α -Receptor antagonists	Urethral relaxation and stress urinary incontinence in women
α -Receptor agonists	Urethral constriction and urinary retention in men
Calcium channel blockers	Urinary retention
Narcotic analgesics	Urinary retention from impaired contractility
Sedative hypnotics	Functional incontinence caused by delirium, immobility
Antipsychotics	Anticholinergic effects and urinary retention
Anticholinergics	Urinary retention
Antidepressants, tricyclic	Anticholinergic effects, α -antagonist effects
Alcohol	Polyuria, frequency, urgency, sedation, delirium
Angiotensin-converting enzyme inhibitors (ACEIs)	Cough as a result of ACEIs may aggravate stress urinary incontinence by increasing intra-abdominal pressure

CLINICAL PRESENTATION

CLINICAL PRESENTATION OF URINARY INCONTINENCE RELATED TO URETHRAL UNDERACTIVITY

General

- The patient usually notes UI during activities such as exercise, running, lifting, coughing, and sneezing. Occurs much more commonly in women (seen only in men with lower urinary tract surgery or injury compromising the sphincter).

Symptoms

- Urine leakage with physical activity (volume is proportional to activity level). No UI with physical inactivity, especially when supine (no nocturia). May develop urgency and frequency as a compensatory mechanism (or as a separate component of bladder overactivity).

Diagnostic Tests

- Observation of urethral meatus while patient coughs or strains.

CLINICAL PRESENTATION OF URINARY INCONTINENCE RELATED TO BLADDER OVERACTIVITY

General

- Can have bladder overactivity and UI without urgency if sensory input from the lower urinary tract is absent.

Symptoms

- Urinary frequency (>8 micturitions per day), urgency with or without urge incontinence; nocturia (≥1 micturition per night) and enuresis may be present.

Diagnostic Tests

- Urodynamic studies are the gold standard for diagnosis. Urinalysis and urine culture should be negative (rule out urinary tract infection as cause of frequency).

CLINICAL PRESENTATION OF URINARY INCONTINENCE RELATED TO URETHRAL OVERACTIVITY AND/OR BLADDER UNDERACTIVITY

General

- Important but rare type of UI in both men and women. Urethral overactivity usually is due to prostatic enlargement (males) or cystocele formation or surgical overcorrection following stress incontinence surgery in women.

Symptoms

- Lower abdominal fullness, hesitancy, straining to void, decreased force of stream, interrupted stream, sense of incomplete bladder emptying. May have urinary frequency and urgency. Abdominal pain if acute urinary retention is present.

Signs

- Increased postvoid residual urine volume.

Diagnostic Tests

- Digital rectal examination or transrectal ultrasound to rule out prostatic enlargement. Renal function tests to rule out renal failure due to acute urinary retention.

² UI may present in a number of ways, depending on the underlying pathophysiology. Generally, SUI is considered the most common type of UI and probably accounts for at least a portion of UI in more than half of all incontinent women. Some studies have found that mixed UI (SUI + UUI) is the most common type of UI.⁶ However, the proportions of SUI versus UUI versus mixed UI vary considerably with age group and sex of patients studied, study methodology, and a variety of other factors. A complete medical history, including an assessment of symptoms and a physical examination, is essential for correctly classifying the type of incontinence and thereby assuring appropriate therapy.

URINE LEAKAGE

UI represents a spectrum of severity in terms of both volume of leakage and degree of bother to the patient. To carefully consider the level of patient discomfort when discussing urine leakage, the clinician must probe during the patient interview to accurately determine the precise nature of the problem.

Use of absorbent products, such as panty liners, pads, or briefs, is an obvious point of discussion, but the clinician must keep in mind that use of these products varies among patients. The number and type of pads may not relate to the amount or type of incontinence, as their use is a function of personal preference and hygiene. A high number of absorbent pads may be used every day by a patient with severe, high-volume UI or, alternatively, by a fastidiously hygienic patient with low-volume leakage who simply changes pads often to prevent wetness or odor. Nevertheless, a large number of pads that are described by the patient as “soaked” is indicative of high-volume urine loss.

Regardless of the volume of urine loss, the desire to seek evaluation and therapy for UI in all patients almost always is elective and contingent on the degree of bother to the individual patient. As with use of absorbent products, patients differ with regard to the amount of urine loss they will tolerate before considering the condition bothersome enough to seek assistance.

SYMPTOMS

Under the best of circumstances, UI is difficult to categorize based on symptoms alone (Table 88-2).²² In a study of patients who appeared to have SUI based on symptoms and patient history, urodynamics showed that only 72% of patients had SUI as the sole cause of incontinence.²³

Patients with urethral underactivity or SUI characteristically complain of urinary leakage with physical activity. Volume of leakage is proportional to the level of activity. They will often leak urine during periods of exercise, coughing, sneezing, lifting, or even

TABLE 88-2 Differentiating Bladder Overactivity from Urethral Underactivity

Symptoms	Bladder Overactivity	Urethral Underactivity
Urgency (strong, sudden desire to void)	Yes	Sometimes
Frequency with urgency	Yes	Rarely
Leaking during physical activity (e.g., coughing, sneezing, lifting)	No	Yes
Amount of urinary leakage with each episode of incontinence	Large if present	Usually small
Ability to reach the toilet in time following an urge to void	No or just barely	Yes
Nocturnal incontinence (presence of wet pads or undergarments in bed)	Yes	Rare
Nocturia (waking to pass urine at night)	Usually	Seldom

when rising from a seated to a standing position. Patients with pure SUI will not have leakage when physically inactive, especially when they are supine. Often they will have little or no UI at night, will not awaken to void during the night (nocturia), will not wet the bed, and often do not even wear absorbent products at bedtime. Urinary urgency and frequency may be associated with SUI, either as a separate component caused by bladder overactivity (mixed incontinence) or as a compensatory mechanism wherein the patient with SUI learns to toilet frequently to prevent large-volume urine loss during physical activity.

Typical symptoms of bladder overactivity include frequency, urgency, and urge incontinence. Nocturia and nocturnal incontinence are often present. Urine leakage is unpredictable, and the volume loss may be large. Patients often wear protection both day and night. Urinary frequency can be affected by a number of factors unrelated to bladder overactivity, including excessive fluid intake (polydipsia) and bladder hypersensitivity states such as interstitial cystitis and urinary tract infection, and should be ruled out. In some patients, bladder overactivity manifests as UI without awareness in the absence of a sense of urinary urgency or frequency. *Urinary urgency*, a sensation of impending micturition, requires intact sensory input from the lower urinary tract. In patients with spinal cord injury, sensory neuropathies, and other neurologic diseases, a diminished ability to perceive or process sensory input from the lower urinary tract may result in bladder overactivity and UI without urgency or urinary frequency. When bladder contraction occurs without warning and sensation is absent, the condition is referred to as *reflex incontinence*.

Patients with overflow incontinence may present with lower abdominal fullness as well as considerable obstructive urinary symptoms, including hesitancy, straining to void, decreased force of urinary stream, interrupted stream, and a vague sense of incomplete bladder emptying. These patients may also have a significant component of urinary frequency and urgency. In patients with acute urinary retention and overflow incontinence, lower abdominal pain may be present. Although these symptoms are not specific for overflow incontinence, they may warrant further investigation, including an assessment of postvoid residual urine volume.

SIGNS

A presenting complaint of UI mandates a directed physical examination and a brief neurologic assessment. The workup ideally includes an abdominal examination to exclude a distended bladder, neurologic assessment of the perineum and lower extremities, pelvic examination in women (looking especially for evidence of prolapse or hormonal deficiency), and genital and prostate examination in men.

SUI usually can be objectively demonstrated by having the patient cough or strain during the examination and observing the urethral meatus for a sudden spurt of urine. In women, SUI may be associated with varying degrees of vaginal prolapse, including cystourethrocele (bladder and urethral prolapse), enterocele (small bowel prolapse), rectocele (rectal prolapse), and uterine prolapse. These conditions may have important implications for therapy.

Perineal skin maceration, erythema, breakdown, and ulceration may be indicative of chronic, severe UI. Patients with chronic incontinence may manifest fungal infections of the skin of the perineum and upper thighs.

In both men and women, digital rectal examination provides an opportunity to check ambient rectal tone and the integrity of the sacral reflex arc (e.g., anal wink) as well as assess the patient's ability to perform a voluntary pelvic floor muscle contraction (i.e., Kegel exercise), which may be an important factor in deciding on appropriate therapy. In men, a digital examination of the prostate assesses for the presence of prostate cancer, inflammation, and BPH.

A targeted neurologic examination includes assessment of reflexes, rectal tone, and sensory or motor deficits in the lower extremities, which might be indicative of systemic or localized neurologic disease. Neurologic diseases have the potential to affect bladder and sphincter function and thus may have significant implications in the incontinent patient.

PRIOR MEDICAL OR SURGICAL ILLNESS

UI may present in the setting of concurrent, seemingly unrelated illnesses. New-onset UI may be the initial manifestation of systemic illnesses such as diabetes mellitus, metastatic malignancies, multiple sclerosis, and other neurologic illnesses. Central nervous system disease, or injury above the level of the pons, generally results in symptoms of bladder overactivity and UUI. Spinal cord injury or disease may manifest as bladder overactivity and UUI or as overflow incontinence, depending on the spinal level and completeness of the injury or disease.

Medications may have wide-ranging effects on lower urinary tract function (see Table 88–1). A thorough inquiry into the use of new medications in the setting of recent-onset UI may show a relationship.

Acute UI manifesting in the immediate postoperative setting may be secondary to a number of factors, including surgical manipulation and immobility, and to a number of medications, especially opioid analgesics. In the postoperative setting, acute urinary retention and overflow incontinence are commonly related to the administration of anesthetic agents and/or opioid analgesics in the perioperative period. These agents may have profound effects on bladder contractility that are completely reversible once the agents are metabolized and excreted.

Prior surgery may have effects on lower urinary tract function. UI following prostate surgery in men is highly suggestive of injury to the sphincter and resultant SUI. Pelvic surgery for benign and malignant conditions may result in denervation or injury to the lower urinary tract. This includes bowel surgery and gynecologic procedures. For example, new-onset total UI following gynecologic surgery suggests intraoperative bladder injury and subsequent development of a postoperative vesicovaginal fistula. Radiation therapy to the pelvis for malignant disease (e.g., prostate cancer or cervical cancer) may result in injury to the bladder or urethra and subsequent UI.

In women, UI may be related to several gynecologic factors, including childbirth, hormonal status, and prior gynecologic surgery. Pregnancy and childbirth, particularly vaginal delivery, are associated with SUI and pelvic prolapse. Significant SUI in the nulliparous woman is uncommon. UI that becomes progressive at or around menopause suggests a hormonal component that may be responsive to estrogen or hormone replacement therapy.

UI may present in the setting of other significant pelvic floor disorders, signs, and symptoms. Constipation, diarrhea, fecal incontinence, dyspareunia, sexual dysfunction, and pelvic pain may be related to UI. A history of gross hematuria in the setting of UI mandates further urologic investigation, including radiologic imaging of the upper urinary tract and cystoscopy. Acute dysuria with or without hematuria in the setting of UI suggests cystitis. Urinalysis and urine culture should be performed in these patients.

TREATMENT

Urinary Incontinence

■ NONPHARMACOLOGIC TREATMENT

3 Nonpharmacologic treatment of UI commonly constitutes the initial form of incontinence management at a primary care level. For

patients in whom pharmacologic or surgical management is inappropriate or undesired, nondrug treatment is the only option. Examples of patients who fulfill these criteria include patients who are not medically fit for surgery, those who plan future pregnancies (which may adversely affect long-term surgical outcomes), those with overflow incontinence whose condition is not amenable to surgery or drug therapy, those with comorbid conditions that place them at high risk for adverse effects from drug therapy, those who are delaying surgery or do not want to undergo surgery, and those with mild to moderate symptoms who do not want to take medication.

For additional information on nonpharmacologic interventions for UI, readers are referred to comprehensive literature reviews and consensus opinions of treatment guidelines on nonpharmacologic interventions by multidisciplinary experts.²⁴ Table 88–3 summarizes the basic nondrug approaches.

Behavioral interventions are the first line of treatment for SUI, UUI, and mixed UI. Interventions include lifestyle modifications, toilet scheduling regimens, and pelvic floor muscle rehabilitation. Because the key to success with any type of behavioral intervention is motivation of patients or caregivers, these individuals must be active participants in developing a treatment plan. Regular followup is needed to help motivate patients and caregivers, provide reassurance and support, and monitor treatment outcomes.

■ PHARMACOLOGIC TREATMENT

Urge Urinary Incontinence

Pharmacotherapy is useful when UUI symptoms are not adequately controlled with nonpharmacologic therapies, particularly in patients with low functional bladder capacity, especially individuals who frequently attempt to toilet and are independent or require only limited assistance in toileting. In many cases, the combined use of pharmacotherapy with nonpharmacologic therapy produces a better response than either intervention alone.

4 Anticholinergic/antispasmodic drugs have proved to be the most effective agents for suppressing premature detrusor contractions, enhancing bladder storage, and relieving UUI symptoms and complications and constitute the pharmacotherapy of first choice for treatment of UUI (Tables 88–4 and 88–5).^{25–44} Drugs with anticholinergic activity act by antagonizing muscarinic cholinergic receptors, through which efferent parasympathetic nerve impulses evoke detrusor contraction. Anticholinergics have been demonstrated to improve quality of life, with no significant differences between agents.⁴⁵ Women with mixed UI or UUI plus urethritis or vaginitis may benefit from a topical estrogen (alone or in combination with an anticholinergic drug). Patients with irritative symptoms of BPH that persist despite specific BPH treatment may benefit from anticholinergic therapy as well (caution is warranted because these agents may precipitate acute urinary retention).

Immediate-Release Oxybutynin Even though a substantial proportion of patients may discontinue oxybutynin immediate-release (IR) therapy because of its nonurinary antimuscarinic effects, oxybutynin IR remains the drug of first choice for treatment of UUI and the gold standard against which other drugs are compared. In addition to antimuscarinic effects (e.g., dry mouth, constipation, vision impairment, confusion, cognitive dysfunction, and tachycardia), oxybutynin IR is associated with orthostatic hypotension secondary to α -adrenergic receptor blockade as well as sedation and weight gain from histamine H_1 -receptor blockade.^{26,31,46–50} Furthermore, adverse effects jeopardize medication adherence and can prevent dose escalation to that needed for optimal benefit.

Emerging evidence suggests that the high incidence of adverse effects, especially dry mouth, with use of oxybutynin IR is largely due to the active metabolite *N*-desethyloxybutynin (DEO), which is generated during extensive first-pass metabolism in the liver and

upper gastrointestinal tract.⁵¹ The lower DEO plasma concentrations seen with long-acting forms of oxybutynin (which are due to reduced first-pass metabolism) compared with those of oxybutynin IR may explain the lesser propensity of the long-acting formulations to cause dry mouth and other anticholinergic adverse effects.

Another factor associated with the adverse effects of oxybutynin IR, especially in older patients, is the transient high peak serum oxybutynin plasma concentrations.⁵² Oxybutynin IR is best tolerated when the dose is gradually escalated from no more than 2.5 mg twice daily to start, to 2.5 mg three times daily after 1 month, then further increased in increments of 2.5 mg/day every 1 to 2 months until the desired response or the maximum recommended or tolerated dose is attained. The optimal response usually requires no more than 5 mg three times daily (see Table 88–4).^{26,53}

Adverse effects of oxybutynin IR can sometimes be managed by a dose reduction if this does not significantly compromise drug efficacy. Dry mouth can be relieved by use of sugarless hard candy, gum, or a saliva substitute. Constipation can be minimized by increasing the intake of water, dietary fiber, physical activity such as walking, or laxative therapy. The need for multiple daily dosing of oxybutynin IR can further jeopardize adherence, especially in people who take multiple medications or those who are cognitively impaired.

Extended-Release Oral Oxybutynin Because of the problems noted with oxybutynin IR, an extended-release (XL) formulation of oxybutynin was developed. It can be considered an alternative first-line therapy of UUI (see Table 88–5).⁵⁴

Unlike oxybutynin IR, oxybutynin XL delivers a controlled amount of oxybutynin continuously throughout the gastrointestinal tract over a 24-hour period, reducing first-pass metabolism by cytochrome P450 (CYP) isoenzyme 3A4, which is present in higher concentrations in the upper portion of the small intestine than in the lower gastrointestinal tract.^{54,55} This results in relative bioavailabilities of oxybutynin and DEO of 153% and 69%, respectively, for oxybutynin XL compared with oxybutynin IR.⁵⁶ The greater ratio of parent drug concentration to active metabolite concentration after oxybutynin XL administration and, probably less importantly, the lower peak plasma drug concentration are believed to be the reasons for fewer dose- and concentration-dependent adverse effects and better patient tolerance with the XL preparation compared with oxybutynin IR.⁵⁷ Elimination of oxybutynin XL is not known to be altered in patients with renal or hepatic impairment or in geriatric patients (up to age 78 years).⁵⁴ The absence of an effect of advanced age on oxybutynin XL pharmacokinetics is unexpected because clearance of oxybutynin IR is significantly lower (by approximately 50%) in older patients compared with younger individuals.

Controlled studies have demonstrated that oxybutynin XL is significantly more effective than placebo and is as effective as oxybutynin IR in terms of reducing the mean number of UI episodes, restoring continence, decreasing the number of micturitions per day, and increasing urine volume voided per micturition (see Table 88–5).^{30,31,46–48,58–60}

In short-term studies of up to 12 weeks' duration, oxybutynin XL was better tolerated than oxybutynin IR, with approximately 7% of patients discontinuing treatment because of adverse effects (compared with approximately 27% of those taking oxybutynin IR).^{26,31,46,47,53,54} The rate and severity of adverse effects did not differ significantly between elderly persons (≥ 65 years old) and younger adults using the XL preparation. A 12-week study demonstrated the superiority of oxybutynin XL over tolterodine IR in reducing the mean number of weekly incontinent episodes and micturitions.³⁹

In the Overactive Bladder: Performance of Extended-Release Agents (OPERA) trial, oxybutynin XL and tolterodine long-acting (LA) were equally effective in decreasing the mean number of incontinence episodes, but oxybutynin XL was superior in reducing weekly micturition frequency and achieving total dryness.⁶¹ In another study

TABLE 88-3 Nonpharmacologic Management of Urinary Incontinence

Intervention	Description	Patient Characteristics
Lifestyle modifications	Self-management strategies targeted toward reducing or eliminating risk factors that cause or exacerbate urinary incontinence	Smoking cessation for patients with cough-induced stress incontinence; weight reduction for obese patients with stress and urge incontinence; prevention of constipation; caffeine reduction, selected dietary and fluid modifications for patients with urge incontinence (e.g., eliminate aspartame, spicy foods, citrus fruits, carbonated beverages)
Scheduling regimens		
Timed voiding	Toileting on a fixed schedule at interval does not change, typically every 2 hours during waking hours	Used for stress, urge, and mixed incontinence in patients with cognitive or physical impairments; used in patients without impairments who have infrequent voiding patterns
Habit retraining	Scheduled toiletings with adjustments of voiding intervals (longer or shorter) based on patient's voiding pattern	Used for institutionalized or homebound patients with cognitive or physical impairments; may be used in patients who have diuretic-induced incontinence
Prompted voiding	Scheduled toiletings that require prompts to void from a caregiver, typically every 2 hours; patient assisted in toileting only if response is positive; used in conjunction with operant conditioning techniques for rewarding patients for maintaining continence and appropriate toileting	Used for patients who are functionally able to use toilet or toilet substitute, able to feel urge sensation, and able to request toileting assistance appropriately; primarily used in institutional settings or in homebound patients with an available caregiver
Bladder training	Scheduled toiletings with progressive voiding intervals; includes teaching urge control strategies using relaxation and distraction techniques, self-monitoring, and use of reinforcement techniques; sometimes combined with drug therapy	Used for stress, urge, and mixed incontinence in patients who are cognitively intact, able to toilet, and motivated to comply with training program
Pelvic floor muscle rehabilitation		
Pelvic floor muscle exercises (e.g., Kegel exercises)	Regular practice of pelvic floor muscle contractions; may involve use of pelvic floor muscle contraction for prevention of stress leakage and urge inhibition	Used for stress, urge, and mixed incontinence in patients who can correctly contract pelvic floor muscles without using accessory muscles; requires cognitively intact and highly motivated patient
Biofeedback	Use of electronic or mechanical instruments to display visual or auditory information about neuromuscular or bladder activity; used to teach correct pelvic floor muscle contraction and/or urge inhibition	Used for stress, urge, and mixed incontinence in patients who have the capability to learn voluntary control through observation and are motivated; used in conjunction with pelvic floor muscle exercises
Vaginal weight training	Active retention of increasing vaginal weights (e.g., Kegel Kones, Milex, Chicago, IL); typically used in combination with pelvic floor muscle exercises at least twice per day	Women with stress incontinence who are cognitively intact, can correctly contract pelvic floor muscles, able to stand, and have sufficient vaginal vault and introitus to retain cone and are highly motivated; contraindicated in patients with moderate to severe pelvic organ prolapse
Acupuncture	Involves insertion of disposable sterile stainless steel needles into points on the skin that are thought to suppress or stimulate spinal and/or supraspinal reflexes to the bladder and/or urethra	Used for urge and mixed incontinence and urinary incontinence due to spinal cord injury
Nonimplantable electrical stimulation	Application of electrical current to sacral or pudendal afferent fibers through vaginal, anal, surface, or needle electrodes; used to inhibit bladder overactivity and improve awareness, contractility, and efficacy of pelvic floor muscle contraction	Used for stress, urge, and mixed incontinence in patients who are highly motivated; contraindicated in patients with diminished sensory perception, moderate or severe pelvic organ prolapse; urinary retention, history of cardiac arrhythmia, or demand cardiac pacemaker
Extracorporeal magnetic innervation	Pulsed magnetic stimulation to pelvic floor musculature causing depolarization of motor neurons, thus inducing pelvic floor muscle contraction; stimulation is provided through a specially designed chair that contains a device for producing a pulsing magnetic field (e.g., Neotonus, Inc., Marietta, GA)	Used for treatment of stress, urge, and mixed incontinence; contraindicated in patients with demand cardiac pacemakers or metallic joint replacements; may be useful treatment option when other approaches fail or are not feasible
Antiincontinence devices		
Pessaries	Intravaginal devices designed to support the bladder neck, relieve minor to moderate pelvic organ prolapse, and change pressure transmission to the urethra (e.g., Milex; Mentor Corporation, Santa Barbara, CA; Adamed, Inc., Rutherford, NJ)	Used for female stress incontinence and mild to moderate pelvic organ prolapse; in postmenopausal women, topical estrogen therapy typically is prescribed to prevent ulceration and breakdown of vaginal tissue; requires good manual dexterity to manipulate device
Bed or pant alarms	Sensor devices that respond to wetness; used to awaken or alert individuals via noise or vibrating mechanism (e.g., Nite Train-r, Koregon Enterprises, Inc., Beaverton, OR; Healthshield Incontinence Detectors, Jonas Inc., Wilmington, DE)	Primarily used for nocturnal enuresis in children; system available for monitoring incontinence in home care and institutional environments
Urethral compression device (men only)	Penile clamp (e.g., Cunningham Incontinence Clamp, Bard Medical, Covington, GA; ActiCuf, GT Urological, Minneapolis, MN; Cook Continence, Cook Wound/Ostomy/Continence, Spencer, IN)	Used in male stress incontinence patients who are intact and have good manual dexterity
Intraurethral occlusive device (urethral plug) (women only)	Small, single-use device worn in the urethra to provide mechanical obstruction to prevent urine leakage; removed for voiding (e.g., FemSoft Insert, Rochester Medical Corp., Stewartville, MN)	Used for female stress incontinence patients who are cognitively intact with good manual dexterity; contraindicated with primary urge incontinence, urinary tract infection, urethral stricture, and any anatomic or pathologic condition that makes catheter passage difficult
External collection devices (men only)	Condom catheter with leg bag	Used in men with urge, stress, and overflow incontinence and in those with functional impairments
Catheters	Disposable, intermittent urethral catheters and indwelling urethral and suprapubic catheters	Used for overflow incontinence; used in patients who are bed-bound or with significant mobility impairments and severe incontinence; those with terminal illness; those with sacral pressure ulcers until healing occurs

(continued)

TABLE 88-3 Nonpharmacologic Management of Urinary Incontinence (continued)

Intervention	Description	Patient Characteristics
Supportive interventions		
Toileting substitutes and other environmental modifications	Female and male urinals, bedside commodes, elevated toilet seats	Used for patients with mobility impairments that make reaching a toilet in timely fashion difficult
Absorbent products	Variety of reusable and disposable pads and pant systems; some products contain a polymer that absorbs and wicks urine away from the body	Used for all types of incontinence
Physical therapy	Gait and/or strength training	Used for frail elderly patients with mobility impairments that make reaching a toilet in timely fashion difficult

that pooled results of two open-label studies, tolterodine LA was associated with significantly greater patient-perceived improvement in bladder control and fewer withdrawals due to adverse effects than oxybutynin XL. However, the treatments were similar in terms of patients' or physicians' perception of benefit over baseline and proportions of withdrawals due to lack of efficacy. However, the lack of blinding may have introduced patient and observer bias.⁶²

Oxybutynin XL, available only in a tablet formulation, is administered once daily, with or without food, and should not be crushed or chewed (see Table 88-4). Like oxybutynin IR, the dosage does not require adjustment in patients of advanced age or in patients with renal or hepatic impairment. However, treatment should be initiated at the smallest recommended dosage in the elderly (5 mg once daily).^{32,54} The maximum benefit of oxybutynin XL may not be realized for up to 4 weeks after starting therapy or after dose escalation. No known clinically relevant drug-drug interactions with either oxybutynin XL or oxybutynin IR have been identified. However, other drugs with anticholinergic activity may increase overall anticholinergic effects (i.e., produce an additive or synergistic pharmacodynamic interaction), as might be expected.⁵⁴ Another

potential pharmacodynamic interaction involves the mutual antagonism of anticholinergic agents and cholinergic stimulants, such as the acetylcholinesterase inhibitors used to treat dementia.

Extended-Release Transdermal Oxybutynin The oxybutynin transdermal system (TDS), which delivers 3.9 mg/day, is applied twice weekly (every 3 or 4 days). Transdermal absorption of oxybutynin from this formulation bypasses first-pass hepatic and gut metabolism, resulting in similar plasma oxybutynin but lower plasma DEO concentrations compared with levels achieved after administration of an equivalent dose via the oral route.^{51,63,64} No dosage adjustment of the TDS product for advancing age is necessary.⁴⁴

Oxybutynin TDS is superior to placebo in reducing the number of incontinence episodes and micturitions and increasing the volume voided per micturition.^{43,44} It is similar to oxybutynin IR in reducing the frequency of UII episodes and improving patient-perceived urinary leakage.⁶⁵ Oxybutynin TDS and tolterodine LA are significantly superior to placebo and similar to each other in reducing the frequency of UII episodes, increasing the volume voided per micturition, attaining complete continence, and improving quality of life.⁴³

TABLE 88-4 Pharmacotherapeutic Options in Patients with Urinary Incontinence

Type	Drug Class	Drug Therapy (Usual Dose)	Comments
Overactive bladder	Anticholinergic agents/antispasmodics	Oxybutynin IR (2.5–5 mg two, three or four times daily), oxybutynin XL (5–30 mg daily), oxybutynin TDS (3.9 mg/day); (apply one patch twice weekly), tolterodine IR (1–2 mg twice daily), tolterodine LA (2–4 mg daily), trospium chloride (20 mg once or twice daily), solifenacin (5–10 mg daily), darifenacin (7.5–15 mg daily)	Anticholinergics are first-line drug therapy (oxybutynin or tolterodine is preferred)
	Tricyclic antidepressants (TCAs)	Imipramine, doxepin, nortriptyline, or desipramine (25–100 mg at bedtime)	TCAs are generally reserved for patients with an additional indication (e.g., depression, neuropathic pain)
	Topical estrogen (only in women with urethritis or vaginitis)	Conjugated estrogen vaginal cream (0.5 g) three times per week for up to 8 months. Repeat course if symptom recurrence, or use estradiol vaginal insert/ring [2 mg (one ring)] and replace after 90 days if needed.	Marginally effective; few adverse effects with vaginal cream and insert
Stress	Duloxetine ^a	40–80 mg/day (one or two doses)	Even though not FDA approved, duloxetine is first-line therapy; most adverse events diminish with time, so support patient during initial period of use
	α -Adrenergic agonists	Pseudoephedrine (15–60 mg three times daily) with food, water, or milk Phenylephrine (10 mg four times daily)	Pseudoephedrine and phenylephrine are alternative first-line therapies for women with no contraindication (notably hypertension); phenylpropanolamine was the preferred agent in the class until its removal from the U.S. market in 2000.
	Estrogen	See estrogens (above). Works best if urethritis or vaginitis are present.	Considered a less-effective alternative to α -adrenergic agonists and duloxetine. Combined α -adrenergic agonist and estrogen may be somewhat more effective than α -adrenergic agonist alone in postmenopausal women.
	Imipramine	25–100 mg at bedtime	Imipramine is an optional therapy when first-line therapy is inadequate.
Overflow (atonic bladder)	Cholinomimetics	Bethanechol (25–50 mg three or four times daily) on an empty stomach	Avoid use if patient has asthma or heart disease. Short-term use only. Never give IV or IM because of life-threatening cardiovascular and severe gastrointestinal reactions.

IR, immediate-release; LA, long-acting; TDS, transdermal system; XL, extended-release.

^aInvestigational. Doses provided are those best supported by clinical trials to date.

TABLE 88-5 Adverse Event Incidence Rates with First-Line Drugs for Bladder Overactivity^a

Drug	Dry Mouth	Constipation	Dizziness	Vision Disturbance
Oxybutynin IR	85	40	32	20
Oxybutynin XL	35	7	5	2
Oxybutynin TDS	7	3	1	1
Tolterodine	61	13	6	8
Tolterodine LA	23	6	2	1
Trospium chloride	20	10	1	1
Solifenacin	11	5	2	4
Darifenacin	20	15	2	2

IR, immediate-release; LA, long-acting; TDS, transdermal system; XL, extended-release.

^aAll values constitute mean data, predominantly using product information from the manufacturers. Due to the absence of information regarding dizziness for oxybutynin IR in the product information, pooled data from references 48 and 65 have been used.

A combined analysis of two phase III studies demonstrated a significant decrease in the number of UII episodes and urinary frequency and increase in the volume voided per micturition from baseline with oxybutynin TDS in a study population, half of whom were elderly. These results were similar to those achieved in other studies with younger adults.⁶⁶ A subgroup analysis of combined placebo-controlled and open-label studies found similar reductions in numbers of UII episodes and daily micturitions in patients 65 years and older compared with younger adults.⁶⁷

The most common adverse effects with the TDS formulation are pruritus (15%) and erythema (9%) at the application site. Dry mouth (7%), constipation (3%), dizziness (1%), and abnormal vision (1%) occur less frequently with the TDS formulation than with the IR formulation and with similar frequency compared to oxybutynin XL and tolterodine IR/LA.^{39,44}

In a study population in which approximately half were elders, the incidences of total adverse events, dry mouth, constipation, abnormal vision, dizziness, and somnolence with oxybutynin TDS were similar to those observed in younger adults.⁶⁶ A subgroup analysis of combined placebo-controlled and open-label studies showed that the incidence of adverse events with oxybutynin TDS in patients 65 years and older was similar to that in younger adults. The rates of pruritus and overall treatment discontinuation were lower in elders compared with younger adults.⁶⁷

Immediate-Release Tolterodine Tolterodine is a competitive muscarinic receptor antagonist that can be considered first-line therapy for UI in patients with symptoms of urinary frequency, urgency, or urge incontinence (see Table 88-4).³³

Controlled studies demonstrated that tolterodine was significantly more effective than placebo and as effective as oxybutynin IR in decreasing the mean daily number of micturitions and increasing the mean volume voided per micturition.^{27,34–38,68,69} Although three controlled trials showed a significant decrease in the mean number of incontinence episodes per 24 hours compared with placebo, most other studies have not confirmed the finding, and the manufacturer's package insert does not claim a significant improvement in this parameter.^{28,34–38,69} The only controlled study of the ability of tolterodine to restore urinary continence reported an insignificant effect size of 9% over placebo.³⁴

Extended-Release Tolterodine In a controlled study of 1,529 adult outpatients with urinary frequency and UII, tolterodine LA, an extended-release formulation of tolterodine, significantly decreased the mean number of weekly incontinence episodes (23% effect size over placebo and 7% effect size over tolterodine IR). Premature study withdrawal rates did not differ significantly between the two active treatments, but dry mouth was observed significantly less

often in patients taking the LA formulation than among those receiving the IR formulation.⁴⁰

Tolterodine LA was significantly superior to placebo and similar in elderly and young patient populations in reducing the frequencies of incontinence episodes and micturitions, increasing the volume voided per micturition and ability to complete tasks before voiding, and enhancing patient perception of benefit. Adverse effect types and frequencies were similar in the two age groups.⁷⁰

A major consideration in using tolterodine is its pharmacokinetics, specifically its metabolism. The agent is predominantly eliminated by hepatic metabolism, which is partially under the control of genetic polymorphism.³³ The principal metabolic pathway in extensive metabolizers involves oxidation of the parent drug by CYP isoenzyme 2D6 to the active 5-hydroxymethyl metabolite (DD01), followed by further oxidation and dealkylation. In poor metabolizers who lack the CYP 2D6 (approximately 7% of the U.S. population), the principal metabolic pathway involves CYP 3A4, with dealkylation of the amino group, oxidation to a dealkylated hydroxy metabolite, and further oxidation to a dealkylated acid metabolite that undergoes glucuronidation. Because tolterodine is principally metabolized by CYP 3A4 in this case, its elimination may be impaired by inhibitors of this isoenzyme (e.g., fluoxetine, sertraline, fluvoxamine, macrolide antibiotics, azole antifungals, and grapefruit juice). For example, fluoxetine, an inhibitor of CYP 2D6 and 3A4, decreases the metabolism of tolterodine to DD01. The result is a mean 4.8-fold increase in the tolterodine area under the plasma concentration–time curve (AUC), mean 52% decrease in peak plasma concentration, and mean 20% decrease in the AUC of DD01.³³ Whether tolterodine significantly alters the pharmacokinetics of drugs metabolized by CYP 2D6 is unknown, so caution is advised with concurrent use with agents metabolized by CYP 2D6.

Single-dose interaction studies have demonstrated that concurrent administration of tolterodine LA with antacid leads to rapid release of drug (70% within 4 hours) and a mean 1.5-fold elevation in tolterodine peak plasma concentration compared with placebo. The same studies showed that the pharmacokinetics of oxybutynin XL were unaltered by concurrent antacid administration.⁷¹ Another single-dose study showed that concurrent administration of tolterodine LA with omeprazole 20 mg once daily resulted in significantly increased peak plasma tolterodine concentrations compared with tolterodine LA given without prior omeprazole use. Conversely, no significant differences in peak plasma concentration of oxybutynin were evident when the XL formulation was administered with or without omeprazole. However, the AUCs of both agents were not significantly affected by omeprazole administration.⁷² The clinical implication of this interaction is unclear. Whether a similar interaction exists with histamine H₂-receptor antagonists is unknown.

One of two phase I pharmacokinetic studies comparing tolterodine pharmacokinetics in healthy elderly volunteers (age 64–80 years) with those in healthy volunteers younger than 40 years found no significant differences in pharmacokinetic parameters between the groups. However, in the second phase I study, the mean serum concentrations of tolterodine and DD01 were 20% and 50% greater in elderly volunteers than in young healthy volunteers, respectively. Despite possibly altered pharmacokinetics in elderly individuals, no differences in the incidences and severity of adverse events between these age groups have been noted in clinical trials, so no dosage adjustment is recommended on the basis of age alone.³³

Tolterodine elimination is diminished in patients with impaired hepatic function. Patients with hepatic cirrhosis who are extensive metabolizers exhibit a significantly higher mean AUC of DD01, higher serum tolterodine and DD01 concentrations, and longer terminal disposition half-life of tolterodine and DD01 than do healthy subjects who are extensive metabolizers. The tolterodine AUC is higher in cirrhotic patients who are poor metabolizers than

in healthy people who are poor metabolizers.³³ If use of tolterodine cannot be avoided in patients with hepatic impairment or in those receiving inhibitors of CYP 3A4 (and possibly inhibitors of CYP 2D6), the initial dose should be reduced by 50% to tolterodine IR 1 mg twice daily or tolterodine LA 2 mg once daily.³³ No formal tolterodine dosage recommendation is possible based on available information for individuals who concurrently have hepatic impairment and are taking a CYP 3A4 and/or 2D6 inhibitor. Intuitively, the initial dose should not exceed 1 mg twice daily (IR) or 2 mg once daily (LA).

Elimination of tolterodine has not been evaluated in patients with impaired renal function; therefore, the drug should be used more cautiously in such individuals (i.e., starting dose of IR product is 1 mg twice daily with gradual dose escalation, if needed, to the usual maximum of 2 mg twice daily or a starting dose of the LA formulation is 2 mg once daily with gradual dose escalation, if needed, to the usual maximum of 4 mg once daily).³³

Tolterodine is better tolerated than oxybutynin IR, with approximately 8% of patients discontinuing treatment prematurely (compared with approximately 27% of individuals taking oxybutynin IR).^{26,28,34,35,37,46,72} The most common adverse effects of tolterodine are dry mouth, dyspepsia, headache, constipation, and dry eyes.³³

Tolterodine, available only as a tablet formulation, can be taken with or without food. The LA product should not be crushed or chewed or taken less than 2 hours before or 4 hours after antacid administration. The maximum benefit from tolterodine may not be realized for up to 8 weeks after starting therapy or dose escalation.

Trospium Chloride Trospium chloride is a quaternary ammonium anticholinergic. It was approved in 2004 by the U.S. Food and Drug Administration (FDA) for the management of overactive bladder but has been available for many years in other countries. Trospium chloride has been comprehensively reviewed.⁷³ The data discussed here derive from that review, supplemented with detailed clinical trial data.

Preclinical studies have demonstrated that trospium chloride is an antimuscarinic agent in bladder and gastrointestinal tract tissues. It is poorly absorbed after oral administration (<10%), and food reduces bioavailability by 70% to 80%. It is principally cleared by the renal route (70%), with 80% of urinary excretion accounted for by the parent compound. The mean terminal disposition half-life in the presence of normal renal function is 10 to 12 hours. Advancing age and mild to moderate hepatic impairment do not affect trospium chloride pharmacokinetics to a clinically significant degree. In contrast, renal impairment does significantly reduce drug clearance. When creatinine clearance is less than 30 mL/min, AUC is increased by a mean of 4.5-fold, peak plasma concentration by a mean of two-fold, and terminal disposition half-life by a mean of two- to three-fold.

Eleven English-language publications on the efficacy/tolerability of trospium chloride for treatment of UUI are available. Except for the two trials (one published) described in the product information, clinical trials have emphasized cystometric, not clinical, endpoints.^{74–83}

The paucity of clinical outcome data makes difficult the evaluation of trospium chloride compared with other approved anticholinergics. Although trospium chloride is statistically superior to placebo, the absolute differences in results between trospium chloride and placebo call into question the clinical relevance of such differences. In the four trials with active controls, results with trospium chloride were statistically equivalent to those with oxybutynin IR and tolterodine IR.^{79–82} No comparative data with LA formulations of these two agents are available.

In a study involving a large proportion of elders (mean age 63 years), the decreases in the number of UUI episodes and daily micturitions and increase in volume voided per micturition were significantly lower in trospium chloride recipients compared with placebo recipients.⁸³

The expected anticholinergic adverse effects occur with trospium chloride as well. Of interest, the frequency of these events is increased in patients 75 years and older compared with younger subjects. This

occurrence is believed to be pharmacodynamic (i.e., increased sensitivity) and not pharmacokinetic in nature. No data at present support the hypothesis that trospium chloride is less neurotoxic than nonquaternary ammonium anticholinergics (based on the hypothesis of reduced transit across the blood–brain barrier of trospium chloride due to its positive electrical charge on the quaternary nitrogen). Available drug–drug interaction data are clearly inadequate.

The usual dosage regimen is 20 mg twice daily. The drug should be taken on an empty stomach. Dosage reduction (by 50% of the daily dose) is recommended when creatinine clearance is less than 30 mL/min. In patients 75 years and older, dose reduction to 20 mg once daily should be considered based upon tolerability. At this time, trospium chloride does not appear to be a significant advance over oxybutynin and tolterodine in managing UUI.

Solifenacin Succinate Solifenacin succinate was approved by the FDA in late 2004 for treatment of overactive bladder with urge incontinence, urgency, and urinary frequency. Solifenacin succinate has been comprehensively reviewed.⁸⁴ The data discussed here derive from that review, supplemented with detailed clinical trial data.

Preclinical studies demonstrated that solifenacin is an antagonist at M₁, M₂, and M₃ muscarinic cholinergic receptors. Based on comparative ex vivo and animal studies with solifenacin and oxybutynin, solifenacin is believed to be a “uroselective” agent. The drug is well absorbed (mean absolute bioavailability 88%), and food has no clinically relevant effect on absorption.^{85,86} It is principally eliminated via metabolism and renal excretion of metabolites, with renal excretion of parent compound less than 10% of the dose. With a mean terminal disposition half-life of 50 to 60 hours, the drug can be dosed once daily.⁸⁷ Results of two placebo-controlled and two placebo- and active (tolterodine)-controlled clinical trials in UUI are available. Like oxybutynin and tolterodine, solifenacin significantly reduced the number of incontinence episodes, urge episodes, and micturitions per day and increased the volume voided per micturition in a dose-dependent fashion compared with placebo. In the active-controlled trials, solifenacin was statistically superior to tolterodine. However, neither of these two studies directly compared solifenacin and tolterodine.^{88,89} Surprisingly, the effect of tolterodine in these trials was no better than that of placebo. A direct comparative trial of tolterodine ER demonstrated that the effect of solifenacin was significantly greater than that of tolterodine in terms of reducing the number of UUI episodes and pad usage and in patients’ perception of their bladder condition.⁹⁰ An analysis of pooled data from two phase III studies showed that solifenacin recipients had significant improvement in five of 10 quality of life domains from baseline compared with placebo recipients.⁹¹

No comparative efficacy/tolerability data with oxybutynin are available. The effect sizes (solifenacin effect minus placebo effect) in these studies were similar to those noted with oxybutynin.

A retrospective analysis of pooled data from elders (mean age 72 years) in four phase III studies showed that compared with baseline, solifenacin recipients achieved a significantly greater decrease in number of UUI episodes, number of urgency episodes, and number of micturitions per day and a greater increase in the proportion of patients who became totally dry compared with placebo recipients.⁹²

The recommended dose of solifenacin is 5 mg once daily. If the drug is well tolerated but the effectiveness is not optimal, the dose can be increased to 10 mg once daily. Little additional benefit is generally achieved with doses exceeding 5 mg daily. Solifenacin can be administered with or without food. For patients with creatinine clearance rates less than 30 mL/min or with moderate hepatic impairment (Child-Pugh class B), the daily dosage should not exceed 5 mg. If the patient has severe hepatic impairment (Child-Pugh class C), the drug should not be used. If the patient is receiving concurrent therapy with one or more potent CYP 3A4 inhibitors, the daily dose should not exceed 5 mg. In contrast to findings of preclinical studies, solifenacin

behaves like a nonselective anticholinergic in humans, causing dry mouth, constipation, blurred vision, and other anticholinergic effects to a similar extent as tolterodine in clinical trials and oxybutynin in pharmacokinetic trials. At this time, solifenacin does not appear to be a significant advance over existing anticholinergics in managing UI.

Darifenacin The data on darifenacin discussed here derive from a review,⁹³ supplemented with detailed clinical trial data.

Preclinical studies have demonstrated that darifenacin is an antagonist at M₁, M₃, and M₅ muscarinic cholinergic receptors. As with solifenacin, darifenacin is believed to be “uroselective” on the basis of preclinical data. The mean absolute bioavailabilities of the 7.5-, 15-, and 30-mg extended-release (ER) formulations are 15%, 19%, and 25%, respectively. Bioavailability is affected by formulation, CYP 2D6 genotype, dose, and race. Bioavailability is enhanced using an ER formulation (70%–110% higher than IR), in heterozygous CYP 2D6 extensive metabolizers and poor metabolizers (40%–90% higher than homozygous extensive metabolizers), and white race (56% higher than Japanese). Darifenacin is extensively metabolized, with cumulative urinary excretion of the parent compound less than 10%. The 2D6 and 3A4 isoenzymes of CYP are responsible for darifenacin metabolism. With a mean terminal disposition half-life of 3 to 5 hours (depending on CYP 2D6 metabolizer status), an ER formulation is needed to allow once-daily dosing. Results of four placebo-controlled clinical trials (one published) on UI are available. Although a comparative study of darifenacin with oxybutynin IR showed that both agents significantly decreased the number of UI episodes, the number of micturitions, urinary urgency and their severity compared with placebo, the active treatments were not directly compared.⁹⁴ A comparison with tolterodine IR and placebo showed that darifenacin 15 mg and 30 mg significantly decreased the number of UI episodes from baseline after 2 weeks compared with placebo, but only the 30-mg daily dose continued to be superior to placebo after 12 weeks. Compared to placebo, tolterodine IR did not significantly decrease the number of UI episodes from baseline at either time point. Darifenacin 30 mg once daily achieved a significantly greater decrease in the number of UI episodes compared with tolterodine IR at both time points. At 12 weeks, both darifenacin and tolterodine IR produced significant improvements from baseline in the number of micturitions per day and volume voided per micturition compared with placebo.⁹⁵

A large pooled subanalysis of patients 65 years and older from three phase III studies demonstrated that darifenacin produced a significant decrease in the number of UI episodes, urgency episodes, and micturition frequency and an increase in volume voided per micturition compared with placebo.⁹⁶ No comparative efficacy/tolerability data with anticholinergics other than tolterodine IR and oxybutynin IR are available.

The recommended daily dose of darifenacin is 7.5 to 15 mg once daily of the ER oral formulation. As with solifenacin, darifenacin behaves like a nonselective anticholinergic in humans, causing dry mouth, constipation, and other well-known anticholinergic adverse effects. Dry mouth was significantly more common with oxybutynin IR than either darifenacin or placebo.⁹⁷ In one study, the rates of treatment discontinuation and adverse events in elderly recipients of darifenacin were similar to those seen in other studies of darifenacin conducted in younger adults.⁹⁶ At this time, darifenacin does not appear to be a significant advance over existing anticholinergics in managing UI.

Other Anticholinergics and Antispasmodics Other drugs for treatment of UI are less effective, are no safer, or have not been adequately studied.^{24,98} Thus, their use is not recommended. Tricyclic antidepressants are generally no more effective than oxybutynin IR and exhibit a high incidence of bothersome and potentially serious adverse effects (e.g., orthostatic hypotension, cardiac conduction abnormalities, dizziness, confusion, and potentially life threatening in overdose). Therefore, their use should be limited to individuals who have one or more additional medical indications for these agents (e.g., depression or neuropathic pain); patients with mixed UI (because of their effect of decreasing bladder contractility and increasing outlet resistance); and possibly those with nocturnal incontinence associated with altered sleep patterns.^{24,98–101} Because of the lower incidence of adverse effects, desipramine and nortriptyline may be preferred over imipramine and doxepin. However, due to their lower anticholinergic activity, they may not be as effective.

Propantheline, a quaternary ammonium anticholinergic and potential treatment, produces a high incidence of adverse effects and is only modestly effective for UI.^{102–106} When used, propantheline appears to be best tolerated at a dose no more than 15 mg three times daily plus 60 mg at bedtime.¹⁰²

Flavoxate is a tertiary amine that relaxes smooth muscle *in vitro*. Four controlled trials revealed that flavoxate is no more effective than placebo for treatment of UI; therefore, flavoxate is not recommended.²⁴

Dicyclomine hydrochloride, an anticholinergic agent that relaxes smooth muscle, produced minimal benefit as well as bothersome adverse effects in two small studies.^{107,108}

Hyoscyamine, an anticholinergic and antispasmodic drug related to atropine, has been suggested for treatment of UI, but data recommending its use are insufficient.²⁴

In a systematic review and pooled analysis of 32 controlled trials of anticholinergic therapy for overactive bladder (January 2002 database), the agents discussed were found to be modestly effective clinically and urodynamically. Although the clinical relevance of the small improvements in clinical and urodynamic parameters were questioned, the effects of these agents were still considered positive.¹⁰⁹

It is hoped that an improved understanding of the pathophysiology of UI will lead to the development of safer and more effective pharmacotherapy.

CLINICAL CONTROVERSY

Which anticholinergic agent should be used as first-line pharmacotherapy of UI (oxybutynin, tolterodine, trospium chloride, solifenacin, or darifenacin) and which formulation of oxybutynin (oral IR, oral XL, or topical) or tolterodine (oral IR, oral LA) is unclear. Financial considerations currently favor generic oxybutynin IR, and this is the initial choice of many clinicians.

Botulinum Toxin A Enthusiasm is considerable for the application of botulinum toxin A for treatment of both neurogenic and nonneurogenic detrusor overactivity. Direct injection of botulinum toxin A into the muscle of interest results in paralysis. Both smooth and striated muscle are affected. In the United States, botulinum toxin A currently is approved for use for the treatment of a variety of conditions associated with muscle spasticity. It also is widely used to reduce skin wrinkles (cosmetic use).

In the lower urinary tract, botulinum toxin A is useful for treating neurogenic spasm of the external sphincter (due to striated sphincter dyssynergia in the patient with spinal injury) and detrusor overactivity. The usual dose for detrusor overactivity is 100 to 300 units. It is delivered directly into bladder muscle via a long needle through a cystoscope, usually in 10-unit increments with or without anesthesia. The toxin is distributed symmetrically using a series of

CLINICAL CONTROVERSY

Should anticholinergic pharmacotherapy be used to treat UI in patients with mild cognitive impairment or mild or moderate dementia?

submucosal injections throughout the bladder, usually avoiding the trigone and openings for the ureters. Preliminary studies suggest good efficacy and tolerability.¹¹⁰ Although the effects appear to be dose dependent; the optimal dosing regimen has not yet been defined. Delivery of too much toxin may lead to detrusor underactivity and urinary retention. Durability of effect ranges from 3 to 9 months, at which time repeat administration is necessary to maintain effect.¹¹¹ Extensive studies of botulinum toxin A are ongoing in the United States and Europe.

Catheterization Combined with Medications Patients with UII and an elevated postvoid residual urine volume due to retention may require intermittent self-catheterization along with frequent voiding between catheterizations.

If intermittent catheterization is not possible, surgical placement of a suprapubic catheter may be necessary. Use of a chronic indwelling catheter should be avoided because of the increased occurrence of urinary tract infections and nephrolithiasis.

Regardless of catheterization status, patients may experience symptom relief with oxybutynin (IR, XL, or TDS formulations), tolterodine (IR or LA formulations), trospium chloride, solifenacin, or darifenacin, as these agents relax the detrusor muscle and enhance bladder storage. Patients with UII and symptoms of retention also may benefit from an α -adrenergic receptor antagonist that relaxes the internal bladder sphincter (e.g., prazosin, terazosin, doxazosin, tamsulosin, and alfuzosin). Although theoretically of benefit, bethanecol, a cholinergic agonist, has not been demonstrated effective in improving bladder emptying in well-done trials. In addition, it causes numerous bothersome (e.g., muscle and abdominal cramping and diarrhea) and potentially life-threatening adverse effects and should not be used in patients with asthma or heart disease.²⁴

Urethral Underactivity

5 Urethral underactivity, or SUI, may be aggravated by agents with α -adrenergic receptor blocking activity, including prazosin, terazosin, doxazosin, tamsulosin, alfuzosin, methyl dopa, clonidine, guanfacine, guanadrel, and labetalol. The goal of therapy is to improve the urethral closure mechanism by stimulating α -adrenergic receptors in the smooth muscle of the bladder neck and proximal urethra, enhancing the supportive structures underlying the urethral epithelium, or enhancing the positive effects of serotonin and norepinephrine in the afferent and efferent pathways of the micturition reflex. There is no role for medications in the management of SUI after radical prostatectomy.¹¹²

Estrogens Local and systemic estrogens have been considered the mainstays of pharmacologic management of SUI since the 1940s. Estrogens are believed to work via several mechanisms, including enhancement of the proliferation of urethral epithelium, local circulation, and numbers and/or sensitivity of urogenital α -adrenergic receptors.¹¹³ However, a trial has questioned whether estrogens exert a stimulatory effect on vaginal collagen production, at least over the short term.¹¹⁴

Open trials support the use of a variety of estrogens in the management of SUI: transdermal estradiol, conjugated estrogen vaginal cream, Estrin, oral-conjugated estrogen, oral quinestradiol, oral estriol, intramuscular estrogens, estriol vaginal suppositories, and oral estradiol.¹¹⁵ Variable effects of estrogen treatment on urodynamic parameters, such as maximum urethral closure pressure, functional urethral length, and pressure transmission ratio, have been noted in these studies.

Results of four placebo-controlled comparative trials have not been as favorable, finding no significant clinical or urodynamic effects for oral estrogen compared with placebo.^{116–119} In fact, observational studies have documented that estrogen use is associ-

ated with an increased risk of UI compared with that in nonusers.^{120–123} Systemic estrogen therapy is associated with numerous adverse effects, including mastodynia, uterine bleeding, nausea, thromboembolism, cardiac and cerebrovascular ischemic events, and enhancement of the risk of certain cancers.⁹⁸ If estrogens are to be used for treatment of SUI, only topical products should be administered. Estrogen use is best justified when SUI exists with urethritis or vaginitis due to estrogen deficiency.

α -Adrenergic Receptor Agonists Numerous open trials have supported the use of a variety of α -adrenergic receptor agonists in SUI, including ephedrine, norepinephrine, phenylpropanolamine, and midodrine.¹¹⁵ Phenylpropanolamine was withdrawn from the U.S. market in late 2000 because of a risk for stroke in women using the agent.¹²⁴ Some patients may have leftover supplies of this agent or may obtain it from international sources. If so, individuals with the contraindications listed below (especially coronary artery disease and/or cardiac arrhythmias) should be warned against self-treatment with this or other α -adrenergic receptor agonists.

Placebo-controlled comparative trials with phenylpropanolamine, norepinephrine, and norephedrine support the modest efficacy of these agents for treatment of mild or moderate SUI.^{115,125} These agents have been found to variably affect maximum urethral closure pressure and functional urethral length.

Adverse effects include hypertension, headache, dry mouth, nausea, insomnia, and restlessness.⁹⁸ Contraindications to the use of these agents include the presence of hypertension, tachyarrhythmias, coronary artery disease, myocardial infarction, cor pulmonale, hyperthyroidism, renal failure, and narrow-angle glaucoma.

Usual doses are ephedrine 25 to 50 mg four times daily (25 mg twice daily in elders), pseudoephedrine 60 mg three times daily (15–30 mg three times daily in elders), and phenylephrine 10 mg four times daily (see Table 88–4).

Several studies have evaluated whether the clinical and urodynamic effects of a combination of estrogen and an α -adrenergic receptor agonist exceed those of the individual therapies in SUI.^{126–130} In general, combination therapy has resulted in somewhat superior clinical and urodynamic responses compared with monotherapy, including severity of complaints, amount of urine lost per episode, number of daily voluntary micturitions, number of leakage episodes per day, patient preference, pad use, maximum urethral closure pressure, functional urethral length, and pressure transmission ratio.

Duloxetine Duloxetine, a dual inhibitor of serotonin and norepinephrine reuptake, was approved in 2004 for treatment of depression and painful diabetic neuropathy.¹³¹ Its use for treatment of SUI (for which the drug is approved by European authorities but not by the U.S. FDA) is based on studies in rats and cats demonstrating that central serotonergic and noradrenergic regions are involved in ascending and descending control of urethral smooth muscle and the external urethral sphincter. These mechanisms facilitate the bladder-to-sympathetic reflex pathway, increasing urethral and external urethral sphincter muscle tone during the storage phase. Data documenting this control mechanism in humans are limited. The mean terminal disposition half-life, clearance, and volume of distribution of duloxetine in healthy volunteers are 10 to 12 hours, 114 to 119 L/h, and 1787 to 1,943 L, respectively. The drug is extensively metabolized to inactive metabolites (via oxidation at the 4, 5, and/or 6 positions in the naphthyl ring, followed by further oxidation or via methylation) with elimination in the urine as conjugated metabolites. CYP 2D6 and 1A2 are involved in the ring oxidations. This involvement was demonstrated in studies of the interaction of duloxetine with the CYP 2D6 substrate desipramine (wherein desipramine's peak plasma concentration, AUC, and terminal disposition half-life were increased 1.7-, 2.9-, and 1.9-fold, respectively, and clearance fell by 66% during concurrent therapy) and the CYP

2D6 inhibitor paroxetine (wherein duloxetine's peak plasma concentration, AUC, and terminal disposition half-life increased 1.6-, 1.6-, and 1.3-fold, respectively, and clearance fell 37% during concurrent therapy). Fluvoxamine, a CYP 1A2 inhibitor, increased duloxetine's peak plasma concentration, AUC, and terminal disposition half-life by over 5-fold, 2.5-fold, and 3-fold, respectively. Thus, clinicians must be careful when prescribing duloxetine concurrently with CYP 2D6 and 1A2 substrates or inhibitors. The effect of advancing age on duloxetine pharmacokinetics is not clinically significant. Moderate hepatic dysfunction (Child-Pugh class B) significantly affects duloxetine disposition, increasing mean AUC and terminal disposition half-life by 5-fold and 3-fold, respectively, and reducing clearance 85% compared with controls. Mild or moderate renal impairment (creatinine clearance 30–80 mL/min) does not affect drug disposition. In severe renal impairment (hemodialysis patients), mean peak plasma concentration and AUC both are increased 100%, whereas metabolite concentrations are increased up to 900%.

Results of six large clinical trials with duloxetine in SUI have been published. All were double-blinded, randomized, placebo-controlled, and parallel group in design. Compared with placebo, duloxetine therapy produced significant reductions in incontinence episode frequency and number of micturitions per day, improvement in Incontinence Quality of Life questionnaire scores and patient self-assessment, and increase in mean micturition interval. Results were independent of baseline UI severity (severity based on incontinent episode frequency). Significant intergroup differences were seen by week 4. However, cure rates were generally not improved by duloxetine. When evaluating the absolute differences between treatments, the actual benefit of duloxetine was generally quite modest.

A randomized, placebo-controlled clinical trial evaluated the effects of duloxetine (80 mg daily), pelvic floor muscle training (PFMT), and the combination of both modalities on incontinent episode frequency, incontinence-related quality of life, pad use, and patient global impression of change. Sham PFMT was used in the placebo group. Results indicated that duloxetine plus PFMT probably were additive in effect and that combination therapy afforded greater improvement than either monotherapy.¹³²

Although duloxetine is an encouraging development in the pharmacologic management of SUI, its adverse event profile may make adherence problematic. In the SUI trials, treatment/emergent adverse events occurred in 68% to 93% of duloxetine and 50% to 72% of placebo recipients. Premature study withdrawal rates (due to adverse events) were 12% to 33% for duloxetine and 2% to 8% for placebo. The frequencies of individual events in duloxetine recipients were nausea 9% to 46%, headache 7% to 27%, insomnia 13% to 14%, constipation 4% to 27%, dry mouth 4% to 22%, dizziness 8% to 16%, fatigue 10% to 18%, somnolence 8% to 13%, vomiting 6% to 13%, and diarrhea 4% to 6%. Of interest, the drug may be associated with small increases in blood pressure (like venlafaxine, another dual reuptake inhibitor) and withdrawal symptoms (sleep disturbances).

Despite these negatives, duloxetine is the first drug approved by a regulatory agency for treating SUI. Based on studies conducted to date, a dosage regimen of 40 to 80 mg/day (in one or two doses) appears reasonable. Initiating therapy with 40 mg daily for 2 weeks and then increasing to 80 mg daily (rather than initiating therapy with 80 mg daily) reduces the risks of nausea, dizziness, and premature drug discontinuation.¹³³ If the drug is to be stopped, it should be withdrawn slowly, reducing the dose by 50% for 2 weeks before discontinuation.¹³³

Overflow Incontinence

Overflow incontinence secondary to benign or malignant prostatic hyperplasia may be amenable to pharmacotherapy. For manage-

ment of malignant prostatic disease, see Chap. 134. The pharmacotherapy of BPH is discussed in Chap. 87.

CURRENT CONTROVERSY

The optimal approach to pharmacotherapy of SUI is unclear. Although not supported by evidence-based medicine, many clinicians initiate a trial of topical estrogen, followed by addition of an α -adrenergic receptor agonist in estrogen nonresponders unless contraindicated. Based on available data, duloxetine is the drug of choice for treatment of SUI, provided it is tolerated.

SURGICAL TREATMENT

Only rarely does surgery play a role in the initial management of UI.¹³⁴ In the absence of secondary complications from UI (e.g., skin breakdown or infection), the decision to surgically treat symptomatic UI should be based on the premise that the degree of bother or lifestyle compromise to the patient is great enough to warrant an elective operation, and that nonoperative therapy either is undesired or has been ineffective.

Successful application of surgery depends most on defining the underlying abnormalities responsible for UI (bladder vs urethra, underactivity vs overactivity). Once the underlying factors are determined, other considerations come into play: renal function, sexual function, severity of leakage, history of abdominal or pelvic surgery, presence of concurrent abdominal or pelvic pathology requiring surgical correction, and finally the patient's suitability for, and willingness to accept the risks of, surgery.

When patients with uncomplicated SUI become dissatisfied with the initial management approaches of pelvic floor exercises, medications, and/or behavioral modification,¹³⁴ surgical treatment assumes the primary role.

Surgical correction of female SUI (urethral underactivity) is directed toward either (1) repositioning the urethra and/or creating a backboard of support, or otherwise stabilizing the urethra and bladder neck in a well-supported retropubic (intraabdominal) position that is receptive to changes in intraabdominal pressure; or (2) creating coaptation and/or compression or otherwise augmenting the urethral resistance provided by the intrinsic sphincteric unit, with (i.e., sling) or without (i.e., periurethral collagen and other injectables) urethral and bladder neck support.

In men, SUI can be treated surgically with collagen or the artificial urinary sphincter. The vast majority of collagen injections in men are performed in a retrograde fashion under direct vision through a cystoscope. However, a transabdominal, transvesical, suprapubic antegrade approach also has been used.¹³⁵ The artificial urinary sphincter is generally considered to be the gold standard for treatment of male SUI. Placement of this manually operated silicone device has been associated with very high long-term success and satisfaction rates.¹³⁶

Most patients with UI are managed nonsurgically with a combination of behavioral modification, pelvic floor exercises, and pharmacologic therapy. Only rarely is surgery applied to the problem of UI. Surgery of UI may involve bladder denervation, implantation of a sacral nerve stimulator (neuromodulation), or augmentation (enlargement) cystoplasty.

Few surgical treatments for bladder underactivity are effective. After an appropriate evaluation for reversible causes is performed, the most effective management of this condition is intermittent self-catheterization performed by the patient or a caregiver three or four times per day. Sacral nerve stimulation (neuromodulation) has shown some efficacy in this patient population, but success rates for detrusor underactivity (nonobstructive urinary retention) are inferior to those seen with urinary frequency and urgency. Proper

patient selection for this therapy remains poorly defined. Alternative methods of management that are less satisfactory or more invasive include indwelling urethral or suprapubic catheters and urinary diversion.

Urethral overactivity is most commonly caused by anatomic obstruction. Anatomic obstruction in men is most often caused by benign prostatic enlargement (see Chap. 87).

Rarely, bladder outlet obstruction is caused by a functional obstruction at the level of the bladder neck. Hypertrophy of the smooth muscle fibers at the level of the bladder neck in men and women may result in obstruction to the flow of urine. In patients who do not respond to pharmacologic therapy with α -adrenergic receptor antagonists, endoscopic incision using the cystoscope is highly effective in treating this very uncommon condition.

EVALUATION OF THERAPEUTIC OUTCOMES

6 During long-term management of UI, patient-specific clinical signs and symptoms of most distress (“bother”) to the individual must be monitored. A daily diary may be useful in this regard. Some of the short-form instruments used in incontinence research for measuring symptom impact and condition-specific quality of life can be used in clinical monitoring. In addition, quantitating the use of ancillary supplies, such as pads, may be useful. The goal of therapy is to minimize the signs and symptoms of most bother to the patient, as well as the use of pads and other ancillary supplies or devices. Total elimination of UI signs and symptoms may not be possible, and patients and practitioners need to mutually establish realistic goals of therapy. Because the therapies for UI frequently have nuisance adverse effects (e.g., anticholinergic effects such as xerostomia, xerophthalmia, and constipation) that may compromise regimen adherence, the presence and severity of adverse effects must be carefully elicited at each visit to the healthcare practitioner. Emergence of adverse effects may necessitate drug dosage adjustment or use of alternative strategies (e.g., chewing sugarless gum, sucking on hard sugarless candy, or use of saliva substitutes in xerostomia) or even drug discontinuation.

ABBREVIATIONS

AUC: area under the plasma or serum concentration-versus-time curve

BPH: benign prostatic hyperplasia

CYP: cytochrome P450

DD01: 5-hydroxymethyl metabolite of tolterodine

DEO: *N*-desethoxybutynin

IR: immediate-release

LA: long-acting

SUI: stress urinary incontinence

TDS: transdermal system

UI: urinary incontinence

UUI: urge urinary incontinence

XL: extended-release

IMMUNOLOGIC DISORDERS

CHAPTER

89

Function and Evaluation of the Immune System

PHILIP D. HALL AND NICOLE A. WEIMERT

KEY CONCEPTS

- 1 After activation, dendritic cells express higher concentrations of major histocompatibility complex (MHC) class II molecules B7–1, B7–2, CD40, ICAM-1, and LFA-3 and produce more interleukin-12 than other antigen-presenting cells. This may explain why in vitro dendritic cells are the most efficient antigen-presenting cell.
- 2 A T lymphocyte expresses hundreds of T-cell receptors. All T-cell receptors expressed on the surface of an individual T lymphocyte have the same antigen specificity.
- 3 A B lymphocyte can simultaneously express membrane immunoglobulin as immunoglobulin (Ig)M (monomeric) or IgD with the same variable region (i.e., antigen binding site). The B lymphocyte then can secrete different isotypes (e.g., IgM [pentamer], IgA, IgG, IgE) with the same variable region as the membrane immunoglobulin.
- 4 A serum protein electrophoresis determines the total concentration of circulating immunoglobulins (i.e., IgG, IgA, IgM, IgD, and IgE). To determine the concentration of the individual isotypes, isotype quantification is necessary. Most clinical laboratories quantitate only IgG, IgM, and IgA because they are the most prevalent isotypes in the bloodstream. In patients with allergic disorders, quantification of IgE may be useful. Depending on the clinical laboratory, results may come back in international units per milliliter or milligrams per deciliter for IgE.
- 5 An understanding of the mechanism by which immunomodulators act and of the immune system allows the clinician to anticipate potential adverse effects. The benefit of manipulating immune responses must be balanced with the potential consequences and long-term sequelae of such manipulation.

The primary function of the immune system is to protect the body against invading pathogens. The immune system evolves and adapts

based on its exposure environment. To undergo these processes, the immune system exhibits specificity, memory, mobility, replicability, and redundancy. *Specificity* indicates the immune system can distinguish between non-cross-reacting antigens. *Memory* ensures a quicker and more vigorous response to a subsequent but similar pathogen. *Mobility* of the elements of the immune system enables local reactions to provide systemic protection. *Replication* of the cellular components of the immune system amplifies the immune response. *Redundancy* refers to the immune system's ability to produce components with the same biologic effect but produced from multiple cell lines, such as inflammatory cytokines. These characteristics make the immune system a formidable defense against offending pathogens. They also make the immune system difficult to control with pharmacotherapy.

The immune system includes two functional divisions: (a) the *innate* or nonspecific, which encodes evolutionary genes aimed at providing rapid responses against nonmammalian targets; and (b) the *adaptive* or specific, which utilizes cells that can genetically rearrange their DNA to create specific structures that bind individual antigens or proteins (Table 89–1).¹ Despite this simple separation, these divisions heavily interact.² Awareness of each component of the immune system and the consequences of disrupting homeostasis must be understood in order to appropriately dose, administer, and monitor the effect of medications given to manipulate immune responses.

METHODS TO DISTINGUISH SELF FROM NONSELF

The immune system is designed to attack and destroy a broad spectrum of foreign antigens/pathogens. However, the immune system must be able to distinguish self from nonself, termed *self-tolerance*, in order to avoid unleashing its components onto self tissues.³ The body uses many tactics to avoid attacking itself; failure of self-tolerance may lead to the development of an autoimmune disease.

INNATE IMMUNE SYSTEM

Physical Defense

Physical and chemical defenses are the most rudimentary form of innate immunity and the first line of defense against invading pathogens. The skin, the largest organ of the body, has the primary

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

TABLE 89-1 Functional Divisions of the Immune System		
	Innate	Adaptive

role of providing a physical defense. Alterations in the skin, such as burns and abrasions, allow an easy portal of entry for pathogens. The gastrointestinal tract also provides physical defense. The low pH of the stomach (pH 1–2) is inhospitable to most organisms. The rapid turnover of intestinal cells limits systemic infection as cells, including infected cells, are sloughed frequently. Drugs, such as cell-cycle specific antineoplastics that disrupt the sloughing process, leave the patient at increased risk for infections. Likewise, the respiratory tract has its forms of physical defense. The mucus coating the epithelial cells serves in part to prevent microorganisms from adhering to cell surfaces, and the cilia lining the epithelium of the lungs help to repel inhaled organisms. The combination of cilia, mucus, and reactive coughing provides a natural barrier to invasion via the respiratory tract. Other examples of mechanical or nonspecific defenses include normal urine flow, lysozymes in tears and saliva, and the normal flora in the throat, lower gastrointestinal tract, and genitourinary tract. Disruption of the normal physical defense system through mechanical ventilation can, for example, place the host at substantial risk for penetration by a pathogenic organism.⁴

Innate Immune Response

If an infectious pathogen invades and is able to infiltrate through a host’s physical defense system, innate immunity is used to halt progression of the infection. Innate immunity is present from birth and utilizes a preexisting but limited repertoire of receptors to recognize and destroy pathogens. Innate immune cells include subgroups of leukocytes, specifically, monocytes/macrophages, neutrophils, basophils, mast cells, and eosinophils. When stimulated by a foreign pathogen, mast cells and basophils secrete inflammatory mediators. Monocytes/macrophages, neutrophils, mast cells, and eosinophils act as phagocytes, which allow them to recognize, internalize, and destroy invading pathogens. This process may occur in two ways: opsonin-dependent or opsonin-independent phagocytosis. For opsonin-dependent phagocytosis, antibody (e.g., immunoglobulin [Ig]G), complement (e.g., C3b), or lectin (e.g., C-reactive protein) coat, or opsonize, the infectious pathogens. Once the pathogen is opsonized, the antibody, complement, or lectin binds to the receptors on the phagocyte (Fig. 89–1) and activates the phagocytic process. For opsonin-independent phagocytosis, innate leukocytes utilize pattern recognition receptors. Pattern recognition receptors recognize highly conserved structures present on a large number of microorganisms. These highly conserved structures are essential for the microorganism’s survival or pathogenicity. The pattern recognition receptors include the macrophage mannose receptor, macrophage scavenger receptor, and members of the toll-like receptor family. Pattern recognition receptors on the phagocytes directly recognize ligands (Table 89–2) on the surfaces of infectious pathogens, leading to immediate phagocytosis of the pathogen (Fig. 89–1). Toll-like receptors are a family of pattern recognition recep-

FIGURE 89-1. Phagocytosis of bacteria by macrophages, dendritic cells, and neutrophils. Macrophages, dendritic cells, and neutrophils recognize bacteria opsonized (coated) with antibody or complement (C3b). On the surface of macrophages, dendritic cells, and neutrophils reside receptors for antibody (Fc receptors) and complement (CR1, CR3, CR4). In addition, these cells may recognize the bacteria by pattern recognition receptors on the surface of macrophages, dendritic cells, and neutrophils. Pattern recognition receptors include toll-like receptors, scavenger receptors, and mannose receptors.

tors on the cell surface of innate leukocytes. To date, 11 toll-like receptors have been identified in humans. They recognize a broad spectrum of antigens ranging from lipopolysaccharide and flagellin on bacteria to zymosan on yeast to double-stranded RNA from RNA viruses (Table 89–2). Binding of the ligand to the toll-like receptors allows the phagocyte to recognize and engulf the pathogen. This binding of toll-like receptors to its ligand also results in secretion of chemokines, inflammatory cytokines, and antimicrobial peptides as well as increased expression of costimulatory proteins (e.g., B7) and the major histocompatibility complex (MHC) proteins by the phagocyte. This leads to the recruitment and activation of antigen-specific lymphocytes.^{2,5,6} Other pattern recognition receptors that mediate phagocytosis include MARCO and DEC205.

Cells of the Innate Immune System

Neutrophils, eosinophils, and basophils are considered granulocytes because of the presence of numerous cytoplasm granules in these cells that contain inflammatory mediators or digestive enzymes. Neutrophils compose the majority of leukocytes in the bloodstream. They are polymorphonuclear cells, which serve as the primary human defense against invasive bacteria. Neutrophils migrate from the bloodstream into infected or inflamed tissue in response to chemotactic factors such as interleukin (IL)-8 and C3a and C5a, breakdown products of complement. In this migration, a process termed *chemotaxis*, neutrophils reach the site of inflammation and then recognize, adhere to, and phagocytose pathogens. Via the complement and antibody receptors located on its surface, neutro-

phils can recognize and engulf pathogens opsonized with complement or IgG (antibody). During phagocytosis, the engulfed pathogen is internalized within the phagocyte into a cytoplasmic lysosome. The neutrophil then releases its granular contents into lysosomes and generates the release of oxidative metabolites that destroy the engulfed pathogens.⁷ Neutrophils also can recognize pathogens via toll-like receptors.

Eosinophils are also granulocytic cells involved in innate immunity. They exhibit motility and migrate from the blood into the tissues. Eosinophils play a less significant role in combating bacterial infections, but they play a major role against nonphagocytatable multicellular pathogens, such as parasites. After activation via high-affinity receptor for IgE (i.e., Fc), eosinophils exocytose their granules, which release basic proteins or reactive oxygen species into the microenvironment, causing lysis of the parasite. In addition to Fc receptors, eosinophils express lower levels of complement receptor 3 and Fcγ for IgG than neutrophils. The high affinity of eosinophils for IgE contribute to their role in the pathogenesis of allergic disorders (i.e., allergic asthma).⁸

Macrophages and monocytes are mononuclear cells capable of phagocytosis. Tissue macrophages arise from the migration of monocytes from the bloodstream into the tissues. Macrophages differ from monocytes by possessing an increased number of Fc and complement receptors. Macrophages are found within specific tissues, such as the liver, spleen, gastrointestinal tract, lymph nodes, brain, bone, and connective tissue. These specific types of macrophages often are called *histiocytes* or are referred to by a specialized name depending on where they are found (e.g., Kupffer cells in the liver, osteoclasts in the bone, microglial cells in the central nervous system). The term *reticuloendothelial system* was commonly used to refer to macrophages found in reticular connective tissue, but the preferred nomenclature now is the *mononuclear phagocyte system*.⁹

Despite the first description in 1868 of Langerhans cells, a type of dendritic cell found in the skin, our current understanding of the biologic function of dendritic cells did not develop until the 1990s. Before pathogen recognition, most dendritic cells are in an immature/

resting state with limited ability to activate T lymphocytes, but they express numerous receptors (e.g., Fc receptors of IgG and IgE, macrophage mannose receptor, toll-like receptors) enabling rapid antigen recognition. Following antigen recognition and particle engulfment, dendritic cells become activated and dramatically increase their expression of the MHC class II, B7, CD40, and adhesion molecules. Dendritic cells then begin to migrate through the tissues toward lymphoid organs (e.g., spleen, lymph nodes) to present antigen to T lymphocytes, which activates the adaptive immune system.¹⁰

① In addition to phagocytosing pathogens, macrophages and dendritic cells act as antigen-presenting cells (APCs) to stimulate the adaptive (specific) system. Macrophages and dendritic cells internalize the organism, digest it into small peptide fragments, and then combine these antigenic fragments together with MHC proteins. Once the APC has formed the antigen/MHC complex, the APC places the complex on its surface. This surface complex then can be recognized by the T-cell receptor (TCR) on the surface of a T lymphocyte. Recognition of the antigen/MHC complex by the TCR is the first step in activation of the T lymphocyte (Fig. 89–2). Other cells (B lymphocytes and mast cells) also can act as APCs (Fig. 89–3).^{9–11}

Mast cells and basophils act primarily by releasing inflammatory mediators. Mast cells are tissue cells predominately associated with

FIGURE 89-2. Induction of T-helper type 1 (TH₁) response. 1. The antigen-presenting cell, in this case a dendritic cell, engulfs the pathogen by any of numerous cell surface receptors (see Fig. 89–1). After phagocytosis of the bacteria by the dendritic cell (A), the pathogen is digested into small peptides and become associated with major histocompatibility (MHC) class II within the endosome (B). Finally, the MHC class II plus peptide is expressed on the surface of the dendritic cell (C). The activated dendritic cell also secretes interleukin (IL)-12. 2. Naive CD4⁺ T-lymphocyte activation requires the T-cell receptor (TCR) to recognize the antigenic peptide in association with MHC class II as well as the B7-1 (CD80) binding to CD28. The binding of CD2-CD58 and LFA-1 (CD11a/CD18) allows adherence between the T lymphocyte and dendritic cell. Upon activation, the TH₁ CD4⁺ T lymphocyte secretes IL-2 and interferon (IFN)-γ and increases the production and expression of the IL-2 receptor. (ICAM, intercellular adhesion molecule.)

FIGURE 89-3. Induction of T-helper type 2 (TH₂) response. 1A, A B lymphocyte recognizes invading bacteria via its surface immunoglobulin (slg). 1B, The bound bacteria are phagocytosed into an endosome, where the bacteria are broken down into small peptide fragments. 1C, The small peptide fragments are placed within major histocompatibility complex (MHC) class II molecules and transported to the surface of the B lymphocyte for antigen presentation to a CD4⁺ T lymphocyte. 2, CD4⁺ T-lymphocyte recognition requires antigen recognition within the MHC class II peptide groove by the T-cell receptor (TCR) and a secondary signal from B7-2 from the antigen-presenting cell, in this case a B lymphocyte binding to CD28 on the T lymphocyte. When both signals are delivered to the CD4⁺ T lymphocyte becomes activated. In the TH₂ environment (see text), the naive CD4⁺ T lymphocyte develops into a TH₂ subtype and secretes interleukin (IL)-4, IL-5, IL-6, IL-10, and IL-13, which promote a TH₂ response. 3, In the presence of these cytokines plus antigen binding to the slg, the B lymphocyte becomes activated. The activated B lymphocyte becomes a plasma cell (4), which produces and secretes immunoglobulin or becomes a memory B lymphocyte (5). A minority of B lymphocytes become memory B lymphocytes.

IgE-mediated inflammation. They are especially abundant in the skin, lungs, nasal mucosa, and connective tissue. Granules within the mast cells contain large amounts of preformed mediators that include histamine, heparin, and serotonin. Mast cells can also phagocytize, destroy, and present bacterial antigens to T lymphocytes.¹⁰ Basophils are similar to mast cells because they contain granules filled with histamine, but they usually circulate in the blood and are not found in connective tissue. Like mast cells, basophils express high-affinity IgE Fc receptors (Fc). IgE-mediated anaphylaxis (type I hypersensitivity; see Chap. 91) is caused by stimulation of mast cell and/or basophil degranulation and release of preformed mediators after allergen binds to IgE bound to the Fc receptor on the surface of mast cells or basophils.¹¹

Soluble Mediators of the Innate Immune System

Soluble mediators of innate immunity include the complement system, mannose-binding lectin, antimicrobial peptides, and C-reactive protein.¹ The complement system consists of more than 30 proteins in the plasma and on cell surfaces that play a key role in immune defense. The four major functions of the complement system include: (a) to lyse certain microorganisms and cells; (b) to stimulate the chemotaxis of phagocytic cells; (c) to coat or opsonize foreign pathogens, which allows phagocytosis of the pathogen by leukocytes expressing complement receptors; and (d) to clear immune complexes. Complement factors (C3a, C5a) act as chemotactic factors for phagocytic cells.¹² Two different pathways stimulate the complement cascade. In the *classic pathway*, antibody binds to its target antigen and activates the first component of complement (C1), thereby initiating the complement cascade. The *alternative complement pathway* relies on the inability of microorganisms to clear spontaneously produced C3b, the active form of the third complement protein, from their surface. Patients with hereditary deficiencies of complement have recurrent bacterial infections or immune complex disease because C3b plays a central role in opsonizing bacteria and clearing immune complexes. Both mannan-binding lectin and C-reactive protein are acute phase reactants produced by the liver during the early stages of an infection. They bind to infectious pathogens that result in activation of the lectin or minor pathway of the complement system. Mannan-binding lectin binds to mannose-rich glycoconjugates on microorganisms, although C-reactive protein binds to phosphorylcholine on bacterial surfaces.^{1,12}

Chemokines play an essential role in linking the innate and adaptive immune response by orchestrating leukocyte trafficking. The chemokine system consists of a group of small polypeptides and their receptors. Chemokines possess four conserved cysteines. Based upon the positions of the cysteines, almost all chemokines fall into one of two categories: (a) CC group, in which the conserved cysteines are contiguous, or (b) CXC subgroup, in which the cysteines are separated by some other amino acid (“X”). As with all ligand–receptor interactions, a cell can respond to a chemokine only if the cell possesses a receptor that recognizes the chemokine. Chemokine receptors are unique in that they traverse the membrane seven times. CC receptors (CCRs) and CXC receptors (CXCRs) bind CC ligands (CCLs) and CXC ligands (CXCLs), respectively (Table 89–3).

Binding of infectious pathogens to pattern recognition receptors stimulates the release of chemokines such as macrophage inflammatory protein (MIP)-1 α , MIP-1 β , MIP-3 α , and IP-10 from macrophages and dendritic cells embedded in the tissues. These chemokines attract more immature dendritic cells to the site of inflammation/infection. Immature dendritic cells constitutively express CCR1, CCR5, and CCR6. The interaction between pattern recognition receptors on the dendritic cell to the infectious pathogen causes the activation and maturation of the dendritic cell. After activation, dendritic cells downregulate the expression of CCR1, CCR5, and CCR6 and upregulate the expression of CCR7. This switch in chemo-

kine receptor expression results in the antigen-loaded dendritic cell leaving the tissue and migrating toward the lymph nodes.¹³

Naturally occurring antimicrobial peptides include α -defensins, β -defensins, and cathelicidins. These peptides exhibit antibacterial, antifungal, and antiviral activity. Human antimicrobial peptides range in length from 29 to 37 amino acid residues. Neutrophils are a rich source of both α - and β -defensins as well as cathelicidins. Other sources of the human antimicrobial peptides include keratinocytes, Paneth cells of the intestinal and genital tracts, and epithelial cells of the pancreas and the kidney. These peptides can be induced at sites of inflammation or can be constitutively produced. The clinical interest in human antimicrobial peptides centers on their broad spectrum activity and their rapid onset of killing. They are believed to work by disrupting microbial membranes. An active area of research is how these peptides discriminate between microbial and host membranes.¹⁴

ADAPTIVE IMMUNE SYSTEM

Adaptive Immune Response: Antigen Recognition

Generally, the body uses both innate and adaptive immune responses to rapidly kill foreign pathogens.¹ The greatest difference between the innate and adaptive immune responses is in specificity and memory, characterized by antigen-specific receptors located on the surface of B and T lymphocytes.³ The adaptive immune response also secretes cytokines to further amplify the innate immune response. The adaptive immune response can evolve with each subsequent infection, whereas the innate response stays the same with each infection. During B- and T-lymphocyte development, an individual B or T lymphocyte rearranges its immunoglobulin and TCR genes, respectively, to produce a unique immunoglobulin or TCR, respectively. This DNA rearrangement generates enough B or T lymphocytes to recognize an estimated 10¹⁵ antigens.

The adaptive immune response can be divided into two major arms: humoral and cell-mediated. The *humoral* response is so denoted because it was discovered that the factors that provided the immune protection could be found in the “humor” or serum. B lymphocytes compose the humoral arm. Activated B lymphocytes can differentiate into plasma cells that secrete immunoglobulin or memory B cells specific for each pathogen. T lymphocytes constitute the cell-mediated arm of the adaptive system. The immune protection provided by T lymphocytes cannot be transferred by serum alone. Rather, it is essential to actually have T lymphocytes present, thus the term *cell-mediated* immunity. T lymphocytes are specially tailored to defend against infections that are intracellular, such as viral infections, whereas B lymphocytes secrete antibodies that can neutralize pathogens prior to their entry into host cells.

Adaptive Immune Response: Cells That Mediate Antigen Recognition

The role of the T lymphocyte is to search and destroy pathogens that infect and replicate intracellularly. When these pathogens enter a

cell, they are no longer vulnerable to innate host defenses. Therefore, it is critical that T lymphocytes be able to distinguish which cells are infected and which cells are not. **2** T lymphocytes do not recognize intact antigens, such as bacterial cell walls. T lymphocytes only recognize processed antigens in association with MHC.

Major Histocompatibility Complex

The MHC, a cluster of genes found on chromosome 6 in humans, is also known as the *human leukocyte antigen (HLA) complex*. The MHC is used by the immune system to distinguish self from nonself and provides a so-called immunologic “fingerprint.” The genes from this complex encode for molecules that play a pivotal role in immune recognition and response. The MHC complex is divided into three different classes: I, II and III. The molecules encoded by class I HLA genes include HLA-A, HLA-B, and HLA-C antigens. These molecules can be found on all nucleated cells within the body as well as on platelets. Class I antigens are not found on mature red blood cells. Molecules encoded by class II HLA genes include HLA-DP, HLA-DQ, and HLA-DR. The expression of these molecules is more restricted and can be found primarily on cells of the immune system, namely, APCs such as macrophages, dendritic cells, and B lymphocytes. Class III HLA antigens encode for soluble factors, complement, and tumor necrosis factors.¹⁵ In order for a CD4⁺ T lymphocyte to become activated, the CD4⁺ T lymphocyte must recognize the antigenic peptide in association with MHC class II (Figs. 89–2 and 89–3). CD8⁺ T lymphocytes recognize antigenic peptide in association with class I molecules. Class I molecules generally contain endogenous peptides from within the cell, such as those derived from viruses, although class II molecules contain exogenous peptides from antigen that has been phagocytized and digested, such as bacterial peptides (Fig. 89–2). For it to destroy a virally infected cell, a CD8⁺ cytotoxic T lymphocyte requires two steps. First, its TCR must recognize the antigenic fragment, such as a viral protein, in association with MHC class I. The second step involves the costimulatory step of B7–CD28 binding. Because any cell can become infected, it is advantageous that CD8⁺ cytotoxic T lymphocytes recognize the MHC class I molecule that is expressed on all cells except red blood cells. The ability of MHC class I to present endogenous peptides allows CD8⁺ cytotoxic T lymphocytes to constantly screen cells for infections.^{15,16} Dendritic cells and macrophages demonstrate the unique capacity to direct exogenous antigens toward MHC class I molecules, a process termed *cross-presentation*.¹⁷

APCs (e.g., macrophages, dendritic cells) engulf the pathogen, digest it, and express its peptide fragments on their cell surface in association with their MHC. T lymphocytes use a specific antigen receptor (TCR) to propagate the immune response. The TCR is composed of two chains, and each chain has a variable and a constant region. The variation of the amino acid sequence within the variable domain of TCR gives the cell its unique antigen specificity. Linked to the TCR is a complex of single chains known as the *CD3 complex*.^{1,11}

Naive T lymphocytes are cells that have not been previously exposed to an antigen specific for their TCR. These cells require two signals for activation. The first signal for activation involves the T lymphocyte recognizing both the processed antigen and the MHC molecule complex. The second signal involves the interaction of the B7-1 (CD80) or B7-2 (CD86) molecule on the APC with the CD28 molecule on the surface of the T lymphocyte (Figs. 89–2 and 89–3). Without the second signal, the naive T lymphocyte becomes anergic or inactive. Memory T lymphocytes are less dependent on the second signal than are naive T lymphocytes. CD28 is expressed on both resting and activated T lymphocytes, although CTLA-4, a second ligand for B7 on T lymphocytes, is expressed only on activated T lymphocytes. CTLA-4 binding B7 transduces a negative signal so it

plays a role in downregulating a T-lymphocyte response.¹⁸ After the two activation signals, a message is sent through the TCR to the CD3 complex into the cell. Then a calcium influx occurs with subsequent activation of the T lymphocyte. Activated CD4⁺ T lymphocytes begin to express the high-affinity IL-2 receptor and to release multiple soluble factors (e.g., IL-2) to stimulate T lymphocytes and other cells of the immune system (Fig. 89–2). Autocrine stimulation by IL-2 leads to proliferation of activated T lymphocytes.

Cell surface markers delineate the functional activity of T-lymphocyte populations. All T lymphocytes express the CD3 protein. Typically, T lymphocytes are further divided into helper cells (CD4⁺), suppressor cells (CD8⁺), and cytotoxic cells (CD8⁺). Each of the subclasses appears to play a distinct role in the cell-mediated immune response. Naive T lymphocytes express CD45RA, a high-molecular-weight isoform of CD45, whereas memory T lymphocytes express CD45RO, a lower-molecular-weight isoform of CD45.¹⁹ The primary role of CD4⁺ cells is to stimulate other cells in the immune response. Functionally, CD4⁺ cells can be divided into TH₁ and TH₂. This functional system was first described in mice. TH₁ cells secrete IL-2 and interferon- γ and stimulate CD8⁺ cytotoxic cells, whereas TH₂ cells secrete IL-4, IL-5, and IL-10 and stimulate B-lymphocyte production of antibody.²⁰ Multiple factors determine whether a naive CD4⁺ T lymphocyte develops into a TH₁ or a TH₂ cell. The cytokine microenvironment plays an important role in this development. IL-12 secreted by the APCs promotes TH₁ development, whereas IL-4 promotes TH₂ development. Other factors that promote TH₁ development include B7-1 (CD80), high-affinity of the TCR for the antigen, interferon- γ , and interferon- α . Factors that promote TH₂ development include B7-2 (CD86), low-affinity of the TCR for the antigen, IL-10, and IL-1.²¹

CD8⁺ T lymphocytes recognize antigen in association with MHC class I. CD8⁺ cytotoxic cells are instrumental in killing cells recognized as foreign, such as those that have become infected by a virus. CD8⁺ cytotoxic T lymphocytes play an important beneficial role in the eradication of tumor cells, but they also are responsible for rejection of transplanted organs.¹¹ Classically, a second type of CD8⁺ T lymphocytes was a suppressor cell. It is clear that some T lymphocytes help suppress the immune responses, but whether this subset is CD8⁺ is debatable. Emerging evidence is leading away from CD8⁺ T lymphocytes and toward CD4⁺CD25⁺ T lymphocytes in maintaining self-tolerance. The preferred term for these suppressive T lymphocytes is *regulatory T lymphocytes*.²²

To fully activate the CD8⁺ cytotoxic T lymphocyte requires CD4⁺ T-lymphocyte activation, namely, the TH₁ subset, and its subsequent secretion of IL-2 (Fig. 89–4A). This model of CD8⁺ cytotoxic T-lymphocyte activation requires the close proximity of two rare antigen-specific T lymphocytes. In addition, some CD8⁺ cytotoxic T-lymphocyte responses can occur in the absence of CD4⁺ T lymphocytes. New data suggest that CD4⁺ T lymphocytes can activate/prime APCs through CD40, which primes the APC (e.g., dendritic cell) to fully activate CD8⁺ cytotoxic T lymphocytes (Fig. 89–4B).²³ Remember that the classification of CD4⁺ lymphocytes as T-helper lymphocytes and CD8⁺ lymphocytes as T-cytotoxic lymphocytes is not an absolute. Some CD8⁺ T lymphocytes secrete cytokines similar to a T-helper lymphocyte, whereas some CD4⁺ T lymphocytes can act as cytotoxic cells.

Unlike neutrophils and macrophages, cytotoxic T lymphocytes are unable to ingest their targets. They destroy target cells by two different mechanisms: the *perforin system* and the *Fas ligand pathway*. After recognition by the cytotoxic T lymphocyte, cytoplasmic granules containing perforins and granzymes are rapidly oriented toward the target cell, and the contents of the granules are released into the intracellular space. Like the membrane attack complex formed after complement activation, perforins form a pore in the target cell membrane. Besides a direct cytotoxic effect on the target

FIGURE 89-4. In the classic model of CD8⁺ T-lymphocyte activation (A), CD4⁺ and CD8⁺ T lymphocytes recognize antigen on the same dendritic cell. In the presence of interleukin (IL)-2 from the activated CD4⁺ T lymphocyte and the recognition of antigen in association with major histocompatibility complex (MHC) class I, the CD8⁺ T lymphocyte becomes activated. In the new model (B), activated CD4⁺ T lymphocytes activate dendritic cells via CD40 ligand binding to CD40. The activated dendritic cell then migrates through the tissues to present antigen to CD8⁺ T lymphocytes. If recognition via the T-cell receptor (TCR) on the CD8⁺ T lymphocyte occurs, the dendritic cell can fully activate the CD8⁺ T lymphocyte without the presence of CD4⁺ T lymphocytes.

cell, the pores produced by perforins allow the granzymes to penetrate into the target cell to induce apoptosis. The second mechanism of cytotoxicity involves the binding of Fas ligand on the cytotoxic T lymphocyte to the Fas receptor on the target cell. The Fas ligand is predominately expressed on CD8⁺ cytotoxic T lymphocytes and natural killer (NK) cells, and its expression increases after activation. After destroying that target cell by either mechanism, the cytotoxic T lymphocyte detaches from the target cell and attacks other targets.²⁴

A B lymphocyte recognizes antigen via its antibody or immunoglobulin located on its cell surface (Fig. 89-3). The antibody on the

surface can recognize an intact pathogen, such as bacteria, and present antigen to T lymphocytes (i.e., acts as an APC). However, the major function of B lymphocytes is to produce antibody to bind to the invading pathogen, a process that first entails activation of the B lymphocyte. Activation of B lymphocytes requires two steps: (a) recognition of antigen by the surface immunoglobulin and (b) presence of B-lymphocyte growth factors (IL-4, IL-5, IL-6) secreted by activated CD4⁺ T lymphocytes. Once activated, the B lymphocyte becomes a plasma cell, a differentiated cell capable of producing and secreting antibody. A fraction of activated B lymphocytes do not differentiate into plasma cells but rather form a pool of memory cells. The memory cells will respond to subsequent encounters with the pathogen, generating a quicker and more vigorous response to the pathogen. Some B lymphocytes can become activated without help from T lymphocytes, but these responses are generally weak and do not invoke memory.^{1,11}

NK cells, often referred to as *large granular lymphocytes*, are defined functionally by their ability to lyse target cells without prior sensitization and without restriction by MHC. Resting NK cells express the intermediate-affinity IL-2 receptor CD122. Upon exposure to IL-2, NK cells exhibit greater cytotoxic activity against a wide variety of tumors. NK cells recognize target cells by two mechanisms. First, NK cells express the IgG Fc receptor CD16, which allows recognition of IgG-coated cells. Second, NK cells express killer-activating and killer-inhibiting receptors. The killer-activating receptors recognize multiple targets on normal cells, but the binding of MHC class I to the killer-inhibitor receptor blocks release of perforins and granzymes. Therefore, cells (e.g., tumor cells, virally infected cells) that downregulate MHC class I expression are susceptible to NK cell cytotoxicity. NK cells play important roles in the surveillance and destruction of tumors and virally infected host cells and in the regulation of hematopoiesis.^{1,25}

Soluble Mediators of the Adaptive Immune Response: Immunoglobulins

3 When a specific antigen binds to the surface immunoglobulin receptor of the B lymphocyte, the B lymphocyte matures into a plasma cell and produces large quantities of antibody that can bind to the inciting antigen. The secreted antibodies may be of five different isotypes. On primary exposure to the pathogen, the plasma cell will secrete IgM, but eventually it switches to predominately IgG. On second exposure, the memory B lymphocytes will predominately produce IgG. Isotype switching from IgM to IgG, IgA, or IgE is controlled by T lymphocytes.

An antibody or immunoglobulin is a glycoprotein composed of two different chains, heavy and light (Fig. 89-5). The basic structure of every immunoglobulin consists of four peptide chains: two identical heavy chains and two identical light chains held together by disulfide bonds. The basic structure of the antibody is a Y-shaped figure. Each arm of the Y is formed by the linkage of the end of the light chain to its heavy chain partner. These arms contain the portions described as the *fragments of antigen binding (Fab)*. The stem of the Y contains the heavy chains, which compose the *fragment crystallizable (Fc fragment)* portion of the antibody. It is within the Fc portion that complement is activated once the antibody has bound its target. Likewise, it is the Fc portion of the antibody that is recognized by Fc receptors on the surface of phagocytes (Fig. 89-1). The amino acid composition of the same isotype is homogenous except in the variable regions of the light (V_L) and heavy chains (V_H). The variation in amino acid composition of the variable region gives the antibody its unique specificity (Fig. 89-5).

IgG, the most prevalent of the antibody classes, composes approximately 80% of serum antibody. IgG usually is the second isotype of antibody produced in an initial humoral immune response. IgG is the only isotype of antibody that can cross the

FIGURE 89-5. Schematic diagram of the structure of the immunoglobulin G (IgG) molecule. IgG molecule consists of two heavy (H) and two light (L) chains covalently linked by disulfide bonds. Each chain is composed of variable (V) and constant (C) regions. A light chain consists of one variable (V_L) and one constant (C_L) region. Heavy chains consist of one variable (V_H) and three or four constant (C_H) regions, depending on the isotype. The variable regions (V_L and V_H) compose the antigen-binding region of the IgG molecule, or fragment antigen binding (Fab). The constant regions provide the structure to the IgG molecule as well as binding the first component of complement (C_H2) and binding to Fc receptors via the Fc portion of the molecule (C_H3).

placenta. Therefore, early maternal humoral protection of neonates is primarily due to maternal IgG that crossed the placenta in utero.

Four different subclasses of IgG have been described: IgG1, IgG2, IgG3, and IgG4. These subclasses differ slightly in their constant amino acid sequences. IgG1 constitutes the majority (60%) of the subclasses. It appears that different subclasses recognize different types of antigen. IgG1 and IgG3 are principally responsible for recognition of protein antigens, although IgG2 and IgG4 commonly bind to carbohydrate antigens. Another difference in the subclasses is the ability to activate complement. IgG3 and IgG1 are the most efficient, and IgG4 is unable to activate the complement system.

IgM can be found on the surface of B lymphocytes as a monomeric Y-shaped structure. In contrast, secreted IgM is a pentamer in which five of the monomers are joined together by a joining chain (J chain). IgM is the first class of antibody produced on initial exposure to an antigen. Because the pentameric form of IgM has no Fc portions exposed, phagocytic cells cannot bind pathogens opsonized by IgM. However, IgM is an excellent activator of the complement cascade by the classic pathway.

IgA is found primarily in the fluid secretions of the body (tears, saliva, nasal fluids) and in the gastrointestinal, genitourinary, and respiratory tracts. IgA functions by preventing pathogens from adhering to and infecting the epithelial cells at these sites. IgA is also secreted in a nursing mother's breast milk, as are IgG and IgM but in lower concentrations. In bodily secretions, IgA is in a dimeric form in which a J chain and a secretory chain hold two monomers together. The dimeric form is resistant to proteolysis in mucosal secretions.

IgD is the least understood isotype. IgD is found on the surface of B lymphocytes at different stages of maturation and may be involved in the differentiation of these cells. The main function of circulating IgD has not yet been determined. However, mice treated with exogenous anti-IgD antibody display a marked increase in immunoreactivity and secretion of all types of immunoglobulins and several T-cell-specific cytokines. High levels of anti-IgD autoantibodies of various subtypes have been observed in most autoim-

mune diseases (frequencies >50%), suggesting that IgD plays an important role in the etiology of these diseases.²⁶

IgE is the least common of the serum antibody isotypes. Most of the IgE in the body is bound to the IgE Fc receptors on mast cells. When the IgE on the surface of mast cells binds antigen, it causes the release of various inflammatory substances (e.g., histamine) from the mast cell. The overall effect is stimulation of inflammation. Asthma and hay fever are two examples of allergic reactions primarily due to antigen binding to IgE.²¹

Soluble Mediators of the Adaptive Immune Response: Cytokines

Cytokines are soluble factors released or secreted by cells that affect the activity of other cells (paracrine) or the secreting cell itself (autocrine). For example, activated $CD4^+$ T lymphocytes secrete IL-2, which activates itself as well as $CD8^+$ T lymphocytes and NK cells. Research has shown that many cytokines (Table 89-4) have a broad spectrum of effects depending on their concentration, the presence of other factors, and the target cell. New cytokine families and their roles in disease processes are being discovered daily. Cytokines provide communication between the divisions of the immune system. Cytokines produced from APCs generally promote chemotaxis of other cells and induce a state of inflammation.²⁷ Monocytes, as previously mentioned, use pattern recognition receptors, enabling the immune system to distinguish pathogenic proteins from non-pathogenic proteins through toll-like receptors stimulating T-lymphocyte activation.²⁷ Cytokines can also prevent activation or response of immunologic cells. For example, IL-10 is an antiinflammatory cytokine that is produced in the respiratory tract to prevent IgE synthesis and activation of eosinophils when exposed to benign inhaled particles.²⁷ In vivo cytokines do not act alone but in combination with other cytokines. For example, activated $CD4^+$ T lymphocytes secrete both IL-2 and interferon- γ , which are synergistic in activating NK cells. Cytokines are broadly classified as regulatory or hematopoietic growth factors (Table 89-4).^{11,28-32} This classification does not describe all their activities. Granulocyte-macrophage colony-stimulating factor (GM-CSF) released by activated T lymphocytes acts as a hematopoietic growth factor but also activates granulocytes and macrophages to phagocytize foreign pathogens.

The division of the immune system into the two functional groups does not imply that the divisions do not interact. In order to generate a vigorous immune response, both soluble mediators (e.g., complement, antibody, and cytokines) and cells (e.g., neutrophils, macrophages, dendritic cells, T lymphocytes, and B lymphocytes) are needed. The innate system usually responds first. Dendritic cells, macrophages, and neutrophils in the tissues recognize pathogen via surface receptors (Fig. 89-1). In order to amplify the immune response, APCs present antigen to $CD4^+$ T lymphocytes (Figs. 89-2 and 89-3). The activated $CD4^+$ T lymphocytes then secrete cytokines to activate B lymphocytes, $CD8^+$ T lymphocytes, NK cells, macrophages, and neutrophils.

DISEASES OF THE IMMUNE SYSTEM

This chapter is not intended to detail the diseases of the immune system, but a review of the terminology and specific examples of diseases of the immune system are necessary to understand the role of monitoring and possible intervention with pharmacotherapy. Diseases of the physical defense immune system are not often thought of as diseases of the immune system, but the loss of normal physical defenses is the most common cause of impaired immunity resulting in infectious sequelae. For example, thick respiratory secretions secondary to altered chloride transport in cystic fibrosis lead to pathogen airway colonization. Primary immunodeficiency

TABLE 89-4 Cytokines

Cytokines	Sources	Principal Effects
Regulatory		
IL-1	Macrophages, fibroblasts, endothelial cells	Activation of T and B lymphocytes, hematopoietic growth factor, induction of inflammatory events
IL-2	CD4 ⁺ T lymphocytes (TH ₁ subset)	Activation of T lymphocytes, B lymphocytes, NK cells
IL-4	CD4 ⁺ T lymphocytes (TH ₂ subset), mast cells, basophils, eosinophils	B- and T-lymphocytes growth factor, activation of macrophages, promotes IgE production, proliferation of bone marrow precursors
IL-5	CD4 ⁺ T lymphocytes (TH ₂ subset), mast cells	Activation of B lymphocytes and eosinophils, promotes IgE production
IL-6	CD4 ⁺ T lymphocytes (TH ₂ subset), macrophages, mast cells, fibroblasts	T- and B-lymphocyte growth factor, hematopoietic growth factor, augments inflammation
IL-8	T lymphocytes, monocytes, endothelial cells, fibroblasts	Neutrophil, basophil, T-lymphocyte chemotaxis
IL-10	T and B lymphocytes, macrophages	Cytokine synthesis inhibitory factor, growth of mast cells
IL-12	Macrophages, neutrophils, dendritic cells	Induce TH ₁ cells, ↑ NK cell activity, ↑ generation of cytotoxic T lymphocytes
IL-13	Activated T lymphocytes	Proliferation of B lymphocytes, suppression of proinflammatory cytokines, directs IgE isotype switching
IL-14	T lymphocytes	Induces B-lymphocyte proliferation, inhibits secretion of Igs
IL-15	Macrophages, fibroblasts, dendritic cells, epithelial cells	T-lymphocyte proliferation, activation of NK cells
IL-16	CD8 ⁺ T lymphocytes, epithelial cells	Chemoattractant for CD4 ⁺ T lymphocytes and eosinophils; stimulation of secondary cytokine secretion from and proliferation of CD4 ⁺ T lymphocytes
IL-18	Macrophages	Induces IFN- γ production
IL-28, IL-29 ^a	Antigen-presenting cells, but proposed that all nucleated cells may produce	Alternative to IFN- α /IFN- β to provide immunity against viral infections by inhibiting viral replication
IL-31	Activated T lymphocytes	Involved in recruitment of polymorphonuclear cells, monocytes, and T cells to site of inflammation
IL-32	NK cells, T lymphocytes, epithelial cells	Induces proinflammatory cytokines including TNF- α and IL-8
TNF- α	Macrophages, NK cells, T and B lymphocytes, mast cells	Activation of neutrophils, endothelial cells, lymphocytes, liver cells to produce acute phase proteins
TNF- β	T lymphocytes	Tumoricidal
IFN α	Monocytes, other cells	Antiviral, activation of NK cells and macrophages, upregulation of MHC class I
IFN γ	T lymphocytes, NK cells	Activation of macrophages, NK cells, upregulation of MHC class I and II
Hematopoietic growth factors		
IL-3	T lymphocytes, macrophages	Maturation and differentiation of hematopoietic and mast cells
IL-7	Bone marrow stromal cells	Lymphopoietin
IL-9	T lymphocytes	Maturation and proliferation of T lymphocytes and mast cells
IL-11	Bone marrow stromal cells	Maturation of B lymphocytes and megakaryocytes
G-CSF	Macrophages, endothelial cells, fibroblasts	Maturation and activation of neutrophils
GM-CSF	T lymphocytes, macrophages, endothelial cells, fibroblasts	Maturation and activation of granulocytes, monocytes/macrophages, and eosinophils
M-CSF	Macrophages, endothelial cells, fibroblasts	Maturation and activation of monocytes/macrophages
Erythropoietin	Kidney, liver	Maturation of red blood cells
Stem cell factor	Bone marrow stromal cells, hepatocytes	Activation of mast cells, early-acting growth factor for myeloid and lymphoid precursors
c-MPL ligand (thrombopoietin)	Bone marrow stromal cells, liver, kidney	Lineage-specific growth factor for megakaryocytes (platelets)
FLT3 ligand	Bone marrow stromal cells	Early-acting growth factor

G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; Ig, immunoglobulin; IL, interleukin; M-CSF, macrophage colony-stimulating factor; MHC, major histocompatibility complex; NK, natural killer; TNF, tumor necrosis factor.

^aAlso known as the new type III IFN λ family.

diseases are characterized as either a genetic inability to produce components of the immune system (e.g., severe combined immunodeficiency or hypogammaglobulinemia) or acquired (e.g., human immunodeficiency virus infection). Autoimmune diseases result from a dysregulation of a component or a combination of components of the immune system (e.g., rheumatoid arthritis, systemic lupus erythematosus).³³ Autoimmune diseases are often characterized by production of autoantibodies against a particular host structure that is critical for normal function or by loss of tolerance or anergy to a ubiquitous antigen (e.g., gluten in celiac sprue).³³ Often medications that suppress the immune system are necessary to control symptoms and halt autoimmune disease progression. Exposure to immunosuppressive agents in the setting of autoimmune disease or organ transplantation may reduce disease symptoms but at the cost of the host's ability to fight off infection or cancer. Exogenous regulation of the immune system must be done judiciously, and we must continue to discover new methods for the appropriate evaluation of immune responses.

EVALUATION OF IMMUNE FUNCTION

Assessment of a patient's immune function requires knowledge and understanding of multiple components, including mechanical defenses, cell phenotypes and cell numbers, and soluble components. Recent developments in biotechnology have allowed for progress in further characterization of immune system components and their functions. This is important because upregulation and downregulation of immune responses is necessary to treat various disease states. Therefore, pharmacotherapeutic considerations must balance the risk of disrupting normal immunologic homeostasis. Improvements in immune monitoring are necessary for the goal of patient-specific immunologic pharmacotherapy. Despite the technologic advances, careful patient evaluations are required to accurately assess the structure and function of the immune system. Specific methods for assessment of patient immune status are discussed here.

INNATE IMMUNITY: EVALUATION OF MECHANICAL IMMUNODEFENSES

The mechanical aspects of host defense are extremely important in protection from infection; therefore, assessment of mechanical defenses is critical. Much of the assessment of mechanical immunodefense is accomplished by recognizing situations where such defense is compromised. Careful patient examination usually reveals the extent of compromise, and laboratory tests are generally not necessary for evaluation of this component. To assess the extent of compromise in mechanical immunodefenses, the clinician should carefully examine the patient and identify the specific types of risks present. Specific examples of altered mechanical defenses are listed in Table 89–5.

INNATE AND ADAPTIVE IMMUNITY: GROSS EVALUATION OF CELLULAR COMPONENTS

A major aspect of the assessment of immune function relates to the cells of the immune system. Assessment of cells in the clinical setting includes determination of cell type, cell number, and/or function. Generally, determination of cell types and quantification of cell numbers are performed first because of the ease of obtaining these results and the common correlation with the clinical situation.

To quickly screen cell numbers, a *white blood (cell) count* (WBC) with differential is performed. Normal cell counts are given in Table 89–6.³⁴ This simple test often steers the differential diagnosis. In interpreting a WBC with differential, the clinician must consider several factors. A normal cell count does not mean that a leukocyte disorder does not exist. For example, in chronic granulomatous disease, a child has a normal neutrophil count, but the neutrophils are unable to destroy the bacteria. Second, a differential is reported as percentage of the WBC; therefore, the absolute number as well as the percentage of white cell subtypes must be assessed. For example, a patient admitted to the hospital with pneumonia has an elevated WBC (15,000 cells/mm³) with a manual differential of 70% mature neutrophils (segs), 10% immature neutrophils (bands), 15% lymphocytes, and 5% monocytes. The WBC is predominately neutrophils: segs or mature neutrophils (70%) and bands or immature neutrophils (10%). The percentage of lymphocytes appears low at 15% (Table 89–6), but the absolute number of lymphocytes is

TABLE 89-6 Leukocyte Counts in Adults

Cell	Absolute Count (Range) ^a	Percent (Range)
White blood cells	7.5 (4.5–11.0)	100
Neutrophils	4.5 (2.3–7.7)	60 (50–70)
Eosinophils	0.2 (0.0–0.45)	3 (0–5)
Basophils	0.04 (0.0–0.2)	1 (0–2)
Monocytes	0.3 (0.0–0.8)	4 (0–10)
Lymphocytes	2.1 (1.6–2.4)	32 (28–39)
T lymphocytes	1.4 (1.1–1.7)	72 (67–76) ^b
CD4 ⁺	0.8 (0.7–1.1)	42 (38–46) ^b
CD8 ⁺	0.7 (0.5–0.9)	35 (31–40) ^b
B lymphocytes	0.3 (0.2–0.4)	13 (11–16) ^b
Natural killer cells	0.3 (0.2–0.4)	14 (10–19) ^b
CD4/CD8 ratio	1.2 (1.0–1.5)	

^a× 10³ cells/mm³.

^bPercent of lymphocyte subpopulations expressed as percentage of total lymphocyte population.

normal at 2,250 cells/mm³ (15,000 cells × 0.15). A third factor to consider is that most lymphocytes are in secondary lymphoid organs (e.g., lymph nodes, spleen), and changes in peripheral blood lymphocytes do not always reflect changes in secondary lymphoid organs. Similarly, most granulocytes, macrophages, and mast cells are in the tissues, not the bloodstream.

The numbers of granulocytes (neutrophils, basophils, eosinophils) and monocytes usually can be assessed by a WBC with differential. It has long been recognized that the lower the absolute neutrophil count, the greater the risk of infection. Drugs (e.g., chemotherapy) and diseases (e.g., collagen vascular disorders) may lower the neutrophil count and make the patient more susceptible to infections. Patients with a neutrophil count <1,500 cells/mm³ are considered to have neutropenia. Functional analysis of these cell types is rarely done in routine clinical practice. Patients with suspected functional deficits in these cell types generally are referred to tertiary medical centers for evaluation and treatment.

A routine WBC with differential can determine the total lymphocyte count. Total lymphocyte count has been used as a measure of nutritional status, which rapidly changes with nutrient loss or repletion. This is a relatively gross measure of a patient's immune status, although it has been correlated to patient outcome and risk of infection.

Lymphocyte populations with different functions or in various stages of activation can be enumerated based on their cell surface markers. These cell surface markers are known as *clusters of differentiation* (CD). The CD is usually a protein or glycoprotein on the surface of the cell. CD followed by a number designates the marker. Hundreds of monoclonal antibodies have been designed to recognize these cell surface markers. Monoclonal antibodies can be labeled with a fluorescent marker. The labeled monoclonal antibodies are then incubated with the patient's cells. The antibodies will recognize and bind to the cells expressing the CD of interest, and the cells are counted with flow cytometry. For flow cytometry, the cell suspension is put under pressure such that the cells flow past a laser in a stream of single cells. The laser excites the fluorescently labeled antibodies bound to the lymphocytes. A light detector counts the labeled cell as the fluorescent tag emits light and determines the size of the cell based on its light scatter. These evaluations are valuable for assessment of patients with immune deficiency states such as acquired immunodeficiency syndrome (AIDS) or leukemia, and for patients who have received organ transplants. For example, clinically quantification of CD3⁺ and CD4⁺ cells is used to monitor muromonab, a monoclonal antibody directed against the CD3 receptor. The number of CD4⁺ cells in human immunodeficiency virus (HIV)-positive patients correlates with the risk of opportunistic infection and delineates the time to initiate antiviral therapy. Some of the more common CD antigens and their respective cellular distributions are listed

TABLE 89-5 Examples of Alteration in Mechanical Immunodefenses That Result in Impaired Immune Status

Reduced gastric pH
Achlorhydria
Use of histamine-2 blockers and proton pump inhibitors
Patients with acquired immune deficiency syndrome (AIDS)
Break in skin barrier
Burns
Surgical incision
Penetrating trauma
Vascular access devices
Impaired mucociliary function of the lungs
Smoking
Impaired esophageal or epiglottal function
Endotracheal intubation
Stroke
Recumbent position
Altered urine flow
Urinary stones
Anatomic deformities obstructing flow
Bladder catheter
Anatomic alterations of the heart resulting in turbulent blood flow and endocarditis

TABLE 89-7 Cluster of Differentiation (CD) Guide: Characterization of Human Leukocyte Antigens

CD	Predominant Cellular Distribution
CD3	All T lymphocytes
CD4	Helper T lymphocytes, either TH ₁ or TH ₂
CD5	T lymphocytes, B-lymphocyte subset
CD8	Cytotoxic/suppressor T lymphocytes
CD14	Monocytes, neutrophils
CD20	B lymphocytes
CD25	Activated T lymphocytes, B lymphocytes, interleukin-2 receptor α -chain (Tac)
CD33	Committed myeloid progenitor cells
CD34	Hematopoietic progenitor cells that include the stem cell
CD56	Natural killer cells
CD83	Dendritic cells

in Table 89–7.³⁵ Flow cytometry can be used for leukocyte phenotyping, tumor cell phenotyping, and for some types of DNA analysis.

INNATE AND ADAPTIVE IMMUNITY: FUNCTIONAL EVALUATION

Several disease states are characterized by an adequate number of cells, but either the cells are nonfunctional or they do not produce cytokines to communicate effectively. No single test can predict the function of the immune system with 100% accuracy. However, tests are available to measure the viability of certain cell lines and communication between cells. Historically, the most common *in vivo* assay of lymphocyte function is the delayed hypersensitivity skin test. This test specifically evaluates the presence of delayed-type hypersensitivity or the presence of memory T lymphocytes. Specifically, a small amount of antigen, of which the patient is known to have been previously exposed, is administered. Under normal immunologic host conditions, exposure to this amount of antigen in the skin should produce lymphocytic infiltrate into the area within a few hours, followed by additional lymphocyte recruitment and phagocyte (e.g., macrophages, neutrophils) translocation. The maximal intensity of the inflammatory reaction occurs within 24 to 72 hours. This reaction often is referred to as type IV hypersensitivity (i.e., cell-mediated; see Chap. 91). A delayed-type hypersensitivity reaction is a test of cell-mediated immunity used to assess immunocompetency. The most common method for assessing delayed-type hypersensitivity is intradermal administration of a panel of recall antigens. Commonly used antigens include *Candida albicans*, mumps, trichophyton, tetanus toxoid, and purified protein derivative of tuberculin.³⁶ Measurements in millimeters of induration at the site of injection should be taken 48 to 72 hours after placement of the antigens. A reaction is considered positive if the diameter of induration is 2 mm or greater. The degree of sensitivity correlates to the area of induration.³⁵ Reaction to even a single antigen indicates a functioning cell-mediated immunity. The majority of immunocompetent individuals show a positive reaction to at least one of these antigens. Possible reasons for not mounting a response to these antigens include congenital T-lymphocyte deficiency, cancer, HIV, or immunosuppressive drug therapy.³⁶ Sometimes, no response is mounted because the individual being tested has not been previously exposed to a particular test antigen, although this is rare.

Global assessment of the *in vivo* immunologic response is used commonly in patients with solid organ transplantation during the diagnosis and assessment of acute rejection. For example, cellular rejection is detected on gross tissue biopsy by counting the number of lymphocytes present in the tissue and correlating their presence with other clinical findings, such as increasing serum creatinine level in patients with kidney transplant.

In vivo assessment of B-lymphocyte function involves immunizing the patient with a protein (e.g., tetanus toxoid) and a polysaccharide

(e.g., pneumococcal polysaccharide vaccine) antigen to elicit and measure antibody responses after immunization. Two to three weeks after immunization, the patient's serum is tested for antibodies specific for the immunized antigen. This test measures B-lymphocyte responsiveness to the inoculated antigens but is reserved for patients who are suspected of having impaired B-lymphocyte function.³⁴

A number of specific lymphocyte functional *in vitro* assays are used in the research setting. A few assays are performed at specialized clinical laboratories. One of these tests is the lymphocyte proliferation assay. In this assay, lymphocytes are obtained from a patient's peripheral blood and cultured *in vitro*. The cells are exposed to nonspecific mitogens such as pokeweed mitogen, phytohemagglutinin, or concanavalin A. Then the cells are incubated in growth media containing tritium-labeled (³H) thymidine, a nucleotide used in the synthesis of DNA. Normally in the presence of the mitogens, lymphocytes are stimulated to proliferate. Proliferating lymphocytes incorporate ³H thymidine as they replicate DNA. The level of radioactivity of the cells can be measured on a β -scintillation counter and is proportional to the degree of proliferation. The patient sample must be compared to lymphocytes from normal, healthy controls. Patients with immune deficiencies (AIDS, cancer, etc.) have fewer active or less active lymphocytes, as detected by this test.

A modification of the lymphocyte proliferation assay can be used in allogeneic hematopoietic stem cell transplantation to evaluate how closely a donor and host are "matched" in order to predict a patient's risk for developing graft-versus-host disease. A mixed lymphocyte culture (MLC) can be used to assess the potential of the donor cells to attack the host cells, a condition known as graft-versus-host disease (see Chap. 142). In this test, donor cells and host cells are incubated *in vitro*. The host lymphocytes are irradiated prior to the incubation so that they cannot proliferate. *In vitro*, ³H thymidine is provided to the cells and uptake is measured. The degree of uptake correlates to level of proliferation of donor lymphocytes. If the cells are well matched, proliferation is minimal. If the cells are mismatched, proliferation is noted, with the level of proliferation predictive of the potential extent of graft-versus-host disease. With the introduction of DNA-based molecular typing of HLA antigens, the MLC is rarely used today. However, the MLC may play a role in selecting not completely histocompatible donors.³⁶

The Cylex immune cell function assay is FDA approved as a novel test for determining the magnitude of suppression of CD4⁺ cells.³⁷ Briefly, activity of CD4⁺ cells is measured by quantification of the amount of ATP produced and characterized as high, medium, or low. Initial retrospective experience in the solid organ transplant population has been reported.³⁸ Although this assay is in its clinical infancy, it is one of the first functional assays aimed at assessing individual patient response to immunosuppressive therapy. This type of testing may allow for tailoring of immunosuppression. In addition to the Cylex immune cell function assay, a number of other tests have been devised to evaluate the function of CD8⁺ T lymphocytes, NK cells, and monocytes/macrophages. Although these evaluations are not commonly performed, they may be helpful in some specific diseases. A thorough discussion of these tests is available.³⁹

EVALUATION OF CYTOKINES AND CHEMOKINES

Disease states involving the loss or upregulation of cytokines and chemokines are often overlooked as diseases of the immune system. However, as just reviewed, cytokines and chemokines are essential components of both the innate and adaptive immune systems and provide the communication linking them together. Assays of humoral components may be either quantitative, to determine the absolute concentration of the factor, or qualitative, to determine the function of the component.

TABLE 89-8 Potential Indications for Measurement of Antigen-Specific Antibody

Environmental or drug allergy
Exposure to or infection with bacteria
Streptococci (ASO titer)
<i>Staphylococcus aureus</i> (teichoic acid antibody)
<i>Neisseria gonorrhoeae</i>
<i>Legionella pneumophila</i>
Exposure to or infection with viruses
Human immunodeficiency virus
Cytomegalovirus
Epstein-Barr virus
Hepatitis A, B, or C
Rubella
Exposure to or infection with other pathogens
Syphilis
Lyme disease
Typhoid
Chlamydia
Immune disorders
Rheumatoid factor antibody, rheumatoid arthritis
Antinuclear antibodies, systemic lupus erythematosus
Platelet-associated immunoglobulin G, idiopathic thrombocytopenic purpura
Blood typing and crossmatching
Transplantation
Human leukocyte antigen (HLA) antibodies

IMMUNOGLOBULINS

Measurement of immunoglobulins is a direct measure of B-cell function. The most common evaluation of immunoglobulins is the estimation of total immunoglobulin. This is estimated by subtracting the albumin concentration from the total protein concentration in serum. This difference provides a gross estimate of the total immunoglobulin concentration. Total immunoglobulin concentration can be more accurately determined by serum protein electrophoresis. Five separate zones are detected by this method: albumin, α_1 -globulin, α_2 -globulin, β -globulin, and γ -globulin.

4 The γ -globulin fraction contains the five isotypes of immunoglobulin (IgG, IgA, IgM, IgE, and IgD). A normal total immunoglobulin or γ -globulin concentration ranges from 0.8 to 1.6 g/dL. This test is used to determine if patients have hypogammaglobulinemia (i.e., primary and secondary immunodeficiencies), a monoclonal peak (e.g., multiple myeloma, Waldenström's macroglobulinemia), or a polyclonal hypergammaglobulinemia (e.g., chronic inflammatory condition, such as systemic lupus erythematosus or chronic active hepatitis). Total immunoglobulin or γ -globulin concentrations cannot be used to measure antigen-specific antibodies or specific isotypes, although other tests are available for this purpose.

In a patient suspected of having humoral immune deficiency or B-lymphocyte failure (i.e., primary and secondary hypogamma-

globulinemia), specific immunoglobulin isotypes in the plasma should be measured.

There are many indications for the measurement of antigen-specific antibody. Some common indications are listed in Table 89-8. Methods for performing these measurements include enzyme-linked immunosorbent assay (ELISA), radioimmunoassay (RIA), and radioallergosorbent test (RAST; Fig. 89-6). The most common reason for measuring antigen-specific antibody is to determine whether a patient has been exposed to an infectious agent. Generally, IgM antibodies directed against the pathogen indicate an active or recent infection, whereas IgG antibodies directed against the pathogen indicate prior exposure. This interpretation is based on our understanding of B-lymphocyte responses in which plasma cells produce IgM initially in response to an infection but later switches to IgG. Therefore, IgM antibodies will be present during an active infection and shortly after recovery from the infection. IgG concentrations will increase at the end of the primary exposure but predominate after a second exposure. IgG predominates after a second exposure because memory B lymphocytes predominately secrete IgG in the serum. Other uses of antigen-specific antibody include determining if a patient has been exposed and is likely to be protected from infection (e.g., hepatitis A virus) or to determine adequate response to vaccination (e.g., hepatitis B vaccine).

Antigen-specific IgE is commonly measured in patients with allergies. Because the presence of antigen-specific IgE is related to clinical allergy, measurement of this antibody can be helpful in diagnosing allergies and determining offending substances. A standard method for determining allergen-specific IgE is the RAST. The basic technique involves adding the antigen of interest, which is bound to beads or disks, to the patient's serum. After precipitation and several washings, the antibody bound to the bead or disk is isolated. Finally, a radiolabeled antibody that binds to IgE is added. After further washings, the radiolabeled antibody bound to IgE, which is bound to the antigen on the bead or disk, is counted on a γ -counter.

Antigen skin testing is the preferred method for determining the presence of allergen-specific IgE. When produced, IgE binds to high-affinity IgE Fc receptors on basophils or mast cells. Contact of an allergen with the specific IgE on the basophil or mast cell surface causes activation of these cells and release of inflammatory mediators (e.g., histamine). When this process occurs systemically, it can cause anaphylaxis. When it occurs in a confined area such as the skin, erythema and induration are observed within a few minutes of allergen injection. This is the principle used for detection of penicillin allergy as well as for environmental or food allergies. A positive skin reaction (≥ 5 mm of induration) within 15 to 20 minutes is indicative of the presence of allergen-specific IgE.

IgG1, IgG2, IgG3, and IgG4 (the four subclasses of IgG) make up 65%, 20%, 10%, and 5% of total plasma IgG, respectively. Concentrations of the subclasses are often measured in patients with suspected primary and secondary hypogammaglobulinemia. IgG2

FIGURE 89-6. Enzyme-linked immunosorbent assay (ELISA). ELISA is a commonly used method for measuring concentrations of a wide variety of substances. To measure the concentration of antibodies to a particular antigen, the antigen is coated onto a solid phase, such as a microtiter plate or beads. If the purpose of the assay is to measure the concentration of antigen in solution, an antibody to the antigen is coated on the solid phase. The biologic fluid, often sera, is added to the wells. An enzyme-labeled anti-human antibody is added next. Finally, the chromogenic substrate for the enzyme is added. The intensity of the color as measured spectrophotometrically is proportional to the concentration of the antibody in the biologic fluid.

and IgG4 deficiencies are associated with chronic infections. IgG4 deficiencies are also associated with autoimmune disorders.

COMPLEMENT SYSTEM

The complement system consists of a group of more than 30 different proteins involved in lysing and opsonizing invading pathogens as well as serving as chemotactic factors. Numbers following the letter C (e.g., C1, C2) name the various proteins of the complement system. A test for the global assessment of the complement system is the CH₅₀, the total hemolytic complement test. This test is based on the premise that complement is needed for a rabbit anti-sheep antibody to lyse sheep red blood cells. The source of the complement is the patient's serum. Each laboratory standardizes the test so normal ranges vary, but a standard curve is developed by adding titrated amounts of sera and measuring the amount of hemolysis. The hemolysis is determined with a spectrophotometer to measure the amount of hemoglobin released. The patient's serum is then tested, and the amount of serum that is needed to lyse 50% of the red blood cells is reported as the CH₅₀. This test does not provide an indication of the function of any specific complement component but is used as a screening test for any complement system defects. If a defect is found, individual complement proteins can be evaluated by functional or immunochemical methods. Assessment of the complement system is important in patients suspected of having humoral immune deficiencies (i.e., recurrent infections).³⁵

Several disease states can alter complement concentrations. Low complement concentrations are frequently found during states of acute inflammation (e.g., systemic lupus erythematosus, rheumatoid arthritis, collagen vascular disorders, poststreptococcal glomerulonephritis, and subacute bacterial endocarditis). These states of apparently low complement concentrations are generally due to high rates of complement utilization or consumption that cannot be compensated for by increased complement synthesis.¹²

The liver is the primary source of several components of the complement system (i.e., C2, C3, C4, factors B and D); therefore, a global decrease in complement factors occurs in severe liver failure. Inherited complement deficiencies have been described in patients with systemic lupus erythematosus, autoimmune diseases, recurrent gonococcal and meningococcal infections, membranoproliferative glomerulonephritis, and hereditary angioedema.¹²

Clinically, the complement system has been used to diagnose and treat solid organ rejection. Antibody-mediated or humoral rejection is evaluated by quantifying the amount of donor MHC-specific antibody present in the recipient's serum. The presence of donor-specific antibodies is correlated with evidence of antibody-mediated rejection on tissue samples. This is characterized by the presence of complement split products, namely, C4d, which is present after complement dependent antibody-mediated rejection. C4d covalently binds to the allograft tissue and can be stained for on biopsy samples. Unfortunately, unless biopsy findings can be correlated with a clinical finding consistent with rejection, the presence of C4d and its prognosis on long-term allograft function are unknown.

CYTOKINES

Cytokines are an important means of communication among cells of the immune system and other organ systems. Multiple cytokines with overlapping and redundant functions have been identified. Methods for detecting and measuring cytokines in biologic samples have been developed. Commercial kits are available to measure nearly all currently identified endogenous and exogenously administered cytokines. The most common and preferable methods for measuring cytokines are the ELISA and RIA. ELISA and RIA are easy to run, and they measure immunoactivity but not biologic activity

(Fig. 89–6). Bioassays measure biologic activity, but are cumbersome and extremely variable. ELISA can measure only how much cytokine was produced by the cells in the culture. The enzyme-linked immunosorbent spot (ELISPOT) is an enzyme-linked assay that detects and enumerates cytokine-producing leukocytes.⁴⁰ In contrast to conventional ELISA, ELISPOT allows the user to detect absolute numbers and frequencies of cytokine-secreting leukocytes.

Interpretation of the clinical relevance of endogenous cytokine concentrations is still in the early stages. Not only is the immune system affected by cytokines such as IL-1, IL-6, and tumor necrosis factor- α (TNF- α), but other systems (e.g., skeletal, endocrine, central nervous system) also are affected. Therefore, measurement of cytokine concentrations may be important in the evaluation of other systems as well as the immune system.

Administration of pharmacologic doses of recombinant cytokines in clinical practice may change not only the concentration of that particular cytokine but also the resultant concentration of other cytokines. For example, systemic administration of GM-CSF to patients increases concentrations not only of GM-CSF but also of TNF- α , IL-6, IL-8, macrophage colony-stimulating factor, and erythropoietin.^{41,42} Secondary endogenous cytokine release should be taken into account when evaluating the therapeutic effects of these agents and monitoring cytokine concentrations.

In the future, tissue concentrations as well as blood concentrations may be measured. For example, many centers currently measure cyclosporine concentrations to estimate the potential for immunosuppressive effects, but monitoring IL-2 concentrations may be advantageous. One of the primary actions of cyclosporine is inhibition of IL-2 production. Furthermore, measuring tissue concentrations of IL-2 in the transplanted organ may be beneficial in obtaining a better estimate of the extent of immunologic suppression.

SOLUBLE RECEPTORS AND RECEPTOR ANTAGONISTS

The inflammatory response is highly regulated. The activity of cytokines, their receptors, and their antagonists are in a delicate balance. Although cytokine receptors usually are found on the surface of the target cell, soluble cytokine receptors can modulate the activity of cytokines in at least two ways: (a) acting as antiinflammatory agents by binding cytokines with high affinity but without biologic activity,⁴³ and (b) augmenting cytokine activity by prolonging the cytokine plasma half-life and even maintaining agonist activity on cells that do not inherently respond to the cytokine.⁴⁴ Finally, antagonists to cytokine receptors have been identified.

TNF- α plays a central role in the inflammatory response by both increasing the expression of adhesion molecules in the tissues and stimulating production of proinflammatory cytokines (e.g., IL-2, IL-8), prostaglandins, and nitric oxide. Soluble tumor necrosis factor receptors act primarily as inhibitors of TNF- α by preventing TNF- α from binding to the membrane-bound TNF- α receptor or by causing the cells to shed the receptor from the surface of the cell so that it can no longer serve as a signaling molecule.⁴⁵ Both monoclonal antibodies against TNF- α (e.g., infliximab) and soluble tumor necrosis factor receptors (e.g., etanercept) have been shown to modulate the activity of TNF- α and are used clinically for treatment of autoimmune diseases.

The best characterized receptor-binding antagonist is the IL-1 receptor antagonist (IL-1RA). IL-1RA blocks the binding of IL-1 to its receptor by competing for the same binding site, but IL-1RA does not possess agonist activity.⁴⁶ Anakinra, a recombinant IL-1RA, is used clinically for treatment of severe rheumatoid arthritis.⁴⁷

Our developing understanding of soluble receptors and receptor antagonists allows us to better mimic natural mechanisms for minimizing the toxicity of exogenously administered cytokines

(e.g., IL-1, IL-2, TNF- α) as well as for immunomodulating of various diseases (e.g., solid organ transplant rejection, collagen vascular disorders, sepsis).

MODULATION OF THE IMMUNE RESPONSE

5 Modulation of the immune response through administration of pharmacologic agents or with blood product components does not come without risks. Providing supplementation to the immune system, for example, during periods of sepsis with recombinant activated protein C (drotrecogin alfa), provides increased levels of protein C that decrease levels of proinflammatory IL-6, potentially limiting the effects of the immune reaction and preventing end-organ damage at the cost of bleeding for overexposure to protein C. Although interfering with the immune system to halt the damage of an autoimmune disorder may suppress symptoms, this strategy may place the patient at risk for opportunistic viral infections, as observed for agents such as etanercept for rheumatoid arthritis. Many of the newer biologic agents directed at a pathway in the immune system are genetically engineered from animals and humanized to increase their biologic effectiveness. As a result, these agents can serve as antigens to the immune system and display variable effectiveness between and among patients over time. For example, an agent commonly used in solid-organ transplantation is rabbit antithymocyte globulin, which is a polyclonal antibody directed against lymphocytes that is given at the time of transplant or to treat rejection. Patients with previous exposure to this agent may have developed antibodies against the rabbit epitope of the drug. This results in either a decrease in the effectiveness of the drug because it is bound by antibody or production of an immunologic reaction, commonly manifested by antibody–antigen complex deposition in the kidneys and joints producing high fevers and renal failure. Based on the few examples presented here, one can understand why manipulation of the immune system must be carefully assessed and appropriate patient instruction given.

IMMUNOSUPPRESSION

Immunosuppression was first developed and used to allow transplantation of foreign tissues or to treat malignancies of the immune system. Today, the number of compounds and disease states in which the immune system is implicated is virtually unquantifiable. Therefore, a thorough review of these drugs is beyond the scope of this chapter. Immunosuppressants often are very expensive and must be administered through an injection. Immunosuppressants block critical steps of the immune response, and patients must be counseled on their risk of infection and the plan to monitor effectiveness of the immunosuppressant. Some key concepts and questions can be used to help clinicians discern the potential benefits and ramifications of administering any immunosuppressant: (a) what is its mechanism of action, (b) what arm of the immune system does it effect, (c) when is its onset of action, (d) how was this compound derived and does it have the potential to stimulate antibody production if the patient is reexposed, (e) is this compound's effect dose or duration related, (f) what type of infection is the patient at risk for and does the clinician need to administer prophylactic medications, and (g) how does the clinician monitor the biologic effect of this compound?

IMMUNOPOTENTIATION

Immunopotentiators are often used in an attempt to restore normal immune system function or to activate the immune system. The best example of immunopotentiality of the immune system is the practice of immunizations. Active immunization with a vaccine or toxoid induces the host's immune system to confer protection against a

pathogen (e.g., hepatitis A, hepatitis B, diphtheria toxoid). This process requires the uptake of the immunogenic epitope by APCs, followed by presentation to CD4⁺ T lymphocytes and subsequent development of either a cellular or humoral immune response.

In contrast to active immunization, passive immunity entails the administration of human immunoglobulin to provide short-term protection to individuals who will be or have been exposed to a pathogen. Intravenous immunoglobulin (IVIG) consists of >90% polyclonal IgG that is prepared from donated plasma. In patients with primary or secondary hypogammaglobulinemia, IVIG restores circulating IgG concentrations, thus decreasing the incidence of infections in these patients. In addition to restoring IgG concentrations, IVIG can potentially immunomodulate the immune response. For example, in idiopathic thrombocytopenic purpura, an autoantibody directed against platelets leads to destruction of the platelets by antibody-dependent cellular cytotoxicity. IVIG saturates the Fc receptors on phagocytic cells, preventing the engulfment of autoantibody-opsonized platelets. IVIG also can contain antiidiotype antibodies to immunomodulate an immune response. Antiidiotype antibodies are directed against the idiotype or hypervariable region of a native antibody. After administration of IVIG, the antiidiotypes bind to the hypervariable region of the autoantibody and prevent the autoantibody from opsonizing circulating platelets. In addition, the antiidiotypes directed against the autoantibody can bind to the surface immunoglobulin on the B lymphocyte producing the autoantibody that leads to destruction of the B lymphocyte.⁴⁸

SUMMARY

Our understanding of the immune system has increased dramatically over the last decade. An immune response encompasses dynamic events involving both immunologic cells (e.g., phagocytes, lymphocytes) and soluble mediators (e.g., complement, cytokines, antibodies). A better understanding of the normal immune response allows us to investigate the pathophysiology of diseases in which the immune response is inappropriate. All clinicians need a basic understanding of the immune system and a familiarity with parameters to monitor immune system function in order to refine the development of immunologic treatments for diseases ranging from diabetes mellitus to collagen vascular disorders to cancer.

JEFFREY C. DELAFUENTE AND KIMBERLY A. CAPPUZZO

KEY CONCEPTS

- 1 Systemic lupus erythematosus (SLE) is a disease that predominantly occurs in women.
- 2 The hallmark of SLE is the development of autoantibodies to cellular nuclear components, resulting in chronic inflammatory autoimmune disease. Symptoms and organ involvement depend on the nature of the autoantibodies.
- 3 SLE has a large spectrum of symptoms and organ system involvement, making therapy highly patient specific. In addition, the signs and symptoms will fluctuate over time.
- 4 The large spectrum of symptoms and organ system involvement makes pharmacotherapy difficult because therapy must be individualized based on each patient's disease activity.
- 5 There is a paucity of quality evidence for the treatment of SLE except for lupus nephritis.
- 6 Almost all classes of medications, including antiinflammatory and immunosuppressive agents, are reported to cause vasculitis in most major organ systems.

The collagen-vascular diseases are a heterogeneous group of diseases that can involve the musculoskeletal system, integument, and blood vessels. Each collagen-vascular disease has its own set of diagnostic criteria, although diagnosis can be difficult because of overlapping and nonspecific clinical presentations. The etiology of the various collagen-vascular diseases is often unknown, but the immune system usually is involved in the pathogenesis and manifestations of the disease. Therefore, pharmacotherapy usually includes antiinflammatory agents with or without immunosuppressive drugs.

Although the prevalence of other collagen-vascular diseases may be greater than that of systemic lupus erythematosus (SLE) (e.g., polymyalgia rheumatica), SLE is discussed most extensively in this chapter because it is a major collagen-vascular disease with numerous clinical manifestations, its pharmacotherapy can be complex, and a plethora of data is available on the therapy of SLE. As all the diseases discussed in this chapter have an immune-mediated pathogenesis, the therapeutic principles of SLE can be applied to other autoimmune collagen-vascular diseases. The collagen-vascular diseases discussed include systemic sclerosis, polymyositis/dermato-

myositis, polymyalgia rheumatica, and drug-induced vasculitis; these were chosen because they are seen in general practice.

SYSTEMIC LUPUS ERYTHEMATOSUS

SLE is a fluctuating multisystem disease with a diversity of clinical presentations. Abnormal immunologic function and formation of antibodies against “self” antigens underlie the pathogenesis of SLE.

The term *lupus erythemateux* was first used in 1851 by Cazenave, a Frenchman who described an illness in a patient with manifestations occurring in the skin. It is not surprising that SLE was first recognized as a skin disorder because cutaneous manifestations constitute one of the most common clinical features of the disease. Further descriptions by Kaposi in 1872 and Osler in 1895 led to the concept of a multisystem disease as it became recognized that patients developed complications in other organ systems.^{1,2}

The hallmark of SLE is the development of autoantibodies to cellular nuclear components that leads to a chronic inflammatory autoimmune disease. Recognition of SLE as an autoimmune disease of multisystemic nature led the American College of Rheumatology to develop criteria for identifying lupus patients (Table 90–1). These criteria were developed in 1971, revised in 1982, and modified slightly in 1997. The criteria do not include all the clinical manifestations of the disease and are used primarily for distinguishing SLE from other collagen-vascular diseases.³ If 4 or more of the 11 criteria are documented at any time in a patient's medical history, the diagnosis of SLE can be made with approximately 95% specificity and 85% sensitivity.⁴ Although these criteria may be helpful, diagnosis requires additional serologic, immunopathologic, and clinical evaluations.

EPIDEMIOLOGY

- 1 The incidence of SLE varies among ethnic groups with the annual incidence in adults ranging from 1.9 to 5.6 per 100,000 persons per year, with a prevalence of 124 cases per 100,000 persons.^{5,6} The disease occurs predominantly in women, with a reported female-to-male ratio approaching 10:1. Those afflicted with SLE are usually diagnosed between the ages of 15 and 45.^{7,8} SLE is reported to be less prevalent in whites than in other ethnic groups, including blacks, Hispanics, Native Americans, and Asians.^{7,8} Although the most typical SLE patient is a young adult woman, the disease can occur in people of any age or race and either gender.

ETIOLOGY

The etiology of abnormal autoantibody production and development of SLE is still unknown. Genetic, environmental, and hormonal factors all may play a role in loss of “self” tolerance and expression of disease. A popular theory is that autoimmune disease such as SLE

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

TABLE 90-1 Revised Criteria for Classification of Systemic Lupus Erythematosus^a

Criterion	Definition
Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds
Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observations
Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by a physician
Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
Serositis	Pleuritis—convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion or Pericarditis—documented by electrocardiogram or rub or evidence of pericardial effusion
Renal disorder	Persistent proteinuria greater than 0.5 g/day or greater than 3+ if quantitation not performed or Cellular casts—may be red cell, hemoglobin, granular, tubular, or mixed
Neurologic disorder	Seizures—in the absence of offending drugs or known metabolic derangements, e.g., uremia, ketoacidosis, or electrolyte imbalance or Psychosis—in the absence of offending drugs or known metabolic derangements, e.g., uremia, ketoacidosis, or electrolyte imbalance
Hematologic disorder	Hemolytic anemia—with reticulocytosis or Leukopenia—fewer than 4,000/mm ³ total on two or more occasions or Lymphopenia—fewer than 1,500/mm ³ on two or more occasions or Thrombocytopenia—fewer than 100,000/mm ³ in the absence of offending drugs
Immunologic disorder	Anti-DNA; antibody to native DNA in abnormal titer or Anti-Smith (Sm) antigen; presence of antibody to Sm nuclear antigen or Positive finding of antiphospholipid antibodies based on (a) an abnormal serum level of immunoglobulin (Ig)G or IgM anticardiolipin antibodies, (b) a positive test result for lupus anticoagulant using a standard method, or (c) a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by <i>Treponema pallidum</i> immobilization or fluorescent treponemal antibody absorption test
Antinuclear	An abnormal titer of antinuclear antibody by immunofluorescence or an antibody equivalent assay at any point in time in the absence of drugs known to be associated with “drug-induced lupus” syndrome

^aThe proposed classification is based on 11 criteria. For the purpose of identifying patients in clinical studies, a person shall be said to have systemic lupus erythematosus if any 4 or more of the 11 criteria are present, serially or simultaneously, during any interval of observation.

From Tan EM, Cohen AS, Fries JF, et al. The 1982 revised criteria for the classification of systemic lupus erythematosus. *Arthritis Rheum* 1982;25:1274; and Hochberg MC. Updating the American College of Rheumatology Revised Criteria for the Classification of Systemic Lupus Erythematosus. *Arthritis Rheum* 1997;40:1725, with permission.

develops in genetically susceptible individuals after exposure to a triggering agent, possibly something in the environment.^{8–10}

Genetic analysis shows that at least four susceptibility genes are required for the expression of lupus in humans.¹⁰ Familial and twin studies indicate a genetic predisposition for the development of SLE. First-degree relatives of SLE patients are about 20 times more likely to develop SLE than the general population; more than 5% of cases are familial. The concordance rate among identical twins

ranges from 24% to 58%, compared with 3% to 10% for nonidentical twins.¹¹ Multiple genes contribute to SLE susceptibility, and at least 100 genes have been linked to SLE in humans. Evidence indicates that major histocompatibility complex genes, particularly several human leukocyte antigen genes, may be important in lupus. However, nonmajor histocompatibility complex genes, such as immunoglobulin receptor genes and mannose-binding protein genes, also may contribute to disease susceptibility.^{10,11} Environmental agents that may induce or activate SLE include sunlight (i.e., ultraviolet light), drugs, chemicals such as hydrazine (found in tobacco) and aromatic amines (found in hair dyes), diet, environmental estrogens, and infection with viruses or bacteria.¹⁰ A number of viruses have been implicated as causative agents in genetically susceptible people, but much of the evidence is circumstantial.¹² Additionally, androgen may inhibit and estrogen may enhance the expression of autoimmunity, and elevated circulating prolactin levels have been associated with lupus in males and females.^{10,13}

PATHOPHYSIOLOGY

2 SLE represents a clinical syndrome rather than a discrete disease with a unique pathogenesis.¹⁴ SLE has a large spectrum of symptoms and organ system involvement. A major event in the development of SLE is excessive and abnormal autoantibody production and the formation of immune complexes. Patients may develop autoantibodies against multiple nuclear, cytoplasmic, and surface components of multiple types of cells in various organ systems in addition to soluble markers such as immunoglobulin G and coagulation factors; these autoantibodies account for the multiple-organ system involvement of the disease.¹⁰

Excessive autoantibody production results from hyperactive B lymphocytes. Multiple mechanisms likely lead to B-cell hyperactivity, including loss of immune “self” tolerance and high antigenic load consisting of environmental and self antigens presented to B cells by other B cells or specific antigen-presenting cells, a shift of T-helper type 1 cells to T-helper type 2 cells that further enhance B-cell antibody production, and defective B-cell suppression. Impairment in other immune regulatory processes involving T lymphocytes (suppressor T cells), cytokines (e.g., interleukins, interferon- γ tumor necrosis factor- α , transforming growth factor- β), and natural killer cells also may be involved.^{10,15}

Many autoantibodies are directed against nuclear constituents of the cell; collectively, they are called *antinuclear antibodies*. Several antinuclear antibodies are important because their presence or absence may aid in the diagnostic and clinical evaluation of patients with SLE. The SLE patient may have more than one antigen-specific antinuclear antibody in the patient’s serum and tissues.¹⁶ These are antibodies against such nuclear constituents as double-stranded, or native, DNA (dsDNA); single-stranded, or denatured, DNA (ssDNA); and RNA. Four RNA-associated antigens frequently occurring in SLE are the Smith (Sm) antigen, the small nuclear ribonucleoprotein (snRNP), the Ro (SS-A) antigen, and the La (SS-B) antigen.^{17,18} Histone, a basic component of chromatin and nucleosomes, is another important nuclear component against which antinuclear antibodies are formed in lupus patients. Antibodies to Ro, La, Sm, or RNP antigens plus antibodies to dsDNA will detect most patients with SLE.¹⁷ Antibodies also may be directed against the phospholipid moiety of the prothrombin activator complex (lupus anticoagulant) and against cardiolipin. The lupus anticoagulant and anticardiolipin antibodies constitute the two main types in a group of autoantibodies called *antiphospholipid antibodies*.

These autoantibodies often are present many years before the diagnosis of SLE.¹⁹ The appearance of these autoantibodies follows a predictable pattern, with accumulation of specific autoantibodies before the onset of clinical illness. For example, antinuclear, anti-La,

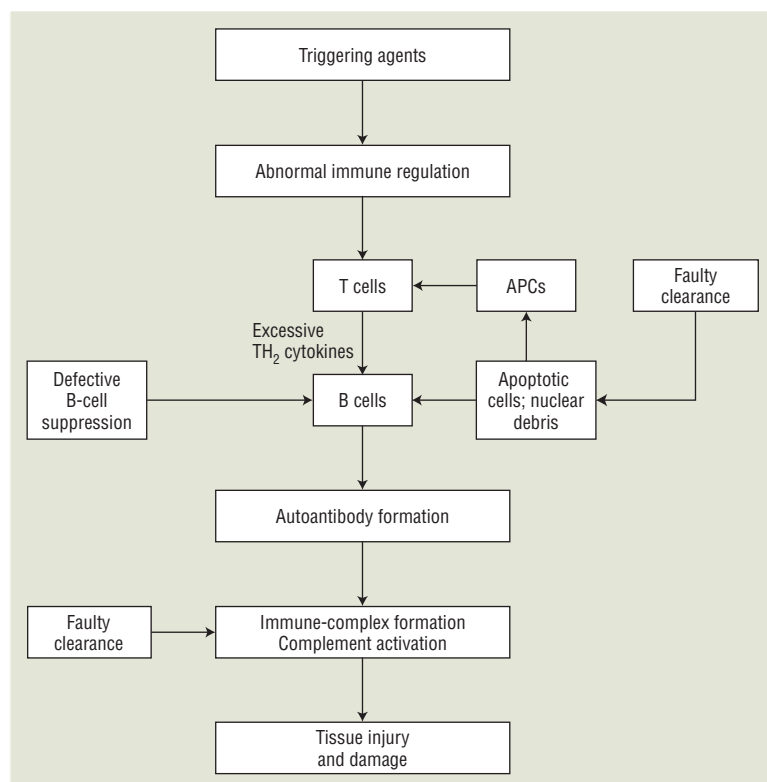

FIGURE 90-1. Pathogenesis of systemic lupus erythematosus. Environmental factors, such as infectious organisms, drugs, and chemicals, serve as triggering agents in genetically and hormonally susceptible individuals to induce a state of immune dysregulation. These abnormal immune responses lead to hyperactive T-helper type 2 lymphocyte and B-lymphocyte function. Suppressor T-lymphocyte function, cytokine production, faulty clearance mechanisms, and other immune regulatory mechanisms also are abnormal and fail to downregulate autoantibody formation from hyperactive B lymphocytes. The autoantibodies formed from this immune dysregulation become pathogenic, form immune complexes, and activate complement that leads to damage of host tissue. (APCs, antigen-presenting cells; TH₂, T-helper type 2.)

anti-Ro, and antiphospholipid antibodies often precede the onset of SLE by many years, whereas anti-Sm and anti-snRNP antibodies appear only months before diagnosis, usually when clinical symptoms begin to manifest.

Immune dysregulation leading to B-cell hyperactivity and subsequent production of pathogenic autoantibodies, coupled with defective clearance of apoptotic cells, followed by immune-complex formation, complement activation, and defective clearance of immune complexes all lead to inflammatory reactions that ultimately result in tissue injury and damage. Figure 90-1 is an overview of the pathogenesis of SLE.¹⁰

CLINICAL PRESENTATION

3 As mentioned previously, SLE is a multisystem disease. Below are many of the signs and symptoms and incidences in patients with SLE.^{20–22} Although certain of these may be more common than others, each patient presents differently, and the course of the disease is highly unpredictable. Furthermore, SLE is not static, and most patients have fluctuations or flare-ups during the course of the disease.

CLINICAL PRESENTATION OF SYSTEMIC LUPUS ERYTHEMATOSUS

Sign/Symptom	Incidence (%)
■ Musculoskeletal	
Arthritis and arthralgia	53–95
■ Constitutional	
Fatigue	81
Fever	41–86
Weight loss	31–71
■ Mucocutaneous	55–85
Butterfly rash	10–61
Photosensitivity	11–45

Raynaud's phenomenon	10–44
Discoid lesions	9–29
■ Central nervous system	13–59
Psychosis	5–37
Seizures	6–26
■ Pulmonary	
Pleuritis	31–57
Pleural effusion	12–40
■ Cardiovascular	
Pericarditis	2–45
Myocarditis	3–40
Heart murmur	1–44
Hypertension	23–46
■ Renal	13–65
■ Gastrointestinal	
Nausea	7–53
Abdominal pain	8–34
Bowel hemorrhage (vasculitis)	1–6
■ Hematologic	
Anemia	30–78
Leukopenia	35–66
Thrombocytopenia	7–30
■ Lymphadenopathy	10–59

Nonspecific signs and symptoms such as fatigue, fever, anorexia, and weight loss are seen frequently in patients with active disease. Musculoskeletal involvement (e.g., arthralgia, myalgia, and arthritis) is very common in SLE,^{20,22,23} with arthritis and arthralgia frequently the chief complaint on initial presentation of the disease.²² All major and minor joints may be affected, and the pattern of arthritis is often

recurrent and of short duration, presenting mainly as joint stiffness, pain, and sometimes inflammation.²⁴ Objective evidence of musculoskeletal disease often is missing, although a few patients may present with deforming arthritis or subcutaneous nodules.

Manifestations in the skin are nearly as common as those involving the musculoskeletal system.^{2,20,22} The most well known of these is the butterfly rash, which occurs over the bridge of the nose and the malar eminences. The classic butterfly rash is seen in about one-half of patients and often is observed after sun exposure. In fact, photosensitivity is common to many SLE patients who present with cutaneous manifestations. Skin lesions characteristic of discoid lupus occur in 10% to 20% of patients with SLE and may occur without other clinical or serologic evidence of lupus.^{20,21,25} Some individuals are said to develop *subacute cutaneous lupus erythematosus*, the nature of whose lesions falls between discoid (one type of *chronic cutaneous lupus erythematosus*) and the butterfly rash (an example of *acute cutaneous lupus erythematosus*).²⁵ Other cutaneous manifestations include vasculitis (which may be ulcerative), livedo reticularis, periungual erythema, Raynaud's phenomenon, and alopecia.^{2,22}

Another common source of symptomatology in SLE is the pulmonary system, with manifestations such as pleurisy, coughing, and dyspnea. Pleurisy may present as pleuritic pain, a pleural rub, or a pleural effusion that usually is exudative in nature. Lupus pneumonitis may present acutely with fever, dyspnea, tachypnea, cough, rales, and patchy infiltrates or chronically with interstitial fibrosis. Lupus pneumonitis is an uncommon manifestation of SLE and can be difficult to distinguish from infectious pneumonia, which is more common in SLE patients and should be the primary consideration when evaluating new pulmonary infiltrates.²⁶ Pulmonary hypertension associated with SLE is more common than previously thought, which is likely a result of asymptomatic increases in pulmonary artery pressures being more common than symptomatic increases. Patients with SLE-associated pulmonary hypertension have a poor prognosis. Pulmonary embolism also should be ruled out in any SLE patient presenting with pleuritic chest pain and dyspnea.

Cardiac manifestations of SLE often present as pericarditis, myocarditis, electrocardiographic changes, or valvular heart disease, including the classic cardiac lesion of Libman-Sacks endocarditis (nonbacterial verrucous endocarditis).²⁶ Coronary artery disease (CAD) is being seen in SLE with increasing frequency as the life expectancy of SLE patients increases.²⁷ The development of heart disease in these patients is probably multifactorial, and traditional CAD risk factors are common in patients with SLE.

Corticosteroid therapy and underlying renal disease are also believed to be contributing factors in the development of these cardiac risk factors.²⁶ Although hypertension, obesity, and hyperlipidemia are common in SLE patients, these traditional risk factors do not account for the strikingly high cardiovascular event rate found in some recent studies.^{28,29} Other SLE-related risk factors highlight the importance of autoimmunity and inflammation in the pathogenesis of accelerated atherosclerotic cardiovascular disease.^{29,30} Additionally, two studies reported that long-term corticosteroid therapy was not associated with a significantly increased risk of accelerated atherosclerosis.^{31,32} In fact, one of the studies³¹ found that patients with higher mean daily doses of prednisone and more frequent use of other common therapies for SLE exhibited less plaque formation, which suggests that more aggressive control of disease activity actually may help to prevent CAD.^{30,31}

CLINICAL CONTROVERSY

Some research suggests that long-term corticosteroid therapy is responsible for the increased incidence of coronary heart disease, whereas other data suggest that it has no effect on atherosclerosis.

Neuropsychiatric manifestations of SLE may present in many ways, including headaches, psychosis, depression, anxiety, seizure, stroke, peripheral neuropathy, cognitive impairment, and others.⁵ Cognitive dysfunction is observed in 12% to 87% of patients with SLE. Depression and anxiety are common among SLE patients, but it is unclear if they are direct manifestations of central nervous system (CNS) involvement or secondary to the distress of living with a chronic illness.³³

Symptoms associated with gastrointestinal manifestations often are nonspecific for lupus and include dyspepsia, abdominal pain, nausea, and difficulty swallowing. Mesenteric vasculitis and venous occlusion owing to thrombosis may be problematic if not diagnosed and treated promptly. Hepatitis and pancreatitis also may be present and may be secondary to drugs used to treat SLE or the disease itself.³⁴

Anemia is found in many patients with SLE. It is usually an anemia of chronic inflammation, with a mild normochromic, normocytic smear and low serum iron concentration but adequate iron stores. Some patients may develop a hemolytic anemia with a positive Coombs test.³⁵ Leukopenia, usually mild, is present in about half of SLE patients. Both granulocytes and lymphocytes may be affected, but there is usually a larger decrease in lymphocytes.^{2,22} Thrombocytopenia may occur in SLE, often during disease exacerbation, but is usually mild and does not increase bleeding tendency.³⁵ Another significant finding associated with SLE is the presence of antiphospholipid antibodies such as the lupus anticoagulant and anticardiolipin antibodies. Although the lupus anticoagulant is directed against the prothrombin activator complex and implies potential bleeding complications, this is not the case. In fact, the presence of lupus anticoagulant, anticardiolipin, or other antiphospholipid antibodies may be associated with thrombosis, neurologic disease, thrombocytopenia, and fetal loss.^{23,36} Thrombotic events occur in more than 10% of patients with SLE.³⁶ Not all patients with antiphospholipid syndrome have lupus. If a patient has no concomitant autoimmune disease, the syndrome is *primary*. If a patient has accompanying SLE, the syndrome is *secondary*.^{37,38}

Clinical evidence of renal involvement, such as a rising serum creatinine or proteinuria level, generally is associated with a poorer outcome compared with patients without renal involvement. Progression to end-stage renal disease is a major cause of morbidity and mortality in SLE. However, the extent and course of renal disease are quite variable, and many lupus nephritis patients do very well. The World Health Organization has classified lupus nephritis on the basis of histologic characteristics observed following renal biopsy. A revision of this system by the International Society of Nephrology and Renal Pathology Society recommends modifying the lupus nephritis classifications as minimal mesangial (class I), mesangial proliferative (class II), focal (class III), diffuse (class IV), membranous (class V), and advanced sclerosing (class VI).³⁹ Many patients progress from one form of nephritis to another during the course of the disease. Predictors of poorer outcome in lupus nephritis include African American race, increased serum creatinine level, poor initial response to immunosuppressive drugs, hypertension, and persistent nephrotic syndrome.⁴⁰

DIAGNOSIS

As mentioned earlier, the diagnostic criteria listed in Table 90–1 should not be the primary means for diagnosing SLE, although many of the criteria may be valuable in the diagnostic process. Epidemiologic characteristics, clinical signs and symptoms, and common laboratory abnormalities all are used in the diagnosis of SLE.

Once the disease is suspected, serologic tests may be helpful in making the diagnosis. A serologic test used extensively to aid in the diagnosis of SLE is the fluorescent antinuclear antibody (ANA) test. Nearly all SLE patients are ANA-positive, but other diseases also can be associated with

TABLE 90-2 Antinuclear Antibody Test: Patterns, Antigens, and Specificities

Pattern	Antigen	Disease
Peripheral Speckled	dsDNA	SLE
	Acidic nuclear protein	Rheumatoid arthritis
	Ribonucleoprotein	SLE
	Extractable nuclear antigen	Scleroderma; mixed connective tissue disease
Homogeneous	dsDNA, ssDNA	Rheumatoid arthritis
	Histones	SLE; drug-induced lupus
Nucleolar	Nucleolar RNA	Progressive systemic sclerosis

ds, double-stranded; SLE, systemic lupus erythematosus; ss, single-stranded.

a positive test (Table 90–2). However, in other diseases, many of the positive ANA tests are of a lower titer. The pattern of immunofluorescence of the ANA test also may be of diagnostic value (Table 90–2), with a peripheral (also called *rim*) pattern being specific for SLE. Detecting antibodies to specific nuclear constituents also may be useful diagnostically. Antibodies to native DNA (dsDNA) and to Sm antigen are quite specific for and are considered diagnostic of SLE.^{10,17,41,42}

PROGNOSIS

In earlier years, SLE was associated with a poor prognosis. For example, three decades ago 5-year survival was approximately 83% and 76% at 10 years.⁵ Today, as a result of improved treatment and improved diagnostic techniques that allow earlier diagnosis, the 5-year survival rate exceeds 96%, and 20-year survival rates approach 70%.^{43,44} The natural course of SLE has changed dramatically not only because of improved therapies but also because of improvement in ability to manage patients with kidney disease (e.g., dialysis), infection, and CAD.^{40,44,45} However, CAD and infection are still among the leading causes of death among SLE patients.

TREATMENT

Systemic Lupus Erythematosus

Desired treatment outcomes for the patient with SLE are twofold: (a) management of symptoms and induction of remission during times of disease flare and (b) maintenance of remission for as long as possible between disease flares. Figure 90–2 outlines an approach to the management of the patient with SLE. Because of the variability in clinical presentation of disease, treatment will vary accordingly and should be highly individualized. Optimal care of the patient with SLE will include education and support services in addition to the nonpharmacologic and pharmacologic treatments discussed below. Numerous lupus organizations exist throughout the world and can be located by contacting the Lupus Foundation of America⁴⁶ (www.lupus.org), the Arthritis Foundation⁴⁷ (www.arthritis.org), and Lupus Canada⁴⁸ (www.lupuscanada.org).

■ NONPHARMACOLOGIC THERAPY

Several nonpharmacologic measures can be employed to manage symptoms and help maintain remission. Fatigue is a common symptom in patients with lupus.⁴³ A balanced routine of rest and exercise, while avoiding overexertion, is essential in managing fatigue.⁴⁹ Avoidance of smoking may be particularly important because hydrazines in tobacco smoke may be an environmental trigger of lupus and likely contribute to accelerated CAD.¹⁰ Smoking also has been associated with increased disease activity in SLE patients.⁵⁰ No specific dietary measures are known to clearly affect the clinical course of lupus. However, fish-oil derivatives might prevent miscarriages in pregnant women with antiphospholipid antibodies,⁵¹ but alfalfa sprouts should be avoided because they contain the amino acid L-canavanine, which has been linked to the development of lupus-like symptoms in

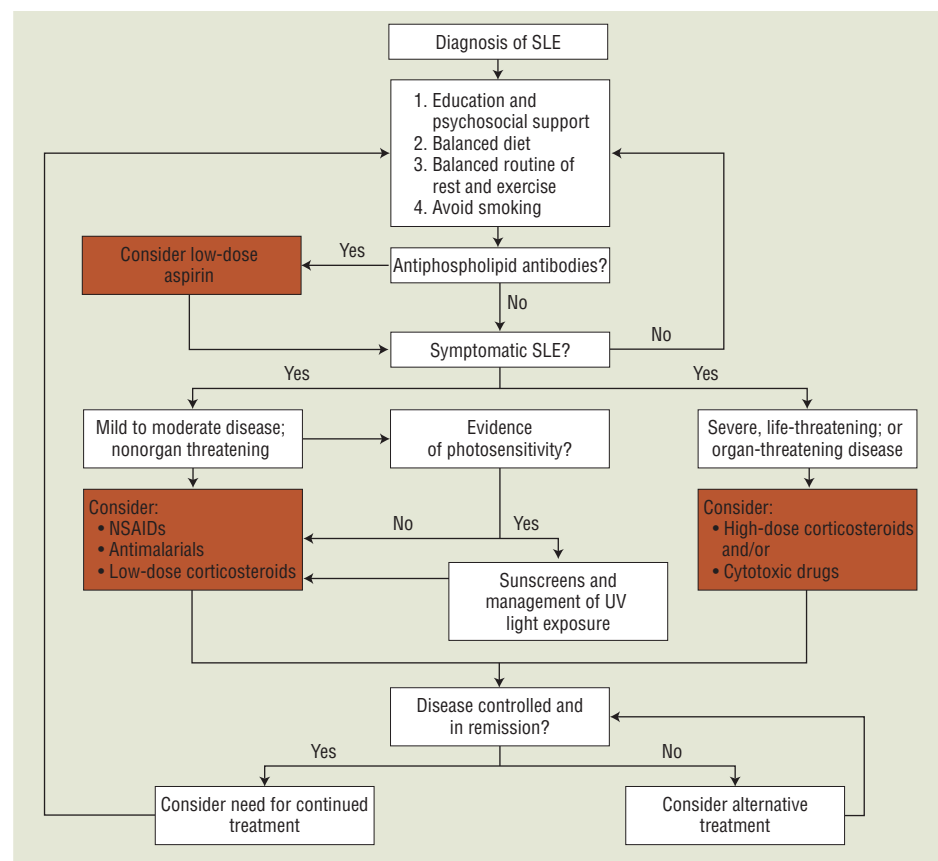

FIGURE 90-2. General approach to the management of systemic lupus erythematosus (SLE). (NSAIDs, nonsteroidal anti-inflammatory drugs; UV, ultraviolet.)

TABLE 90-3 Drug Treatment of Systemic Lupus Erythematosus

Drug Class	Drug and Dose	Indication
NSAID	Various agents Antiinflammatory dose	Mild disease: fever, arthritis, skin rash, serositis
Antimalarial	Hydroxychloroquine 200–400 mg po daily Chloroquine 250–500 mg po daily	Mild disease: arthritis, skin rash, serositis
Corticosteroid	Prednisone 1–2 mg/kg/day po (or equivalent) <1 mg/kg/day (or equivalent)	Initial control of severe disease Control of mild disease or maintenance after disease suppression with higher doses
	Methylprednisolone 500–1,000 mg IV daily × 3–6 day	Life-threatening disease
Cytotoxic	Cyclophosphamide 0.5–1 g/m ² IV monthly for 6 months; then every 3 months for 2 years or for 1 year after remission Azathioprine 1–3 mg/kg po daily Cyclophosphamide 1–3 mg/kg po daily Mycophenolate mofetil 1–3 g po daily	Most commonly used in severe lupus nephritis; may be necessary for other severe disease manifestations

IV, intravenously; NSAID, nonsteroidal antiinflammatory drugs; po, orally.

numerous case reports.¹⁰ Many patients with SLE will need to limit exposure to sunlight and use sunscreens to block the possible exacerbating effects of ultraviolet light.⁵¹ The amount of sunlight exposure limitation should be individualized.

■ PHARMACOLOGIC THERAPY

5 Drug therapy for SLE is often designed to suppress the immune response and inflammation. Except for lupus nephritis, large controlled clinical trials comparing treatment options for SLE are needed. Table 90–3 lists common agents and doses used to control

SLE. In general, the choice of drug therapy depends on the extent and severity of disease. Table 90–4 describes selected monitoring parameters and adverse events for many of the drugs used to treat collagen-vascular diseases.

Nonsteroidal Antiinflammatory Drugs

As discussed earlier, signs and symptoms such as fever, arthritis, and serositis are among the most common in patients with active disease. Therefore, in many patients with mild disease, initial treatment with a nonsteroidal antiinflammatory drug (NSAID) is a logical choice. The choice of NSAIDs in SLE is empirical. The dose used should be adequate to provide antiinflammatory effects, although low-dose aspirin may be useful in the management of patients with antiphospholipid syndrome.³⁶

Nonselective cyclooxygenase NSAIDs significantly increase the risk of gastric irritation and peptic ulceration. Coprescribing with a gastroprotective agent such as a proton pump inhibitor may be beneficial.³⁸ Patients with SLE taking NSAIDs may experience a decline in renal function because of drug effects and not the underlying disease. NSAIDs can decrease renal blood flow and glomerular filtration rates, and should be used cautiously in patients with nephritis. Awareness of this adverse effect is important because declining renal function may be attributed mistakenly to progression of lupus nephritis. Patients with SLE have a higher incidence of hepatotoxicity than do other patients taking traditional NSAIDs. The use of NSAIDs is also associated with aseptic meningitis in SLE patients.^{4,23,51}

Antimalarial Drugs

Antimalarial agents such as chloroquine and hydroxychloroquine have been used successfully in the management of discoid lupus and SLE. A few controlled trials provide evidence for the role of antimalarial therapy in controlling disease exacerbations and as steroid-sparing agents.⁵⁴ In general, the manifestations of SLE that can be managed with antimalarials are cutaneous manifestations, arthralgia,

TABLE 90-4 Monitoring Adverse Effects of Drugs Commonly Used in Systemic Lupus Erythematosus

Drug	Toxicities to Monitor	Baseline Evaluation	Monitoring	
			System Review	Laboratory
Salicylates, NSAIDs	Gastrointestinal bleeding, hepatic toxicity, renal toxicity, hypertension	CBC, creatinine, urinalysis, AST, ALT	Dark/black stool, dyspepsia, nausea/vomiting, abdominal pain, shortness of breath, edema	CBC yearly, creatinine yearly
Corticosteroids	Hypertension, hyperglycemia, hyperlipidemia, hypokalemia, osteoporosis, avascular necrosis, cataract, weight gain, infections, fluid retention	Blood pressure, bone densitometry, glucose, potassium, cholesterol, triglycerides (HDL, LDL)	Polyuria, polydipsia, edema, shortness of breath, blood pressure, visual changes, bone pain	Glucose every 3–6 months, total cholesterol yearly, bone densitometry yearly to assess osteoporosis
Hydroxychloroquine	Macular damage	None unless patient is older than 40 years of age or has previous eye disease	Visual changes	Funduscopy and visual fields every 6–12 months
Azathioprine	Myelosuppression, hepatotoxicity, lymphoproliferative disorders	CBC, platelet count, creatinine, AST or ALT	Symptoms of myelosuppression	CBC and platelet count every 1–2 weeks with changes in dose (every 1–3 months thereafter), AST yearly, Pap test at regular intervals
Cyclophosphamide	Myelosuppression, myeloproliferative disorders, malignancy, immunosuppression, hemorrhagic cystitis, secondary infertility	CBC and differential and platelet count, urinalysis	Symptoms of myelosuppression, hematuria, infertility	CBC and urinalysis monthly, urine cytology and Pap test yearly for life
Mycophenolate mofetil	Myelosuppression, hepatotoxicity, lymphoproliferative disorders, malignancy	CBC, hepatic function tests, renal function tests	Symptoms of myelosuppression, diarrhea, nausea/vomiting, dyspepsia, abdominal pain, dark/black stool or blood in stool	CBC weekly during first month, twice monthly during the second and third months, then monthly through the first year

ALT, alanine transaminase; AST, aspartate transaminase; CBC, complete blood count; HDL, high-density lipoprotein; LDL, low-density lipoprotein; NSAIDs, nonsteroidal anti-inflammatory drugs; Pap, papanicolaou. Modified from American College of Rheumatology Ad Hoc Committee on Systemic Lupus Erythematosus Guidelines. Guidelines for referral and management of systemic lupus erythematosus in adults. *Arthritis Rheum* 1999;42:1790, with permission. Other references 23, 52, and 53.

pleuritis, mild pericardial inflammation, fatigue, and leukopenia.^{23,38} Because these drugs are not effective immediately, they are best used in long-term management. Response to chloroquine occurs within 1 to 3 months, whereas the maximal effect of hydroxychloroquine may not occur for 3 to 6 months.²⁵ Hydroxychloroquine is probably safer than chloroquine and is considered the antimalarial of first choice.

The mechanism of action of the antimalarial drugs is uncertain. It has been proposed that antimalarials interfere with T-lymphocyte activation.²³ Other effects of antimalarials that may benefit patients with SLE include inhibition of cytokines, decreased sensitivity to ultraviolet light, antiinflammatory activity, antiplatelet effects, and antihyperlipidemic activity.^{23,30}

Dosage and duration of therapy depend on patient response, tolerance of side effects, and development of retinal toxicity, which is a potentially irreversible adverse reaction associated with long-term therapy, especially with chloroquine. Current recommended doses of antimalarials in SLE are hydroxychloroquine 200 to 400 mg/day and chloroquine 250 to 500 mg/day. After 1 or 2 years of treatment, gradual tapering of dosage can be attempted. Some patients may require only 1 or 2 tablets per week to suppress cutaneous manifestations.^{23,55}

Side effects of these drugs include CNS effects (e.g., headache, nervousness, insomnia, and others), rashes, dermatitis, pigmentary changes of the skin and hair, gastrointestinal disturbance (e.g., nausea), and reversible ocular toxicities such as cycloplegia and corneal deposits. Potentially serious retinal toxicity is uncommon when the currently recommended doses are used and is least common with hydroxychloroquine.⁵⁶ However, because of the possibility of permanent damage associated with the retinopathy, an ophthalmologic evaluation should be done at baseline and every 3 months when chloroquine is used and every 6 to 12 months when hydroxychloroquine is used. If retinal abnormalities are noted, antimalarial therapy should be discontinued or the dose reduced.²³

Corticosteroids

Corticosteroid therapy is commonplace in therapeutic regimens for SLE. Although evidence for improved survival with corticosteroid therapy is inadequate, these agents are known to suppress the clinical expression of disease and are considered by many to be a major factor in the improved prognosis in recent years. Most controlled trials of corticosteroid therapy have been conducted in patients with severe lupus nephritis, but evidence suggests that corticosteroids are also effective in the management of severe cases of CNS disease, pneumonitis, polyserositis, vasculitis, thrombocytopenia, and other clinical manifestations.²³

A patient with the diagnosis of SLE does not automatically require corticosteroid therapy. Mild disease with such manifestations as fever, arthralgia, pleuritis, or skin manifestations may respond adequately to NSAIDs or antimalarials, but patients with clinical manifestations that are more serious or unresponsive to other drugs usually require corticosteroids. Some patients with lupus dermatitis may benefit from topical or intralesional administration of corticosteroids.²³

The goal of treatment with corticosteroids in SLE is to suppress and maintain suppression of active disease with the lowest dose possible. In patients with mild disease, low-dose therapy (prednisone 10 to 20 mg/day) is adequate,^{38,42} but in patients with more severe disease (severe hemolytic anemia or cardiac involvement), higher doses, such as prednisone 1 to 2 mg/kg daily, may be required. Once adequate suppression of disease is achieved, the dose should be tapered to the minimum amount required for continued disease suppression. When analyzing the need to treat with corticosteroids, the clinician should consider other conditions that may increase the risk of corticosteroid therapy, such as infection, hypertension, atherosclerotic disease, diabetes, obesity, osteoporosis, and psychiatric disease.^{4,23,38}

Steroid pulse therapy is the administration of short-term, high-dose intravenous corticosteroids with the goal of inducing remission in SLE

patients with serious, life-threatening disease, such as severe active nephritis, CNS involvement, or hemolytic disease. A standard pulse regimen consists of intravenous methylprednisolone 500 to 1000 mg for 3 to 6 consecutive days. Pulse therapy usually is followed by high-dose prednisone (1 to 1.5 mg/kg per day) therapy that is tapered rapidly to low-dose maintenance therapy.²³ Potential advantages of pulse therapy over high-dose oral steroids include a quicker response and avoidance of side effects associated with the longer duration of therapy required with oral steroids. Although generally well tolerated, methylprednisolone pulse therapy may result in significant adverse effects, including infection, gastrointestinal disturbances, rapid increases in blood pressure, arrhythmias, seizures, and sudden death. Furthermore, there are insufficient data from controlled clinical trials to clearly define the role of pulse steroids in the management of SLE. Thus pulse therapy represents an alternative mode of treatment for patients with life-threatening disease or disease unresponsive to other pharmacotherapy.

Cytotoxic Drugs

A considerable amount of literature exists describing the use of cytotoxic and immunosuppressive drugs in SLE, although few of these are reports of controlled clinical trials. Included in this category are the alkylating agent cyclophosphamide and the antimetabolite azathioprine. These agents, usually used in combination with corticosteroids, have been the mainstays of immunosuppressive therapy. Although both are known to suppress and stabilize extrarenal disease activity, much of the evaluation of these agents has focused on lupus nephritis, a major factor associated with morbidity and mortality in SLE.

Evidence supporting the use of cyclophosphamide in lupus nephritis has been collected over the last several decades. Controlled clinical trials have shown that cyclophosphamide improves long-term outcomes in lupus nephritis.^{38,57,58} Based on controlled trials, combination prednisone and cyclophosphamide has become standard treatment for focal and diffuse proliferative lupus nephritis (World Health Organization classes III/IV) and is superior to prednisone alone.¹⁴ No studies have evaluated cyclophosphamide in earlier stages of nephritis (World Health Organization classes II/III), and therefore, corticosteroids remain the treatment of choice for these less severe forms of nephritis.⁵⁷ Pulse intravenous cyclophosphamide plus prednisone is more effective at slowing progression to end-stage renal disease than either prednisone alone or prednisone plus azathioprine.⁵⁹ Cyclophosphamide plus corticosteroids, the current standard of care, decreases the risk of developing end-stage renal failure requiring dialysis and renal transplantation.^{14,60} Intermittent pulse administration of intravenous cyclophosphamide is preferred over daily oral therapies because of reduced adverse effects. However, pulse cyclophosphamide plus prednisone is not always effective.

When used in combination with corticosteroids, cyclophosphamide is dosed at 1 to 3 mg/kg for oral therapy and 0.5 to 1 g/m² of body surface area for intravenous therapy. The most common route of cyclophosphamide administration is intravenous, although there is little evidence that this is better than oral administration.^{57,58} Likewise, there is no evidence to suggest the optimal duration of treatment. Based on empirical experience, cyclophosphamide generally is dosed monthly for 6 months and then every 3 months for a period of either 2 years or for 1 year after the nephritis is in remission.^{40,57,58} Of course, cyclophosphamide therapy is not without risk. Serious toxic effects include suppression of hematopoiesis, opportunistic infections, bladder complications (e.g., hemorrhagic cystitis and cancer), sterility, and teratogenesis. White blood cell counts must be monitored during cyclophosphamide therapy, and if the nadir is less than 1,500/mm³, the dose must be adjusted to keep the white cell count above 1,500/mm³. Nausea and vomiting associated with cyclophosphamide can be controlled with oral ondansetron plus dexamethasone.⁵⁷

Azathioprine can be used as a “steroid-sparing” agent, allowing for the reduction of corticosteroid doses.^{38,42} Azathioprine has not been studied as extensively as cyclophosphamide for lupus nephritis. Additionally, azathioprine is only slightly more effective than prednisone alone.⁴⁰ Azathioprine may be useful in treating early onset and less-severe nephritis.^{38,40} Long-term maintenance azathioprine therapy also may prevent renal flares after successful induction with cyclophosphamide.⁵⁸ Azathioprine is given orally in doses of 1 to 3 mg/kg per day, often in combination with corticosteroids for severe disease.²³ Azathioprine generally is less toxic than cyclophosphamide, but adverse reactions may be serious and include myelosuppression, opportunistic infections including herpes zoster, cancer, hepatotoxicity, and ovarian failure.

Cyclophosphamide often is administered intravenously in intermittent pulse doses to minimize toxicity. To decrease the risk of bladder toxicity, patients should be well hydrated with oral or intravenous fluids, and urinary output should be monitored. Mesna may be used to prevent hemorrhagic cystitis. Mesna is dosed at 20% of the total cyclophosphamide dose and is administered immediately before cyclophosphamide therapy and 3, 6, and 9 hours after therapy.⁶¹

Cyclophosphamide may be of benefit to some patients with other serious, refractory manifestations of lupus, including neurologic manifestations.⁶² Reports of the use of other cytotoxic drugs for lupus in recent years include methotrexate,²³ mycophenolate mofetil,^{6,23,38,58} mechlorethamine (nitrogen mustard), chlorambucil, and cyclosporine.^{6,23,38,58}

Because of the adverse effects of cyclophosphamide, other approaches to treating lupus nephritis have been attempted. Mycophenolate mofetil is an immunosuppressive agent that has become an established treatment of severe renal and nonrenal lupus refractory to conventional cytotoxic agents.^{38,58} Mycophenolate mofetil has been investigated as an alternative to cyclophosphamide for induction of remission. In an open-label trial, mycophenolate mofetil was more effective than standard cyclophosphamide therapy, achieving a higher rate of complete and partial remissions.⁶⁰ Prednisone was used in both treatment arms. Mycophenolate mofetil was also better tolerated. In this study, mycophenolate mofetil was initially dosed at 500 mg twice daily and was increased to 750 mg twice daily after 2 weeks; the dose continued to be increased weekly to a maximum of 1,000 mg three times daily. A larger study with longer followup is needed before any definitive conclusion can be drawn about the superiority of mycophenolate mofetil as induction therapy. Patients with the most severe forms of lupus nephritis should receive the standard boluses of intravenous cyclophosphamide plus corticosteroid therapy, but mycophenolate mofetil plus corticosteroid therapy may be a reasonable option for patients with mild-to-moderate nephritis and good renal function.⁶³

Alternatives to cyclophosphamide for maintenance therapy have also been studied. Following induction therapy with the standard cyclophosphamide protocol, patients were assigned to either intravenous cyclophosphamide, 0.5 to 1 g/m²; 1 to 3 mg/kg per day of oral azathioprine; or 500 to 3,000 mg of oral mycophenolate mofetil per day, with dose titrations. All groups received prednisone.⁶⁴ This open-label study showed that standard cyclophosphamide induction therapy followed by mycophenolate mofetil or azathioprine was more effective and better tolerated than standard cyclophosphamide bolus therapy. Although these data need to be interpreted cautiously because of study design limitations, azathioprine and mycophenolate mofetil are good options for maintenance therapy in lupus nephritis.⁶⁵

Cytotoxic therapy is useful in combination with corticosteroids, allowing for lower steroid doses and improved efficacy compared with steroids alone. However, cytotoxic therapy must be monitored closely for adverse effects, and maximum response may take 6 months or longer in some patients. No data from controlled trials are available to support the combination of two or more cytotoxic

agents; however, this approach has been used in patients refractory to standard therapies.^{14,57}

■ ALTERNATIVE AND EXPERIMENTAL TREATMENTS

As the pathogenesis of SLE continues to be elucidated, new and promising treatments are being developed. Table 90-5 lists several alternative treatments reportedly successful in managing various manifestations of SLE^{49,59,66-69}; however, many of these reports are uncontrolled trials. Furthermore, in addition to reports of success, the literature contains reports of unsuccessful or controversial treatments for many of these therapies (e.g., plasmapheresis or immunoglobulin for lupus nephritis). A number of newer agents are being evaluated and include various biologic therapies that interfere with immune response, ablative chemotherapy with hematopoietic stem cell transplantation, and combination chemotherapy.^{14,51,70,71}

■ SPECIAL POPULATIONS

Pregnancy

Pregnancy in SLE patients is associated with exacerbation of disease during pregnancy, exacerbation during the early postpartum period, a greater incidence of spontaneous abortion, and a greater chance of developing preeclampsia or pregnancy-induced hypertension (particularly in patients with nephritis).

Lupus flares during pregnancy are associated with prematurity. Whether there is an increased risk for lupus flares during pregnancy versus those who are not pregnant is controversial, but exacerbation of lupus during pregnancy seems to be less likely if the disease is in remission at conception.^{6,72,73} Disease exacerbations can be managed aggressively with corticosteroids, if needed, with little concern about harm to the fetus.⁷² The decision to use other classes of drug therapy to control disease exacerbation should be highly individualized, although hydroxychloroquine is safe during pregnancy.⁷⁴⁻⁷⁶ In fact, it may be safer to continue hydroxychloroquine during pregnancy than to discontinue it.^{38,72} The decision to use cytotoxic drugs during pregnancy should be made with extreme caution because of potential harmful effects (e.g., teratogenesis, fetal loss) to the fetus.⁷⁷ Azathioprine may be the safest of the cytotoxic drugs if needed during pregnancy.^{72,74}

Antiphospholipid antibodies may be associated with a greater likelihood of spontaneous abortion.^{6,38} Corticosteroids, intravenous immunoglobulin, aspirin, and heparin, alone and in various combinations, have been used to try to improve fetal outcome.⁴² Fetal survival increases with all these therapies, and none has been shown to be superior.²³ The optimal treatment regimen for pregnant patients with antiphospholipid antibodies is yet to be determined, although it has been recommended that women with antiphospholipid antibodies and no prior fetal losses should receive low-dose daily aspirin. High-risk women with a history of recurrent fetal loss

TABLE 90-5 Alternative and Experimental Treatments for Systemic Lupus Erythematosus

dsDNA, double-stranded DNA.

should be treated with low-dose subcutaneous heparin with or without aspirin.^{23,72} Low-molecular-weight heparin may be an effective alternative to low-dose heparin in the treatment of antiphospholipid syndrome-related pregnancy loss.^{6,23,72}

Although there is an increased chance of a high-risk pregnancy in women with SLE, appropriate planning and disease management will result in a high likelihood of a successful pregnancy and a healthy child.

Contraception

Estrogen-containing oral contraceptives have been avoided in women with SLE because of the link between estrogens and disease activity. Uncontrolled trials suggest that oral contraceptives exacerbate SLE, but this issue was only recently rigorously examined. There are good reasons to prescribe oral contraceptives in SLE: (a) outcomes of pregnancy are better when pregnancies are planned and conception occurs during disease remission; (b) women with very active disease or receiving teratogenic medications should use a very reliable method of birth control and; (c) estrogen-containing oral contraceptives may have a beneficial effect counteracting glucocorticoid-induced osteoporosis.⁷⁸

The use of a combined oral contraceptive (ethinyl estradiol plus levonorgestrel), a progestin-only contraceptive (levonorgestrel), and an intrauterine device were compared in women with SLE.⁷⁹ This 12-month study showed comparable rates of disease flares and no clinically significant differences among all three groups during the trial. A placebo-controlled trial of ethinyl estradiol plus norethindrone also showed no difference in disease activity between the two groups over 12 months.⁸⁰ Neither of these two trials studied combined oral contraceptives in severe active SLE, leaving the issue of oral contraceptives in these patients unanswered. Because of the risk of thrombotic events in estrogen-treated women and the risk of thrombosis in SLE, antiphospholipid antibodies should be measured before oral contraceptives are started, and oral contraceptives should probably be avoided if these antibodies are present.⁷⁸

Antiphospholipid Syndrome and Thrombosis

As mentioned earlier, the presence of antiphospholipid antibodies may result in several clinical manifestations, including thrombosis. There is no agreement on prophylaxis of patients with antiphospholipid antibodies without a history of thromboembolism.³⁶ In such patients, low-dose aspirin (100 to 325 mg/day) may be used prophylactically, although efficacy has not been established.³⁶ Patients with an acute thrombotic event should receive standard treatment with anticoagulants (e.g., heparin). Followup treatment with warfarin to prevent recurrence may require an international normalized ratio of 3 or greater in patients with antiphospholipid syndrome.^{6,42} However, there is no consensus on the intensity of anticoagulation or duration of secondary prophylaxis, but as recurrence is common, patients usually are treated with oral anticoagulants indefinitely.⁴²

CLINICAL CONTROVERSY

The optimal dose of aspirin and the intensity of anticoagulation therapy have not been well established, and clinicians will use various strategies for prevention of thrombosis in the presence of antiphospholipid antibodies.

Drug-Induced Lupus

Up to 10% of SLE cases may be drug-induced.⁸¹ More than 80 drugs have been implicated as causing drug-induced lupus (DIL), although the incidence for most of these drugs is low.^{81,82} Procainamide and hydralazine are associated most commonly with DIL (Table 90–6). A

TABLE 90-6 Medications Implicated in Drug-Induced Lupus^a

Acetabulol	Interleukin 2	Pindolol
Amiodarone	Isoniazid	Primidone
Anti-tumor necrosis factor therapies	Labetalol	Procainamide
Atenolol	Lisinopril	Propranolol
Captopril	Lithium	Propylthiouracil
Carbamazepine	Lovastatin	Quinidine
Chlorpromazine	Mephenytoin	Reserpine
Ciprofloxacin	Methimazole	Simvastatin
Clobazam	Methyldopa	Streptomycin
Clonidine	Metoprolol	Sulfasalazine
Clozapine	Minocycline	Tetracycline
Diltiazem	Nifedipine	Thiazide diuretics
Ethosuximide	Oral contraceptives	Ticlopidine
Fluvastatin	Para-aminosalicylate	Timolol
Gold salts	Penicillamine	Tocainide
Griseofulvin	Penicillin	Valproate
Hydralazine	Phenytoin	Verapamil
Hydroxyurea	Phenylbutazone	Zafirlukast
Interferon (α , γ)	Phenelzine	

^aDrugs in **boldface** represent those with best evidence of association.

Data from references 81 to 85.

consensus on diagnostic criteria for DIL does not exist. To meet criteria for DIL, a patient should have exposure to a suspected drug, no prior history of idiopathic SLE prior to the use of the drug, development of ANAs (usually antihistone antibodies) and at least one clinical feature of SLE, and rapid improvement of symptoms with a gradual decline in ANAs following drug discontinuation.^{81,82,84,85} The epidemiologic characteristics of DIL are different from those of idiopathic SLE. In general, patients with procainamide- or hydralazine-induced lupus develop the disease much later in life compared with idiopathic SLE probably because most people who use these drugs are older. There is also an absence of female predominance when compared with idiopathic SLE.

Patients of the slow acetylator phenotype may have a greater risk for developing DIL, particularly with procainamide and hydralazine.^{10,81} Procainamide-induced lupus can present as early as 1 month or even after years of therapy. Hydralazine-induced lupus is dose-related, leading to the recommended maximum dose of 100 mg/day for men and 50 mg/day for women to minimize the risk of DIL.⁸⁶

Musculoskeletal symptoms are the most common clinical manifestations, while renal manifestations and CNS involvement are rare. Other common features of DIL include fever, fatigue, pericarditis, pleurisy, and weight loss.⁸⁵ The classic malar rash is rare in DIL and skin manifestations are generally less frequent than idiopathic SLE.⁸¹ A positive ANA test is found in nearly all (~90%) hydralazine-induced cases and in 50% to 90% of procainamide-induced disease. The immunofluorescence pattern usually is homogeneous, and antibodies are primarily against ssDNA and not dsDNA as in idiopathic SLE. Antihistone antibodies are specific for DIL but might be found in only 20% of patients with idiopathic SLE.⁸¹

If signs and symptoms of SLE appear in a patient and are suspected to be drug-related, the drug should be discontinued. If the lupus is drug-induced, the clinical manifestations should disappear in days to weeks, although it may take up to 1 year or longer for symptoms and serologic abnormalities to resolve completely.³⁸ A NSAID might be useful in treating musculoskeletal manifestations. Other, more aggressive drug therapy should not be necessary unless manifestations are deemed more serious.

PHARMACOECONOMIC CONSIDERATIONS

Treating patients with SLE is costly, requiring frequent visits to physician offices for monitoring therapy and treating adverse reactions from therapy and hospitalization for disease exacerbation and

adverse drug effects. Therefore, it is particularly important in the management of a potentially debilitating chronic disease such as SLE to achieve desired treatment outcomes in an optimal manner to minimize the impact on use of healthcare resources. Costs of treating patients with SLE are slightly higher in the United States compared to Canada and the United Kingdom, but outcomes are similar.⁸⁷ The estimated annual direct cost in the United States is about \$4,200, with mediations contributing approximately 29% of direct costs.⁸⁸

Lupus patients with poor physical or poor psychological functioning have been shown to incur higher direct medical costs, whereas patients with the poorest psychological functioning and those with the most severe pain incur higher indirect costs (costs associated with loss of productivity such as days of work missed).⁸⁹ Higher direct, indirect, and total costs also are associated with higher education level, greater disease activity, and lower physical functioning in another study.⁸⁹ Specific treatment strategies that incorporate therapies to improve physical and psychological functioning, as well as reduce disease activity and end-organ damage, might reduce use of healthcare resources.

SYSTEMIC SCLEROSIS

CLINICAL MANIFESTATIONS

Systemic sclerosis is characterized by alteration of the microvasculature and by massive deposition of collagen. This disease can present as a spectrum of differing manifestations depending on affected areas and the extent of disease. Sclerosis of the skin is a hallmark for this disease, but other manifestations include a proximal diffuse (truncal) sclerosis, with skin tightness and marked skin thickening involving most of the body. Internal organs can also be involved, such as the gastrointestinal tract, lung, kidney, or heart, and can result in death. *Scleroderma* refers to patients with only skin involvement. Disease that affects only the fingers and toes is referred to as *sclerodactyly*.

CLINICAL PRESENTATION OF SYSTEMIC SCLEROSIS

General

- Sclerosis of the skin

Symptoms

- Raynaud's phenomenon
- Dyspepsia
- Constipation
- Diarrhea
- Steatorrhea
- Esophageal dysmotility

Most patients with systemic sclerosis have Raynaud's phenomenon, where the digits turn white, followed by a bluish color, which is then followed by reddening in response to an appropriate stimulus. The precipitating event is usually cold temperature or emotion. The pallor is caused by vasospasm, the bluish color is from ischemia, and the reddish color is caused by a reactive hyperemia. Raynaud's phenomenon is a common manifestation of other syndromes, and most patients with Raynaud's phenomenon do not have systemic sclerosis. Approximately 50% to 80% of patients with systemic sclerosis have gastrointestinal symptoms, and 75% to 90% of patients have esophageal dysmotility.^{90,91}

Survival rates are highly variable depending on the extent of disease presentation, organ involvement, and other factors. In general, the 5-year survival rate is greater than 60%, which diminishes to approximately 50% at 10 years.^{92,93}

ETIOLOGY AND PREVALENCE

The cause of systemic sclerosis is unknown. Ninety-five percent of patients have identifiable autoantibodies. There are two major subsets of the disease: limited cutaneous and diffuse systemic sclerosis. Patients with limited cutaneous involvement often have the CREST syndrome (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasias), whereas patients with diffuse systemic sclerosis have a more aggressive disease with renal, cardiac, or pulmonary involvement. The prevalence of the disease is estimated to be between 138 and 286 cases per 1 million population.⁹³ The wide range may be a result of differences in diagnostic criteria, regional variation, or sample sizes used to estimate the prevalence.

TREATMENT

Systemic Sclerosis

Treatment is empirical because there are no well-controlled trials evaluating and comparing various forms of therapy. Available data are difficult to interpret because of the heterogeneity of the disease, spontaneous remissions that can occur, and lack of objective measures to assess changes in clinical status. D-Penicillamine has been used for skin involvement. When started within the first 2 years of the disease, this drug does seem to improve the skin manifestations and prolong survival.⁹⁴ The initial dose of D-penicillamine is 250 mg/day, with gradual increases in dose every 2 to 3 months to an optimal dose of 750 to 1,000 mg/day. Response occurs over many months, and the drug is not always effective. The high incidence of severe adverse events and the increased dropout rates for D-penicillamine limit its usefulness. Methotrexate appears promising as an effective therapy for skin involvement.⁹⁵ Other agents currently used are cyclophosphamide and mycophenolate mofetil, although there are no controlled trials to support their use.⁹⁶ Antiinflammatory agents and corticosteroids have not been effective in systemic sclerosis.

Angiotensin-converting enzyme (ACE) inhibitors have improved survival dramatically in patients with renal involvement and improve outcomes in patients with disease-associated pulmonary hypertension or myocardial involvement.^{97,98} Patients with sclerosis of the kidneys develop hypertension, leading to a renal crisis. In these patients, plasma renin activity and angiotensin concentrations can be more than twice normal. Renal involvement should be anticipated in all systemic sclerosis patients who develop hypertension. Patients with systemic sclerosis and hypertension should be treated and maintained with an ACE inhibitor regardless of renal involvement. ACE inhibitors should be used in patients on dialysis, and have allowed some dialysis-dependent systemic sclerosis patients to discontinue dialysis.^{96,97} Angiotensin receptor blockers are less effective than ACE inhibitors, but may have an additive effect to ACE inhibitors in refractory cases.⁹⁶ Treatment of Raynaud's phenomenon requires patient education and sometimes drug therapy. Patients must maintain their peripheral extremity and core body temperatures. Wearing appropriate clothing in cold environments is essential. Reaching into a freezer with unprotected hands should be avoided. Drugs that can cause peripheral vasoconstriction, such as pseudoephedrine and β -blockers, should be avoided in patients with Raynaud's phenomenon or systemic sclerosis. Smoking causes cutaneous vasoconstriction and should be eliminated, including passive smoke. When preventive measures are insufficient, calcium channel blocking agents have become the agents of choice for Raynaud's phenomenon. Nifedipine (10 to 20 mg three or four times per day) decreases the frequency and duration of attacks; diltiazem (60 mg three or four times per day) also can be used. The sustained-release formulations of these agents may enhance patient adherence. Although there are limited data, other agents that may be beneficial

for Raynaud's are selective serotonin reuptake inhibitors and angiotensin II receptor antagonists.⁹¹

POLYMYOSITIS AND DERMATOMYOSITIS

CLINICAL MANIFESTATIONS

Polymyositis (PM) and dermatomyositis (DM) are chronic inflammatory diseases of skeletal muscle and skin of unknown etiology. DM is distinguished from PM by a typical rash, which is red, scaly, and plaque-like over the knuckles, wrists, elbows, and knees. A blue-purple discoloration on the upper eyelids with edema also can occur in dermatomyositis.

There is an increase in serum creatine kinase concentration and electromyography abnormalities. Other serum enzymes, such as the alanine transaminase, aspartate transaminase, and lactate dehydrogenase, also may be increased.⁹⁹ Muscle biopsies show a necrotizing inflammatory process. The skin lesions of DM show an immune-complex-mediated necrosis of the microvasculature. PM appears to be related to cytotoxic T-cell activity, and up to 20% of patients with inflammatory myopathies have ANAs and cytoplasmic antibodies.

CLINICAL PRESENTATION OF POLYMYOSITIS AND DERMATOMYOSITIS

General

- Inflammation of skeletal muscle and skin

Symptoms

- Muscle weakness in shoulder and hip girdles and trunk
- Insidious onset
- Arthritis, Raynaud's phenomenon, and other symptoms of connective tissue diseases

TREATMENT

Polymyositis and Dermatomyositis

Large, controlled trials of drug therapy have not been conducted. The goal of therapy is to increase muscle strength so as to improve function in activities of daily living (e.g., bathing, dressing, feeding, and toileting). Treatment consists of physical therapy during periods of remission and rest during periods of disease activity. Prednisone is the first line of drug therapy for PM and DM. Although the optimal dose of prednisone is not clear, most clinicians use prednisone at a starting dose of 60 to 100 mg/day or about 1 mg/kg per day as a single morning dose.^{99–101} Higher prednisone doses of 1.5 mg/kg per day can be used if needed.¹⁰² The initial dose of prednisone is continued for 1 to 2 months or until maximum benefit is achieved or a remission is induced. The full effect of prednisone may not be evident for several months. After 4 months of treatment, approximately 85% of patients treated with prednisone will have normal muscle strength. The prednisone dose is tapered when muscle strength improves and serum creatine kinase concentrations decrease. If the patient is responding to prednisone and there are no serious side effects, the drug is tapered slowly. One expert advocates using prednisone for 3 to 4 weeks and then tapering the dose over 10 weeks to an every-other-day regimen.⁹⁹ The dose that maintains a good clinical response can be used as maintenance. Tapering too quickly can cause an exacerbation of disease activity. Monitoring serum creatine kinase concentrations is useful because they tend to increase several weeks before clinical symptoms become apparent. Some clinicians will treat patients with

daily prednisone for 1 or more years, whereas others may use every-other-day therapy for many years.

One complication from corticosteroid use is the development of a myopathy. Based on symptoms, it is difficult to know if increased muscle weakness is caused by the corticosteroid or to worsening disease status. Lowering the prednisone dose may be useful. If patients get better on a lower dose of prednisone, then most likely the muscle weakness was caused by the drug. It may take 2 to 8 weeks for this to become evident clinically. Use of serum creatine kinase concentration also may be helpful because this does not increase with steroid myopathy. It is possible that a steroid myopathy and worsening disease can coexist.

Although most patients with PM or DM improve with prednisone, some will not, and some will develop corticosteroid resistance. In these patients, azathioprine has been used at a dose of 2 to 3 mg/kg per day in divided doses, with a maintenance dose of 0.5 mg/kg per day.¹⁰¹ Clinical response may take 3 to 6 months. Another alternative is methotrexate at a dose of 5 to 20 mg once weekly.¹⁰¹ In patients resistant to these therapies, cyclophosphamide, cyclosporine, or chlorambucil can be tried. Intravenous immunoglobulin at a dose of 2 g/kg per month for 3 months may be effective in patients with refractory disease.¹⁰² Alternative therapies are often used in PM or DM, but there is no convincing evidence to support their use. These alternative therapies also may be beneficial in patients who cannot take corticosteroids because of serious adverse effects.

POLYMYALGIA RHEUMATICA AND GIANT CELL ARTERITIS

CLINICAL MANIFESTATIONS

Polymyalgia rheumatica (PMR) and giant cell arteritis are closely related diseases, and some experts consider them to be different phases of the same disease.^{103,104}

Giant cell arteritis is a vasculitis of large and medium-size vessels. The most frequent symptom is headache, with pain usually in the temporal or occipital areas; signs of systemic inflammation are also usually present.^{103,105} Giant cell arteritis was referred to previously as "temporal arteritis" or "granulomatous arteritis." Both PMR and giant cell arteritis occur in people older than 50 years of age, and the incidence increases with age, peaking between ages 70 and 80 years.¹⁰¹ Some patients go from exhibiting no symptoms to overt clinical manifestations overnight, whereas others have a gradual onset of symptoms over a number of weeks. The etiology is unknown.

CLINICAL PRESENTATION OF POLYMYALGIA RHEUMATICA AND GIANT CELL ARTERITIS

General

- Aching and morning stiffness of neck, shoulder, and pelvic girdle musculature and torso.

Symptoms

- Pain and morning stiffness lasting 1 to 6 hours
- Fatigue, malaise, and weight loss are usually present
- Anorexia
- Headache in giant cell arteritis

Signs

- Low-grade fever

Laboratory Tests

- Erythrocyte sedimentation rate is generally >40 mm/h and often >100 mm/h

TREATMENT

Polymyalgia Rheumatica and Giant Cell Arteritis

The treatment of choice for PMR is prednisone at a dose of 10 to 20 mg/day, and giant cell arteritis requires doses of 40 to 60 mg/day. Pulse therapy with intravenous methylprednisolone, 1,000 mg/day for 3 days, may be used in patients experiencing visual loss.^{103,104} Corticosteroid therapy is so effective that if improvement does not occur within a week, another diagnosis should be considered. The erythrocyte sedimentation rate (ESR) should decrease by 2 weeks and become normal after 4 weeks of therapy. The prednisone should be tapered beginning several weeks following control of symptoms. The rate of tapering is based on clinical response. A taper of 2.5 mg/day at 2- to 4-week intervals to 5 to 10 mg/day followed by a slower tapering of 1 mg/day at monthly intervals has been suggested.^{106,107} The lowest dose of prednisone that controls symptoms should be used for maintenance, which is usually between 7 and 15 mg/day. Maintaining the ESR and C-reactive protein concentration in the normal range is a good monitoring approach. For elderly patients, the normal ESR may be slightly higher than that usually given as a reference value by the clinical laboratory. PMR is a self-limited disease, and patients usually continue maintenance therapy for 2 to 5 years. Patients may experience a relapse when the prednisone is discontinued. Every-other-day prednisone has not been as successful as daily therapy. Because these are diseases of the elderly, it is particularly important to use calcium and vitamin D supplements to prevent corticosteroid-induced osteoporosis. Prophylactic bisphosphonate therapy also should be considered. Unlike most other autoimmune diseases, other forms of immunosuppressive therapy are not as effective as corticosteroids in PMR and giant cell arteritis.¹⁰⁵

DRUG-INDUCED VASCULITIS

CLINICAL MANIFESTATIONS

6 Drugs are common causes of vasculitis, often occurring in the skin, but other organ involvement can occur. The pathogenesis of inflammation of small and medium-size blood vessel walls caused by drugs is poorly understood.¹⁰⁸ Even drugs used to treat inflammatory and immune-mediated disease, such as NSAIDs, sulfasalazine, and etanercept, can cause vasculitis.

CLINICAL PRESENTATION OF DRUG-INDUCED VASCULITIS

General

- Signs and symptoms depend on organ involvement

Symptoms

- Rash
- Glomerulonephritis
- Hepatitis
- Fatigue
- Myalgia
- Arthralgia

Signs

- Fever

Symptoms can occur within hours of drug administration or after more than 15 years of using a drug.¹⁰⁹ Most classes of medications

have been reported to cause vasculitis. Although there are no specific diagnostic tests for drug-induced vasculitis, antineutrophil cytoplasmic autoantibodies have been identified in many cases of drug-induced vasculitis.^{108,109} Eosinophilia, leukocytosis, and elevated ESR also may occur.

TREATMENT

Drug-Induced Vasculitis

The first step in therapy of drug-induced vasculitis is to discontinue the suspected inducing agent. This may be all that is necessary to abate symptoms in mild cases. For more serious cases, corticosteroids may be used, and where life-threatening organ involvement occurs, immunosuppressive therapy with agents such as cyclophosphamide may be used.¹⁰⁹ Following therapy, symptoms resolve within a few weeks to a few months.

EVALUATION OF THERAPEUTIC OUTCOMES

The diversity of clinical features and disease severity associated with the collagen-vascular diseases leads to a number of possible clinical outcomes with a broad range of desired therapeutic outcomes. Achieving desired therapeutic outcomes for most of the collagen-vascular diseases is highly variable. Currently, it is not possible to predict which patients will have a satisfactory therapeutic response and which will have unrelenting progressive disease. These diseases often have fluctuating courses, necessitating frequent changes in drug therapy and drug doses.

Evaluation of drug therapy of several of the collagen-vascular diseases often only requires monitoring for resolution of symptoms such as rash or muscle pain. However, patients with life-threatening disease receiving aggressive pharmacotherapy may require intensive monitoring and evaluation of therapy. For example, the patient receiving cytotoxic drug therapy for severe lupus nephritis requires close monitoring of laboratory indices of renal function, as well as monitoring of symptomatology and laboratory indices for possible bone marrow suppression, infection, cystitis, or other potential adverse effects.

Evaluation of therapeutic outcomes also should include an awareness of the possibility of drug therapy mimicking signs and symptoms of disease, such as the lupus patient receiving NSAID therapy and presenting with renal insufficiency or the patient with PM receiving prednisone and presenting with an exacerbation of muscle weakness.

As patients live longer, as is the case with SLE, outcome measures other than mortality will be needed to assess the effect of treatment. Clinicians and researchers working with lupus patients have developed and continue to refine some of these alternative outcome measures. Three important domains for assessing lupus patients are disease activity, accumulated damage, and quality of life.¹¹⁰ Table 90-7 lists several instruments useful for assessing patients with SLE. Increased use of these and similar instruments for assessment of treatment outcomes in patients with SLE can be expected.

CONCLUSION

SLE is a disease that affects multiple organ systems and consists of abnormal immunologic function and the development of autoantibodies. The disease is quite variable in clinical presentation and progression. The cause of lupus is unknown, although several factors (e.g., genetics, environment, and hormones) may predispose an individual to the development of the disease. Although SLE was

Data from reference 110.

once thought to be rapidly fatal, today nearly 90% of patients survive 10 years.

Drug therapy is nonspecific and is aimed at suppressing the inflammation and abnormal immune response associated with active disease. Clinical trials with various agents often have been inadequate and contradictory, and the therapeutic management of lupus is not optimal. Nevertheless, drug therapy of recent years probably has contributed significantly to the improved survival of these patients. As the understanding of SLE progresses and advances in molecular biology occur, we can expect to see the development of more specific and optimal treatment and further improvement in survival.

Each of the collagen-vascular diseases has its own recommended form of therapy. For most of these diseases, there are few well-controlled clinical trials evaluating pharmacotherapy. Treatment of most of these diseases requires antiinflammatory or immunosuppressive drugs. Monitoring therapeutic outcomes is essential because drugs and drug doses may need to be modified frequently.

Allergic and Pseudoallergic Drug Reactions

JOSEPH T. DIPIRO

KEY CONCEPTS

- 1 Allergic reactions are responsible for 6% to 10% of adverse reactions to medications. Although some reactions are relatively well defined, the majority are due to mechanisms that are either unknown or poorly understood.
- 2 The following criteria suggest that a drug reaction may be immunologically mediated: (a) the reaction occurs in a small percentage of patients receiving the drug, (b) the observed reaction does not resemble the drug's pharmacologic effect, (c) the type of manifestation is similar to that seen with other allergic reactions (anaphylaxis, urticaria, serum sickness), (d) there is a lag time between first exposure of the drug and reaction, (e) the reaction is reproduced even by minute doses of the drug, (f) the reaction is reproduced by agents with similar chemical structures, (g) eosinophilia is present, or (h) the reaction resolves after the drug has been discontinued. Exceptions to each of these criteria are observed commonly.
- 3 Anaphylaxis is an acute, life-threatening allergic reaction involving multiple organ systems that generally begins within 30 minutes but almost always within 2 hours after exposure to the inciting allergen. Anaphylaxis requires prompt treatment to restore respiratory and cardiovascular function. Epinephrine is administered as primary treatment to counteract bronchoconstriction and vasodilation. Intravenous fluids should be administered to restore intravascular volume.
- 4 Factors that influence the likelihood of allergic drug reactions are the dose of the allergen, the route of exposure, and the sensitivity of the individual as determined by age, genetics, or environmental factors. For many drugs, the severity of a reaction is determined by the dose and duration of exposure.
- 5 Patients with a history of a reaction to penicillin are advised not to receive cephalosporins if they can be avoided. Patients who have negative penicillin skin tests or experienced only mild cutaneous reactions, such as maculopapular rashes, have a low risk of serious reactions to cephalosporins.
- 6 Less than 1% of patients receiving nonionic radiocontrast agents experience some type of adverse reaction. Of the variety of reactions reported, approximately 90% are allergic-like, mostly urticarial, with severe reactions occurring as infrequently as 0.02%.
- 7 Aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs) can produce two general types of reactions, urticaria/angioedema and rhinosinusitis/asthma, in susceptible patients. About 20% of asthmatics are sensitive to aspirin and other NSAIDs.
- 8 Adverse reactions to trimethoprim-sulfamethoxazole occur much more frequently in patients with acquired immune deficiency syndrome (AIDS) compared with those without AIDS (50% to 80% of AIDS patients compared with 10% in other immunocompromised patients).
- 9 The basic principles of management of allergic reactions to drugs or biologic agents include (a) discontinuation of the medication or agent when possible, (b) treatment of the adverse clinical signs and symptoms, and (c) substitution, if necessary, of another agent.
- 10 One of the most helpful tests to evaluate risk of penicillin allergy is the skin test. Skin testing can demonstrate the presence of penicillin-specific immunoglobulin E and predict a relatively high risk of immediate hypersensitivity reactions. Skin testing does not predict the risk of delayed reactions or most dermatologic reactions.

1 *Allergic drug reactions* are adverse medication effects that involve immunologic mechanisms. Adverse drug effects not proven to be immune mediated but resembling allergic reactions in their clinical presentation are referred to as *allergic-like* or *pseudoallergic reactions*. Immunologically mediated adverse drug reactions account for 6% to 10% of all adverse drug reactions and even up to 15% by some estimates.^{1,2} Examples of allergic drug reactions are anaphylaxis from β -lactam antibiotics, halothane hepatitis, dermatitis from sulfonamides, hypotension after protamine, and serum sickness from phenytoin.³ Examples of pseudoallergic reactions are shock after radiocontrast media, aspirin-induced asthma, opiate-related urticaria, and flushing after vancomycin infusion.³

The true frequency of allergic drug reactions is difficult to determine because many reactions may not be reported, and others may be difficult to distinguish from nonallergic adverse events. Dermatologic reactions represent the most frequently recognized and reported form of allergic drug reaction.⁴

MECHANISMS OF ALLERGIC DRUG REACTIONS

Drugs can cause allergic reactions by a variety of immunologic mechanisms. Although some reactions are relatively well defined, most are due to mechanisms that are either unknown or poorly understood.^{2,3}

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

TABLE 91-1 Classification of Allergic Drug Reactions				
Type	Descriptor	Characteristics	Typical Onset	Drug Causes
I	Anaphylactic (IgE mediated)	Allergen binds to IgE on basophils or mast cells, resulting in release of inflammatory mediators.	Within 30 min	Penicillin immediate reaction Blood products Polypeptide hormones Vaccines Dextran
II	Cytotoxic	Cell destruction occurs because of cell-associated antigen that initiates cytotoxicity by antigen-specific antibody (IgG or IgM). Most often involves blood elements.	Typically 5–12 h	Penicillin, quinidine, phenylbutazone, thiouracils, sulfonamides, methyldopa
III	Immune complex	Antigen–antibody complexes form and deposit on blood vessel walls and activate complement. Result is a serum sickness-like syndrome.	3–8 h	May be caused by penicillins, sulfonamides, radiocontrast agents, hydantoins
IV	Cell-mediated (delayed)	Antigens cause activation of lymphocytes, which release inflammatory mediators.	24–48 h	Tuberculin reaction

2 The following criteria suggest that a drug reaction may be immunologically mediated²: (a) the observed reaction does not resemble the drug’s pharmacologic effect, (b) there is a lag time between first exposure of the drug and reaction unless the recipient has been sensitized by prior exposure to the drug, which can lead to immediate reactions, (c) the reaction may occur even by minute doses of the drug, (d) the symptoms are characteristic of an allergic reaction (e.g., anaphylaxis, urticaria, serum sickness), (e) the reaction resolves after the drug has been discontinued, and (f) the reaction may be reproduced by agents with similar chemical structures. Exceptions to each of these criteria are observed commonly. Many allergic reactions can be classified into one of four immunopathologic categories: type I, II, III, or IV (Table 91–1 and Fig. 91–1).^{2,3,5}

EFFECTORS OF ALLERGIC DRUG REACTIONS

Allergic drug reactions can involve most of the major components of the immune system, including the cellular elements, immunoglobulins, complement, and cytokines. Most immunoglobulin isotypes have been implicated in immunologically mediated drug reactions. Immunoglobulin E (IgE) bound to basophils or mast cells mediates immediate (anaphylactic-type) reactions. IgG or IgM antibodies also may be involved in allergic reactions, resulting in destruction of cells and tissues. T lymphocytes are important in some types of allergic reactions.^{2,5}

CELLULAR ELEMENTS

A variety of cells are involved in immunologic drug reactions. Basophils, mast cells, eosinophils, and lymphocytes are involved most frequently. Platelets and vascular endothelial cells are important because they also can release a number of inflammatory mediators.⁶ Most cells of the body, including nerve cells, can become involved directly or indirectly in allergic drug reactions.

MEDIATORS OF ALLERGIC REACTIONS

The release of a number of preformed, pharmacologically active chemical mediators (e.g., histamine, heparin, proteases such as trypsin and chymase, and a variety of other enzymes) is triggered when antigens cross-link IgE molecules on the surface of circulating basophils and tissue mast cells. Newly formed mediators include platelet-activating factor and arachidonic acid metabolites (e.g., prostaglandins, thromboxanes, and leukotrienes).

Histamine is a low-molecular-weight amine compound formed by decarboxylation of histidine and is stored in basophil and mast cell granules.⁷ Release of histamine from these cells is triggered by antigen cross-linking IgE bound to specific receptors on the surface membranes of mast cells and basophils. The tissue effects of his-

tamine are evident within 1 to 2 minutes, but it is rapidly metabolized within 10 to 15 minutes. The major effects of histamine on target tissues include increased capillary permeability, contraction of bronchial and vascular smooth muscle, and hypersecretion of mucus glands. Four classes of histamine receptors (H₁–H₄) are present to varying degrees in organs and tissues. H₁ receptors are most prominent in blood vessels and bronchial and intestinal smooth muscle.

Platelet-activating factor (PAF) is a glyceride-derived substance that is released by mast cells, alveolar macrophages, neutrophils, platelets, and other cells but not by basophils. It has potent bronchoconstrictor effects and causes platelet aggregation and lysis. It attracts neutrophils and causes their activation. PAF enhances vascular permeability and can cause pain, pruritus, and erythema.

The leukotrienes (LTs) are metabolites of arachidonic acid produced through the 5-lipoxygenase pathway that have potent effects on bronchial and vascular smooth muscle. Three important leukotrienes,

FIGURE 91-1. Types of hypersensitivity reactions.

LTC₄, LTD₄, and LTE₄, are produced by basophils or mast cells. These three substances are also referred to as *cysteinyl leukotrienes* and in older literature as *slow-reacting substances of anaphylaxis*. The LTs have more potent and longer-lasting bronchoconstrictor effects than histamine and can increase vascular permeability and cause arteriolar vasoconstriction followed by vasodilation. Their effects are slower in onset but longer lasting than those of histamine. Another product, LTB₄, is a potent chemoattractant, particularly for neutrophils. It is also produced by neutrophils, macrophages, and monocytes.

Prostaglandins (PGs) and thromboxanes are metabolites of arachidonic acid produced through the cyclooxygenase pathway. Some PGs have vasoconstrictive and/or bronchodilatory properties, whereas others are vasodilatory and/or bronchoconstrictive. PGD₂ is the major PG product of mast cells. It is a potent inhibitor of platelet aggregation and is a bronchoconstrictor. Thromboxanes cause platelet aggregation and are important regulators of coagulation.

The complement system consists of approximately 30 plasma proteins and is involved in hypersensitivity through a variety of immunologic responses, including enhancement of phagocytosis (opsonization of target cells), cell lysis, and generation of anaphylatoxins (C3a, C4a, and C5a), which can cause non-IgE-mediated activation of mast cells and release of inflammatory mediators.

CLASSIFICATION OF IMMUNOPATHOLOGIC DRUG REACTIONS

Immunologic mechanisms have been identified for some drug reactions, and many can be classified into one of four immunopathologic reactions, first described by Coombs and Gell. Small-molecular-weight molecules (<10,000 MW) are not usually immunogenic. Most drugs are <1,000 MW. To become immunogenic, these small compounds must first combine with carrier proteins in plasma or tissue. The combination of the drug bound to a carrier protein can be recognized as foreign, leading to an immune response. The more likely that large amounts of the drug become chemically bound to a protein, the greater the risk of producing an allergic reaction. Penicillin G (356 MW) is an example of a drug that binds covalently to serum proteins through amide or disulfide linkages. For drugs such as the sulfonamides, the parent compound first must be converted to a metabolite before it can combine with the macromolecule. The species that combines with the carrier macromolecule is referred to as a *hapten* or an *incomplete antigen*.⁸ Some macromolecular drugs such as insulin are referred to as *complete antigens* because they are large enough to initiate an immune response without binding to another protein. Drugs may also interact directly with T cells with or without the involvement of antigen-presenting cells.⁵

TYPE I

Type I reactions require the presence of IgE specific for the drug or the portion of the drug that becomes a hapten. IgE specific for the drug allergen is produced on initial exposure to the drug. It then binds to basophils and mast cells through high-affinity receptors. On repeat exposure to the drug, two or more IgE molecules on the basophil or mast cell surface may bind to one multivalent antigen molecule (referred to as *cross-linking*; see Fig. 91–1), initiating an activation of the cell. Activation causes the extracellular release of granules with preformed inflammatory mediators, including histamine, heparin, proteases (tryptase in the mast cell), as well as generation of newly formed mediators, as previously discussed, such as LTs, PGs, thromboxanes, and PAF, among others.

Generation of a type I reaction can be evident as an immediate hypersensitivity reaction, or anaphylaxis. Immediate reactions may be limited to single organs, typically in the nasal mucosa (rhinitis),

respiratory tract (acute asthma), skin, or gastrointestinal tract, or they can involve multiple organs simultaneously, termed *anaphylaxis*.

TYPE II

Type II immunopathologic reactions involve destruction of host cells (usually blood cells) through cytotoxic antibodies by one of two mechanisms (see Fig. 91–1). First, the drug binds to the cell as a hapten (e.g., the platelet or red blood cell). Antibodies (IgG or IgM) specific for the bound drug or to a component of the cell surface that has been altered by the drug then bind, initiating a cytolytic reaction. Cell destruction may be mediated by complement or by phagocytic cells that have antibody Fc receptors on their surfaces. Activation of complement near the cell surface can result in loss of cell membrane integrity and cell death. Alternatively, neutrophils, monocytes, or macrophages may bind to an antibody-coated cell through IgG Fc receptors on their cell surfaces, resulting in phagocytosis of the target cell. The process of enhancement of phagocytosis by antibody binding to cell surfaces or other particles is referred to as *opsonization*. In addition, cell-bound IgG may direct the nonphagocytic action of T cells or natural killer cells, which results in cell destruction by a process called *antibody-dependent cellular cytotoxicity*. This process can proceed in a nonspecific fashion as T cells bind to the target cell through IgG Fc receptors on the T-cell surface. Contact between the target and effector cells is necessary.

Cells commonly affected by these types of reactions include erythrocytes, leukocytes, and platelets, resulting in hemolytic anemia, agranulocytosis, or thrombocytopenia, respectively. This process may be initiated by drugs such as penicillin, quinidine, quinine, phenacetin, cephalosporins, and sulfonamides.

Another type of reaction that may affect the formed elements in blood is the “innocent bystander” reaction. With this type of reaction, antigen–antibody complexes formed in blood adhere nonspecifically to cells. Complement is then activated, resulting in cell lysis.

TYPE III

Type III immunologic reactions are caused by antigen–antibody complexes that are formed in blood. The complexes form with drug allergen and antibody in varying ratios and may deposit in tissues, resulting in local or disseminated inflammatory reactions. Antigen–antibody complex formation can result in platelet aggregation, complement activation, or macrophage activation. Chemotactic substances such as C4a also are produced. These substances cause the influx of neutrophils and result in the release of a number of toxic substances from the neutrophil (e.g., proteinases, collagenases, kinin-generating enzymes, and reactive oxygen and nitrogen substances), which can cause local tissue destruction.

Platelet aggregation may occur as a result of immune-complex formation, resulting in the formation of microthrombi and the release of vasoactive mediators. Also, insoluble complexes may be phagocytized by macrophages and activate these cells.

The formation of antigen–antibody complexes can lead to clinical syndromes such as the Arthus reaction. In this model, a high level of preformed specific IgG antibody combines with antigen to produce a localized edematous, erythematous reaction within 5 to 8 hours. The reaction involves local formation of insoluble antigen–antibody complexes, complement activation with release of C3a and C5a collectively referred to as *anaphylatoxins*, mast cell degranulation, and influx of polymorphonuclear cells.

TYPE IV

Type IV reactions are delayed hypersensitivity reactions that typically are demonstrated as dermatologic reactions and are mediated

by T cells ($CD4^+$ or $CD8^+$).⁹ Four subclasses of type IV reactions have been described.⁵ Type IV reactions require memory T cells specific for the antigen in question. On exposure to the antigen, T cells become activated and produce an inflammatory response. Although these reactions may be associated with adverse effects (e.g., contact dermatitis, maculopapular exanthemas, bullous exanthemas, eczema, or pustular exanthemas), they also may be useful for diagnostic purposes. Examples of the latter include the purified protein derivative (PPD) antigen from *Mycobacterium tuberculosis* used in the tuberculin skin test and other recall skin test antigens, such as mumps. After intradermal injection, these antigens produce a local reaction (erythema and induration) within 48 to 72 hours. Delayed contact hypersensitivity also can be caused by a wide variety of chemicals and drugs.

OTHER ALLERGIC REACTIONS

The precise mechanism of many drug reactions is not known, although the reactions are believed to be immune mediated. Perhaps most common are the delayed dermatologic reactions that occur with a variety of drugs (especially penicillins and sulfonamides).^{5,9} These reactions may be evident as macropapular, morbilliform, or erythematous rashes; exfoliative dermatitis; photosensitivity reactions; or eczema. These reactions also may be manifest as pruritus, urticaria, and angioedema.

Other serious dermatologic syndromes may be the result of immunologic reactions. Erythema multiforme is an acute syndrome characterized by a variety of skin lesions. The skin lesions typically start as a maculopapular eruption that may progress to irregular lesions with central clearing (target lesions), mostly on the extremities. The rash may be accompanied by bullous lesions that break down into erosions involving more of the body, especially mucous membranes. This more extensive disease usually associated with fever and extensive purpura is called *erythema multiforme major* or *Stevens-Johnson syndrome* (SJS). Some have termed these types of reactions *febrile mucocutaneous syndromes*. If the skin lesions progress to sloughing of large portions of the skin, resembling third-degree burns, the term *toxic epidermal necrolysis* (TEN) is applied. Mortality from TEN can be as high as 40%.¹⁰ Drugs commonly associated with these syndromes include the penicillins, sulfonamides, nonsteroidal antiinflammatory drugs (NSAIDs), and anti-convulsants such as phenytoin and phenobarbital, as well as a number of other agents. Drug-induced fever also may involve immunologic mechanisms. Other general types of reactions believed to be immune mediated in some cases include hepatic drug reactions (cholestatic or hepatocellular) and pulmonary reactions, for example, interstitial pneumonitis, which has been associated with nitrofurantoin.

ANAPHYLACTOID REACTIONS

Various drugs and other substances can produce anaphylactoid (anaphylaxis-like) reactions that are similar to anaphylaxis in clinical signs and symptoms. The substances causing these reactions can produce the direct release of inflammatory mediators from cells by a pharmacologic or physical effect rather than through cell-bound IgE. These reactions are sometimes referred to as *pseudoallergic*, but not all pseudoallergic reactions are anaphylactoid. Drugs that can produce anaphylactoid reactions include vancomycin, opiates, iodinated radiocontrast agents, amphotericin B, and D-tubocurarine. The “red man syndrome” is a common example of an anaphylactoid reaction from vancomycin. If vancomycin is infused too rapidly, it can cause the direct release of histamine and other mediators from cutaneous mast cells, producing a typical clinical picture of itching, flushing, and hives, first around the neck and face

and then progressing to the chest and other parts of the body usually beginning shortly after the infusion has begun. Most patients who have had “red man syndrome” will tolerate vancomycin if the rate of infusion is slowed. A number of other agents (including aspirin) may produce anaphylactoid reactions by altering the metabolism of inflammatory mediators such as PGs or kinins.

CLINICAL MANIFESTATIONS OF ALLERGIC AND ALLERGIC-LIKE REACTIONS

ANAPHYLAXIS

4 Anaphylaxis is an acute, life-threatening allergic reaction involving multiple organ systems that occurs in 10 to 20 per 100,000 population per year.^{11,12} Approximately 1,500 deaths from anaphylaxis occur annually in the United States.¹³ From 1.2% to 15% of the U.S. population may be at risk for anaphylactic reactions.¹⁴ Although many drugs may cause anaphylaxis (or anaphylactoid) reactions, the most commonly reported are aspirin and other NSAIDs, penicillins, and insulins.¹¹ The manifestations of anaphylaxis may include signs and symptoms referable to the skin (flushing, pruritus, urticaria, angioedema), respiratory tract (tightness of the throat and chest, dysphagia, dysphonia and hoarseness, cough, stridor, shortness of breath, dyspnea, congestion, rhinorrhea, sneezing), gastrointestinal tract (nausea, crampy abdominal pain, vomiting, diarrhea), cardiovascular system (hypotension, syncope, altered mental status, chest pain, dysrhythmia), or any combination of these systems.¹²

A consensus panel has constructed a definition of anaphylaxis as follows.^{12,15} Anaphylaxis is highly likely when any one of the following three criteria are fulfilled:

1. Acute onset of an illness (minutes to several hours) with involvement of the skin, mucosal tissue, or both (e.g., generalized hives, pruritus or flushing, swollen lips/tongue/uvula) AND at least one of the following:
 - Respiratory compromise (e.g., dyspnea, wheeze/bronchospasm, stridor, reduced peak expiratory flow, hypoxemia)
 - Reduced blood pressure or associated symptoms of end-organ dysfunction (e.g., hypotonia, syncope, incontinence)
2. Two or more of the following that occur rapidly after exposure to a likely allergen (minutes to several hours):
 - Involvement of skin/mucosal tissue (as above)
 - Respiratory compromise (as above)
 - Reduced blood pressure or associated symptoms
 - Persistent gastrointestinal symptoms (e.g., crampy abdominal pain, vomiting)
3. Reduced blood pressure after exposure to known allergen (minutes to several hours)

The panel indicated that other presentations may indicate anaphylaxis and that the potential exists for false-positive results.

Anaphylactic reactions generally begin within 30 minutes but almost always within 2 hours of exposure to the inciting allergen. The risk of fatal anaphylaxis is greatest within the first few hours. After apparent recovery, anaphylaxis may recur 6 to 8 hours after antigen exposure. Because of the possibility of these “late-phase” reactions, patients should be observed for at least 12 hours after an anaphylactic reaction. Fatal anaphylaxis most often results from asphyxia due to airway obstruction either at the larynx or within the lungs. Cardiovascular collapse may occur as a result of asphyxia in some cases, whereas in others cases cardiovascular collapse may be the dominant manifestation from the release of mediators within the heart muscles and coronary blood vessels.

SERUM SICKNESS

Serum sickness is a clinical syndrome resulting from the effects of soluble circulating immune complexes that form under conditions of antigen excess. The reaction commonly results from the use of antisera containing foreign (donor) antigens such as equine serum in the form of antitoxins or antivenins. The onset of serum sickness usually occurs 7 to 14 days after antigen administration. The onset may be more rapid with reexposure to the same agent in an individual with prior serum sickness. Fever, malaise, and lymphadenopathy are the most common clinical manifestations. Arthralgias, urticaria, and morbilliform skin eruption also may be present. Although often associated with administration of heterologous antisera, serum sickness also may be caused by drugs, including sulfonamides, hydantoins, penicillins, minocycline, and cephalosporins (especially cefaclor). In addition, immune complex-mediated systemic lupus erythematosus (SLE)-like syndrome has been attributed to reactions from drugs such as hydralazine, procainamide, isoniazid, and phenytoin.

DRUG FEVER

Fever may occur in response to an inflammatory process or develop as a manifestation of a drug reaction. Drug fever occurs in as many as 10% of hospital inpatients.¹⁶ Many drugs have been reported to cause fever, including methyldopa, procainamide, phenytoin, barbiturates, quinidine, and a variety of antibiotics. These drugs may affect the central nervous system directly to alter temperature regulation or stimulate the release of endogenous pyrogens (e.g., interleukin-1 and tumor necrosis factor) from white blood cells. Drugs also may cause fever as a result of their pharmacologic effects on tissues, for example, fever resulting from massive tumor cell destruction caused by chemotherapy. However, the mechanism of drug fever remains unknown for agents such as amphotericin B and radiographic contrast agents.

The temperature pattern of drug-induced fever is quite variable and therefore of little help in the diagnosis. It may be low grade and continuous or spiking and intermittent. A temporal relationship between drug administration and occurrence of fever has been noted for some medications. Generally, withdrawal of the causative agent results in prompt defervescence as soon as the drug is eliminated completely. Fever usually recurs on readministration of the causative agent.

DRUG-INDUCED AUTOIMMUNITY

Autoimmune diseases have been associated with drugs and may involve a variety of tissues and organs. A commonly recognized drug-related autoimmune disorder is SLE induced by procainamide, hydralazine, quinidine, or isoniazid.¹⁷ Exposure of susceptible persons to these agents appears to alter normal body proteins, RNA, or DNA in such a way as to make these components antigenic, leading to the formation of autoreactive antibodies and cells. The most common clinical manifestations include arthralgias, myalgias, and polyarthritides. Facial rash, ulcers, and alopecia occur less frequently. Renal or pulmonary involvement also may occur. These reactions typically develop several months after beginning the drug and generally resolve soon after the drug is discontinued.¹⁸

Other syndromes believed to involve autoimmune mechanisms include drug-induced hemolytic anemia attributed to methyldopa, renal interstitial nephritis produced by methicillin, and hepatitis caused by phenytoin and halothane. Interstitial nephritis is characterized by fever, rash, and eosinophilia associated with proteinuria and hematuria. Hepatic damage due to drugs generally is manifested as either hepatocellular necrosis or cholestatic hepatitis. Drug-induced hepatitis has been associated with phenothiazines, sulfonamides,

halothane, phenytoin, and isoniazid (see Chap. 40). Hepatocellular destruction is evidenced by elevations in serum transaminases. Hepatomegaly and jaundice sometimes may be evident. Cholestasis may be manifested by jaundice and elevations in serum alkaline phosphatase and sometimes by rash, fever, and eosinophilia.

VASCULITIS

Vasculitis is a clinicopathologic process characterized by inflammation and necrosis of blood vessels walls. The vasculitic process may be limited to the skin, or it may involve multiple organs, including the liver or kidney, joints, or central nervous system. Characteristically, cutaneous vasculitis is manifested by purpuric lesions that vary in size and number. Vasculitis also may be manifested as papules, nodules, ulcerations, or vesiculobullous lesions, generally occurring on the lower extremities but sometimes involving the upper extremities, including the hands. Drugs associated with vasculitis include allopurinol, β -lactam antibiotics, sulfonamides, thiazide diuretics, and phenytoin.

DERMATOLOGIC REACTIONS

A wide variety of dermatologic drug reactions have been reported to have an immunologic basis.^{2,19} Cutaneous reactions are the most common manifestations of allergic drug reactions. Although most dermatologic reactions are mild and resolve promptly after discontinuing the drug, some may progress to serious or even life-threatening reactions (e.g., TEN or SJS). SJS is a serious dermatologic reaction characterized by blistering of the mucous membranes (mouth, eyes, vagina) and patchy rashes that can cover most of the body. Patients may experience fever, headache, and cough. TEN is a syndrome similar to SJS, characterized by blistering of skin and mucous membranes in response to administration of a drug. Large areas of skin may peel off.

Cutaneous adverse reactions were reported to occur in 2.7% of hospitalized patients.²⁰ Serious dermatologic drug reactions are estimated to occur in 1.9 cases per one million people per year and can have a mortality rate as high as 40%.^{21,22} Table 91-2 lists drugs and agents associated most commonly with cutaneous reactions.²³ Antimicrobials are implicated most frequently with reaction rates ranging from 1% to 8%. In a report of almost 6,000 children, approximately 12% developed rashes with cefaclor compared with 7.4% with penicillins and 8.5% with sulfonamides.²⁴

RESPIRATORY REACTIONS

Drugs may produce upper or lower respiratory tract reactions, including rhinitis and asthma. Respiratory tract manifestations may result from direct injury to the airways or may occur as a component of a systemic reaction (e.g., anaphylaxis). Asthma may be

TABLE 91-2 Top 10 Drugs or Agents Reported to Cause Skin Reactions

	Reactions per 1,000 Recipients
Amoxicillin	51.4
Trimethoprim-sulfamethoxazole	33.8
Ampicillin	33.2
Iopodate	27.8
Blood	21.6
Cephalosporins	21.1
Erythromycin	20.4
Dihydralazine hydrochloride	19.1
Penicillin G	18.5
Cyanocobalamin	17.9

Data from Roujeau JC, Stern RS. *New Engl J Med* 1994;331:1272-1285.

induced by aspirin and other NSAIDs or by sulfites used as preservatives in foods and medications. Other pulmonary drug reactions believed to be immunologic include acute infiltrative and chronic fibrotic pulmonary reactions. The latter is often caused by antineoplastic agents such as bleomycin. For a more detailed discussion of drug-induced pulmonary disease, see Chap. 31.

HEMATOLOGIC REACTIONS

Most formed elements and soluble components of the hematopoietic system may be affected by immunologic drug reactions. Eosinophilia is a common manifestation of drug hypersensitivity and may be the only presenting sign. Hemolytic anemia may result from hypersensitivity to drugs. Other hematologic reactions include thrombocytopenia, granulocytopenia, and agranulocytosis. For a detailed discussion of hematologic drug reactions, see Chap. 107.

FACTORS RELATED TO THE OCCURRENCE OR SEVERITY OF ALLERGIC DRUG REACTIONS

3 Among the factors that influence the likelihood of allergic drug reactions are the dose of the drug, how the drug is metabolized, the degree to which the drug and metabolites bind to human proteins, the route of exposure, and the sensitivity of the individual as determined by age, genetics, and environmental factors. For many drugs, the severity of a reaction is determined by the dose and the duration of exposure. A relatively larger dose or longer duration of treatment encourages development of drug sensitivity. The route of administration also influences drug sensitivity. The topical route of drug administration appears to be the most likely to sensitize and predispose to drug reactions. The oral route is the safest, and the parenteral route is the most hazardous for administration of drugs in sensitive individuals. Relatively few cases of immediate hypersensitivity-associated deaths with oral β -lactam antimicrobials have been reported. Although intravenous administration is more likely to result in severe immediate reactions in a sensitized individual, it may be the least likely route for initially inducing sensitivity. One possible explanation is that intravenous administration results in systemic drug exposure for the shortest period of time.

Individual host factors are important in determining drug sensitivity. There may be a genetic predisposition for some types of allergic reactions. For example, slow acetylators of procainamide and hydralazine are at increased risk for SLE.

Drug allergies appear to develop with equal frequency in atopic and nonatopic individuals. In addition, patients with a history of drug allergy appear to be at increased risk for adverse reactions to other pharmacologic agents.³ Age seems to be related to the risk of allergic reactions, as they occur less frequently in children. This may be related to immaturity of the immune system or decreased exposure. The presence of some concurrent diseases, particularly viral infections, predisposes to drug reactions. Examples include the morbilliform rash that occurs after ampicillin administration to patients with infectious mononucleosis and the reactions that occur with trimethoprim-sulfamethoxazole in patients with acquired immune deficiency syndrome (AIDS).

DRUGS COMMONLY CAUSING ALLERGIC OR ALLERGIC-LIKE DRUG REACTIONS

β -LACTAM ANTIMICROBIALS

Allergy to β -lactam antibiotics is commonly reported by patients in healthcare settings.²⁵ Allergic reactions to penicillin occur in 0.7% to 8% of treatment courses but was as high as 15% in one

retrospective report of hospitalized patients treated with penicillin.^{26,27} Although most patients reporting penicillin allergy do not have allergy, a reported history is associated with a higher likelihood of positive skin test reactivity.²⁸ Only 10% to 20% of patients reporting penicillin allergy are found to be allergic by skin testing.²⁸ Patients with a history of penicillin allergy who have a negative penicillin skin test are unlikely to react on subsequent courses of penicillins.²⁹

The most common reactions to penicillin include urticaria, pruritus, and angioedema. All four of the major types of hypersensitivity reactions have been reported with penicillin, as well as some reactions that do not fit into these categories. A wide variety of idiopathic reactions occur, such as maculopapular eruptions, eosinophilia, SJS, and exfoliative dermatitis. Cutaneous reactions can occur in up to 4.4% of treatment courses of penicillin³⁰ and in up to 8% with aminopenicillins.³¹ The incidence of ampicillin rash is close to 100% in patients with viral infections such as infectious mononucleosis.²²

Some aspects of the mechanism of penicillin immunogenicity have been determined. Because benzylpenicillin is a relatively small molecule (356 MW), it must combine with macromolecules (presumably proteins) to elicit an immune response. Penicillin may bind covalently to the lysine residues of proteins such as albumin through an amide linkage involving the β -lactam ring (Fig. 91-2). This is the penicilloyl-protein conjugate and is referred to as the *major antigenic determinant*. In addition, a number of other penicillin metabolites may bind covalently to proteins. These are referred to as *minor antigenic determinants*. The terms *major* and *minor* refer to the relative proportions of these conjugates that are formed and not to the clinical severity of the reactions generated. Immediate hypersensitivity reactions may be mediated by IgE for both minor and major determinants. In fact, the minor antigenic determinants are more likely to cause life-threatening anaphylactic reactions.

Patients who are allergic to penicillins also may be sensitive to other β -lactams.³² The exact incidence of cross-reactivity between cephalosporins and penicillins is not known but is believed to be low.³³ Patients who report penicillin allergy and a positive penicillin skin test have an eightfold greater risk of allergic reaction to cephalosporins compared with patients not reporting penicillin allergy. One to eight percent of patients with penicillin-specific IgE may develop an immediate-type hypersensitivity reaction to cephalosporins.³³ In contrast, patients with reported penicillin allergy and negative skin test are at no greater risk.³⁴

5 Most allergists would not administer cephalosporins to patients with a history of hives or other immediate hypersensitivity reactions from penicillin, although some studies have suggested there is little risk of an allergic response to a cephalosporin even in a person with a positive skin test to penicillin.³⁵⁻³⁷ One postmarketing surveillance report states there was no increase in allergic reactions to second- and third-generation cephalosporins in patients with histories of penicillin allergy.³⁵ Results of skin testing with cephalosporins are not reliable because the mechanism of cephalosporin sensitivity has not been clearly defined. At present, patients with positive penicillin skin tests are advised not to receive cephalosporins if they can be avoided. Patients who have negative penicillin skin tests or experienced only mild cutaneous reactions from penicillin, such as maculopapular rashes, may receive cephalosporins with caution.

Aztreonam only weakly cross-reacts with penicillin and can be administered safely to most patients who are penicillin allergic.³⁸ In contrast, there is considerable cross-reactivity between imipenem (a carbapenem) and penicillin. Therefore, imipenem (and other carbapenems) should not be administered to patients who have positive penicillin skin tests.

FIGURE 91-2. Formation of a benzylpenicilloyl hapten-protein complex.

RADIOCONTRAST MEDIA

6 Radiocontrast agents frequently cause allergic-like reactions because these agents are used commonly in medical practice and are administered as large, rapidly infused intravenous boluses. From <1% to >3% of patients receiving nonionic contrast media experienced an adverse reaction, with reports as high as 12.7% for mild reactions.^{39,40} Delayed skin reactions occur in 1% to 3% of patients over 5 to 7 days. Severe, immediate anaphylactic reactions occur in 0.01% to 0.04% of patients.³⁹ In addition, radiocontrast agents may cause dose-dependent toxic reactions that can produce renal impairment, cardiovascular effects, and arrhythmias.^{39,41} The older, high-osmolar agents that are now used less commonly have a greater frequency of reactions compared with the newer, low-osmolar agents.³⁹

The mechanism of reactions to radiocontrast agents is not clearly understood. Histamine release and mast cell triggering have been documented in severe immediate reactions, suggesting an IgE-mediated mechanism.⁴² The older, high-osmolar radiocontrast agents can activate mast cells and basophils directly (IgE-independent mechanism), resulting in the release of inflammatory mediators. The low-osmolar contrast agents appear to result in fewer anaphylactoid reactions.

Patients at risk for reactions to radiocontrast agents are difficult to identify. History is helpful because a patient who previously experienced reactions is more likely to experience subsequent reactions. The risk of allergic reactions to radiocontrast media is greater in women and in patients with a history of atopy or asthma.^{43,44} Other recognized risk factors include a history of previous reaction, severe allergy, cardiac disease, and treatment with β -blockers.⁴⁰ Despite a common misconception, a seafood allergy does not predispose to radiocontrast media reactions. Neither skin tests nor oral tests are useful for predicting reactions to these agents. Some regimens have been recommended to prevent reactions in patients who have experienced them previously; however, the value of these preventive regimens has not been proven.⁴⁵ One consensus guideline recommends oral prednisone (30 mg) or methylprednisolone (32 mg) 12 and 2 hours before exposure in high-risk patients to prevent immediate reactions. Ephedrine has also been recommended for premed-

ication.⁴⁶ Other studies have examined the use of H₁- and H₂-antihistamines, clemastine, or cimetidine, respectively.⁴⁵

INSULIN

Insulin is capable of producing allergic reactions through a variety of immunologic mechanisms. A protein molecule, insulin is a complete antigen. Allergic reactions have been reported with beef, pork, and recombinant human insulin, although the frequency of reactions with human insulin appears low. Reactions to insulin may involve the insulin molecule itself or other substances that have been added to insulin (e.g., protamine). Most patients have anti-insulin IgG antibodies after a few months of therapy.

Insulin reactions may be limited to the site of injection, or they may produce systemic reactions. Local reactions present most often as a wheal and flare at the injection site and may occur immediately after injection or up to 8 to 12 hours later. Generally, these reactions are mild, do not require treatment, and resolve with continued insulin administration. If a patient does not tolerate the local reaction well, antihistamines may be given or a different insulin source (or product of higher purity) may be substituted. Rarely, systemic reactions to insulin (e.g., urticaria or anaphylaxis) occur. IgE-mediated reactions to insulin allergy appear to be declining with greater use of human insulins.⁴⁷ Skin testing with various products can aid in selecting the type of insulin least likely to cause a systemic reaction. Human insulin appears to be least allergenic but occasionally may cause reactions. In some patients, insulin desensitization may be indicated.

ASPIRIN AND NONSTEROIDAL ANTIINFLAMMATORY DRUGS

7 Aspirin and other NSAIDs can produce eight general types of reactions, four of which are related to cyclooxygenase inhibition.^{48,49} These reactions can involve asthma and rhinitis, urticaria/angioedema, anaphylaxis and anaphylactoid reactions, aseptic meningitis, or pneumonitis. Approximately 9% to 20% of asthmatics are sensitive to aspirin and other NSAIDs.^{48,50}

The rhinosinusitis/asthma syndrome typically develops in middle-aged patients who are nonatopic and have no history of aspirin intolerance. Generally, it progresses from rhinitis to sinusitis with nasal polyps and steroid-dependent asthma. It is uncommon in children and young adults. However, children with asthma may be aspirin sensitive. Aspirin-sensitive asthma appears to be an inherited disorder characterized by overexpression of LTC₄ synthase in airways.⁵¹ In aspirin-sensitive asthmatics, administration of aspirin and NSAIDs may provoke severe and sometimes fatal asthmatic attacks. The mechanism of aspirin sensitivity is not completely understood.

One suspected mechanism of aspirin and NSAID sensitivity is cyclooxygenase-1 blockade, which may facilitate production of alternative arachidonic acid metabolites (e.g., LTs).⁴⁸ This is supported by the observed correlation between the degree of cyclooxygenase-1 blockade and the risk of a reaction; thus, agents such as acetaminophen, which minimally block cyclooxygenase-1, rarely cause reactions. Additional support is found in the clinical observation that LT-modifying drugs can reduce the severity of aspirin-induced reactions.⁴⁸ It is possible that aspirin and NSAIDs stimulate mast cells directly to release inflammatory mediators. Subjects with aspirin-induced asthma also have a marked increase in airway responsiveness to LTs.⁵² Aspirin and the cyclooxygenase-2-selective inhibitors celecoxib and rofecoxib do not appear to be cross-reactive.^{53–55}

In patients with asthma or those suspected of being sensitive to aspirin, an oral challenge can be performed. Protocols to detect aspirin or NSAID sensitivity have been recommended, but the risk for anaphylaxis cannot be reliably predicted.⁴⁸ The challenge should be performed with great caution in a hospital setting with resuscitation equipment at hand. For patients known to be aspirin-sensitive, the major preventive measure is avoidance. Other agents reported to be cross-reactive with aspirin include tartrazine dye, indomethacin, and phenylbutazone.

NSAIDs have been associated with pulmonary infiltrates and eosinophilia syndrome. Pulmonary infiltrates and eosinophilia syndrome is associated with fever, cough, dyspnea, infiltrates on chest roentgenogram, and a peripheral eosinophilia that develop 2 to 6 weeks after initiating treatment. Pulmonary infiltrates and eosinophilia syndrome occurs more frequently for naproxen compared with other NSAIDs and is noted to resolve rapidly after discontinuation of the offending agent.⁵⁶

SULFONAMIDES

Sulfonamide drugs, including antimicrobials, diuretics, oral hypoglycemics, and carbonic anhydrase inhibitors, are a common cause of allergic reactions. Allergic reactions were recognized in 4.8% of 20,226 patients who received a sulfonamide antibiotic and in 2% of patients who received a nonantibiotic sulfonamide.⁵⁷ Although immediate IgE-mediated reactions such as anaphylaxis can occur, sulfonamides typically cause delayed cutaneous reactions, often beginning with fever and then followed by a rash (e.g., morbilliform eruptions, erythema multiforme, or, less frequently, SJS/toxic epidermal necrolysis).¹ Other reactions to sulfonamides may include mucocutaneous, gastrointestinal, hepatic, renal, or hematologic complications, which may be fatal. Immune-mediated sulfonamide reactions involve the production of reactive metabolites (hydroxylamines).⁵⁸ Patients with the slow acetylator phenotype may be at increased risk for these reactions.⁴

Although allergic reactions to sulfonamides can occur with a wide variety of chemical entities, cross-reactivity between sulfonamide antibiotics and nonantibiotics appears to be minimal, with cross-reactivity characterized as “highly unlikely.”⁵⁹ The occurrence of allergic reactions after receipt of nonantibiotic sulfonamides may

reflect a predisposition to allergic reactions rather than cross-reactivity with sulfonamide antibiotics.⁵⁷ In fact, the cross-reactivity between sulfonamide antibiotics and penicillin appears higher than between antibiotic and nonantibiotic sulfonamides.⁵⁸

8 Trimethoprim-sulfamethoxazole is used frequently for preventive or active treatment of *Pneumocystis carinii* pneumonia in patients with AIDS. Adverse reactions to trimethoprim-sulfamethoxazole occur much more frequently in human immunodeficiency virus (HIV)-positive patients.⁶⁰ Adverse effects to trimethoprim-sulfamethoxazole occur in 50% to 80% of AIDS patients compared with 10% of other immunocompromised patients.⁶¹ Trimethoprim-sulfamethoxazole was associated with an adverse event rate of 26.3 per 100 person-years and hypersensitivity events at 22 per 100 person-years. The adverse event rate was related to lower CD4⁺ cell count. When the CD4⁺ cell count was <100/mm³, the adverse drug event rate was 31 per 100 person-years.⁶²

PHARMACEUTICAL EXCIPIENTS AND ADDITIVES

Pharmaceutical products contain a number of “inert” additives (e.g., dyes, fillers, buffers, and stabilizers) in addition to the therapeutic ingredients. These additives are not always inert and may cause adverse effects, including allergic reactions.

The azo dye tartrazine (FD&C Yellow No. 5) is associated with anaphylactoid reactions, acute bronchospasm, urticaria, rhinitis, and contact dermatitis.^{63,64} Although the immunologic mechanisms are unclear, approximately 10% of aspirin-sensitive asthmatics are also intolerant to tartrazine,⁶⁵ suggesting a role for tartrazine as a cyclooxygenase inhibitor. As little as 0.85 mcg or as much as 25 mg tartrazine has provoked positive responses.⁶⁵

Sulfites (including sulfur dioxide, sodium sulfite, sodium and potassium bisulfite, and sodium and potassium metabisulfite) are used commonly as antioxidants in pharmaceutical products and some foods. Many cases of adverse reactions associated with ingestion of sulfites (usually in foods) have been reported to the Food and Drug Administration (FDA),⁶⁶ including wheezing, dyspnea, chest tightness, urticaria, angioedema, flushing, weakness, nausea, anaphylaxis, and death.

IgE-mediated and nonimmunologic sulfite hypersensitivity has been demonstrated in children with a history of chronic asthma. Adverse reactions to sulfite-preserved injectables, such as gentamicin, metoclopramide, lidocaine, and doxycycline, have been reported. In contrast to reactions caused by foods, these reactions do not occur more frequently in steroid-dependent asthmatics and do not always coincide with a positive oral sulfite challenge.⁶⁷ Blunted bronchodilation may be observed in asthmatics following inhalation of sulfite-containing nebulizer solutions. Although many nebulizer solutions contain sulfites, metered-dose inhalers do not. Many aqueous epinephrine products also contain sulfites. The FDA labeling states that in emergency situations when sulfite-free preparations are not available, sulfite-containing epinephrine should not be withheld from a sulfite-intolerant individual because small subcutaneous doses of sulfites usually are well tolerated. However, an increased risk of anaphylaxis exists after subcutaneous injection in rare patients with a positive oral challenge to 5 to 10 mg sulfite.

Parabens (including methyl-, ethyl-, propyl-, and butylparaben) are used widely in pharmaceutical products as a biocidal agent. Most allergic reactions to parabens are observed after topical exposure.⁶⁸ Delayed hypersensitivity contact dermatitis occurs more often in individuals with preexisting dermatitis.⁶⁵ Immediate hypersensitivity after parenteral administration is rare. Although these agents are chemically related to benzoic acid and *p*-aminobenzoic acid, the evidence for cross-sensitivity is lacking.⁶⁵

CANCER CHEMOTHERAPY AGENTS

Chemotherapy agents are implicated in hypersensitivity reactions in 5% to 15% of patients who receive them.⁶⁹ Up to 65% of patients receiving L-asparaginase experience immediate hypersensitivity reactions such as urticaria and anaphylaxis.⁷⁰

The combination regimen of paclitaxel (or docetaxel) and carboplatin frequently is responsible for producing hypersensitivity reactions. Each agent precipitates a distinct reaction, allowing for differentiation between causative factors. Hypersensitivity reactions have been observed with paclitaxel and docetaxel as frequently as 34% of patients.^{1,71,72} The reaction, typically occurring shortly after initiation of the first dose, is due to Cremophor EL, the polyoxyethylated castor oil vehicle for paclitaxel. Severe reactions are characterized by dyspnea, bronchospasm, urticaria, and hypotension. Minor reactions include flushing and rashes. In patients receiving a 3-hour infusion, the incidence of severe reactions is reduced to 1.3%, and the incidence of minor reactions is 42%.⁷³ To reduce the risk of hypersensitivity reaction, patients are routinely premedicated with corticosteroids and H₁- and H₂-receptor antagonists. A protein-bound formulation of paclitaxel (Abraxane) is available that avoids most of the hypersensitivity reactions.

Carboplatin hypersensitivity develops after six or more courses of carboplatin or its parent compound cisplatin.⁷⁴ Reactions typically develop shortly after completing the infusion or up to 3 days after therapy.⁷⁵ Symptoms of severe reaction include tachycardia, dyspnea, facial swelling, rigors, and hypotension. Mild reactions include itching, erythema, and facial flushing. Desensitization with carboplatin usually is not successful owing to previous prolonged exposure. Skin testing is useful because a negative test has a high predictive value for nonreactivity.⁷⁶

Oxaliplatin hypersensitivity has been reported in as many as 12% of patients. Symptoms range from facial flushing to dyspnea. Management strategies include decreasing the rate of infusion and administration of corticosteroids and H₁- and H₂-receptor antagonists.⁷⁷ Desensitization has been successful in patients desiring to continue treatment after experiencing a hypersensitivity reaction.^{78,79}

ANTICONSULSANTS

Many anticonvulsant drugs produce a variety of hypersensitivity reactions and pseudoallergic reactions. Drugs such as phenytoin, phenobarbital, carbamazepine, and lamotrigine can cause an “anti-convulsant hypersensitivity syndrome” characterized by fever, rash, lymphadenopathy, and internal organ involvement. Eosinophilia is frequently present. Onset usually occurs several weeks into therapy.⁸⁰ In some cases, morbilliform rash develops into exfoliative dermatitis. Concomitant use of valproate with lamotrigine significantly increases the risk of hypersensitivity as a result of reduced lamotrigine metabolism, leading to a prolonged elimination half-life.⁸¹

TREATMENT

Allergic Reactions

9 The basic principles for management of allergic reactions to drugs or biologic agents include (a) discontinuation of the medication or agent when possible, (b) treatment of the adverse clinical signs and symptoms, and (c) substitution, if necessary, of another agent.⁸²

Identification of patients at high risk for allergic drug reactions requires a careful history and, where appropriate, performance of drug provocation tests to evaluate sensitivity.^{83,84} One of the most helpful tests for evaluating risk is the allergen skin test. For some

drugs, skin testing can demonstrate the presence of drug-specific IgE and predict a relatively high risk of immediate hypersensitivity reactions. Note that skin testing does not predict the risk of delayed or most dermatologic reactions.

A higher proportion of patients report an “allergic reaction” to penicillin than actually experience a reaction. However, patients with a history of penicillin allergy are recognized to have a fourfold to sixfold greater risk of subsequent reactions.²⁶ In addition, a negative history of penicillin allergy does not eliminate the risk of immediate reactions because many serious and even fatal allergic reactions to β -lactam antibiotics occur in patients who have no history of penicillin allergy.²⁶

10 Skin testing can reduce the uncertainty of penicillin sensitivity and should be performed in all patients who have a history of penicillin allergy and require treatment with these agents. Penicillin skin testing in advance of need for penicillin treatment in patients with a history of penicillin allergy does not appear to induce sensitization.⁸⁵ Testing for the major penicillin determinant is accomplished with penicilloyl-polylysine (PPL; Pre-Pen), but this product is not currently available in the United States. If this agent is used alone, patients reacting only to minor determinants will be missed. At present, there is also no commercially available product that can be used to test for most of the minor determinants. Benzylpenicillin (at a concentration of 10,000 units/mL) has been used, but some reactive patients still will be missed. When commercially available β -lactams are used for skin testing, as many as 15% of patients with β -lactam allergies will be missed.⁸⁶ Penicillin skin testing can facilitate the safe use of penicillin in 90% of patients with a history of penicillin allergy.⁸⁷ The incidence of penicillin skin test positive reactivity is low (<1%) in patients with a negative history and up to 72% in patients with a convincing positive history of penicillin allergy.⁸⁸ Even in patients who report a history of penicillin allergy but are skin test negative, penicillin treatment does not appear to cause resensitization.⁸⁹ The procedure for performing penicillin skin testing is given in Table 91–3.

A negative penicillin skin test indicates that the risk of life-threatening reactions is extremely low with administration of penicillin or other β -lactams. Patients occasionally may experience systemic reactions after skin testing. Also, certain types of patients (e.g., those with dermatographism or taking antihistamines) may be unsuitable for skin testing because a false-positive or false-negative test may result. Penicillin is the only drug for which the predictive value of skin testing has been well established. The value of skin testing for evaluating the risk of adverse reactions to other drugs is largely unknown, but these tests are recommended in selected patients with histories of immediate reactions to nonpenicillin antibiotics.⁸⁴

ANAPHYLAXIS

Anaphylaxis requires prompt treatment to minimize the risk of serious morbidity or death. On presentation, attention should be given first to stopping the likely offending agent, if possible, and restoring respiratory and cardiovascular function. A protocol for treatment of anaphylaxis is presented in Table 91–4. Epinephrine is administered as primary treatment to counteract bronchoconstriction and vasodilation. Epinephrine should be administered intramuscularly in the lateral aspect of the thigh.⁹⁰ If blood pressure is not restored by epinephrine, crystalloid intravenous fluids should be administered to restore intravascular volume. Typically, 1 L of 0.9% sodium chloride or lactated Ringer solution is administered over 10 to 15 minutes. This can be repeated if the patient is still believed to be volume depleted. A maintenance intravenous fluid then is initiated. Intravenous fluids should be given early in the course of treatment in an attempt to prevent shock. An immediate priority is to establish and maintain an airway by the use of

TABLE 91-3 Procedure for Performing Penicillin Skin Testing

A. Percutaneous (prick) Skin Testing	
Materials	Volume
Pre-Pen 6×10^6 M (currently not commercially available in the United States)	1 drop
Penicillin G 10,000 units/mL	1 drop
β -Lactam drug 3 mg/mL	1 drop
0.03% albumin-saline control	1 drop
Histamine control (1 mg/mL)	1 drop
1. Place a drop of each test material on the volar surface of the forearm. 2. Prick the skin with a sharp needle inserted through the drop at a 45° angle, gently tenting the skin in an upward motion. 3. Interpret skin responses after 15 minutes. 4. A wheal at least 2×2 mm with erythema is considered positive. 5. If the prick test is nonreactive, proceed to the intradermal test. 6. If the histamine control is nonreactive, the test is considered uninterpretable.	
B. Intradermal Skin Testing	
Materials	Volume
Pre-Pen 6×10^6 M (currently not commercially available in the United States)	0.02 mL
Penicillin G 10,000 units/mL	0.02 mL
β -Lactam drug 3 mg/mL	0.02 mL
0.03% albumin-saline control	0.02 mL
Histamine control (0.1 mg/mL)	0.02 mL
1. Inject 0.02–0.03 mL of each test material intradermally (amount sufficient to produce a small bleb). 2. Interpret skin responses after 15 minutes. 3. A wheal at least 6×6 mm with erythema and at least 3 mm greater than the negative control is considered positive. 4. If the histamine control is nonreactive, the test is considered uninterpretable.	
Antihistamines may blunt the response and cause false-negative reactions.

endotracheal intubation if necessary. When a patient with anaphylaxis is hypotensive, vasopressors will be needed in addition to crystalloids. Norepinephrine is the vasoconstrictor agent of choice for treatment of anaphylactic shock, although dopamine also may be useful. Patients in shock should remain supine with raised legs.²⁹

Other agents may be required for treatment of anaphylactic reactions. Corticosteroids (hydrocortisone sodium succinate intravenously) can reduce the risk of late-phase reactions. Aminophylline can be used as adjunctive therapy for bronchospasm. Histamine (H_1) receptor blockers (e.g., diphenhydramine) can be administered to reduce some of the symptoms associated with anaphylaxis, but these agents are not effective as primary therapy.

■ DESENSITIZATION

For some patients allergic to penicillin, no reasonable alternatives exist, and penicillin therapy may be necessary for treatment of severe, life-threatening infection. In this situation, penicillin desensitization should be considered. Desensitization can reduce the risk of anaphylaxis but does not influence the likelihood of other types of reactions such as exfoliative dermatitis or SJS.

Penicillin desensitization should be performed by a physician experienced in the risks and management of severe allergic reactions. Desensitization should be performed in a hospital setting with resuscitation equipment available. The potential risks and benefits should be discussed with the patient. Prior to initiating the protocol, the patient should be stabilized and fluid, pulmonary, and cardiovascular function optimized. The use of premedications (antihistamines or corticosteroids) is controversial because these agents may mask the early signs of acute reactions and do not reliably reduce the severity of acute reactions. Approximately one third of patients who have undergone desensitization experience mild, transient allergic reaction either

TABLE 91-4 Treatment of Anaphylaxis

1. Place patient in recumbent position and elevate lower extremities.
2. Monitor vital signs frequently (every 2–5 minutes) and stay with the patient.
3. Administer epinephrine 1:1,000 into nonoccluded site: (adults: 0.01 mL/kg up to a maximum of 0.2–0.5 mL every 10 to 15 minutes as needed; children: 0.01 mL/kg up to a maximum dose of 0.2–0.5 mL) subcutaneously or intramuscularly. If necessary, repeat every 15 minutes, up to 2 doses.
4. Administer oxygen, usually 8–10 L/min; however, lower concentrations may be appropriate for patients with chronic obstructive pulmonary disease. Maintain airway with oropharyngeal airway device.
5. Administer the antihistamine diphenhydramine (Benadryl, adults 25–50 mg; children 1–2 mg/kg) usually given parenterally. Apply tourniquet proximal to site of antigen injection; remove every 10–15 minutes.
6. If anaphylaxis is caused by an injection, administer aqueous epinephrine 1:1,000 into site of antigen injection; 0.15–0.3 mL into the injection site.
7. Treat hypotension with IV fluids or colloid replacement, and consider use of a vasopressor such as dopamine.
8. Treat bronchospasm with a β_2 -agonist given intermittently or continuously, consider the use of aminophylline 5.6 mg/kg as an IV loading dose, given over 20 minutes, or to maintain a blood level of 8–15 mcg/mL.
9. Give hydrocortisone, 5 mg/kg, or approximately 250 mg IV (prednisone 20 mg orally can be given in mild cases) to reduce the risk of recurring or protracted anaphylaxis. These doses can be repeated every six hours as required.
10. In refractory cases not responding to epinephrine because a β -adrenergic blocker is complicating management, glucagon 1 mg IV as a bolus may be useful. A continuous infusion of glucagon, 1–5 mg/h, may be given if required.

Reprinted and adapted from *J Allerg Clin Immunol* 1998;101:5465–528.

during the desensitization procedure or during penicillin therapy.²⁶ Patients who can take oral medication should undergo desensitization with oral penicillin. Protocols for oral and intravenous penicillin desensitization are given in Tables 91–5 and 91–6. Once the desensitization protocol is begun, it should not be interrupted except for severe reactions. Antihistamines or epinephrine can be administered to treat reactions. In addition, if the patient completes the desensitization regimen and then undergoes penicillin treatment, a lapse between doses of as few as 24 hours can allow for reemergence of sensitivity. Protocols are available for desensitization of other β -lactam antibiotics.⁹¹

Desensitization of trimethoprim–sulfamethoxazole can be achieved within 2 days in most AIDS patients.^{1,92} This can be accomplished by

TABLE 91-5 Protocol for Oral Desensitization

Phenoxymethyl Penicillin

using the following schedule of doses (milligrams of sulfamethoxazole–trimethoprim): day 1: 9 AM, 4 and 0.8 mg; 11 AM, 8 and 1.6 mg; 1 PM, 20 and 4 mg; 5 PM, 40 and 8 mg; day 2: 9 AM, 80 and 16 mg; 3 PM, 160 and 32 mg; 9 PM, 200 and 40 mg; day 3: 9 AM, 400 and 80 mg, and 400 and 80 mg daily thereafter. Other investigators have described a 6-hour graded challenge in HIV-infected patients.⁹³

Skin tests often become negative during and shortly after desensitization. The mechanism by which desensitization is protective is unclear. It does not appear that penicillin-specific IgE is neutralized or that IgG as “blocking antibody” is produced. One possible explanation is that basophils and mast cells attain some degree of tolerance on exposure to the antigen.

ABBREVIATIONS

IgE: immunoglobulin E

LT: leukotriene

NSAID: nonsteroidal antiinflammatory drug

PAF: platelet-activating factor

PG: prostaglandin

PPD: purified protein derivative

SLE: systemic lupus erythematosus

TEN: toxic epidermal necrolysis

KRISTINE S. SCHONDER AND HEATHER J. JOHNSON

KEY CONCEPTS

- 1 Acute allograft rejection is primarily due to the activation of T cells, which is mediated, to a large degree, by interleukin (IL)-2.
- 2 A combination of two to four immunosuppressive drugs is used to target different levels of the immune cascade to prevent allograft rejection and to allow lower doses of individual agents to be used to minimize toxicity.
- 3 The goals of immunosuppression are to decrease the incidence of acute and chronic rejection while minimizing adverse events associated with immunosuppressive medications.
- 4 Calcineurin inhibitors (CIs), such as cyclosporine and tacrolimus, are the backbone of immunosuppressive regimens because they inhibit IL-2 and thereby block T-cell activation. However, they are associated with significant adverse effects, namely, nephrotoxicity and neurotoxicity.
- 5 Calcineurin inhibitor-induced nephrotoxicity is one of the most common side effects observed in transplant recipients and is the leading cause of renal dysfunction in nonrenal transplant patients.
- 6 Corticosteroids are a key component of immunosuppressive regimens because they block the initial steps in allograft rejection. However, the adverse effects associated with long-term use of corticosteroids have prompted the investigation of corticosteroid-free immunosuppressive protocols.
- 7 Antiproliferative agents such as azathioprine and mycophenolate inhibit T-cell proliferation by altering purine synthesis to prevent acute rejection. Bone marrow suppression is the most significant adverse effect associated with these agents.
- 8 Sirolimus exerts its activity by inhibiting the mTOR (mammalian target of rapamycin) receptor, which alters T-cell response to IL-2. The adverse effects associated with sirolimus include thrombocytopenia, anemia, and hyperlipidemia.
- 9 The effect of antibody preparations on T cells depends on the specific target receptors on the surface of T cells. Most antibody preparations are associated with significant infusion-related reactions.

- 10 Long-term allograft and patient survival is limited by chronic rejection, cardiovascular disease, and long-term immunosuppressive complications, such as malignancy.

Solid-organ transplantation provides a lifesaving treatment for patients with end-stage cardiac, kidney, liver, lung, and intestinal disease. In 2004, the most recent year for which data is available, 26,539 solid organ transplants were performed. Kidney transplants remain the most common; 9,025 were from cadaveric donors and 6,646 from living donors. The next most frequently transplanted organ was the liver, with 5,457 from cadaveric donors and 323 from living donors. Heart and pancreas (or combined kidney-pancreas) transplants account for almost 2,000 and 1,500 transplants, respectively.¹ Despite the demand for transplantation, the number of cadaveric donors has remained relatively stable during the past decade. In 2006, more than 90,000 persons in the United States were waiting for a transplant (almost 70,000 people were awaiting a kidney, 17,000 a liver, and almost 3,000 were on the list for a heart transplant). Median waiting time for a cadaveric kidney is more than 3 years. For liver transplantation the median time to transplant is more than 2 years, whereas for heart transplantation it is approximately 6 months. For heart, liver, and lung transplantation clinical status is an important factor affecting waiting times, with the sickest patients receiving priority for available organs.

To increase the number of organs available for transplantation, several strategies have been employed in the past several years. The use of living donors for renal transplantation represents almost half of all kidney transplants, more than any other organ. Living-donor transplantation is also becoming increasingly important for those with end stage liver and lung disease. Efforts to expand the cadaveric donor pool have included relaxation of age restrictions, development of better preservation solutions, use of “extended-criteria” and non-heart-beating donors, and the transplantation of one liver to more than one recipient, as well as the implantation of only a segment of a liver.

Despite all these efforts, patients continue to die awaiting transplantation. In 2004, more than 7,000 people died who were on transplantation waiting lists. In all areas, efforts have been made to improve organ allocation, moving toward allocation based primarily on “medical necessity” versus time-on-waiting-list. Although dialysis can be used for an extended period of time to partially replace the function of the kidneys, such options are not readily available for most liver and heart transplantation candidates. Left ventricular assist devices are now used commonly as a bridge to transplantation for many heart transplantation candidates, however, hepatocyte transplantation and artificial liver support remain investigational alternatives or bridges to liver transplantation.²

Patient and graft survival rates following transplantation have improved significantly over the past 30 years as a result of advances

in pharmacotherapy, surgical techniques, organ preservation, and the postoperative management of patients (Table 92–1). In fact, the number of people living with transplants exceeded 110,000 in 2004. In this chapter the epidemiology of endstage kidney, liver and heart disease is briefly reviewed, the pathophysiology of organ rejection is reviewed, the pharmacotherapeutic options for individualized immunosuppressive regimens are critiqued and the unique complications of these regimens along with the therapeutic challenges they present are discussed.

EPIDEMIOLOGY AND ETIOLOGY

KIDNEY

Renal transplantation is the preferred long-term therapeutic option for most patients with end-stage renal disease because it provides patients with the greatest potential improvement in quality of life. Dialysis catheter-related infections, peritoneal dialysis-associated peritonitis, and scheduled dialysis treatments are avoided, and dietary restrictions are fewer. Patients who receive a renal transplant before the initiation of dialysis have markedly improved quality of life and prolonged life expectancy. The use of living-donor transplantation has made this increasingly possible. Although the analysis of quality of life is complex, patients generally report improved quality of life following transplantation as compared with patients on maintenance dialysis.³

Diabetes mellitus, hypertension, and glomerulonephritis are the most common causes of end-stage renal disease leading to kidney transplantation, accounting for more than 70% of patients (see Chapters 47 and 48).⁴ Patients with medical conditions such as unstable cardiac disease or recently diagnosed malignancy, for whom the risk of surgery or chronic immunosuppression would be greater than the risks associated with chronic dialysis, are generally excluded from consideration for transplantation.

LIVER

Noncholestatic cirrhosis (hepatitis C, alcoholic cirrhosis, hepatitis B, cryptogenic cirrhosis, and autoimmune hepatitis) is the primary cause of end-stage liver disease and more than 70% of liver transplant recipients have been diagnosed with one of these conditions.¹ Hepatitis C remains the most common indication leading to liver transplantation, accounting for 40% of all cases. Livers are allocated based on a United Network for Organ Sharing-adapted, Model for End-stage Liver Disease (MELD) score. This score, which is based on serum creatinine concentration, total serum bilirubin concentration, international normalization ratio, and etiology of cirrhosis, has been demonstrated to be a useful tool to predict impending mortality.

There are few absolute contraindications to liver transplantation. Patients should be free from active alcohol or substance abuse. Although hepatitis B and C can recur in the transplanted liver, these are not absolute contraindications to liver transplantation.^{2,5}

CLINICAL CONTROVERSY

Retransplantation for hepatitis C recurrence after liver transplantation often depends on the time frame in which recurrence occurs. If recurrence occurs within 6 months of transplantation, retransplantation is contraindicated. If recurrence occurs after 1 year, some clinicians may consider retransplantation. However, other clinicians consider recurrence at any point to be a contraindication for another transplant.

HEART

Cardiac transplant candidates typically are patients with end-stage heart failure who have New York Heart Association class III or IV symptoms despite maximal medical management and have an expected 1-year mortality risk of 25% or greater without a transplant.⁶ Idiopathic cardiomyopathy and ischemic heart disease account for heart failure in more than 90% of heart transplantation recipients.¹ Other etiologies include valvular disease, retransplantation for graft atherosclerosis or dysfunction, and congenital heart disease. Chapters 16 and 20 discuss the role of heart transplantation as a therapeutic option for patients with heart failure.

Absolute contraindications to orthotopic cardiac transplantation include the presence of an active infection (except in the case of an infected ventricular assist device, which is an indication for urgent transplantation) or the presence of other diseases (i.e., malignancy) that may limit survival and/or rehabilitation and severe, irreversible pulmonary hypertension.

CLINICAL CONTROVERSY

Many clinicians do not consider patients infected with human immunodeficiency virus (HIV) to be appropriate candidates for transplantation, although some transplant centers will transplant organs to HIV-infected patients. A similar debate exists with regards to elderly patients, who are in otherwise good health.

SURGICAL PROCEDURES

Kidney transplantation is generally performed by placing the allograft retroperitoneally in the right iliac fossa. The renal artery and vein are anastomosed to the external iliac artery and vein, respectively, and the donor ureter is connected directly to the bladder. If the donor kidney has not undergone prolonged ischemia, the production of urine immediately follows revascularization. For the most part, native kidneys are not removed.⁷

The transplanted liver, in contrast to the kidney, is placed orthotopically; the recipient's own liver must be removed. Liver transplantation occurs in several phases: removal of recipient liver, donor graft revascularization, and biliary reconstruction. During the anhepatic phase, the patient is placed on venovenous bypass to preserve venous return from the kidney and lower extremities. Size may be a limiting factor in liver transplantation. Donor and recipient are usually matched for size to prevent splinting of the diaphragm and pulmonary complications that would result from transplantation of an excessively large liver.⁸

Heart transplantation is usually an orthotopic procedure. Leaving most of the atria and septum of the recipient, the patient is placed on cardiopulmonary bypass. The donor heart is implanted by anastomosis of the left atrium to the residual left atrial wall and joining the right atrial wall and septum. The main pulmonary artery is connected to the ascending aorta.⁹

PHYSIOLOGIC CONSEQUENCES OF TRANSPLANTATION

Transplantation is truly lifesaving for heart, liver, and lung transplantation recipients, whereas renal transplantation is associated with improved quality of life and survival when compared with dialysis.¹⁰ Most heart transplantation patients return to New York Heart Association functional class I following transplantation. Although not all return to work, 89.9% of patients consider themselves to have no limitations on activity at 1-year followup.¹¹ The specific physiologic consequences of kidney, liver, and heart transplantation are discussed below.

KIDNEY TRANSPLANTATION

The glomerular filtration rate of a successfully transplanted kidney may be near normal almost immediately after transplantation. In some patients, however, the concentration of standard biochemical indicators of renal function, such as serum creatinine and blood urea nitrogen, may remain elevated for several days. Standard formulas used to predict drug dosing rely on a stable serum creatinine and may be inaccurate immediately following transplantation (see Chap. 44).

Although the allograft is able to remove uremic toxins from the body, it may take several weeks for other physiologic complications of chronic renal failure, such as anemia, calcium and phosphate imbalance, and altered lipid profiles, to resolve. The renal production of erythropoietin and 1-hydroxylation of vitamin D may return toward normal early in the postoperative period. Because the onset of physiologic effects may be delayed, continuation of pretransplantation calcitriol, calcium supplementation, and/or phosphate binders may be warranted in some patients.

Primary nonfunction of a renal allograft or delayed graft function (DGF) is characterized by the need for dialysis in the first 7 postoperative days or the failure of the serum creatinine to fall below 4 mg/dL or by 30% of the pretransplantation value. The incidence of DGF in primary cadaveric renal transplantation ranges from 8% to 50% and results in a slower return of the kidney's excretory, metabolic, and synthetic functions. DGF is associated with prolonged hospital stays, higher costs, difficult management of immunosuppressive therapy, slower patient rehabilitation, and poor graft survival. Urinary complications, such as ureteral obstruction, thrombosis, or leak or vascular complications, including arterial or venous stenosis or thrombosis, also may result in early graft dysfunction.

The primary cause of DGF is acute tubular necrosis (ATN). The incidence of ATN increases when kidneys are harvested from donors who recently experienced a cardiac arrest, from donors who were hypotensive or on vasopressors, or from older donors (age >55 years). Prolonged periods of ischemia can increase the risk of ATN. The management of patients with ATN may be difficult (see Chap. 45). Cyclosporine and tacrolimus may be implicated in the prolongation of ATN, but a clear cause-and-effect relationship has not been established. DGF predisposes patients to acute rejection, possibly as a consequence of decreased calcineurin inhibitor levels.

LIVER TRANSPLANTATION

The physiologic consequences of liver transplantation are complex, involving changes in both metabolic and synthetic function. Postoperatively, the liver transplant recipient likely will have many fluid, electrolyte, and nutritional abnormalities. Biliary tract dysfunction may alter the absorption of fats and fat-soluble drugs.¹² Poor absorption of the lipid-soluble drug cyclosporine improves after successful liver transplantation and reestablishment of bile flow. Vitamin E deficiency and its neurologic complications in liver

TABLE 92-2 Perioperative Changes in Drug Disposition and Elimination following Liver Transplantation

	Result	Comment
Serum proteins		
↓ Albumin	↑ Free fraction of drugs usually bound to albumin	Diazepam, salicylic acid binding greater in liver transplant than chronic liver disease because of endogenous binding inhibitors (up to 45 days post-transplant)
↑ alpha-1-Acid glycoprotein	Lower free fraction of drugs	Lidocaine
Metabolism/elimination		
Microsomal enzymes	↑ CYP2E1 activity ↔ CYP2D6 ↓ CYP activity	Increased drug metabolism (induction) Unaffected Decreased drug elimination (inhibition)
Oxidation	Stable	
Conjugation	Normalizes after transplant	
Biliary function	↓ Absorption of lipophilic compounds ↑ Cyclosporine metabolites in blood	
Renal elimination	Elimination of gentamicin, vancomycin, cephalosporins less than predicted by serum creatinine	Renal elimination of metabolites limited

Adapted from reference 12.

failure patients are reversed after successful liver transplantation. In stable adult liver transplant patients, the concentrations of retinol and tocopherol are similar to those seen in normal healthy subjects, indicating recovery of transplanted liver production and excretion of bile salts needed for fat-soluble vitamin absorption. Table 92-2 summarizes the effects of liver transplantation on metabolism and renal elimination which are seen in the immediate postoperative period. Most of these changes resolve as liver function normalizes.

The newly transplanted liver fails to function in 10% to 15% of recipients as the result of several different mechanisms. Early graft failure can result from preexisting disease in the donor, and even coagulation defects have been acquired through donor organs. The technical complexity of the operation can produce flaws in revascularization that also lead to graft nonfunction. Surgical complications encountered include portal vein thrombosis, hepatic artery thrombosis, and bile duct leaks. Ischemic injury to the donor liver through preservation is difficult to predict and can result in early graft dysfunction. Perioperative immune events rarely lead to the classic picture of hyperacute rejection in liver transplantation, but graft failure in the first 2 postoperative weeks may indicate antibody-mediated graft destruction.

HEART TRANSPLANTATION

The orthotopically transplanted heart is denervated and no longer responds to physiologic stimuli and pharmacologic agents in a normal manner (Table 92-3).¹³ Patients, for example, do not experience angina. In situations requiring an increased heart rate (e.g., exercise or hypotension), the denervated heart is unable to acutely increase heart rate but instead relies on increasing the stroke volume. Later in the course of exercise or hypotension, heart rate increases in response to circulating catecholamines. While the maximum exercise capacity of heart transplant recipients is below normal, most patients are able to resume normal lifestyles and reasonably vigorous activity levels. Partial reinnervation may occur

TABLE 92-3 Altered Responses to Cardiac Drugs in the Denervated Transplanted Heart

Drug	Effect	Mechanism	Comment
Digitalis	Normal inotropic effect; minimal effect on AV node	Direct myocardial effect; denervation	
Atropine	No effect on AV node	Denervation	
Adrenaline/ noradrenaline	Increased contractility; increased chronotropy	Denervation; hypersensitivity	Increased cardiac output mediated by increased heart rate
Isoproterenol	Normal increase in contractility; normal increase in chronotropy	No neuronal uptake	
Quinidine	No vagolytic effect	Denervation	
Verapamil	AV block	Direct effect	
Nifedipine	No reflex tachycardia	Denervation	
Hydralazine	No reflex tachycardia	Denervation	
β -Blocker	Increased antagonist effect	Denervation	Impaired heart rate response, use sparingly
Adenosine	Negative chronotropic effect	Hypersensitivity; effect on sinus node of denervated heart	Life-threatening asystole (>0.5 min) may occur if used to treat supraventricular arrhythmia or stress testing
Acetylcholine	Negative chronotropic effect	Hypersensitivity; effect on sinus node of denervated heart	

AV, atriovenous node.

Deng MC. Heart failure: Cardiac transplantation. *Heart* 2002;87:177-184. Reproduced with permission from the BMJ Publishing Group.

over time, thereby facilitating more normal physiologic and pharmacologic responses and better exercise capacity.¹⁴

In the first 6 weeks after transplantation, a number of autoregulatory, anatomic, and physiologic responses present in the normal heart are interrupted or blunted. The donor sinus node function may be impaired by preservation injury, direct surgical trauma at excision, the presence of long-acting antiarrhythmics (e.g., amiodarone) taken prior to transplant by the recipient, and a lack of “conditioning” responsiveness to catecholamines.¹⁴ Consequently, the transplanted heart generally requires chronotropic support with either milrinone or pacing in the perioperative period to maintain a heart rate of 90 to 110 beats per minute and satisfactory hemodynamics (i.e., blood pressure, urine output, and tissue perfusion). Approximately 10% to 20% of transplant patients will have persistent chronotropic incompetence requiring either short courses of medications, such as terbutaline or theophylline, or permanent cardiac pacing.

Right ventricular function frequently is impaired, presumably as a result of preservation injury and elevated pulmonary vascular resistance. A “restrictive” hemodynamic pattern may be present initially, but it usually improves over the 6 weeks following transplantation. Donor–recipient size mismatch may contribute to early post-transplantation hemodynamic abnormalities characterized by higher right and left ventricular end-diastolic pressures. Supraventricular arrhythmias are usually transient and may result from overvigorous use of catecholamines or milrinone. If this type of arrhythmia occurs after the perioperative period, the astute clinician should consider the possibility of acute rejection.

Myocardial depression frequently occurs and generally requires inotropic support with agents such as dobutamine, milrinone, and epinephrine. On occasion, intra- or postoperative administration of vasodilators, including nitric oxide, and inotropic agents may be necessary to treat right-sided failure in the transplant patient; milrinone and isoproterenol are preferred in this setting.

Persistent abnormalities of diastolic function are often noted in the transplanted heart such that intracardiac pressures increase in an exaggerated fashion in response to exercise and/or volume infusion.¹⁴ These abnormalities are due in part to denervation, but also to acute rejection or to the scarring secondary to previously treated rejection episodes, hypertension, or cardiac allograft vasculopathy.

Hypertension may occur following surgery secondary to the effect of elevated catecholamine levels and systemic vascular resistance as the residual effects of end-stage heart failure on the healthy heart. Systolic blood pressure should be maintained at 110 to 120 mm Hg to enhance cardiac function. In the acute post-transplantation period, intravenous

nitroprusside or nitroglycerin may be needed, whereas oral angiotensin-converting enzyme inhibitors (ACEIs) and/or amlodipine are commonly used once the patient can ingest oral medications.

PATHOPHYSIOLOGY OF REJECTION

GENERAL CONCEPTS

1 Rejection of any transplanted organ is primarily mediated by activation of alloreactive T cells and antigen-presenting cells such as B lymphocytes, macrophages, and dendritic cells. Acute allograft rejection is caused primarily by the infiltration of T cells into the allograft, which triggers inflammatory and cytotoxic effects on the graft. Complex interactions between the allograft and cellular cytokines, cell-to-cell interactions, CD4+ and CD8+ T cells, and B cells ultimately lead to chronic rejection and graft loss if adequate immunosuppression is not maintained.¹⁵

The sequence of events that underlies graft rejection is recognition of the donor’s histocompatibility differences by the recipient’s immune system, recruitment of activated lymphocytes, initiation of immune effector mechanisms, and finally graft destruction.

Class I and II antigens of the major histocompatibility complex (MHC) are important for histocompatibility in transplantation.¹⁶ Class I antigens are present on virtually all nucleated cells in the body, whereas the class II antigens are located primarily on B lymphocytes, antigen-presenting cells, and vascular endothelium.¹⁶ T-helper cells, specialized to direct the immune system, can only recognize foreign antigen in the presence of MHC type II. Cytotoxic T cells, specialized to destroy, can only recognize antigen in the presence of MHC type I antigens. Lymphocytes are the only cells in the body that can recognize specific antigens and are central to allograft rejection.

T-cell activation is caused by interactions between T-cell receptors, the MHC, cellular adhesion molecules, and costimulatory molecules. Among the series of events is calcineurin activation, which ultimately promotes interleukin (IL)-2 proliferation. After initial T-cell activation, the process of clonal expansion and immunologic progression is mediated by cytokines. IL-2 is released from T cells and activates T lymphocytes locally and in other regions of the body. Undifferentiated T-helper cells can be induced to develop along two lines: T-helper type 1 cells secrete IL-2, interferon- γ and IL-12 and favor cytotoxicity, whereas T-helper type 2 cells secrete IL-4, IL-5, IL-10, and IL-13, which stimulate B-cell and immunoglobulin development. A predominance of T-helper type 2 cells is associated with tolerance (the ability of the body to

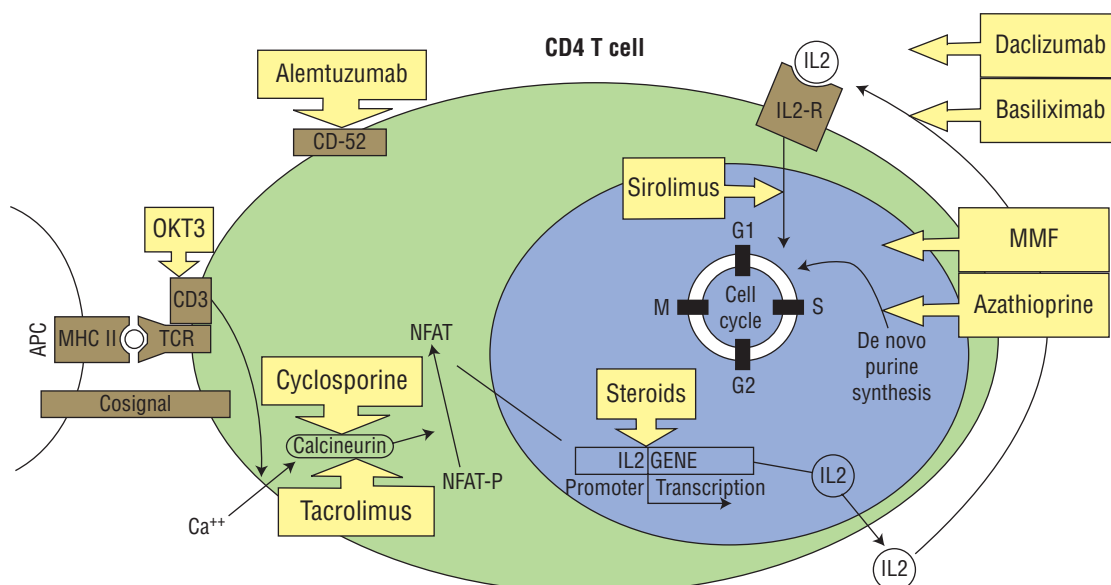

FIGURE 92-1. Stages of CD4 T-cell activation and cytokine production with identification of the sites of action of different immunosuppressive agents. Antigen major histocompatibility complex (MHC) II molecule complexes are responsible for initiating the activation of CD4 T cells. These MHC-peptide complexes are recognized by the T-cell recognition complex (TCR). A costimulatory signal initiates signal transduction with activation of second messengers, one of which is calcineurin. Calcineurin removes phosphates from the nuclear factors (NFAT-P) allowing them to enter the nucleus. These nuclear factors specifically bind to an interleukin (IL)-2 promoter gene facilitating IL-2 gene transcription. Interaction of IL-2 with the IL-2 receptor (IL-2R) on the cell membrane surface induces cell proliferation and production of cytokines specific to the T cell. (APC, antigen-presenting cells; MMF, mycophenolate mofetil.) (With permission from reference 17.)

recognize the transplanted allograft as “self”) in some experimental models. The complex nature of these cytokine interactions makes it very difficult to design drugs with exclusive actions (Fig. 92-1). Allograft inflammation is thus the result of specific T-cell interactions with antigen-presenting cells and nonspecific immunologic mechanisms (natural killer cell chemotaxis, release of vasoactive substances). Rejection of the transplanted tissue can take place at any time following surgery and is classified clinically as hyperacute rejection, acute cellular rejection, and/or humoral or chronic rejection.

Efforts are made to allocate well-matched, according to human leukocyte antigens (HLA)-A, -B, and -DR, kidneys to minimize rejection and enhance survival rates. However, the benefit of having no recipient donor mismatches may be negated by excessive cold ischemia time (>36 hours) and donor age older than 60 years. HLA tissue matching is not performed routinely before transplantation for livers and hearts because organ availability is more limited and the optimal cold ischemia time is shorter. However, if the potential recipient is reactive against a panel of random donor antigens (i.e., patient has a positive panel reactive antibody [PRA] >10% to 20%), a negative T-cell crossmatch is required prior to transplantation. Transplanted organs must be matched for ABO blood group compatibility with the recipient as ABO mismatching will result in hyperacute rejection. Liver transplantation may be carried out in emergency situations across ABO blood groups, but survival is lower, because of the risks of acute and chronic complications.

HYPERACUTE REJECTION

Hyperacute rejection may be evident within minutes of the transplantation procedure when preformed donor-specific antibodies are present in the recipient at the time of the transplant. Hyperacute rejection can also be induced by immunoglobulin G antibodies that bind to antigens on the vascular endothelium, such as class I MHC, ABO, and vascular endothelial cell antigens. Tissue damage can be mediated through antibody-dependent, cell-mediated cytotoxicity

or through activation of the complement cascade. The ischemic damage to the microvasculature rapidly results in tissue necrosis.

Hyperacute rejection has become uncommon in kidney and heart transplants because transplant donors are matched for ABO blood groups and crossmatch testing is done to determine the presence of donor-specific lymphocytotoxic antibodies. A positive crossmatch presents a serious risk for graft failure even if hyperacute rejection does not occur. A negative lymphocytotoxicity crossmatch does not entirely rule out the possibility of hyperacute rejection because non-MHC antigens on the vascular endothelium can serve as targets of donor-specific antibodies. Early graft dysfunction is treated with supportive care and retransplantation if possible. Hyperacute rejection however rarely occurs in patients receiving a liver transplant. The reason for this is not fully understood, but the local release of cytokines may alter the immunologic reaction in the liver.

ACUTE CELLULAR REJECTION

Acute rejection is most common in the first few months following transplantation but can occur at any time during the life of the allograft. Acute rejection generally is reversible within 1 to 3 days, if treated. Acute cellular rejection is mediated by alloreactive T-lymphocytes that appear in the circulation and infiltrate the allograft through the vascular endothelium. After the graft is infiltrated by lymphocytes, the cytotoxic cells specifically target and kill the functioning cells in the allograft. At the same time local release of lymphokines attracts and stimulates macrophages to produce tissue damage through a delayed hypersensitivity-like mechanism. These immunologic and inflammatory events lead to the nonspecific signs and symptoms of acute rejection: pain and tenderness over the graft site, fever, and lethargy.

Kidney

Acute rejection, which may affect up to 20% of patients during the first 6 months following transplantation, is evidenced by an abrupt

rise in serum creatinine concentration of $\geq 30\%$ over baseline. A specific histologic diagnosis can be obtained via biopsy of the allograft and often is used to guide therapy for rejection. A biopsy specimen with a diffuse infiltrate of lymphocytes is consistent with acute cellular rejection. After the diagnosis of rejection has been confirmed, the potential risks and benefits of specific antirejection therapies must be evaluated. Hypertension often worsens during an episode of rejection and edema and weight gain are common as a result of sodium and fluid retention. Symptomatic azotemia also may develop in severe cases. Appropriate adjustments in pharmacotherapy are warranted in the face of diminished renal function.

Liver

The liver appears to be less immunogenic and more likely to promote immunologic tolerance than the other vascularized organs. Approximately 18% of liver transplantation recipients will experience a rejection episode in the first post-transplant year. The clinical signs of acute cellular rejection include leukocytosis and a change in the color or quantity of bile for those who still have an external drainage tube in place. An increased serum bilirubin concentration and increases in hepatic enzymes are sensitive markers of rejection. Although a liver biopsy provides definitive evidence of the diagnosis of rejection, a prompt response to antirejection medication also has proven useful as a means to differentiate rejection from other causes of hepatic dysfunction.

Heart

Acute rejection is a major determinant of survival following cardiac transplantation and accounts for approximately 17% of all deaths.¹⁷ More than 60% of heart transplantation recipients will experience at least one episode of rejection during the first year. The incidence of rejection is substantially higher during the early months following transplantation, with 90% of all rejections occurring within the first 6 months. Because the incidence of acute rejection is highest during this time period, endomyocardial biopsies are often performed at regularly scheduled intervals following transplantation because rejection of the cardiac allograft is not necessarily accompanied by overt clinical signs or symptoms. A typical biopsy schedule would be weekly for the first postoperative month, biweekly for the next 2 months, and monthly to bimonthly through the remainder of the first post-transplant year. Biopsy frequency subsequently decreases based on patient clinical status. Nonspecific findings may include low-grade fever, malaise, and mild reduction in exercise capacity, whereas heart failure or atrial arrhythmias may reflect more severe rejection. The “gold standard” for detection of rejection is histologic confirmation after examination of the endomyocardial biopsy specimens. The majority of rejection episodes are characterized histologically by lymphocytic infiltrates with or without myocyte degeneration.¹⁸ Cardiac function is assessed by either echocardiography or measurement of right-sided heart and pulmonary wedge pressures and cardiac output by pulmonary artery catheterization at the time of each biopsy.

HUMORAL REJECTION

Humoral rejection, sometimes referred to as vascular rejection, is an antibody-mediated process directed against HLA antigens present on the donor vascular endothelium. It can be characterized by capillary deposition of immunoglobulins, complement, and fibrinogen on immunofluorescence staining. Circulating immune complexes often precede humoral rejection. This form of rejection is less common than cellular rejection and generally occurs in the first 3 months after transplantation. It is associated with an increased fatality rate and appears to be more common when antilymphocyte antibodies are used for rejection prophylaxis. An increased risk of

humoral rejection is associated with female gender, elevated PRA, cytomegalovirus seropositivity, a positive crossmatch, and prior sensitization to OKT3 (muromonab CD3).¹⁹ Strategies to reverse humoral rejection include plasmapheresis, often in combination with intravenous immunoglobulin, high-dose intravenous corticosteroids, antithymocyte globulin, cyclophosphamide, rituximab, and mycophenolate mofetil.

CHRONIC REJECTION

Chronic rejection is a major cause of late graft loss and is one of the most important problems that remains to be resolved. Although chronic rejection simply may be a slow and indolent form of acute cellular rejection, the involvement of the humoral immune system and antibodies against the vascular endothelium appear to play a role. Persistent perivascular and interstitial inflammation is a common finding in kidney, liver, and heart transplantation. As a result of the complex interaction of multiple drugs and diseases over time, it is difficult to delineate the true nature of chronic rejection. For example, cytomegalovirus is associated with the development of chronic rejection in both liver and heart transplant recipients. Unlike acute rejection, chronic rejection is not reversible with any of the immunosuppressive agents currently available.

Kidney

Advances in the management of acute rejection during the last decade have increased the duration of functioning grafts from living and cadaveric donors by more than 70%.²⁰ Chronic allograft nephropathy remains the most common cause of graft loss in the late post-transplantation period (>1 year). The histopathologic characteristics of chronic allograft nephropathy include vascular intimal hyperplasia, tubular atrophy, interstitial fibrosis, and chronic transplant glomerulopathy. Structural changes associated with chronic allograft nephropathy are seen in as many as 40% of kidney transplantation patients 1 year after transplantation, and may present as early as 3 months.²¹ Hypertension, proteinuria, and a progressive decline in renal function represent the classic clinical triad of chronic allograft nephropathy. Factors that contribute to the development of chronic allograft nephropathy include calcineurin inhibitor nephrotoxicity, polyomavirus infection, hypertension, chronic rejection, which results from slowly progressing immunologic activity, donor-related factors including ischemia time and undetected kidney disease in the donor kidney, and recurrence of the primary kidney disease in the recipient.

Liver

Chronic rejection, which affects approximately 3% to 5% of transplanted livers, is characterized by an obliterative arteriopathy and the gradual loss of bile ducts, often referred to as the vanishing bile duct syndrome. Initially patients experience an asymptomatic rise in the alkaline phosphatase and γ -glutamyl transpeptidase. As levels of bilirubin increase, patients become jaundiced and may experience itching. These changes are considered the result of immunologic and ischemic injury and can be seen in patients who have not responded adequately to therapy for acute rejection.

Heart

Cardiac allograft vasculopathy, characterized by accelerated intimal thickening or development of atherosclerotic plaques, is the leading cause of graft failure and death in heart transplant recipients.²² Endothelial injury, caused by both cell-mediated and humoral responses, is the first step in the process. Vasculopathy is restricted to the transplanted allograft and rarely affects the recipient's native vessels. Lipid abnormalities and cytomegalovirus have been linked

to the development of vasculopathy. Routine surveillance with coronary angiography, intravascular ultrasound, or other procedures can aid in the diagnosis of vasculopathy. Evidence of cardiac allograft vasculopathy can be seen in as many as 14% of patients within 1 year of transplantation and in as many as 50% of patients within 5 years.²² β -Hydroxy- β -methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors and ACEIs have been used to decrease the incidence of vasculopathy.²² More recently, sirolimus and everolimus have been shown to reduce the incidence and slow progression of cardiac allograft vasculopathy.²³ Percutaneous transluminal coronary angioplasty and coronary artery bypass grafting have been used in severe cases of vasculopathy; these procedures, however, are limited by significantly increased mortality compared with the general population.²²

TREATMENT

Immunosuppression

■ DESIRED OUTCOME

The goals of immunosuppression vary depending on the time interval since transplantation. Immediately following surgery, the primary goal of therapy is to prevent hyperacute and acute rejection. The high doses of immunosuppressants required to achieve this goal, if maintained long-term, may result in serious complications (e.g., nephrotoxicity, infection, thrombocytopenia, and drug-induced diabetes). Therefore rapid dosage reductions are frequently used to minimize these effects. Transplant immunosuppression must be balanced in terms of graft and patient survival (the prevention of rejection versus the risk of adverse effects associated with therapy, including life-threatening infection or malignancy).

■ GENERAL APPROACH TO TREATMENT

② A multidrug approach is rational from an immunomechanistic viewpoint because the many agents have overlapping and potentially synergistic mechanisms of action. Furthermore, the use of a multidrug immunosuppression regimen may allow the use of lower doses of individual agents, thus reducing the severity of dose-related adverse effects (Fig. 92–2). The protocols and individual drug regimens tend to be center specific; although induction therapy may not be uniformly used, in almost every setting, patients receive IV methylprednisolone during the perioperative period. The patient will then begin the maintenance immunosuppressive regimen. The center-specific protocols generally combine a drug from two or three of the following classes: calcineurin inhibitors; antimetabolites or sirolimus; and corticosteroids.

If rejection is suspected, a biopsy can be done for definitive diagnosis or the patient may be empirically treated for rejection. Empiric treatment generally involves administration of high-dose corticosteroids, usually 500 to 1,000 mg of methylprednisolone intravenously for one to three doses. If signs and symptoms of rejection are resolved with empiric therapy, the maintenance immunosuppressive regimen is generally modified to provide a greater level of overall immunosuppression. If rejection is confirmed by biopsy, treatment may be based on the severity of rejection with polyclonal and monoclonal antibodies being reserved for moderate to severe rejections or those which have not responded to a course of corticosteroids.

Induction Therapy

Induction therapy involves the use of a high level of immunosuppression at the time of transplantation with or without the immediate introduction of cyclosporine or tacrolimus (see Fig. 92–2).

Induction historically included the use of polyclonal or monoclonal antibodies in addition to triple therapy of azathioprine, high-dose corticosteroids, and a calcineurin inhibitor at the time of transplantation. Today, induction therapy consists of one of two perioperative immunosuppressive strategies: (a) the provision of a highly intense level of immunosuppression, either universally or on the basis of patient-specific risk factors such as age and race, or (b) the use of antibody therapy to provide enough immunosuppression to delay the initiation of therapy with the nephrotoxic calcineurin inhibitors. The rationale for delayed calcineurin inhibitor administration varies slightly depending on the type of transplant. In renal transplantation, the newly transplanted kidney is very susceptible to nephrotoxic injury, whereas in liver and heart transplantation, the idea is to protect patients with pre-existing renal insufficiency from further insults during the perioperative period. Additionally, calcineurin inhibitor dosage adjustment to maintain target concentrations is quite difficult in the perioperative period.

CLINICAL CONTROVERSY

Some clinicians use induction therapy with IL-2 receptor antagonists, such as daclizumab or basiliximab or antithymocyte globulin for all transplant recipients. Others reserve induction therapy for patients who are at a higher risk for rejection, such as those who have a high PRA, had a previous transplant or multiple pregnancies, or are of nonwhite race.

Acute Rejection

The primary goal of acute rejection therapy is to minimize the intensity of the immune response and prevent irreversible injury to the allograft. The available options include (a) increasing the doses of current immunosuppressive drugs, (b) “pulse” corticosteroids with subsequent dose taper, (c) addition of another immunosuppressant indefinitely, or (d) short-term treatment with a polyclonal or monoclonal antibody. The treatment of acute rejection varies among transplant centers and by type of allograft, but almost always begins with “pulse” corticosteroid therapy for several days (oral or intravenously). Recent data in renal transplantation indicate, however, that African Americans do not respond as well to corticosteroids as non-African Americans. Other therapies, such as antithymocyte globulin, thus may be preferable for this patient population.²⁴

Cytolytic agents are often reserved for those with corticosteroid-resistant rejection, signs of hemodynamic compromise (heart), or more severe rejections. Other innovative forms of therapy for persistent or intractable rejection have been investigated, including mycophenolate mofetil, tacrolimus, low-dose methotrexate, sirolimus, total lymphoid irradiation, and plasmapheresis and intravenous immunoglobulin. Prophylactic agents such as valganciclovir, nystatin, trimethoprim-sulfamethoxazole, H₂-receptor antagonists or proton-pump inhibitors, and/or antacids may be used to minimize adverse effects associated with these intensive immunosuppression regimens.

Maintenance Therapy

③ The goal of maintenance immunosuppression is to prevent acute and chronic rejection while minimizing drug-related toxicity. As patients progress through the post-transplant course, the risk of acute rejection decreases; thus allowing the clinician to gradually reduce, the doses of immunosuppressants or in some cases totally withdraw them over a period of 6 to 12 months in an effort to minimize adverse effects. It is important to recognize that while the goal of transplant immunosuppression is universal, protocols for immunosuppressive therapy vary widely among institutions.

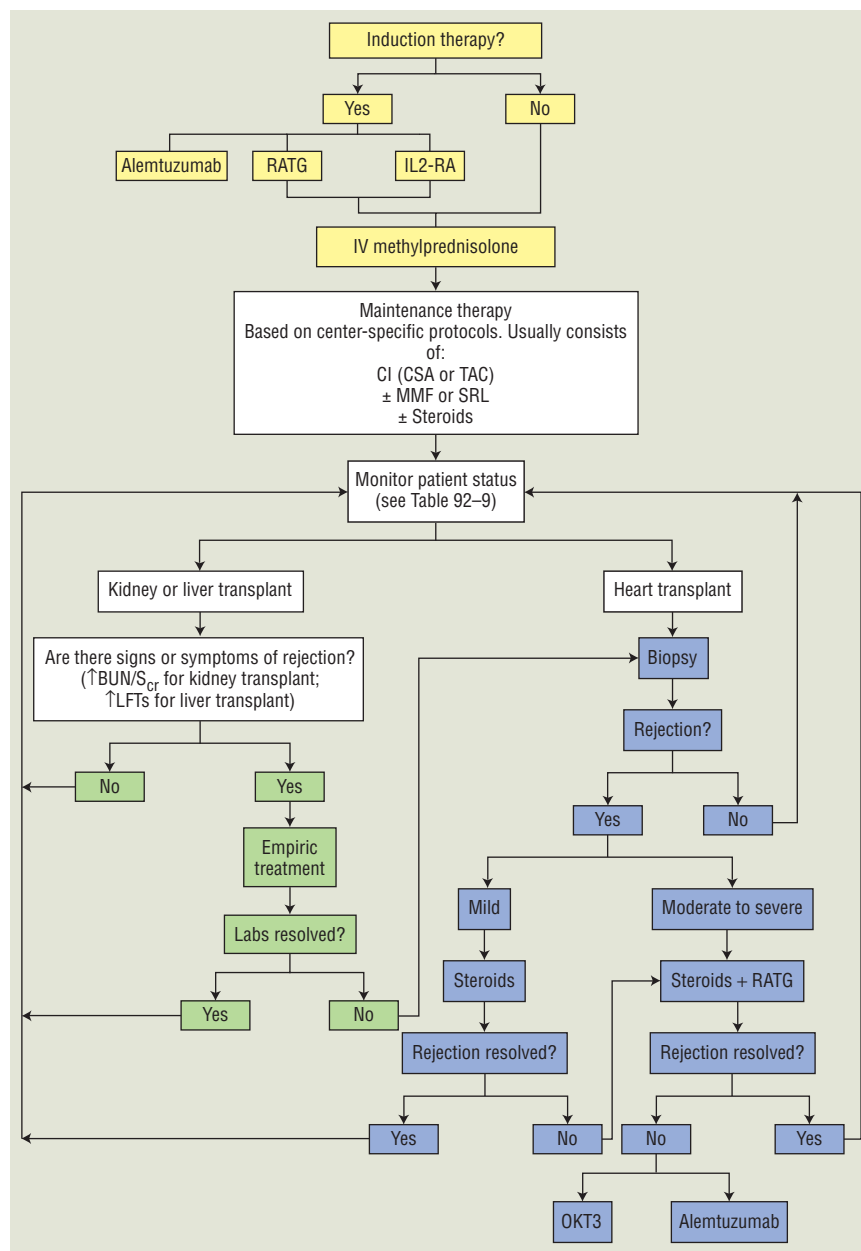

FIGURE 92-2. General approach to solid-organ transplant immunosuppression. (BUN, blood urea nitrogen; CI, calcineurin inhibitor; CSA, cyclosporine; IL2RA, interleukin-2 receptor antagonist; LFTs, liver function tests; MMF, mycophenolate mofetil; OKT3, muromonab CD3; RATG, rabbit antithymocyte immunoglobulin; S_{cr} , serum creatinine; SRL, sirolimus; TAC, tacrolimus.)

Transplant organ and type (cadaveric versus living-donor), the degree of HLA mismatch, time after transplantation, post-transplantation complications (including the number of acute rejections), previous immunosuppressive adverse reactions, compliance, and financial considerations are among the patient-specific factors considered in individualizing maintenance immunosuppression. Calcineurin inhibitors generally are a central component in most maintenance regimens, although calcineurin inhibitor-free immunosuppression remains the “Holy Grail” of transplantation immunology as this is the most direct way to decrease the complications associated with calcineurin inhibitor-induced nephropathy. Ideally, immunosuppression should be optimized to prevent acute rejection episodes and minimize the occurrence of chronic rejection. However, the changes seen with chronic rejection are not reversible with current immunosuppressive therapies.

■ CALCINEURIN INHIBITORS

4 Cyclosporine and tacrolimus are the two calcineurin inhibitors currently used for most solid-organ transplant recipients. The introduction of cyclosporine dramatically improved the outcomes of transplantation significantly with a lower incidence of acute

rejection episodes and severe infectious complications. A decade later, tacrolimus produced similar results, solidifying calcineurin inhibitors as the backbone of the transplant immunosuppression. Today, tacrolimus is used more commonly than cyclosporine by most transplant centers. However, despite the reduction in the incidence and severity of acute rejection, the incidence of chronic rejection and long-term complications, including hypertension and compromised kidney function, have not changed with the use of calcineurin inhibitors.

Pharmacology/Mechanism of Action

Calcineurin inhibitors block T-cell proliferation by inhibiting the production of IL-2 and other cytokines by T cells (see Fig. 92-1). The drugs bind to unique cytoplasmic immunophilins: cyclosporine binds to cyclophilin and tacrolimus binds to FK-binding protein-12 (FKBP12). In both cases, the drug-immunophilin complex inhibits the action of calcineurin, an enzyme that activates the nuclear factor of activated T cells, which is, in turn, responsible for the transcription of several key cytokines necessary for T-cell activity, including IL-2. IL-2 is a potent growth factor for T cells and ultimately is responsible for activation and clonal expansion.

Pharmacokinetics

The calcineurin inhibitors are highly lipophilic compounds, with variable but generally low bioavailability of approximately 30% for both drugs (range: 5% to 60%). Unlike tacrolimus, cyclosporine depends on bile for intestinal absorption, which lends to more interpatient and inpatient variability. Liver recipients with a T-tube for diversion of bile may thus experience incomplete and erratic absorption of cyclosporine.

Because of the significant variability in absorption of cyclosporine, peak concentrations are reached within 2 to 6 hours of oral administration. To overcome the pharmacokinetic problems of cyclosporine, a microemulsion formulation was developed. Both forms are available commercially in the United States and are referred to as “cyclosporine, USP” and “cyclosporine, USP [MODIFIED].” The two formulations are not bioequivalent and should not be used interchangeably. The microemulsion formulation is self-emulsifying and forms a microemulsion spontaneously with aqueous fluids in the gastrointestinal tract, making it less dependent on bile for absorption. The result is a significantly greater rate and extent of absorption and decreased intraindividual variability in pharmacokinetic parameters. Bioavailability is enhanced owing to better dispersion and absorption and does not require bile excretion. The relative bioavailability of the microemulsion formulation is 60%. Peak concentrations generally are reached within 1.5 to 2 hours after oral administration and decline in a log linear fashion with a terminal half-life of about 8 hours. Tacrolimus, on the other hand, has a more predictable absorption pattern, reaching peak concentrations within 1 to 3 hours.

Following oral absorption, both cyclosporine and tacrolimus are highly protein bound. Ninety percent of cyclosporine is bound to lipoproteins in the blood. In contrast, 99% of tacrolimus is bound primarily to albumin and α_1 -acid glycoprotein. Cyclosporine is distributed widely into tissue and body fluids, resulting in a large and variable volume of distribution, ranging from 3 to 5 L/kg. Because of the high concentration of FKBP12 that is found in red blood cells, tacrolimus is distributed primarily in the vasculature, with a volume of distribution of 0.8 to 1.9 L/kg. Both drugs are extensively metabolized by the cytochrome P450 3A4 (CYP3A4) system in both the gut and the liver, which accounts for both the poor bioavailability and numerous drug interactions (see Chap. 6). Children have an increased rate of metabolism, which results in a shorter half-life for both drugs. The terminal half-life is approximately 8.5 hours for the cyclosporine microemulsion and tacrolimus, but can be as long as 19 hours for the conventional formulation of cyclosporine.

Efficacy

The introduction of the calcineurin inhibitors significantly improved the outcomes of solid-organ transplantation in terms of patient and graft survival. Both cyclosporine and tacrolimus are currently approved for prophylaxis of organ rejection in kidney, liver, and heart transplantations. When compared with the standard formulation, the microemulsion formulation of cyclosporine has demonstrated equivalent or superior efficacy in kidney, liver, and heart

transplantation recipients. Studies comparing tacrolimus with either formulation of cyclosporine as primary immunosuppression demonstrate equivalent efficacy between the two agents in kidney, liver, and heart transplantations.

Monotherapy with calcineurin inhibitors has been described.^{25,26} The avoidance of long-term corticosteroids is the primary advantage of calcineurin inhibitor monotherapy, whereas the primary disadvantage is the higher incidence of rejection. As a result, calcineurin inhibitors are rarely used as monotherapy.

Adverse Effects

Table 92–4 summarizes the adverse effects of calcineurin inhibitors, cyclosporine and tacrolimus, and other immunosuppressants. Nephrotoxicity is often evidenced by an increase in serum creatinine concentration, decrease in glomerular filtration rate, proteinuria, and hyperkalemia. The nephrotoxic potential of both drugs is equal and is often related to the dose and duration of exposure. Neurotoxicity typically manifests as tremors, headache, and peripheral neuropathy; occasionally, however, seizures have been observed. Tacrolimus may be associated with an increased occurrence of neurologic complications compared to cyclosporine.

Cyclosporine appears to have a greater propensity to cause or worsen hypertension and hyperlipidemia compared to tacrolimus.^{27–30} On the other hand, hyperglycemia is more common with tacrolimus than cyclosporine, but is often reversible when doses of tacrolimus and/or corticosteroids are reduced.²⁸ Cyclosporine is associated with cosmetic changes, such as hirsutism and gingival hyperplasia, which may be managed by converting from cyclosporine to tacrolimus or by proper hygiene in patients who cannot be switched to tacrolimus. Tacrolimus, in contrast, has been reported to cause alopecia, which is usually self-limiting and reversible.

Drug–Drug and Drug–Food Interactions

Drug interactions occur frequently with the calcineurin inhibitors because they are substrates for CYP3A4 and P-glycoprotein.^{31–33} The most commonly administered drugs that are known to significantly alter cyclosporine and tacrolimus levels are highlighted in Table 92–5. Inhibitors of CYP3A4, such as diltiazem or erythromycin, can increase drug concentrations significantly, whereas drugs that induce CYP3A4 activity, such as phenytoin or rifampin, can decrease drug concentrations significantly. Some centers take advantage of these interactions by routinely prescribing CYP3A4 inhibitors to reduce the dosage and cost of calcineurin inhibitor therapy while maintaining the same therapeutic concentrations.³⁴ One distinct drug interaction with tacrolimus that differs from cyclosporine is an interaction with antacids. In vitro data suggest that drugs that increase the pH of the GI tract, such as magnesium-, aluminum-, or calcium-containing antacids, sodium bicarbonate, and magnesium oxide, can cause a pH-mediated degradation of tacrolimus by physically adsorbing to tacrolimus in the GI tract.^{35,36} Such compounds should be separated from tacrolimus administration by at least 2 hours to prevent the physical interaction.

TABLE 92-4 Comparison of Common Adverse Effects of Maintenance Immunosuppressants

AZA	MMF	SIR	Steroids	CSA	TAC
Nausea, vomiting	Diarrhea, nausea	Hyperlipidemia	GI bleeding	Hyperlipidemia	Diarrhea, nausea

Cyclosporine and to a lesser extent, tacrolimus are inhibitors of CYP3A4.³⁸ The inhibitory effects of cyclosporine and tacrolimus on CYP3A4 can be seen with weaker substrates, such as the HMG-CoA reductase inhibitors. Concomitant administration of a calcineurin inhibitor with an HMG-CoA reductase inhibitor results in an increase in the HMG-CoA reductase inhibitor levels, which increases the risk of HMG-CoA reductase inhibitor adverse effects, most notably myopathy.³⁹ Patients should be monitored for clinical signs of myopathy when receiving HMG-CoA reductase inhibitors in combination with cyclosporine and tacrolimus.

Consistency in administration of the calcineurin inhibitors with regard to meals and food intake is important to sustain an effective concentration time profile. High-fat meals can enhance both plasma clearance and the volume of distribution of cyclosporine by more than 60%.⁴⁰ Food reduces the rate and extent of tacrolimus absorption and a high-fat meal may further delay gastric emptying and further reduce tacrolimus concentrations and pharmacokinetics, including maximum serum concentration (C_{max}), time of maximal concentration (t_{max}), and the area under the concentration–time curve (AUC).³³ Grapefruit juice increases both cyclosporine and tacrolimus concentrations significantly. Furocoumarins, such as quercetin, naringin, and bergamottin, found in grapefruit juice, are potent inhibitors of CYP3A4. The AUC and C_{max} of cyclosporine have been reported to be increased by more than 55% and 35%, respectively.⁴¹

Dosing and Administration

Starting doses of calcineurin inhibitors are often weight-based; subsequent doses are then adjusted based on serum concentrations. Initial oral cyclosporine doses range from 8 to 18 mg/kg per day divided into two doses administered every 12 hours. Higher doses of cyclosporine are used more commonly in two-drug regimens, whereas lower doses are part of triple-drug regimens. Oral tacrolimus doses range from 0.1 to 0.3 mg/kg per day given in two divided doses every 12 hours. If oral administration is not possible, both drugs can be administered intravenously at one-third the oral dosage, to account for first-pass metabolism. The usual intravenous dose of cyclosporine is 2 to 5 mg/kg per day, given as a continuous infusion or, more commonly, as a single or twice-daily injection. Intravenous tacrolimus doses range from 0.05 to 0.1 mg/kg per day, and must be administered by continuous infusion. Children require higher doses to maintain therapeutic drug concentrations, up to 14 to 18 mg/kg per day for cyclosporine and 0.3 mg/kg per day for

tacrolimus, which is often two- to four-fold higher than adults on a milligram per kilogram basis for both drugs.

Calcineurin inhibitor serum concentrations are measured routinely in an attempt to optimize therapy. The most common and practical method for monitoring calcineurin inhibitors is by measuring trough blood concentrations. Radioimmunoassay (RIA) and fluorescence polarization immunoassay are the most commonly used methods to measure cyclosporine concentrations. Tacrolimus concentrations are most commonly measured by microparticle enzyme immunoassays or enzyme-linked immunoassays. Both drugs can be measured by high-performance liquid chromatography (HPLC), which is recognized as the reference procedure.⁴² It is important to determine which assay methodology the laboratory is using because target ranges vary between nonspecific assays, such as RIA and microparticle enzyme immunoassay, which quantitate parent plus metabolite concentration, and specific assays, such as HPLC using mass spectrometry, which quantitate only the parent compound. Thus, the target concentrations will be lower for the specific assays (HPLC) compared to nonspecific assays (RIA and microparticle enzyme immunoassays) by approximately 20% to 25%. The therapeutic range for whole-blood cyclosporine concentration is 375 to 400 ng/mL for RIA and 100 to 300 ng/mL for HPLC. In serum or plasma, the therapeutic range for RIA or HPLC is 150 to 250 ng/mL and 75 to 150 ng/mL, respectively. The therapeutic range for tacrolimus for RIA is 5 to 20 ng/mL and 8 to 13 ng/mL for HPLC. The specific goal level for both drugs is dependent on transplant type, time after transplantation, concomitant immunosuppression, and transplantation center. One review of the role of tacrolimus in renal transplantation suggests that target 12-hour whole blood concentrations for tacrolimus are 15 to 20 ng/mL (0 to 1 month after transplantation), 10 to 15 ng/mL (1 to 3 months after transplantation), and 5 to 12 ng/mL (>3 months after transplantation).²⁷ Serum drug concentrations should be measured frequently (daily or three times per week) following initiation of the drug and during the stabilization period after transplantation. As the time increases after transplantation, serum concentrations are measured less frequently, usually monthly.

Studies have revealed lack of predictive value of trough cyclosporine concentrations and rejection.⁴³ Alternative strategies, including AUC and peak concentration, have been suggested to better correlate with rejection.⁴⁴ Limited sampling techniques using two to five blood samples within the first 4 hours after an oral dose have been used. AUC levels >4,400 mcg/L per hour correlate with a reduction

in rejection.⁴⁴ Peak concentrations measured 2 hours after an oral dose (C_2) have a better predictive value in terms of rejection compared with trough concentrations.⁴⁵ Some transplantation centers have adopted this strategy to manage cyclosporine levels because of the convenience of a single blood sample. The suggested therapeutic range for C_2 cyclosporine levels is 1,500 to 2,000 ng/mL for the first few months after transplant and 700 to 900 ng/mL after 6 to 12 months.⁴³ The predictive value of trough concentrations and rejection is also being questioned with tacrolimus. As a result, pharmacokinetic profiling with AUC and peak concentrations to determine alternative monitoring strategies are also being explored with tacrolimus.⁴³

Calcineurin Inhibitor Nephrotoxicity

5 A common side effect observed in all transplantation recipients who are receiving maintenance cyclosporine or tacrolimus therapy is nephrotoxicity. Two types of toxicity can occur. Acute nephrotoxicity frequently is seen early and is dose dependent and reversible, but chronic nephropathy is more common. Clinical manifestations of calcineurin inhibitor nephrotoxicity include elevated serum creatinine and blood urea nitrogen levels, hyperkalemia, hyperuricemia, mild proteinuria, and a decreased fractional excretion of sodium. Calcineurin inhibitor nephrotoxicity is recognized as the leading cause of renal dysfunction following nonrenal solid-organ transplant.

The predominant mechanism for calcineurin inhibitor nephrotoxicity is renal vasoconstriction, primarily of the afferent arteriole, resulting in increased renal vascular resistance, decreased renal blood flow by up to 40%, reduced glomerular filtration rate by up to 30%, and increased proximal tubular sodium reabsorption with a reduction in urinary sodium and potassium excretion. A number of other mechanisms have been implicated, including changes in the renin–angiotensin–aldosterone system, prostaglandin synthesis, nitrous oxide production, sympathetic nervous system activation, and calcium handling.⁴⁵

Measures to reduce calcineurin inhibitor nephrotoxicity include delaying administration immediately postoperatively in patients at high risk for nephrotoxicity (using alternative induction protocols including an IL-2 receptor antagonist or antilymphocyte globulin), monitoring calcineurin inhibitor trough blood levels and reducing the calcineurin inhibitor dosage if the vasoconstrictive effects are problematic, and avoiding other nephrotoxins (e.g., aminoglycosides, amphotericin B, and nonsteroidal antiinflammatory agents) when possible. Currently, no proven therapies consistently prevent or reverse the nephrotoxic effects of cyclosporine.⁴⁶

In patients who have received a kidney transplant, it is often difficult to differentiate calcineurin inhibitor nephrotoxicity from renal allograft rejection. Because the clinical features of acute renal allograft rejection and calcineurin inhibitor nephrotoxicity may overlap considerably, a renal biopsy continues to be the diagnostic “gold standard” (Table 92–6). However, differentiating between chronic renal allograft rejection and calcineurin inhibitor nephrotoxicity may be more difficult because, in addition to clinical signs and symptoms, biopsy findings also may be similar.

CLINICAL CONTROVERSY

Although calcineurin inhibitors are the mainstay of immunosuppressive protocols, some clinicians attempt to use calcineurin inhibitor-sparing protocols to avoid the significant adverse effects associated with calcineurin inhibitors. Others will delay the initiation of calcineurin inhibitors to avoid the dose-related adverse effects associated with their use during the early post-transplantation period.

TABLE 92-6 Differential Diagnosis of Acute Rejection and Cyclosporine or Tacrolimus Nephrotoxicity

	Acute Rejection	CSA or TAC Nephrotoxicity
History	Often <4 weeks postoperatively	Often >6 weeks postoperatively
Clinical presentation	Fever Hypertension Weight gain Graft swelling/tenderness Decreased daily urine volume	Afebrile Hypertension Graft nontender Good urine output
Laboratory biopsy	Rapid rise in serum Cr (0.3 mg/dL/day) Normal CSA or TAC concentration Interstitial lymphocytic infiltrates	Gradual rise in serum Cr (>0.15 mg/dL/day) Elevated CSA or TAC concentration Interstitial fibrosis, tubular atrophy, glomerular thrombosis, arterial inflammation

Cr, creatinine; CSA, cyclosporine; TAC, tacrolimus.

CORTICOSTEROIDS

Corticosteroids have been used since the beginning of the modern transplantation era. Despite their many adverse events, they continue to be a cornerstone of immunosuppression regimens in many transplant centers. The most commonly used corticosteroids in transplantation are methylprednisolone and prednisone.

Pharmacology/Mechanism of Action

Corticosteroids block cytokine activation by binding to corticosteroid response elements, thereby inhibiting IL-1, IL-2, IL-3, IL-6, γ -interferon, and tumor necrosis factor- α synthesis (see Fig. 92–1). Additionally, corticosteroids interfere with cell migration, recognition, and cytotoxic effector mechanisms.⁴⁷

Pharmacokinetics

Prednisone is converted to active prednisolone in the body and has multiple effects on the immune system. Prednisone is very well absorbed from the gastrointestinal (GI) tract and has a long biologic half-life, so it can be dosed once daily.

Efficacy

6 Animal models of transplantation in the 1950s and 1960s used corticosteroids empirically in combination with azathioprine. Corticosteroids subsequently became a part of the immunosuppressive regimens used in the first human transplantations⁴⁸ and continue to be used in immunosuppressive protocols today. The efficacy of corticosteroids is irrefutable based on the decades of clinical experience. Systematic studies comparing corticosteroid-free immunosuppressive agent combinations with conventional therapy are difficult to perform because of the hundreds of potential combinations that now exist. However, recent studies of corticosteroid-free immunosuppressive agent combinations with newer, more specific immunosuppressants suggests that corticosteroids may in the future have less of a role in maintenance immunosuppression.^{26,27}

Adverse Effects

Adverse effects of prednisone that occur in more than 10% of patients include increased appetite, insomnia, indigestion (bitter taste), and mood changes. Side effects that occur less often but which are seen with high doses or prolonged therapy include cataracts, hyperglycemia, hirsutism, bruising, acne, sodium and water retention, hypertension, bone growth suppression, and ulcerative esophagitis (see Table 92–4).

Drug–Drug and Drug–Food Interactions

Barbiturates, phenytoin, and rifampin induce hepatic metabolism of prednisone and thus decrease the effectiveness of prednisone. Prednisone decreases the effectiveness of vaccines and toxoids.⁴⁷

Dosing and Administration

An intravenous corticosteroid, commonly high-dose methylprednisolone, is given during the perioperative period. The dose of methylprednisolone is tapered rapidly and discontinued within days, and oral prednisone is initiated. Prednisone doses are tapered progressively over time, depending on the type of additional immunosuppression and organ function. As doses are tapered, it is preferable to administer corticosteroids every other day and between 7 AM and 8 AM to mimic the body's diurnal release of cortisol. Although conversion to alternate-day regimens or complete withdrawal of prednisone in patients with stable post-transplantation courses has been used with success in some transplantation centers, corticosteroids often are continued for the entire life of the functional graft. Long-term corticosteroid use and its associated deleterious effects are well recognized and particularly troublesome in transplantation patients (see Table 92–4).

The first-line therapy for the treatment of acute graft rejection is high-dose intravenous methylprednisolone (250 to 1,000 mg) daily for 3 days or oral prednisone (200 mg). Doses of oral prednisone are then tapered over 5 days to 20 mg/day. Prednisone should be taken with food to minimize GI upset. The dose of prednisone varies with the transplant center's protocol but usually is highest immediately following transplantation and during treatment for acute rejection. It is becoming a frequent practice to taper prednisone, with the goal of discontinuation over a period of months. Corticosteroids never should be discontinued abruptly; tapering should be gradual because of suppression of the hypothalamic–pituitary–adrenal axis. Corticosteroids slow the growth rates in children, prompting clinicians to use alternate-day dosing or to withhold corticosteroids until rejection occurs.

■ ANTIMETABOLITES

7 Antimetabolites have been used since the early days of transplantation because they prevent proliferation of lymphocytes. Azathioprine has been considered a part of the “gold standard” regimen with cyclosporine and corticosteroids, to which all newer regimens have traditionally been compared. However, mycophenolate is more specific in its effects on lymphocytes and has fewer side effects. Because each agent is unique in its profile and actions, they are discussed separately.

Mycophenolate

Mycophenolic acid (MPA) was first isolated from the *Penicillium glaucum* mold. Two formulations of MPA are currently available in the United States: mycophenolate mofetil is the morpholinoethyl ester of MPA, whereas mycophenolate sodium is available as an enteric-coated formulation of the sodium salt of MPA.

Pharmacology/Mechanism of Action The immunosuppressive effect of MPA is exerted through noncompetitive binding to inosine monophosphate dehydrogenase, the key enzyme responsible for guanosine nucleotide synthesis via the de novo pathway. Inhibition of inosine monophosphate dehydrogenase results in decreased nucleotide synthesis and diminished DNA polymerase activity, ultimately reducing lymphocyte proliferation.⁴⁹ The actions of MPA are more specific for T and B cells, which use only the de novo pathway for nucleotide synthesis (see Fig. 92–1). Other cells within the body have a salvage pathway by which they can synthesize nucleotides, making them less susceptible to the actions of MPA and

thereby reducing, but not eliminating, the potential for the hematologic adverse effects seen with azathioprine, which affects both the de novo and salvage pathways. In addition to the decreasing lymphocyte proliferation, MPA also may downregulate activation of lymphocytes.⁵⁰

Pharmacokinetics Because MPA is unstable in an acidic environment, mycophenolate mofetil acts as a prodrug that is readily absorbed from the GI tract, after which it is rapidly and completely converted to MPA by first-pass metabolism. The enteric coating of mycophenolate sodium protects MPA from the acidic gastric pH and allows for MPA to be released directly into the small intestine for absorption. The absolute bioavailability of MPA when delivered from mycophenolate mofetil and mycophenolate sodium is 94% and 72%, respectively. Peak concentrations of MPA are reached within 1 hour following administration of either preparation.

A total of 97% of MPA is bound to albumin in the blood. MPA is eliminated by the kidney and also undergoes glucuronidation in the liver to an inactive glucuronide metabolite (MPAG) that is excreted in the bile and urine. Enterohepatic cycling of MPAG can lead to deconjugation, thereby recirculating MPA into the bloodstream. The half-life of MPA is 18 hours.

Efficacy Currently, mycophenolate mofetil is approved for use in kidney, liver, and heart transplantations. Mycophenolate sodium was approved in 2004 for use in kidney transplantations only. Early studies comparing mycophenolate to azathioprine in patients receiving cyclosporine and corticosteroids demonstrated a statistically significant difference in patient and graft survival at 1 and 3 years.⁵¹ Subsequent studies have confirmed the efficacy of mycophenolate combined with tacrolimus.

Mycophenolate has also demonstrated efficacy in the treatment of acute rejection. Kidney transplantation recipients converted to mycophenolate mofetil after the first acute rejection episode had fewer subsequent rejections compared with those who continued with azathioprine after rejection treatment. The change in therapy was associated with no increase in adverse effects or malignancies and a trend toward better graft function and survival.⁵²

Mycophenolate is a key component of calcineurin inhibitor-sparing protocols. Although mycophenolate monotherapy has been investigated, patients experienced an unacceptable increase in rejection. Combination of mycophenolate with sirolimus, on the other hand, resulted in improved renal function with no change in acute rejection and patient and graft survival.⁵¹

Adverse Effects Unlike cyclosporine and tacrolimus, mycophenolate is not associated with nephrotoxicity, neurotoxicity, or hypertension. The most common side effects are related to the GI tract, including nausea, vomiting, diarrhea, and abdominal pain (see Table 92–4), which occur with similar frequency during intravenous and oral therapy. Clinically, GI symptoms may be alleviated in some patients by reducing the dose, dividing the total daily dose into three or four doses, administration with food, or titrating upward from lower doses during initial therapy. Mycophenolate also has hematologic effects, such as leukopenia and anemia, particularly with higher doses. Because peripheral intravenous mycophenolate administration is associated with local edema and inflammation, central venous administration may be the preferred route.

Drug–Drug and Drug–Food Interactions Food has no effect on MPA AUC, but delays the absorption and decreases MPA C_{max} by 40% and 33% when mycophenolate mofetil and mycophenolate sodium, respectively, are administered. Administration with aluminum- and magnesium-containing antacids or cholestyramine, significantly decreases the AUC of MPA and should be avoided.⁴⁹ It has been suggested that administration of iron may produce similar results, but this has not been tested.

Acyclovir, commonly used in renal transplant recipients for the treatment and prevention of viral infections, competes with MPAG for renal tubular secretion. AUCs of both entities are increased with concomitant acyclovir and mycophenolate administration.⁴⁹ Single-dose intravenous ganciclovir in combination with mycophenolate produced no change in the disposition of ganciclovir, MPA, or MPAG.⁵³ Although no pharmacokinetic interaction in a single-dose study was demonstrated, there is potential for additive pharmacodynamic effects such as bone marrow suppression.

Decreased MPA trough concentrations have been reported when mycophenolate is administered with cyclosporine compared with those achieved when mycophenolate is given with tacrolimus or sirolimus. This interaction is most likely a result of cyclosporine interference with the enterohepatic recycling of MPAG, which results in decreased MPA concentrations.⁵⁴ To achieve equivalent MPA and MPAG serum concentrations, it may be necessary to administer higher doses of mycophenolate with cyclosporine compared to tacrolimus.

Dosing and Administration Mycophenolate mofetil is currently available in both oral and intravenous formulations. Although intravenous administration of equal doses closely mimics oral administration, the two cannot be considered bioequivalent.⁵⁵ Mycophenolate sodium is only available as an oral formulation. Unlike other immunosuppressive agents, there is no compelling indication that mycophenolate should be dosed in adult patients on a milligram per kilogram basis given the weak correlation between MPA AUC and body weight.⁴⁹ To optimize immunosuppression and minimize adverse effects, mycophenolate is administered in two divided doses given every 12 hours. The total daily dose for kidney and liver transplants is 2 g/day for mycophenolate mofetil and 1.44 g/day for mycophenolate sodium. A higher level of immunosuppression is required for heart transplants, thus for these patients a total daily dose of 3 g/day for mycophenolate mofetil and 2.16 g/day for mycophenolate sodium is recommended. The recommended pediatric dose is 600 mg/m² for mycophenolate mofetil and 400 mg/m² for mycophenolate sodium, in two divided doses.

Plasma appears to be the most appropriate medium in which to measure MPA for therapeutic drug monitoring. Trough concentrations are not accurate in predicting total drug exposure during a 12-hour interval and AUC monitoring has been proposed as the most appropriate measure of MPA drug exposure to predict therapeutic outcomes.⁴³ Better outcomes are associated with MPA AUC levels of greater than 42.8 mcg/mL per hour (by HPLC),⁵⁶ although a reference range of 30 to 60 mcg/mL per hour has been proposed.⁵⁷ However, the correlation between MPA AUC levels and adverse effects is low. Further studies are required to determine the best means to evaluate MPA levels, the acceptable targets for each, and the appropriate strategy to monitor MPA levels.^{56,57}

Azathioprine

Azathioprine, a prodrug for 6-mercaptopurine, has been used as an immunosuppressant in combination with corticosteroids since the earliest days of the modern transplantation era. It is associated with substantial toxicities, however, and its use has dramatically declined with the availability of newer, less-toxic immunosuppressants.

Pharmacology/Mechanism of Action Azathioprine is an inactive compound that is converted rapidly to 6-mercaptopurine (6-MP) in the blood and is subsequently metabolized by three different enzymes. Xanthine oxidase, found in the liver and GI tract, converts 6-MP to the inactive final end product, 6-thiouric acid. Thiopurine S-methyltransferase, found in hematopoietic tissues and red blood cells, methylates 6-MP to an inactive product, 6-methylmercaptopurine. Finally, hypoxanthine-guanine phosphoribosyltransferase is the first step responsible for converting 6-MP to 6-thioguanine

nucleotides (6-TGNs), the active metabolites, which are incorporated into nucleic acids, ultimately disrupting both the salvage and de novo pathways of DNA, RNA, and protein synthesis. This process is toxic to the cell and renders the cell unable to proliferate (see Fig. 92–1). 6-TGNs eventually are catabolized by xanthine oxidase and thiopurine S-methyltransferase to inactive products.

Pharmacokinetics Oral bioavailability of azathioprine is approximately 40%. Metabolism of 6-MP is primarily by xanthine oxidase to inactive metabolites, which are excreted by the kidneys. The half-life of azathioprine, the parent compound, is very short, approximately 12 minutes. The half-life of 6-MP is longer, ranging from 0.7 to 3 hours. However, it is the activity of the 6-TGNs that determines the pharmacodynamic half-life of the drug. The half-life of 6-TGNs has been estimated to be 9 days.⁵⁸

Adverse Effects Dose-limiting adverse effects of azathioprine are often hematologic (see Table 92–4). Leukopenia, anemia, and thrombocytopenia can occur within the first few weeks of therapy and can be managed by dose reduction or discontinuation of azathioprine. Other common adverse effects include nausea and vomiting, which can be minimized by taking azathioprine with food. Alopecia, hepatotoxicity and pancreatitis are less-common adverse effects of azathioprine; they generally are reversible on dose reduction or discontinuation.

Drug–Drug and Drug–Food Interactions Allopurinol inhibits xanthine oxidase and can increase the bioavailability of azathioprine and 6-MP concentrations by as much as fourfold. The metabolic pathways shift to favor production of 6-TGNs, which ultimately results in increased bone marrow suppression and pancytopenia. Doses of azathioprine should be reduced by 50% to 75% when allopurinol is added. Additional clinically significant drug interactions include other bone marrow-suppressing agents such as ganciclovir, trimethoprim-sulfamethoxazole, and sirolimus, and other drugs that irritate the GI tract.

Dosing and Administration Initial doses of azathioprine are 3 to 5 mg/kg per day intravenously or orally. Individualization to maintain the white blood cell count between 3,500 and 6,000 cells/mm may be accomplished in some with doses as low as 0.25 mg/kg per day.² Patients often are instructed to take azathioprine in the evening when initiating or titrating therapy to allow for dose adjustments based on morning determinations of their white blood cell count.

■ MAMMALIAN TARGET OF RAPAMYCIN INHIBITORS

8 The newest class of immunosuppressive agents consists of drugs that target the mammalian target of rapamycin and are collectively known as mTOR inhibitors. Currently, sirolimus is the only drug approved in this class, but a second agent, everolimus, is currently being studied in kidney transplantation. Sirolimus, also known as rapamycin, is an immunosuppressive macrolide antibiotic that is structurally similar to tacrolimus, and is effective in reducing the risk of acute rejection. Sirolimus is thought to have potential to reduce chronic rejection, but this remains to be proven.

Pharmacology/Mechanism of Action Sirolimus binds to FKBP12, but the resulting complex does not inhibit the activity of calcineurin. Whereas the tacrolimus-FKBP12 complex inhibits cytokine production, the sirolimus-FKBP12 complex binds to mTOR, which inhibits the response to these cytokines (see Fig. 92–1). IL-2 stimulates mTOR to activate kinases that ultimately advance the cell cycle from G₁ to the S phase. Thus sirolimus inhibits T-cell proliferation by inhibiting the cellular response to IL-2 and progression of the cell cycle.⁵⁹

Pharmacokinetics Bioavailability after oral administration is low, only 15%, with peak concentrations being reached within 1 to 2 hours.⁶¹ Sirolimus has a high volume of distribution, readily distributing into most tissues of the body, even though it binds extensively to erythrocytes because of the high FKBP12 concentration found in red blood cells. Metabolism occurs primarily by CYP3A4 both in the gut and in the liver. The half-life is reported to be 60 hours but can be as long as 110 hours in patients with liver dysfunction.⁶⁰

Efficacy Currently, sirolimus is only approved for the prevention of rejection in kidney transplant recipients when given in combination with corticosteroids and cyclosporine or after withdrawal of cyclosporine in patients with low to moderate immunologic risk. Sirolimus has also been demonstrated to be effective in combination with tacrolimus or mycophenolate in kidney transplants, with patient survival rates >99% and graft survival rates >96%.^{61–64} Combination therapy with sirolimus and mycophenolate can be used to avoid the use of calcineurin inhibitors and decrease the risk of nephrotoxicity.

Two clinical trials evaluated the use of sirolimus in kidney transplants. All patients in both studies received cyclosporine and corticosteroids and were randomly assigned to one of three groups: (a) Sirolimus in a fixed dose—a 6-mg loading dose followed by 2 mg daily; (b) a 15-mg loading dose followed by 5 mg daily; or (c) azathioprine in the U.S. trial or placebo in the global trial. The results of both studies showed similar patient and graft survival in all groups at 12 months but lower rates of acute rejection in the sirolimus arms compared with azathioprine and placebo.^{65,66}

Early cyclosporine withdrawal has been studied in patients receiving sirolimus-based immunosuppressive protocols. Patients receiving sirolimus who did not have a recent or severe rejection episode and adequate renal function 3 months after transplant were enrolled. Patients were randomly assigned to continue triple-drug therapy with sirolimus (adjusted to trough concentrations of greater than 5 ng/mL), cyclosporine, and corticosteroids or to double-drug therapy with sirolimus (adjusted to trough concentrations of 20 to 30 ng/mL) and corticosteroids. The results showed a low risk of acute rejection following cyclosporine discontinuation (5.6%) and no difference in graft survival. Long-term followup (2 years) showed improved renal function and blood pressure without an increase in acute rejection or graft loss in patients who discontinued cyclosporine.⁶⁷

Currently, because the safety and efficacy of sirolimus has not been established in liver or lung transplants, it is recommended that its use be avoided in these populations immediately following transplant. In contrast, limited data on the use of sirolimus in heart transplantation indicate benefit in reversing acute rejection in patients who do not respond to antilymphocyte therapy.⁶⁸ Furthermore, sirolimus may slow the progression of vasculopathy, which may have an impact on chronic rejection and long-term patient survival after heart transplantation.²³

Adverse Effects Myelosuppression associated with sirolimus appears to be dose-related. Thrombocytopenia is usually seen within the first 2 weeks of sirolimus therapy but generally improves with continued treatment; leukopenia and anemia are also typically transient.⁶⁹ Sirolimus trough serum concentrations greater than 15 ng/mL have been correlated with thrombocytopenia and leukopenia.⁷⁰ Hypercholesterolemia and hypertriglyceridemia are quite common in patients receiving sirolimus. It is postulated that the mechanism of this adverse effect is related to an overproduction of lipoproteins or inhibition of lipoprotein lipase. Peak cholesterol and triglyceride levels are often seen within 3 months of starting sirolimus but usually decrease after 1 year of therapy and can be managed by reducing the dose, discontinuing sirolimus, or by initiating therapy with an HMG-CoA reductase inhibitor or fibric acid derivative. One study suggests that the dyslipidemia associated with sirolimus is not a major risk factor for early cardiovascular compli-

cations following kidney transplantation.⁷¹ Delayed wound healing and dehiscence could be a result of inhibition of smooth muscle proliferation and intimal thickening.⁷² Mouth ulcers also have been reported with sirolimus, more commonly with the oral solution. The cause may be a direct effect of the drug or secondary to activation of herpes simplex virus.⁷³ Reversible interstitial pneumonitis has been described in kidney, liver, and heart-lung transplantation recipients.⁶⁰ Other adverse effects reported with sirolimus include increased liver enzymes, hypertension, rash, acne, diarrhea, and arthralgia (see Table 92–4).

Drug-Drug and Drug-Food Interactions The major metabolic pathway for sirolimus is CYP3A4; thus the drug interactions mediated by induction or inhibition of the CYP3A4 enzyme system are similar to those seen with cyclosporine and tacrolimus (see Table 92–5). Administration of the microemulsion formulation of cyclosporine with sirolimus significantly increases the AUC and trough sirolimus levels. The same is not seen with the standard formulation of cyclosporine. Conversely, cyclosporine concentrations and AUC are also increased when it is given concomitantly with sirolimus. The mechanism is proposed to be competitive binding to CYP3A4 and P-glycoprotein.⁶⁰ It is recommended that patients separate the dose of sirolimus and cyclosporine by 4 hours to minimize the interaction.⁷⁴ Concomitant administration of tacrolimus does not affect sirolimus levels.⁷⁵

As with cyclosporine and tacrolimus, grapefruit juice increases sirolimus levels. Administration of sirolimus with a high-fat meal is associated with a delayed rate of absorption, decreased C_{max} , and increased AUC, indicating an increased drug exposure, whereas the half-life remained unchanged.⁷⁶ The clinical significance of this is unknown.

Dosing and Administration A fixed sirolimus dosing regimen is approved for concomitant use with cyclosporine that includes a loading dose of 6- or 15-mg followed by 2 or 5 mg daily, respectively. Therapeutic monitoring of sirolimus is advocated using whole-blood concentrations measured by HPLC, which is specific for the parent compound. The target concentration range is 10 to 15 ng/mL when used in combination with a calcineurin inhibitor, or 15 to 25 ng/mL, when used in regimens that do not. When RIA is used, which measures the parent compound and metabolites, reference ranges of 15 to 20 ng/mL and 20 to 30 ng/mL should be used, respectively.

CLINICAL CONTROVERSY

Routine therapeutic drug monitoring of sirolimus therapy is not recommended in patients who are receiving triple-drug therapy with cyclosporine and corticosteroids. However, many clinicians now believe that sirolimus drug levels should be monitored in all patients, although there is no universally accepted therapeutic range.

■ POLYCLONAL ANTIBODIES (ANTITHYMOCYTE GLOBULINS)

9 There are currently two antithymocyte globulins available in the United States: ATG (Atgam, Pfizer, NY, NY), an equine polyclonal antibody, and RATG (Thymoglobulin, Genzyme, Cambridge, MA), a rabbit polyclonal antibody. The rabbit preparation is less immunogenic and may have other advantages over the equine preparation. Both ATG and RATG are currently approved only for the treatment of rejection; however, the drugs are used often as induction therapy to prevent acute rejection.

Pharmacology/Mechanism of Action Because of their polyclonal antibody nature, both ATG and RATG exert their immuno-

suppressive effect by binding to a wide array of lymphocyte receptors, including CD2, CD3, CD4, CD8, CD25, and CD45. Binding of ATG or RATG to the various receptors results in complement-mediated lysis and subsequent lymphocyte depletion. T cells are the major lymphocytic target for the compounds; however, other blood cell components are also affected, including B cells and other leukocytes (see Fig. 92–1). Damaged T cells are removed subsequently by the spleen, liver, and lungs.

Pharmacokinetics ATG is poorly distributed into lymphoid tissue and binds primarily to circulating lymphocytes, granulocytes, and platelets. The terminal half-life of ATG is 5.7 days. RATG has a volume of distribution of 0.12 L/kg and its terminal half-life in renal transplant recipients is significantly longer than ATG at 30 days.⁷⁷ Peak plasma concentrations are reached after 5 to 7 days of ATG or RATG infusions. Antiequine antibodies can form in up to 78% of patients who are receiving ATG therapy. Similarly, antirabbit antibodies have been reported in up to 68% of patients who are receiving RATG therapy. The effects of preformed antibodies on the efficacy and safety of these preparations has not been studied adequately.

Efficacy ATG and RATG are used most commonly for the treatment of acute allograft rejection or as induction therapy to prevent acute rejection. ATG is currently approved for both indications in kidney transplants. RATG is approved only for the treatment of acute allograft rejection in kidney transplantations. However, both drugs have been studied extensively for both indications. A meta-analysis revealed that polyclonal antibodies demonstrated a significantly higher reversal rate for first acute rejection episodes compared to corticosteroids. However, there was no difference between the two groups in preventing subsequent rejections.⁷⁸ Accordingly, polyclonal antibodies are most often reserved for the treatment of corticosteroid-resistant or moderate to severe acute rejection episodes.

The efficacy of ATG and RATG induction therapy has been described in liver and heart transplantation recipients. Use of RATG as part of quadruple therapy in liver transplantation is associated with similar rates of patient and graft survival and acute rejection compared with dual therapy; however, a significant increase in the number of cytomegalovirus infections was noted.⁷⁹ Quadruple-drug therapy results in similar rates of patient and graft survival and malignancy in heart transplantations, but a significantly lower rate of acute rejection and infection episodes is seen at 1 year compared with triple-drug therapy.⁸⁰

Adverse Effects Most adverse effects reported with ATG and RATG are related to the lack of specificity for T cells owing to their polyclonal nature. Dose-limiting myelosuppression, including leukopenia, anemia, and thrombocytopenia, occurs frequently. Other adverse effects include anaphylaxis, hypotension, hypertension, tachycardia, dyspnea, urticaria, and rash. Serum sickness is seen more frequently with ATG than RATG. Nephrotoxicity has been reported but is rare in the absence of serum sickness. Infusion-related febrile reactions are most common with the first few doses and can be managed by premedicating the patient with acetaminophen, diphenhydramine, and corticosteroids. Finally, as with any immunosuppressive agent, ATG and RATG are associated with an increased risk of infections, particularly viral infections, and malignancy.

Drug-Drug and Drug-Food Interactions Administration of ATG or RATG can interfere with the immune response to live vaccines, such as varicella vaccine. If a live vaccine is administered within 2 months of receiving one of these immunoglobulins, protection may not be conferred.

Dosing and Administration ATG doses range from 10 to 30 mg/kg per day as a single dose for 7 to 14 days. RATG is a more potent compound and is administered at doses of 1 to 1.5 mg/kg per day as a single dose for 7 to 14 days for acute rejection or for 5 to 10

days for induction of immunosuppression. Although literature reports now support peripheral administration of both agents it is recommended that both ATG and RATG be administered through a central line or through a high-flow vein with an in-line 0.22-micron filter over at least 4 hours to minimize phlebitis and thrombosis whenever possible.^{81,82}

■ MONOCLONAL ANTIBODIES

Monoclonal antibodies are more specific than the polyclonal antibodies for targeting a single receptor on the T cells. The result of their actions varies, depending on the nature of and target of the antibody.

Interleukin-2 Receptor Antagonists

There are currently two available IL-2 receptor antagonists: basiliximab, a chimeric monoclonal antibody (25% murine), and daclizumab, a humanized monoclonal antibody (90% human, 10% murine). Daclizumab contains a greater proportion of human sequences, making it theoretically less immunogenic. The percentage of murine component determines the antibody's affinity for the epitope. Consequently, the chimeric antibody basiliximab has a higher affinity than daclizumab.⁸³

Pharmacology/Mechanism of Action Both basiliximab and daclizumab exert their immunosuppressive effect by specifically binding to the α -chain (CD25) on the surface of activated T lymphocytes (see Fig. 92–1). Binding of either basiliximab or daclizumab to the IL-2 receptor prevents IL-2-mediated activation and proliferation of T cells, a critical step in clonal expansion of T cells and the development of allograft rejection. Saturation of the IL-2 receptor occurs rapidly and confers an immunosuppressive effect immediately.⁸³

Pharmacokinetics Most of the pharmacokinetic data available for both basiliximab and daclizumab are in renal transplantation patients. Caution must be used when extrapolating these data to nonrenal transplantation recipients. The volume of distribution is approximately 5.3 L for daclizumab and 8 L for basiliximab. Basiliximab and daclizumab saturate CD25 in vivo at serum concentrations of 0.2 and 1 mg/L or greater, respectively.⁸⁴ The terminal half-life of daclizumab is about 20 days in renal transplantation patients compared with 3 to 4 days in bone marrow transplant recipients. Basiliximab has a shorter half-life of approximately 7 days in renal transplant recipients. Clearance of both drugs is increased in patients who have received a liver transplant, primarily as a consequence of drainage of ascites. It is recommended that patients with greater than 10 L of ascites receive an additional dose of basiliximab on postoperative day 8.⁸⁵ Therapeutic concentrations of daclizumab range from 5 to 10 mg/L.

Efficacy Both basiliximab and daclizumab are approved for use in kidney transplantation in combination with cyclosporine and corticosteroids, although induction therapy has also been studied extensively in liver and heart transplantation recipients. A meta-analysis of daclizumab and basiliximab in renal transplantation concluded that IL-2 receptor antagonists reduced the risk of rejection significantly with no increases in graft loss, infectious complications, malignancy, or death.⁸⁶ Similar results were seen in liver and heart transplantation.^{87,88}

IL-2 receptor antagonists offer a reasonable addition to calcineurin inhibitor- or corticosteroid-sparing protocols. Although calcineurin inhibitor therapy can not be completely avoided in most cases,⁸⁴ IL-2 receptor antagonists allow for delayed use or reduced doses of calcineurin inhibitors, thus minimizing the risk of nephrotoxicity in the early post-transplantation period. Similar rates of rejection and corticosteroid-resistant rejection were seen in patients

with DGF who received an IL-2 receptor antagonist in conjunction with lower tacrolimus doses compared with patients without DGF who received standard tacrolimus doses and no IL-2 receptor inhibitor induction.⁸³

Adverse Effects Few adverse effects have been reported with basiliximab and daclizumab. In contrast to polyclonal antibody preparations and OKT3, basiliximab and daclizumab have not been associated with infusion-related reactions. However, since the marketing of basiliximab, an increased number of hypersensitivity reactions have been reported. Of note, only one patient developed anti-idiotypic antibodies to the murine portion during clinical trials.⁸⁵ The manufacturer of basiliximab reported an increase in mortality in a placebo-controlled trial, which was associated with an increase in severe infections. No increased risk of malignancy as has been noted with standard immunosuppression has been reported.

Drug-Drug and Drug-Food Interactions Reports of increased cyclosporine and tacrolimus levels in patients receiving concomitant basiliximab were recently published.^{89,90} Both authors hypothesized a potential interaction with the cytochrome P450. No drug interactions have been reported with daclizumab.

Dosing and Administration Basiliximab is administered as two 20-mg intravenous doses: intraoperatively and again on postoperative day 4. Basiliximab is compatible with both 0.9% sodium chloride and 5% dextrose and can be administered either centrally or peripherally over 20 to 30 minutes in a volume of 50 mL. This regimen results in saturation of the IL-2 receptor for 30 to 45 days. The approved daclizumab dosing regimen for renal transplantation is 1 mg/kg every 2 weeks from the time of transplant for a total of 5 doses. Daclizumab should be diluted in 50 mL of sterile 0.9% sodium chloride and administered peripherally or centrally over 15 minutes. This regimen saturates the IL-2 receptors for approximately 90 to 120 days after renal transplantation.^{47,83} Alternative dosing regimens have been proposed for daclizumab in combination with tacrolimus, mycophenolate, and corticosteroids: 1 mg/kg every 2 weeks for 5 doses, 2 mg/kg every 2 weeks for 2 doses, or 2 mg/kg on day 0 followed by 1 mg/kg on day 5.^{91,92}

Muromonab-CD3

Pharmacology/Mechanism of Action OKT3 is a murine monoclonal antibody to the CD3 receptor on mature human T cells (see Fig. 92-1). Minutes following the administration of OKT3, T-cell concentrations decrease dramatically, as measured by CD3 levels. Cells reappear after a few days but bear no CD3 receptors. After cessation of OKT3 therapy, T-cell function normalizes in a week.⁹³

Pharmacokinetics OKT3 has a volume of distribution of 6.5 L and half-life of about 18 hours. Concentrations above 0.9 mcg/mL are considered therapeutic. An OKT3 concentration of 0.8 mcg/mL or greater in combination with a CD3+ T-cell count of <25 cells/mL is also a reasonable therapeutic target. If CD3 levels begin to rise, this may signify the presence of antimurine antibodies antagonizing the actions of OKT3. Administration of mycophenolate mofetil has been suggested to reduce the formation of antimurine antibodies during OKT3 administration. Although T-cell depletion is achieved within minutes of administration, resolution of rejection takes 3 to 4 days.

Efficacy OKT3 has been used as induction therapy at doses of 5 mg/day for 7 to 14 days. OKT3 can be used safely and successfully as an acute rejection therapy in patients who have undergone previous OKT3 induction.⁹³ Specifically, these studies confirm that the presence of low anti-OKT3 antibody titers ($\leq 1:100$) does not preclude successful retreatment with OKT3 for rejection. However, today, OKT3 is generally reserved for treatment of corticosteroid-resistant rejection.

Adverse Effects OKT3 administration is associated with significant first-dose adverse reactions. The cytokine-release syndrome related to OKT3, including fever, chills, rigors, pruritus, and alterations in blood pressure, may occur with the first several doses. Methylprednisolone, acetaminophen, diphenhydramine, indomethacin, and pentoxifylline have been used as premedications to prevent or minimize the severity of this syndrome. Other adverse effects include capillary leak syndrome and pulmonary edema, especially in fluid overloaded patients. It is recommended that patients be within 3% of their dry weight and have chest radiographs evaluated prior to administration. Aseptic meningitis is another potential complication of OKT3 therapy. If encephalitic symptoms develop, OKT3 should be discontinued and appropriate care initiated. Other adverse effects include encephalopathy, nephrotoxicity, infection, and post-transplantation lymphoproliferative disorder.⁴⁷

Drug-Drug and Drug-Food Interactions No drug or food interactions have been reported with OKT3.

Dosing and Administration OKT3 should be filtered with a 0.2- to 0.22-micron filter and then administered as an intravenous push over 1 minute. The dose of OKT3 usually is 5 mg/day for 5 to 14 days. Induction with 2.5 mg/day also has been used effectively.⁹³ Vital signs should be assessed frequently during the first few doses, and it is advisable to have a physician present for the first dose. A high proportion of patients treated with OKT3 form antibodies to one of the components of OKT3 and may not be able to receive or adequately respond to retreatment.⁹³ The dosages of other immunosuppressant drugs often need to be decreased while administering corticosteroids, OKT3, or antithymocyte globulin therapy.

Alemtuzumab

Alemtuzumab is approved for use in B-cell chronic lymphocytic leukemia. However, its effects on depleting both T and B lymphocytes make it useful in solid-organ transplants. Although alemtuzumab use in solid-organ transplantation is considered to be investigational, it is increasingly recognized as a viable therapeutic option and, consequently, its use is increasing despite the lack of sound clinical evidence.

Pharmacology/Mechanism of Action Alemtuzumab is a humanized monoclonal antibody directed at cells that express the CD52 surface antigen, which is found on both T and B lymphocytes, as well as macrophages, monocytes, eosinophils, and natural killer cells. When alemtuzumab binds to the CD52 surface antigen, antibody-dependent lysis occurs, which removes both T and B lymphocytes from the blood, bone marrow, and organs, resulting in complete lymphocyte depletion.

Pharmacokinetics The pharmacokinetics of alemtuzumab in solid-organ transplantation patients has not been investigated. Data from patients with B-cell chronic lymphocytic leukemia indicate that the volume of distribution of alemtuzumab after repeated dosing was 0.18 L/kg. The mean half-life after the first 30 mg dose was 11 hours, but increased to 6 days after 12 weeks of therapy. The extrapolation of this data to solid-organ transplantation is difficult because of the differences in dosing strategies (single or double doses in solid-organ transplantation versus weekly to three times weekly dosing in B-cell chronic lymphocytic leukemia). One or two doses of alemtuzumab result in complete and prolonged lymphocyte depletion. Following administration, B lymphocyte counts return to normal within 3 to 12 months. T lymphocytes, however, remain depressed for as long as 3 years following administration.⁹⁴

Efficacy Recent data suggests that alemtuzumab is effective as induction therapy for the prevention of acute rejection in kidney, liver, pancreas, intestinal, and lung transplants.⁹⁵ Additionally, alem-

tuzumab has been used to successfully treat acute rejection following transplantation and is effective for corticosteroid- and antibody-resistant rejection.⁹⁵ The most promising role of alemtuzumab in solid-organ transplantation is its use in corticosteroid-sparing protocols, which allow for calcineurin inhibitor monotherapy following transplantation. Tacrolimus appears to be the optimal calcineurin inhibitor to use for monotherapy immunosuppression in patients who receive alemtuzumab induction.

Adverse Effects The adverse effects of alemtuzumab include infusion-related reactions, hematologic effects, and infections. Infusion-related reactions include rigors, hypotension, fever, shortness of breath, bronchospasms, and chills. The potential for developing these reactions can be reduced by administering premedications, including corticosteroids, diphenhydramine, and acetaminophen, or by administering smaller doses and escalating the dose gradually. Hematologic effects include pancytopenia, neutropenia, thrombocytopenia, and lymphopenia. Dose modifications are recommended based on the degree of thrombocytopenia.

Drug–Drug and Drug–Food Interactions No drug or food interactions have been reported with alemtuzumab.

Dosing and Administration Several dosing regimens have been proposed for alemtuzumab in solid-organ transplantation. The most commonly recommended dosing strategy for alemtuzumab is 30 mg as a single dose; some centers administer a second dose 1 to 5 days after transplantation.⁹⁵ Other studied dosing strategies include 0.3 mg/kg per dose, as a single- or multiple-dose regimen, and, finally, two 20-mg doses given on the day of transplantation and the first postoperative day.⁹⁶

EVALUATION OF THERAPEUTIC OUTCOMES

10 The success of transplantation can be measured in terms of length of graft and patient survival or quality of life. Several donor and recipient factors that have an impact on graft and patient survival have been identified (Table 92–7). The greatest risk to short-term graft survival is acute rejection. Routine surveillance of appropriate biochemical markers and serum drug concentrations are essential to minimize the potential for acute rejection. These parameters should be assessed daily to weekly for the first 1 to 3 months after transplantation. Monitoring should include complete blood counts, serum electrolyte concentrations, serum creatinine and blood urea nitrogen concentrations, and the appropriate serum drug concentrations. Liver function tests should also be evaluated using the same schedule in liver transplantation recipients. Routine biopsies are necessary to monitor for acute rejection in heart transplantation recipients. As the time after transplantation increases, the frequency of monitoring decreases. Once 3 months have elapsed after

TABLE 92-7 Factors Negatively Affecting Allograft and Patient Survival

	Kidney	Liver	Heart
Donor factors	Decreased HLA matching Increased age Increased serum creatinine Cardiac instability Prolonged ischemia time History of hypertension	Size mismatch Age (youngest, oldest)	Size mismatch Increased age Prolonged ischemia time
Recipient factors	Age <15, >50 years Retransplantation African race Elevated PRA Multiparous women Poor drug compliance	Increased age Retransplantation African race ICU pretransplant ABO blood type Poor drug compliance	Age <5, >60 years ICU pretransplant Mechanical ventilation LVAD IABP Poor drug compliance

transplantation, monitoring of these parameters can be reduced to biweekly or monthly for most patients.

Long-term graft survival is limited by chronic rejection. Overall survival rates for solid-organ transplantations are described in terms of half-life, or the time after transplantation at which only 50% of transplanted organs are still functioning. Estimated half-lives for kidneys are 26.9 years for HLA-identical grafts and 12.2 and 10.8 years, respectively, for grafts from a sibling or parent who are 1-haplotype matches. The estimated half-life for HLA-matched grafts was 17.3 years while a markedly lower value of 7.8 years has been noted with mismatched kidneys.²⁰ The overall median patient survival time for heart transplantation recipients is 9.8 years, but in these patients surviving the first year after transplantation, the median survival increases to 12 years.¹ The highest rate of mortality occurs within the first year after liver transplantation due to the risks of surgery and early postoperative complications. Table 92–8 depicts a typical post-transplantation laboratory monitoring plan.

IMMUNOSUPPRESSION-RELATED COMPLICATIONS

Comorbidities such as cardiovascular disease and malignancy, recurrent disease, drug toxicities (namely nephrotoxicity), and chronic

TABLE 92-8 Laboratory Monitoring after Transplantation as a Function of Time Post-Transplant

	1–2 Weeks	1 Month	2–4 Months	4–12 Months	>12 Months
SCr/BUN	Daily	1–2 times per week	Every 1–2 weeks	Monthly	Every 1–2 months
Chemistries ^a	Daily	1–2 times per week	Every 1–2 weeks	Monthly	Every 1–2 months
Liver function tests ^b					
Kidney or heart recipient	Once	Once	Monthly	Every 1–3 months	Every 1–3 months
Liver recipient	Daily	1–3 times per week	Every 1–2 weeks	Monthly	Every 1–2 months
Immunosuppressant level	Daily	1–2 times per week	Every 1–2 weeks	Monthly	Every 1–2 months
Complete blood count ^c	Daily	1–2 times per week	Every 1–2 weeks	Monthly	Every 1–2 months
Lipid panel ^d	Once	Every 3 months	Every 3 months	Every 3 months	Every 3 months
HbA _{1c}	Once	Every 3 months	Every 3 months	Every 3 months	Every 3 months

BUN, blood urea nitrogen; HbA_{1c}, hemoglobin A1c; SCr infusion, serum creatinine.

^aChemistries include sodium, potassium, chloride, CO₂ content, magnesium, calcium, phosphorus and blood glucose.

^bLiver function tests include total bilirubin, aspartate transaminase (AST), alanine transaminase (ALT), gamma glutamyl transpeptidase (GGTP), alkaline phosphatase.

^cComplete blood count includes white blood cells (WBC), red blood cells (RBC), platelets and/or differential.

^dLipid panel includes total cholesterol, low-density lipoprotein (LDL), high-density lipoprotein (HDL), triglyceride and/or very low-density lipoprotein (VLDL).

TABLE 92-9 Special Pharmacotherapy Considerations in Transplant Recipients

Problem	Pharmacotherapy	Special Considerations
Infection		
Perioperative prophylaxis		Donor culture results Penicillin allergy: vancomycin
<i>Pneumocystis carinii</i> pneumonia prophylaxis	Bowel decontamination TMP-SMX 400/80 daily or thrice weekly Pentamidine 300 mg inhaled monthly or dapsone 50–100 mg po daily or atovaquone 750–1,500 mg po daily	Sulfa allergy
Fungal Prophylaxis Treatment	Nystatin, clotrimazole Fluconazole, itraconazole, voriconazole Amphotericin B	Inhibit P450 3A4; monitor CSA and TAC levels; decrease doses Consider liposomal products; decrease or stop CSA or TAC to minimize nephrotoxicity Remember to adjust doses of renally eliminated drugs, e.g., acyclovir, ganciclovir, TMP-SMX, valganciclovir
Hyperkalemia	Restrict dietary intake; dialysis	May be exacerbated by CSA or TAC or ACEIs, acidosis or RI; fludrocortisone acetate 0.1 mg PO once daily or twice daily for refractory hyperkalemia
Hyperglycemia		
Diabetes pretransplant	Insulin, oral hypoglycemics	Corticosteroids, TAC, and CSA also increase hypoglycemic requirements Insulin requirements will increase with improving renal function Avoid in those with RI
Post transplant diabetes	Metformin Insulin Oral hypoglycemics	Risk factors: obesity, family history, African American race, cadaveric kidney, TAC > CSA May resolve/improve as immunosuppressive doses decrease
Ulcer prophylaxis	H ₂ -receptor antagonists Sucralfate	Adjust dose in those with RI Decreased TAC absorption If RI: caution aluminum content No RI: caution hypophosphatemia
	Proton pump inhibitors	
Hyperlipidemia	Diet HMG-CoA reductase inhibitors (“statins”) Gemfibrozil	CSA > TAC; consider switch to TAC; discontinue or hold SRL CSA/TAC may increase “statin” levels; start at lowest dose Monitor for muscle cramps, CPK levels and LFTs Adjust dose in those with RI Caution with concomitant “statin”
Hypertension	Calcium channel blockers ACEIs; angiotensin II receptor antagonists	Diltiazem, verapamil inhibit CSA/TAC metabolism Dihydropyridines may potentiate CSA-gingival hyperplasia May exacerbate hyperkalemia Monitor K ⁺ , S _{Cr} to assess for renal allograft vascular disease; may be useful in post-transplant erythrocytosis (HCT >55%)
Osteoporosis	Oral calcium supplementation (1,000–1,500 mg/day) Oral vitamin D Calcifediol (1,000 international units/day) Calcitriol (0.5 mcg/day) Hormone-replacement therapy Calcitonin or oral bisphosphonates	If daily intake <1,000 mg elemental calcium Documented deficiency If kidney functioning If kidney not functioning Postmenopausal women without contraindications Documented loss in bone mineral density >3% Data lacking for bisphosphonates in patients with RI
Malignancy		
Prevention	Minimize immunosuppressant doses; avoid sun exposure (sun block, hats, clothing); routine self-examinations (skin, lymph nodes); yearly gynecologic/prostate exams	AZA particularly associated with skin cancers CSA/TAC may be associated with lymphoproliferative disorders (lymphomas)
Treatment	Discontinue or minimize immunosuppressants Surgical, radiologic, or antineoplastic therapy	Do not abruptly withdraw corticosteroids

ACEI, ACE inhibitor; CMV, cytomegalovirus; CPK, creatinine phosphokinase enzymes; CSA, cyclosporine; HCT, hematocrit; K⁺, potassium; LFTs, liver function tests; RI, renal insufficiency; S_{Cr}, serum creatinine; SRL, sirolimus; TAC, tacrolimus; TMP-SMX, trimethoprim-sulfamethoxazole.

rejection are the primary causes of mortality in patients who have a functioning graft 5 or more years after transplantation.¹ Special considerations for the management of these conditions in transplant patients are discussed below and summarized in Table 92–9.

CARDIOVASCULAR DISEASE

Cardiovascular disease is a leading cause of morbidity and mortality in transplant patients.⁹⁷ Preexisting cardiovascular disease, which is common in end-stage organ failure, is not reversed with transplantation. Additionally, hypertension, hyperlipidemia, and diabetes are common

complications in transplantation recipients and are independent risk factors that contribute significantly to cardiovascular disease. Chronic rejection has been linked to hypertension and hyperlipidemia.^{98,99}

HYPERTENSION

Corticosteroids, cyclosporine, tacrolimus, and impaired kidney graft function may cause post-transplantation hypertension. The primary mechanism of calcineurin inhibitor-associated hypertension in heart transplantation recipients may be related to the calcineurin inhibitor-induced stimulation of intact renal sympathetic nerves and the

absence of reflex cardiac inhibition of the sympathetic nervous system, but a number of other mechanisms, including decreased prostacyclin and nitric oxide production, also have been proposed.^{45,100,101} In addition to the propensity to cause peripheral vasoconstriction, calcineurin inhibitors promote sodium retention, resulting in extracellular fluid volume expansion. Tacrolimus appears to have less potential to induce hypertension following transplantation than cyclosporine.²⁹ Most classes of antihypertensive medications effectively reduce blood pressure in transplantation patients.¹⁰²

Calcium channel blockers traditionally have been the first-line agents to treat hypertension after transplantation.¹⁰³ In addition to their ability to control blood pressure, calcium channel blockers may ameliorate the nephrotoxic effects of cyclosporine, improve renal hemodynamics, decrease the incidence of delayed graft function and the development of allograft atherosclerosis, and provide some immunosuppression. Calcium channel blockers, however, also may contribute to gingival hyperplasia that is often associated with cyclosporine-based immunosuppression.⁹⁸ CYP3A4 interactions with cyclosporine and tacrolimus are of concern with this class of medications, particularly with diltiazem, verapamil, and nicardipine, and cyclosporine or tacrolimus concentrations must be monitored to ensure proper dosage adjustments.

ACEIs and angiotensin II receptor blockers traditionally have been avoided in kidney transplantation recipients, especially in the perioperative phase, because of the potential for hyperkalemia and their potentially negative influence on glomerular filtration rate. ACEIs and angiotensin II receptor blockers are now considered to be an equivalent alternative to calcium channel blockers for the treatment of hypertension in all transplant recipients. When ACEIs or angiotensin II receptor blockers are used in patients after transplantation, serum creatinine and potassium levels should be monitored closely. If the increase in serum creatinine is greater than 30% within 1 to 2 weeks after initiating ACEIs or angiotensin II receptor blockers, the drug should be discontinued and other measures used to control blood pressure (see Chap. 49).

CLINICAL CONTROVERSY

Many clinicians avoid using ACEIs in kidney transplantation recipients because of the potential to decrease the glomerular filtration rate by promoting efferent arteriole vasodilation in the presence of calcineurin inhibitor-induced afferent arteriole vasoconstriction. Emerging evidence suggests that this situation does not occur.

Multiple antihypertensive agents usually are necessary to achieve the goal blood pressure in transplant recipients; consequently, the addition of a β -blocker, diuretic, or centrally acting antihypertensive is usually necessary. β -Blockers generally are considered to be second-line therapy in solid-organ transplantation recipients, because of the potential to worsen metabolic disturbances caused by immunosuppressants, such as hyperkalemia and dyslipidemia. Calcineurin inhibitor-induced hypertension is often salt-sensitive, making it very responsive to diuretics. Central-acting agents (e.g., clonidine) are used often as adjunctive therapy in transplantation recipients who are unable to achieve blood pressure control with calcium channel blockers or ACEIs.

HYPERLIPIDEMIA

Hyperlipidemia may be exacerbated by corticosteroids, calcineurin inhibitors, sirolimus, diuretics, and β -blockers.¹⁰⁴ Corticosteroids promote insulin resistance and a decrease in lipoprotein lipase activity, as well as excessive triglyceride production. The mechanism of

calcineurin inhibitor-induced hyperlipidemia is not well understood. Calcineurin inhibitors may decrease the activity of the low-density lipoprotein (LDL) receptor or lipoprotein lipase, altering LDL catabolism.⁹⁹ Tacrolimus appears to have less potential to induce hyperlipidemia than cyclosporine.^{27,28,30} post-transplantation hyperlipidemia is characterized by elevated LDL, very-low-density lipoprotein, triglyceride apolipoprotein B, and lipoprotein(a) levels.⁹⁹ It is controversial whether the management of hyperlipidemia in transplantation recipients should be more aggressive than current guidelines for the general population established by the National Cholesterol Education Program.¹⁰⁵ Aggressive lipid lowering may not only arrest the progress or prevent the complications of atherosclerosis but also may promote graft survival in the kidney and heart transplantation population. With the use of lipid-lowering agents, potential interactions with immunosuppressive regimens must be considered.

Dietary intervention, although safe, may be relatively ineffective for the treatment of hyperlipidemia in the transplant population. Along with dietary modification, dose reduction or withdrawal of cyclosporine and/or corticosteroids may assist in minimizing hyperlipidemia. For most patients, the combination of dietary intervention and an HMG-CoA reductase inhibitor should be considered the treatment of choice. HMG-CoA reductase inhibitors are highly effective in the treatment of hyperlipidemia, especially increased LDL, in transplantation patients. HMG-CoA reductase inhibitors as a class have immunomodulatory effects on MHC expression and T-cell activation and reduce cardiac allograft rejection.^{99,106}

HMG-CoA reductase inhibitors should be used with caution in transplantation recipients because of several reports of rhabdomyolysis when these agents are combined with calcineurin inhibitors.^{39,106,107} Safety measures, including the use of low HMG-CoA reductase inhibitor doses and avoiding inappropriately high cyclosporine or tacrolimus concentrations. The concurrent use of medications known to increase the risk of myopathy (such as gemfibrozil) should be avoided.⁹⁹ Patients should be informed of the signs and symptoms of rhabdomyolysis. Baseline and followup creatine phosphokinase measurements (every 6 months) have been used to identify patients who develop subclinical rhabdomyolysis when cholesterol-lowering therapy is used. Pravastatin may be preferred as a result of its lower interactive potential with calcineurin inhibitors because it is not metabolized by CYP3A4. The potential for hepatotoxicity from HMG-CoA reductase inhibitors warrants close monitoring of liver function in all transplantation recipients.¹⁰⁴

Bile acid-binding resins may be used to lower cholesterol in transplant patients, but adequate doses are difficult to achieve without the development of GI adverse effects. Because the absorption of cyclosporine is dependent on the presence of bile in the GI tract, patients should be instructed to separate dosing of bile acid-binding resins and cyclosporine by at least 2 hours. Bile acid-binding resins also should be separated from other immunosuppressants by at least 2 hours to avoid physical adsorption in the GI tract. For transplantation patients who have hypertriglyceridemia refractory to dietary intervention, fish oil and fibric acid derivatives are well-tolerated, effective alternatives (see Chap. 23). Fibric acid derivatives are most effective in lowering serum triglyceride concentrations.

POST-TRANSPLANTATION DIABETES MELLITUS

Corticosteroids and calcineurin inhibitors can impair glucose control in previously diabetic patients, as well as cause new-onset post-transplantation diabetes mellitus (PTDM) in 4% to 20% of patients. Corticosteroids induce insulin resistance and impair peripheral glucose uptake, whereas calcineurin inhibitors appear to inhibit insulin production.¹⁰⁸ Tacrolimus seems to be more diabetogenic than cyclosporine, although recent studies have failed to show a statistical

difference.²⁷ Other possible risk factors that have been identified for PTDM include ethnicity (African American or Hispanic), age (>40 years), pretransplant diabetes status, family history, and weight.¹⁰⁹

Patients with PTDM should be referred for nutritional counseling and advised on the merits of weight loss (if appropriate). There are, however, some special considerations in transplantation patients. Up to 40% of patients with PTDM will require insulin therapy.¹⁰⁸ In diabetic patients who can be managed with an oral hypoglycemic agent, glipizide, which is metabolized extensively by the liver, may be preferred over renally eliminated agents such as glyburide. Metformin should be used with extreme caution because of the risk of accumulation and lactic acidosis in those with moderate renal impairment. Regardless of therapy, frequent blood glucose monitoring is imperative in the early postoperative phase both to improve glucose control and to identify those with PTDM. Changes in renal function secondary to calcineurin inhibitor nephrotoxicity or delayed graft function or acute rejection in kidney transplantation recipients affects the elimination of many hypoglycemic agents, including insulin, and may result in hyper- or hypoglycemia. Patients and clinicians also should be aware that dose changes of immunosuppressant drugs also affect glycemic control. Tapering of immunosuppressive medications may result in reduced insulin requirements, whereas corticosteroid pulses for the treatment of rejection may result in increased insulin requirements.

INFECTION

Both the severity and incidence of infections and deaths caused by infections have decreased dramatically since the introduction of cyclosporine and the use of lower corticosteroid dosages. Nonetheless, infection and rejection remain the most frequently encountered complications associated with immunosuppression in the first year after transplantation.¹¹⁰ The risk of infection is related directly to the overall level of immunosuppression and is greatest during the first 3 postoperative months, as well as following treatment of acute rejection episodes.¹¹¹ Infectious complications following transplantation generally are classified according to the causative organism, site of infection, and time of appearance following surgery. Bacterial infections occur most frequently within the first month after transplantation and generally affect the urinary tract, wound, or vascular access sites. Viral infections are caused most commonly by herpes simplex (early transplantation), herpes zoster (late post-transplantation), or cytomegalovirus (CMV). Chapter 126 discusses the treatment of infection in the immunocompromised host. Special considerations for CMV, herpes, and *Pneumocystis carinii* infections in transplant patients are described in the following paragraphs.

CMV is the most important viral pathogen affecting transplant patients; 50% to 60% of patients are infected with the virus. Following transplantation, patients may develop symptomatic primary or secondary CMV infections. A previously CMV-seronegative patient who receives an organ or blood product from a CMV-seropositive donor is considered to have primary CMV infection. A secondary infection is characterized by reactivation of the latent virus or reinfection in a previously seropositive patient. Patients with primary infections generally are more symptomatic than patients with secondary infections.

The incidence and severity of CMV infections in transplant recipients are related to the intensity of immunosuppression required to prevent graft rejection. Patients treated on multiple occasions with high-dose corticosteroids or patients receiving antilymphocyte preparations or OKT3 and patients with poor HLA matching, cadaveric allografts, and CMV-positive donor serology tend to have more severe CMV disease. Transplantation centers use different strategies for managing CMV, which often are based on the risk of CMV infection. Prophylactic strategies may include oral or intravenous

antiviral or immunoglobulin preparations to prevent the reactivation or emergence of CMV. Prophylaxis is used most often in high-risk patients (i.e., donor–recipient CMV–serology mismatch or for those receiving antilymphocyte preparations). Some centers routinely screen transplantation recipients for CMV via blood tests (i.e., pp65 antigenemia, polymerase chain reaction) and use preemptive therapy in patients who have a positive test. Treatment is given to all patients who have evidence of active CMV infection. Ganciclovir and valganciclovir have been used prophylactically and pre-emptively in transplant patients. Other treatment strategies include intravenous immunoglobulin and CMV hyperimmune immunoglobulin. Ganciclovir and CMV hyperimmune immunoglobulin are the mainstays for treatment of CMV infection. CMV has been linked to chronic rejection and cardiac allograft vasculopathy.

CLINICAL CONTROVERSY

Some clinicians use CMV prophylaxis for all patients receiving a transplant. Others will reserve prophylaxis for only those patients who are at a high risk for CMV infection, such as those with donor–recipient CMV–serology mismatch or recipients who have received induction therapy or rejection treatment with antithymocyte globulin. A third strategy is to pre-emptively treat patients who have laboratory evidence of CMV infection.

Herpes simplex virus infections in transplant patients are most commonly the result of reactivation of a previous infection. Symptomatic herpes simplex virus infection usually presents as labial or oral lesions in the first 1 to 3 months after transplantation, but patients also may present with reactivation of varicella-zoster as “shingles.” Prophylactic therapy with low-dose oral acyclovir delays the development of herpes simplex virus infections in patients following transplantation.

The incidence of *P. carinii* pneumonia within the first year after transplantation is reported to be 3% to 5%.¹¹³ Low-dose trimethoprim-sulfamethoxazole (400 mg/80 mg three times weekly) is effective in the prevention of *P. carinii* pneumonia infections. Alternative agents include aerosolized pentamidine (300 mg every month), dapsone, and atovaquone. The duration of *P. carinii* pneumonia prophylaxis is unclear. Because the risk of infection caused by *P. carinii* is likely to decrease as immunosuppression is reduced, prophylaxis in patients requiring treatment for acute rejection may be appropriate.

Polyomavirus infection is a common cause of kidney allograft dysfunction. The specific polyomavirus that infects kidney allografts is the BK virus. Primary infection with BK virus occurs in childhood as an asymptomatic infection in 50% to 90% of the general population. The precise mechanism of transmission is not clear, but is suspected to be via the oral or respiratory routes. The virus then remains latent primarily in the genitourinary tract. Reactivation of BK virus is limited to people with compromised immune function and is most common in kidney transplant recipients. Reactivation can be detected as the presence of BK virus in the urine of approximately 30% to 40% of kidney transplant recipients, although it does not progress to nephropathy in the majority of patients. However, BK viremia if it develops has been noted to progress to allograft nephropathy in 50% of patients.¹¹⁵ The development of BK virus nephropathy results in graft loss in as many as 45% to 67% of affected patients.¹¹⁵

Nephropathy associated with BK virus is definitively diagnosed by kidney allograft biopsy, although it is easily mistaken for acute rejection to the pathologist who does not recognize the presence of BK virus inclusions in renal tubular cells. It is important to differentiate the two because treatment of acute rejection with increased immunosuppression can worsen BK virus nephropathy. The main-

stay of treatment is a reduction in immunosuppression, which should be instituted when BK viremia is detected. The risks of acute rejection resulting from decreased immunosuppression must be weighed against the potential benefits of resolving BK viremia. Cidofovir, a potent nephrotoxic antiviral used for the treatment of CMV retinitis, has also been used for the treatment of BK virus in very low doses (0.25 mg/kg administered every 1 to 3 weeks).¹¹⁴

Hepatitis C recurs almost universally following liver transplantation, resulting in chronic hepatitis or cirrhosis in 90% of patients by 5 years. These patients tend to experience a much more aggressive course than that observed in immunocompetent patients. While short-term survival is not affected, hepatitis C virus infection recurrence results in the need for retransplantation in more than 10% of patients originally transplanted for hepatitis C virus. Pegylated interferons as monotherapy or in combination with ribavirin have been used after liver transplantation, in both the acute and chronic phases of hepatitis C virus infection and as prophylactic or preemptive therapy. Although some patients do achieve sustained viral responses, the rates are generally lower than for immunocompetent patients, 10% to 30% versus 30% to 70%, respectively, for combination therapy. Preexisting anemia and renal dysfunction make it difficult to maintain ribavirin at effective doses. Combination of immunosuppressive drugs and interferon may result in dose-limiting neutropenia. Administration of hematopoietic growth factors may be needed to allow administration of adequate doses of interferons and ribavirin. Even with these adjunctive therapies high rates of therapy discontinuation are still reported.^{116,117}

In the absence of preventative therapy, hepatitis B recurs in approximately 80% of patients. Initial studies with short-term intravenous administration of hepatitis B immunoglobulin (HBIG) showed equally high rates of recurrence upon discontinuation of therapy. However, strategies that employ the long-term administration of HBIG with or without antiviral therapy report much lower recurrence rates, 15% to 30% and 20% to 40%, for nonreplicative and replicative hepatitis B virus, respectively. Common strategies include intravenous HBIG 10,000 units during the anhepatic phase followed by 10,000 units daily for 6 days. Antihepatitis B surface titer should be monitored weekly to ensure adequate levels for protection, as well as optimize HBIG use. HBIG has been typically dosed to maintain titers >100 to 500 international units/L. Monotherapy with lamivudine is insufficient. Treatment for active hepatitis B virus graft infection should include HBIG, antiviral therapy such as lamivudine or adefovir, and concomitant reduction in immunosuppression.¹¹⁷

MALIGNANCY

Advances in immunosuppression have decreased the incidence of acute rejection and increased patient survival, thus increasing the patient's lifetime exposure to immunosuppression. Although the precise mechanism is unclear, post-transplantation malignancy seems to be related to the overall level of immunosuppression, as evidenced by a difference in the rates of malignancy associated with quadruple versus triple versus dual immunosuppressant regimens. The risk of malignancy in transplantation recipients is increased three- to fourfold over the general population. Although the risk of lung, breast, colon, and prostate cancers does not appear to increase, a number of cancers that are uncommon in the general population often occur with a higher prevalence in transplantation recipients: post-transplantation lymphomas and lymphoproliferative disorders (PTLD), Kaposi sarcoma, renal carcinoma, in situ carcinomas of the uterine cervix, hepatobiliary tumors, and anogenital carcinomas. Skin cancers are the most common tumors, accounting for 38% of all malignancies. Factors that may predispose transplant recipients to skin cancers include copious sun exposure and therapy with azathioprine, possibly as a result of azathioprine's metabolite, nitroimida-

zole, which causes significant photosensitivity.¹¹⁸ Azathioprine therapy is associated with a 2:1 predominance of squamous over basal cell carcinomas, whereas basal cell carcinoma occurs more frequently in the general population. Azathioprine-induced cutaneous squamous cell carcinoma is also associated with more metastatic disease and accounts for 6% of all deaths in comparison with less than 1% with cyclosporine. Patients must be encouraged to use effective techniques to reduce sun exposure.¹¹⁸

PTLD encompasses a broad spectrum of disorders, ranging from benign polyclonal hyperplasias to malignant monoclonal lymphomas. Factors that predispose patients to PTLD include Epstein-Barr virus seronegativity at transplantation and intense immunosuppression, particularly with OKT3 and antithymocyte globulin. Nonrenal transplantation recipients are more likely to develop PTLD secondary to the heavy immunosuppression used to reverse rejection. Administration of ganciclovir or acyclovir pre-emptively during antilymphocyte therapy may decrease the risk of eventual PTLD. Treatment of life-threatening PTLD generally includes severe reduction or cessation of immunosuppression. Other options include systemic chemotherapy or rituximab.¹¹⁹

Post-transplantation malignancies appear an average of 5 years after transplantation and increase with the length of followup. As many as 72% of patients surviving greater than 20 years may be affected. Malignancy accounts for 11.8% of deaths after cardiac transplantation and is the single most common cause of death in the sixth to the tenth post-transplant years.¹¹³

CONCLUSIONS

Transplantation is a lifesaving therapy for several types of end-organ failure. Advances in the understanding of transplant immunology have produced an unprecedented number of choices in terms of immunosuppression. The increasing number of effective immunosuppressive medications and therapies offer clinicians diverse ways to prevent allograft rejection in a patient-specific manner. However, the vast array and efficacy of currently available immunosuppressive agents make it increasingly difficult to evaluate their long-term efficacy. Clinicians must be keenly aware of the adverse effects of immunosuppressive medications and their treatment in order to optimize the care of the transplanted patient.

ABBREVIATIONS

- 6-MP: 6-mercaptopurine
- ACEI: angiotensin-converting enzyme inhibitor
- ATG: antithymocyte globulin
- ATN: acute tubular necrosis
- AUC: area under the concentration curve
- C₂: concentration 2 hours after dose
- C_{max}: peak concentration
- CMV: cytomegalovirus
- CYP: cytochrome P450 liver enzyme system
- DGF: delayed graft function
- FKBP: FK-binding protein
- GI: gastrointestinal
- HBIG: hepatitis B immunoglobulin
- HIV: human immunodeficiency virus
- HLA: human leukocyte antigen
- HPLC: high-performance liquid chromatography

IL: interleukin

LDL: low-density lipoprotein

MELD: model for end-stage liver disease

MHC: major histocompatibility complex

MPA: mycophenolic acid

MPAG: mycophenolic acid glucuronide

mTOR: mammalian target of rapamycin

OKT3: muromonab-CD3

PRA: panel of reactive antibodies

PTDM: post-transplantation diabetes mellitus

PTLD: post-transplantation lymphoproliferative disorder

RIA: radioimmunoassay

t_{\max} : time to peak concentration

SECTION 12

RHEUMATOLOGIC DISORDERS

CHAPTER

93

Osteoporosis and Other Metabolic Bone Diseases

MARY BETH O'CONNELL AND SHERYL F. VONDRACEK

KEY CONCEPTS

- 1 Postmenopausal women, men older than age 65 years, and those with potential disease- or drug-induced bone loss should be assessed for osteoporosis. Patients with premature or severe osteoporosis should be evaluated for secondary causes of bone loss.
- 2 Central bone densitometry can determine bone mass, predict fracture risk, and influence patient and provider treatment decisions. Portable equipment can be used for screening in the community to determine the need for further testing.
- 3 Vitamin D insufficiency and deficiency, which sometimes causes osteomalacia, can be insidious and coexist with osteoporosis. A serum 25(OH) vitamin D concentration should be obtained in patients with decreased oral vitamin D intake, limited or no sun exposure, or unexplained muscle weakness or pain.
- 4 All people, regardless of age, should incorporate a bone-healthy lifestyle beginning at birth, which emphasizes regular exercise, nutritious diet, tobacco avoidance, minimal alcohol use, and fall prevention to prevent and treat osteoporosis.
- 5 The adequate intake for calcium in American adults is 1,000 to 1,500 mg of elemental calcium daily in divided doses from diet or supplements. The adequate intake for American adults, especially seniors, is 600 to 1,000 units of vitamin D daily from mainly supplements, with some experts recommending even higher doses.
- 6 Bisphosphonates decrease vertebral, hip, and nonvertebral fractures and are considered the drug of choice for osteoporosis treatment.
- 7 Raloxifene is an alternative treatment option to prevent vertebral fractures, particularly in women who cannot tolerate, should not, or will not take bisphosphonates. Postmenopausal

women at high risk for breast cancer might choose this medication to obtain dual actions.

- 8 Male osteoporosis is often secondary to specific diseases and drugs and responds well to a bone-healthy lifestyle, bisphosphonate therapy, and in some cases, testosterone replacement.
- 9 Patients taking chronic oral glucocorticoids (e.g., rheumatoid arthritis, cystic fibrosis, transplantation, bowel disorders, cancer) need to be identified and started on a bone-healthy lifestyle, higher doses of calcium and vitamin D, and bisphosphonate therapy to prevent or treat osteoporosis.
- 10 Patients with certain diseases such as gastrectomy, celiac disease, inflammatory bowel disease, and organ transplantation, or taking medications known to influence vitamin D and/or bone metabolism should be evaluated for disease and drug-induced osteopenia and osteoporosis.

Osteoporosis is a major public health threat for an estimated 44 million Americans, or 55% of the people 50 years of age and older.¹ In the United States, 8 million women and 2 million men are estimated to have the disease. Osteoporosis is defined as a “skeletal disorder characterized by compromised bone strength predisposing a person to an increased risk of fracture.”² The development of osteoporosis and osteoporotic fractures is multifactorial, beginning with genetics and unhealthy bone lifestyles, along with other skeletal factors, which lead to compromised bone strength, and nonskeletal factors that lead to falls (Fig. 93–1). President Clinton declared 2002 to 2011 to be the Decade of the Bone and Joint. To coincide with this initiative, the Surgeon General released a report in 2004 on Bone Health and Osteoporosis, providing information, challenges, and opportunities for change.³ Healthcare practitioners must take an active role in educating people of all ages and healthcare providers on healthy bone habits and osteoporosis treatment options.

EPIDEMIOLOGY

Osteopenia (low bone mass), osteoporosis, and osteoporotic fractures are very common and affect all ethnic groups. Almost 34 million Americans are estimated to have low bone mass (osteopenia),¹

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

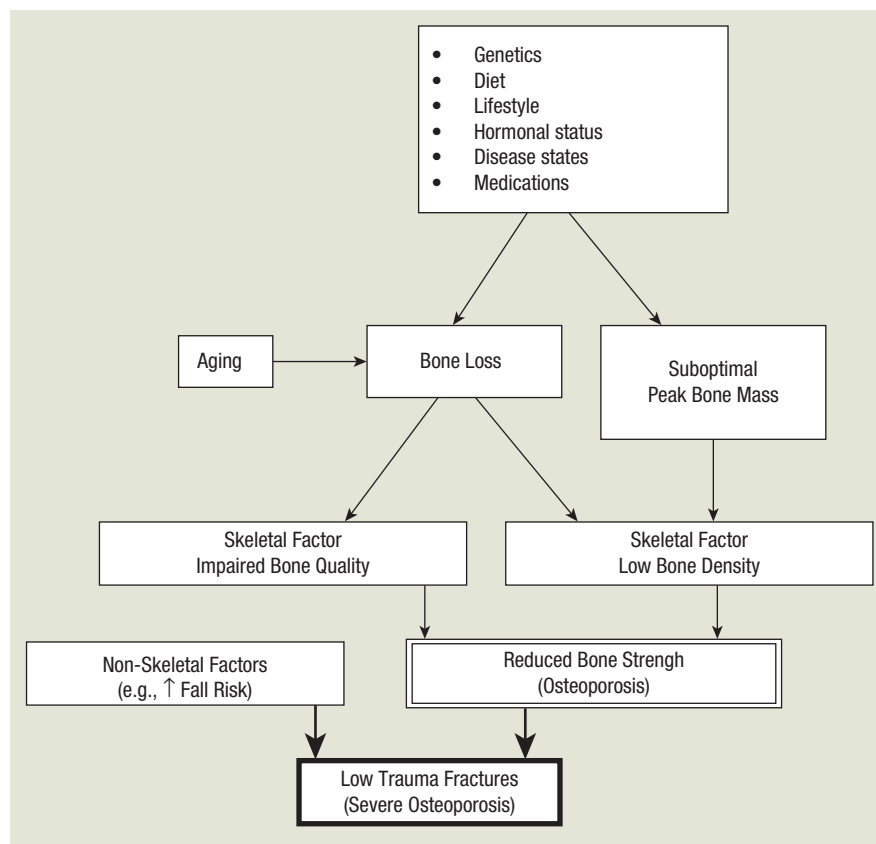

FIGURE 93-1. Etiology of osteoporosis.

including 50% of Asian, 47% of Hispanic, 45% of Native American, 40% of white, and 28% of black women.⁴ Osteoporosis affects 12% of Native American, 10% of Asian, 10% of Hispanic, 7% of white, and 4% of black women. Disease prevalence greatly increases with age; from 4% in women 50 to 59 years of age to 44% to 52% in women 80 years of age and older.^{5,6} Fragility or low trauma wrist and vertebral fractures are common throughout adulthood, whereas hip fractures are more common in seniors. Fracture incidence was estimated to be 2 million (71% in women, 29% in men) in 2005, with an estimated total medical cost of \$17 billion.⁷ Fractures in women accounted for 75% of the costs and in seniors 87% of the costs. Hip fractures represented 72% of these costs. Forecasting predicts 3 million fractures at a cost of \$25 billion in 2025. In a women's lifetime, hip fracture risk is 17% for whites, 14% for Hispanics, and 6% for African Americans.⁵ In a man's lifetime, hip fracture risk is 6% to 11%.⁸

BONE PHYSIOLOGY

Bone is made of collagen and mineral components. The collagen component gives bone its flexibility and energy-absorbing capability.⁹ The mineral component gives bone its stiffness and strength. The correct balance of these substances is needed for bone to adequately accommodate to stress and strain and resist fractures. Imbalances can impair bone quality and lead to reduced bone strength.

Bone strength reflects the integration of bone quality and bone mineral density (bone mass). Bone mass increases rapidly throughout childhood and adolescence. Ninety percent of peak bone mass is attained by age 18 to 20 years, with small gains until approximately age 30 years. Peak bone mass is highly dependent on genetic factors that account for approximately 60% to 80% of the variability.^{5,10,11} The remaining 20% to 40% is influenced by modifiable factors such as nutritional intake (e.g., calcium, vitamin D, and protein), exercise, adverse lifestyle practices (e.g., smoking), hormonal status, and certain diseases and medications. Optimizing peak bone mass is

important for preventing osteoporosis. The higher the peak bone mass, the more bone one can lose before being at an increased fracture risk.

The skeleton is composed of mostly cortical bone (80%) with some trabecular bone (20%), which varies by bone site. The forearm is predominantly cortical bone (95%), the spine is predominantly trabecular bone (66% to 75%), and the femoral neck of the hip and wrist are mostly cortical bone (50% to 75%, respectively).¹² Of note, trabecular bone has a 5 to 10 times higher metabolic turnover rate than cortical bone.

Bone remodeling is a dynamic process that occurs continuously throughout life. One to two million tiny sections of bone are in the process of remodeling at any given time. The complete physiology of bone remodeling is not fully known but appears to begin with signals from lining cells or osteocytes (bone communication cells) that are triggered by stress, microfractures, biofeedback systems, and potentially certain diseases and medications (Fig. 93-2, step 1).^{12,13} Many cytokines, growth factors, and hormones influence each remodeling step. A major stimulus for hematopoietic stem cell (monocyte-macrophage lineage) differentiation to become mature osteoclasts (bone resorbing cells) is the receptor activator of nuclear factor kappa B ligand (RANKL), which is emitted from the osteoblast (bone-forming cells) in step 2. RANKL also stimulates mature osteoclast activation and bone adherence via integrins to resorb bone. Proteinases are secreted to resorb the protein matrix, and hydrogen ions are secreted to dissolve the mineralized component (step 3). After bone is resorbed and a cavity is created, additional cytokines and growth factors are released that first mature osteoblasts from mesenchymal stem cells and then stimulate osteoblast bone formation (step 4). Mature osteoblasts produce osteoprotegerin (OPG) that binds (step 4) to RANKL, thereby stopping bone resorption.

Bone formation occurs over two phases. First, osteoblasts fill the resorption cavity with osteoid and then mineralization occurs (step 5). Once bone formation is complete, mature osteoblasts undergo

FIGURE 93-2. Bone remodeling cycle.^{12,13} ($1\alpha,25(\text{OH})_2\text{D}_2$, calcitriol/ $1,25(\text{OH})_2$ vitamin D; BMP, bone morphogenetic protein; Ca, calcium; CSF, colony-stimulating factors; EAA, estrogen agonist/antagonist; FGF, fibroblast growth factor; IGF, insulin-like growth factor; IL, interleukin; Mg, magnesium; MMP, matrix metalloproteinases; NCP, noncollagenous proteins; OPG, osteoprotegerin; PDGF, platelet-derived growth factor; PG, prostaglandin; Phos, phosphorous; PTH, parathyroid hormone; PThrP, parathyroid hormone-related protein; SERM, selective estrogen receptor modulator; TGF, transforming growth factor; TNF, tumor necrosis factor; Trap, tartrate-resistant acid phosphate.)

apoptosis or become lining cells or osteocytes (step 6). Quiescence is the phase when bone is at rest until another remodeling cycle is initiated at that site.

Estrogen has many positive effects on the bone remodeling process, with most of its actions helping to maintain a normal bone resorption rate. Estrogen suppresses the proliferation and differentiation of osteoclasts and increases osteoclast apoptosis. Estrogen decreases the production of several cytokines that are potent stimulators of osteoclasts including interleukins 1 and 6, and tumor necrosis factor- α . Estrogen also decreases the production of RANKL and increases the production of OPG; both of which reduce osteoclastogenesis.¹⁴

VITAMIN D, PARATHYROID HORMONE, AND CALCIUM

Vitamin D and parathyroid hormone (PTH) maintain calcium homeostasis.¹⁵ The most abundant source of vitamin D is the endogenous production from exposure to ultraviolet B light. The sun's ultraviolet B light converts 7-dehydrocholesterol in the skin to cholecalciferol (vitamin D₃). Maximal skin production occurs within 20 minutes for whites and 60 to 120 minutes for blacks or darker-skin individuals.¹⁶ Dietary vitamin D sources include cholecalciferol and ergocalciferol (vitamin D₂). Subsequent conversion of cholecalciferol and ergocalciferol to 25-hydroxyvitamin D [$25(\text{OH})\text{D}$] (calcidiol) occurs in the liver and then PTH stimulates conversion of $25(\text{OH})\text{D}$ via $25(\text{OH})\text{D}$ -1 α -hydroxy-

lase to its final active form, $1\alpha,25$ -dihydroxyvitamin D (calcitriol), in the kidney.¹⁵ Calcitriol binds to the intestinal vitamin D receptor and then increases calcium binding protein. As a result, calcium and phosphorous intestinal absorption is increased. Vitamin D receptors are also found in many tissues, such as bone, intestine, brain, heart, stomach, pancreas, lymphocytes, skin, and gonads.

Calcium absorption under normal conditions is approximately 30% to 40%, decreasing to 10% to 15% with low vitamin D concentrations.¹⁵ Calcium absorption is predominantly rate limited through vitamin D controlled intestinal transport with less than 23% absorbed through passive paracellular diffusion, which is not rate limited.¹⁷ Elevated PTH concentrations secondary to hypocalcemia increase kidney calcitriol production and calcium reabsorption by the kidney. PTH concentrations also increase when vitamin D concentration falls below around 30 ng/mL, the minimum normal therapeutic vitamin D concentration.¹⁸ Sometimes the increased fractional calcium absorption is insufficient and thus bone resorption is needed. Together, PTH and calcitriol increase osteoclast activity, thereby releasing calcium from bone to restore calcium homeostasis.

ETIOLOGY

1 Figure 93–1 depicts a model describing the etiology of osteoporosis and fractures. Table 93–1 lists risk factors for osteoporosis and Table 93–2 lists secondary causes.

^aProposed factors included in World Health Organization fracture risk model.
^bMajor risk factors per National Osteoporosis Foundation.

LOW BONE DENSITY

Bone mineral density (BMD) is a major predictor of fracture risk.¹⁹ Every standard deviation decrease in BMD in women represents a 10% to 12% decrease in bone mass and a 1.5- to 2.6-fold increase in fracture risk.⁵ Low BMD can occur as a result of failure to reach a normal peak bone mass and/or bone loss.

Bone loss occurs when bone resorption exceeds bone formation, usually from high bone turnover; when the number and/or depth of bone resorption sites greatly exceed the rate and ability of osteoblasts to form new bone. Women and men begin to lose a small amount of bone mass starting in the third to fourth decade of life as a consequence of a slight reduction in bone formation.⁹ During perimenopause and for up to 5 to 7 years after menopause, women can experience an accelerated rate of bone loss because of the drop in circulating estrogen and an increase in bone resorption. The rate and duration of loss can vary greatly, with up to 3% to 5% of bone density lost per year, and can differ depending on the skeletal site measured. Seniors steadily lose bone mass at approximately 0.5% to 1% per year as a consequence of an accelerated rate of bone remodeling combined with reduced bone formation.

The major factors (see Tables 93–1 and 93–2) influencing bone losses are hormonal status, exercise, aging, nutrition, lifestyle, disease states, medications, and some genetic influences. Nonhormonal risk factors are similar between women and men.

IMPAIRED BONE QUALITY

In addition to BMD, the strength of bone is highly impacted by the quality of the bone’s material properties and its structure.⁹ For example, accelerated bone turnover can result in bone loss, but also can impair bone quality and the structural integrity of bone by increasing the quantity of immature bone that is not yet adequately mineralized. Bone quality assessment is important because changes in bone quality effect bone strength much more than bone mass changes. Future osteoporosis diagnostic testing will assess both bone quality and density.

FALLS

Although up to 50% of vertebral fractures can occur spontaneously with minimal to no trauma, most wrist fractures and greater than 90% of hip fractures result from a fall from standing height or less.²⁰

TABLE 93-2	Secondary Causes for Osteoporosis in Children and Adults
Disease States	Drugs
Primary or secondary ovarian failure	Chronic systemic glucocorticoids
Testosterone deficiency	Excessive thyroxine
Thyrotoxicosis	Anticonvulsant therapy (e.g., phenytoin, carbamazepine, phenobarbital, valproic acid)
Cushing’s syndrome	Depot medroxyprogesterone acetate (DMPA)
Growth hormone deficiency	Cytotoxic chemotherapy
Primary hyperparathyroidism	Cyclosporine
Type 1 diabetes	Gonadotropin-releasing hormone (GnRH) agonists or analogs (e.g., leuprolide)
Disorders of calcium balance	Long-term unfractionated heparin
Anorexia nervosa	Aromatase inhibitors
Chronic liver disease (e.g., primary biliary cirrhosis)	Highly-active antiretroviral therapy for human immunodeficiency virus (e.g., zidovudine, nucleoside reverse transcriptase inhibitors)
Malabsorptive states	Long-term proton pump inhibitor therapy
Inflammatory bowel disease	Selective serotonin reuptake inhibitors
Crohn’s or celiac disease	
Gastrectomy or Billroth I	
Rheumatoid arthritis	
Ankylosing spondylitis	
Osteogenesis imperfecta

Down’s syndrome	
Marfan’s syndrome	
Klinefelter’s syndrome	

One-third to one-half of all seniors fall each year with 50% falling more than once. Up to 5% of all falls will result in a fracture. In 2003, more than 1.8 million seniors were treated in the emergency department, and more than 400,000 were hospitalized for a fall-related injury.

Risk of falling increases with advanced age predominantly as a result of balance, gait, and mobility problems, poor vision, reduced muscle strength, impaired cognition, multiple medical conditions (e.g., stroke, Alzheimer’s dementia, Parkinson’s disease), and polypharmacy. Psychoactive medications such as benzodiazepines, antidepressants, antipsychotics, sedative hypnotics, and narcotics have been strongly associated with falls. The ability to adapt to falls also decreases with aging. Seniors are more likely to sustain a hip or pelvic fracture because they tend to fall backwards or sideways instead of forward.

PATHOPHYSIOLOGY

Osteoporosis pathophysiology depends on gender, age, and presence of secondary causes.

POSTMENOPAUSAL OSTEOPOROSIS

The accelerated bone loss during perimenopause and postmenopause results from enhanced resorption mainly as a result of the loss in ovarian hormone production, specifically estrogen. Estrogen deficiency increases proliferation, differentiation, and activation of new osteoclasts and prolongs survival of mature osteoclasts.¹⁴ The number of remodeling sites increases and resorption pits are deeper and inadequately filled by normal osteoblastic function. Significant bone

density is lost and bone architecture is compromised. Trabecular bone is most susceptible leading to vertebral and wrist fractures.

MALE OSTEOPOROSIS

Men are at a lower risk for developing osteoporosis and osteoporotic fractures because of larger bone size, greater peak bone mass, and fewer falls.²¹ Men also do not undergo a period of accelerated bone resorption similar to menopause. However, men have a higher mortality rate after fractures.

The etiology of male osteoporosis tends to be multifactorial with secondary causes (see Table 93–2) and aging being the most common contributing factors. In young and middle-age men, a secondary cause for bone loss is usually identified, with hypogonadism being the most common. Idiopathic osteoporosis (no known cause) can occur and is probably a result of genetic factors that have yet to be determined.

AGE-RELATED OSTEOPOROSIS

Age-related osteoporosis occurs in seniors mainly as a result of hormone, calcium, and vitamin D deficiencies leading to an accelerated bone turnover rate in combination with reduced osteoblast bone formation. Hip fracture risk rises dramatically in seniors as a consequence of the cumulative loss of cortical and trabecular bone and an increased risk for falls.

SECONDARY CAUSES OF OSTEOPOROSIS

1 A secondary cause (see Table 93–2) is identified in more than half of premenopausal and perimenopausal women, about one-third of postmenopausal women, and more than two-thirds of men.²² The two most common secondary causes for osteoporosis are vitamin D deficiency and glucocorticoid therapy, which are discussed in Osteomalacia and Glucocorticoid-Induced Osteoporosis sections later. A potential drug-induced cause of bone loss in premenopausal women is depot medroxyprogesterone acetate (DMPA or Depo-Provera), a long-acting progestin-only contraceptive injection. This drug contains a “black box” warning based on data from several studies that demonstrated significant bone loss or impaired bone mass accrual.²³ Some women will recover some or all bone loss after discontinuation, especially if the agent has been used for a short time. Although more information is needed to fully understand the risks associated with depot medroxyprogesterone acetate, more than 2 years’ use warrants consideration of BMD testing using central dual-energy x-ray absorptiometry (DXA).

CLINICAL PRESENTATION

Table 93–3 outlines the clinical presentation of osteoporosis.

Osteoporosis is diagnosed by BMD measurement or presence of a low trauma fracture. Two-thirds of patients with a vertebral fracture are asymptomatic or attribute mild lower back pain to “old age.” The other third present with moderate to severe back pain that radiates down their leg after a new vertebral fracture. The pain usually subsides significantly after 2 to 4 weeks; however, residual chronic lower back pain may persist. Multiple vertebral fractures decrease height and sometimes curve the spine (kyphosis or lordosis) with or without significant back pain. Patients who have experienced a nonvertebral fracture frequently present with severe pain, swelling, and reduced function and mobility at the fracture site.

CONSEQUENCES OF OSTEOPOROSIS

A fragility or low-trauma fracture is defined as one that occurs as a result of a fall from standing height or less or with minimal to no

TABLE 93-3 Clinical Presentation of Osteoporosis

General
<ul style="list-style-type: none"> Many patients are unaware they have osteoporosis and only present after fracture Fractures can occur after bending, lifting, or falling, or independent of any activity
Symptoms
<ul style="list-style-type: none"> Pain Immobility Depression, fear, and low self-esteem from physical limitations and deformities Two-thirds of vertebral fractures are asymptomatic
Signs
<ul style="list-style-type: none"> Shortened stature (>1.5" loss), kyphosis, or lordosis Vertebral, hip, wrist, or forearm fracture Low bone density on radiography
Laboratory tests
<ul style="list-style-type: none"> Routine tests to detect a possible secondary cause: complete blood count, liver function tests, creatinine, urea nitrogen, calcium, phosphorous, alkaline phosphatase, albumin, thyroid-stimulating hormone, free testosterone, 25(OH) vitamin D, and 24-hour urine concentrations of calcium and phosphorous. Urine or serum biomarkers (e.g., NTX, osteocalcin) are sometimes used, especially to determine if high bone turnover exists. Additional testing might be necessary if the patient's history, physical examination, or the initial investigation suggests a specific secondary cause.
Other diagnostic tests
<ul style="list-style-type: none"> Spine and hip bone-density measurement using DXA Radiograph to confirm vertebral fracture

DXA, dual-energy x-ray absorptiometry; NTX, N-terminal crosslinking telopeptide of type 1 collagen.

trauma. The most common osteoporosis-related fractures are those of the vertebrae, proximal femur, and distal radius (wrist or Colles fracture).²⁴ Fractures of the face, skull, fingers, and toes are typically not considered osteoporosis-related. Osteoporotic fractures can lead to increased morbidity and mortality and decreased quality of life. Depression is common because of fear, pain, loss of self-esteem from physical deformity, and loss of independence and mobility.

Symptomatic vertebral fractures can cause significant pain, physical deformity, and adverse health consequences. Patients with severe kyphosis can experience respiratory problems as a result of compression of the thoracic region and gastrointestinal complications, such as poor nutrition, from intraabdominal compression. Women and men who suffer a symptomatic vertebral fracture have a lower 5-year survival rate compared to those without a fracture history.

Wrist fractures occur more commonly in younger postmenopausal women and are frequently a result of a fall on an outstretched hand. Negative outcomes include prolonged pain and weakness, and decreased advanced activities of daily living (such as cooking and shopping).

Hip fractures are associated with the greatest increase in morbidity and mortality. In 1999, hip fractures resulted in approximately 340,000 hospital admissions.²⁵ After a hip fracture, only 33% to 40% of patients regain their ability to perform basic activities of daily living, while 20% become nonambulatory. Three to 4% of patients die during the initial hospitalization for hip fracture, and 14% to 36% will die within 1 year either from complications of the hip fracture or other comorbid disease processes. Men have a twofold higher 1-year mortality rate after hip fracture than women.

Once a low-trauma fracture has occurred, the risk for subsequent fractures goes up exponentially. In subjects with one clinical vertebral fracture, the chance of experiencing any new fracture was 2.8-fold higher, and with two or more vertebral fractures it was 12-fold higher, than for subjects who did not have baseline fractures.²⁶

PATIENT ASSESSMENT

Bone pain, postural changes (i.e., kyphosis), and loss of height are simple useful physical examination findings. Height loss greater than

1.5 inches from the tallest mature height is considered significant and warrants further investigation. Height should be routinely measured using a wall-mounted stadiometer. A spine radiograph can confirm vertebral fractures. Low bone density or osteopenia reported on routine radiographs requires an evaluation for osteoporosis. In addition to physical examination and laboratory studies (see Table 93–3), patients can be assessed with risk factor assessment, osteoporosis questionnaires, peripheral and central DXA, and biomarkers.

RISK FACTOR ASSESSMENT

The aim of an initial fracture risk assessment (see Table 93–1) is to identify those patients who are at highest risk for low bone density and who would benefit from further evaluation. Many risk factors for osteoporosis have been identified and are similar for both sexes. The majority of risk factors are predictors of either low BMD (e.g., female gender, ethnicity) or an increased fall risk (e.g., cognitive impairment, previous falls). The most important risk factors are those associated with fracture risk independent of BMD and fall risk. These major risk factors, in combination with BMD, are used to determine which patient will benefit most from pharmacologic intervention. Current smoker, low body weight (<127 lb in postmenopausal women), history of osteoporotic fracture in a first-degree relative, and personal history of low-trauma fracture as an adult are all considered major risk factors by the National Osteoporosis Foundation.²⁷ Other identified independent risk factors include age, high bone turnover, low body mass index (<19 kg/m²), rheumatoid arthritis, and glucocorticoid use.

RISK ASSESSMENT TOOLS

Several clinical predication tools help clinicians determine who should undergo BMD testing. The Osteoporosis Risk Assessment Instrument (ORAI) decision tool for postmenopausal women is based on age range, weight range, and current estrogen therapy, with high sensitivity (93%) but low specificity (61%). The Simple Calculated Osteoporosis Risk Estimation (SCORE) decision tool, also for postmenopausal women, assesses race, rheumatoid arthritis, use of estrogen therapy (ever), number of osteoporotic fractures, age, and weight, with a sensitivity and specificity similar to that of the Osteoporosis Risk Assessment Instrument. Both the Osteoporosis Risk Assessment Instrument and Simple Calculated Osteoporosis Risk Estimation performed well when compared to other prediction rules.^{28,29} Other tools are the Osteoporosis Self-Assessment Tool, Osteoporosis Self-Assessment Tool for Asians, and the FRACTURE index.

A fracture prediction model is being developed by the World Health Organization (WHO) to determine which patients would benefit most from therapy, not to determine which patient should undergo BMD testing.²⁹ The WHO model uses the following risk factors: age, previous fracture, family history of hip fracture, body mass index, glucocorticoid use (ever), current smoking, alcohol use >2 units/day, and rheumatoid arthritis with or without BMD to predict an individual's percent absolute probability of fracturing in the next 10 years.

SCREENING USING PERIPHERAL BONE MINERAL DENSITY DEVICES

2 Peripheral bone density devices that utilize x-ray absorptiometry or quantitative ultrasonometry are helpful as screening tools to determine which patients require further evaluation with central DXA. They should not be used for diagnosis or monitoring response to therapy. Peripheral DXA of the forearm, heel, and finger uses a low amount of radiation. Heel quantitative ultrasonometry uses sound waves without radiation or need for specialty training.

Because peripheral devices are considerably less expensive than central DXA, easy to use, portable, fast (<5 minutes), and can predict general fracture risk, they are very popular for screening patients at health fairs, community pharmacies, and clinics.³⁰ No guidelines specifically address who should undergo peripheral bone density screening.³¹ However, the best population to screen is younger postmenopausal women without major risk factors for osteoporosis. A low peripheral BMD value for postmenopausal women would warrant further testing. The specific T-score threshold for referral is not universally defined and varies by device.³¹ Healthy premenopausal women and patients already identified as being at high risk for osteoporosis based on risk factors, fragility fracture, or secondary causes for osteoporosis, should not be screened but rather referred to a physician for central DXA testing.

CLINICAL CONTROVERSY

The use of peripheral BMD screenings for older men and perimenopausal women with risk factors for osteoporosis is controversial. Data supporting fracture risk predication with these devices are either lacking or not as robust in older men and perimenopausal women. The T-score thresholds for referral in these populations are unknown. In addition, many peripheral devices do not have a male reference database. More data are needed on the predictive value of peripheral screening devices in these populations before routine use.

CENTRAL DUAL-ENERGY X-RAY ABSORPTIOMETRY

2 BMD measurements at the hip or spine can be used to assess fracture risk, establish the diagnosis and severity of osteoporosis, and sometimes confirm osteoporosis as causative for low-trauma fractures. Central DXA is considered the gold standard for measuring BMD because of its high precision, short scan times, low radiation dose (comparable to the average daily dose from natural background), and stable calibration. Measurement of both lumbar spine and proximal femur or total hip BMD are recommended with the lowest BMD value used for diagnosis. Newer methods, such as micromagnetic resonance imaging, are undergoing investigation to provide measurements of bone quality in addition to bone density.

1 2 Several consensus guidelines or position statements are available that discuss which women should undergo central DXA.^{5,27,32,33} Most are consistent in recommending central BMD testing for all senior women aged 65 years or older, postmenopausal women younger than 65 years of age with risk factors for fracture, women with a low-trauma fracture, and women with an identified secondary cause for bone loss. The United States Preventive Services Task Force recommends screening all senior women and women 60 to 64 years of age who are at increased risk for osteoporotic fractures.³⁴ The International Society for Clinical Densitometry recommends central BMD testing using a male database in all men older than age 70 years, men with a history of a low-trauma fracture as an adult, and men with an identified secondary cause for bone loss.³⁵ Ethnic-specific reference databases are not recommended at this time. In the absence of a suspected or known secondary cause for osteoporosis or a history of a low trauma fracture, central BMD testing is not recommended for premenopausal or perimenopausal women.

A central DXA BMD report provides the actual bone density value, T-score, and Z-score. The actual bone density value (g/cm²) is most useful for serial monitoring of drug therapy response. The T-score is a comparison of the patient's measured BMD to the mean BMD of a healthy, young (20- to 29-year-old), sex-matched white reference population. The T-score is the number of standard devia-

tions from the mean of the reference population. The Z-score compares the patient's BMD to the mean BMD for a healthy, sex, and age-matched white population and is usually low when secondary causes of osteoporosis are present.

LABORATORY TESTS

Laboratory testing (see Table 93–3) is used to identify secondary causes of bone loss. If a preliminary investigation indicates a possible secondary cause, additional testing might be needed.

③ Serum 25(OH) D is the best indicator of total body vitamin D status.¹⁵ Data suggest that serum 25(OH) D concentrations of at least 30 ng/mL are necessary to maximize intestinal calcium absorption, minimize secondary hyperparathyroidism, and reduce fracture risk.^{15,36} Osteomalacia can occur at concentrations less than 8 to 10 ng/mL.¹⁸ Although no consensus exists, a reasonable definition for vitamin D deficiency can be considered a 25(OH) D concentration of ≤ 10 ng/mL, insufficiency as a concentration between 11 and 29 ng/mL, and sufficiency as ≥ 30 ng/mL (1 ng/mL = 2.5 nmol/L).

Vitamin D insufficiency and deficiency are common in all age groups, especially in seniors and individuals who are malnourished, living in an institution (e.g., nursing home), or living in extreme northern latitudes.^{15,18,36} Low vitamin D concentrations result from insufficient intake, decreased sun exposure, decreased skin production, or decreased liver and renal metabolism. Endogenous synthesis of vitamin D can be decreased by factors that impact exposure to or decrease skin penetration of ultraviolet B light. Sunscreen use, full body coverage with clothing (e.g., women wearing veiled dress), and darkly pigmented skin can all cause a decrease in vitamin D production. Seasonal variations in vitamin D concentrations are also seen with nadirs in late winter and peaks in late summer.

Because vitamin D assays are expensive and large interlab assay variability exists, routine vitamin D screening cannot be recommended.¹⁵ A 25(OH) D concentration should be considered in anyone at high risk for vitamin D deficiency (e.g., seniors with minimal sun exposure, insufficient intake, dark pigmented skin), low bone density, history of a low-trauma fracture or frequent falls, on medications known to affect vitamin metabolism, or with a history of unexplained muscle and/or bone pain.¹⁵

BONE TURNOVER MARKERS

Urine and serum bone turnover markers are either enzymes or proteins produced during bone formation or breakdown. Bone-specific alkaline phosphatase, osteocalcin and procollagen type 1 propeptides are examples of bone formation markers. Hydroxypyridinium crosslinks of collagen pyridinoline and deoxypyridinoline, C-terminal crosslinking telopeptide of type 1 collagen and N-terminal crosslinking telopeptide of type 1 collagen are examples of bone resorption markers. Increased concentrations of bone resorption markers (≥ 2 standard deviations above the premenopausal range) have been shown in some studies to predict fracture risk; however, results have been inconsistent.¹⁹ Although not diagnostic, these tests may be helpful in identifying accelerated bone turnover and increased fracture risk or in monitoring response to therapy.

DIAGNOSIS OF OSTEOPOROSIS

The diagnosis of osteoporosis is based on a low-trauma fracture or central hip and/or spine DXA using WHO T-score thresholds. Osteopenia or low bone mass is a T-score of -1 to -2.4 and osteoporosis is a T-score at or below -2.5 . Although these definitions are based on data from postmenopausal white women, they are applied to other racial/ethnic groups and senior men. The International Society for Clinical Densitometry recommends the

presence of risk factors in addition to a low T-score before the diagnosis of osteoporosis can be made in men ages 50 to 65 years.

PREVENTION AND TREATMENT

Osteoporosis

Osteoporosis prevention and treatment begins with a bone-healthy lifestyle and uses nonprescription and prescription medications as needed.

■ DESIRED OUTCOMES

The primary goal of osteoporosis management should be prevention. Optimizing skeletal development and peak bone mass accrual in childhood, adolescence, and early adulthood will ultimately reduce the future incidence of osteoporosis. Once osteopenia or osteoporosis develops, the objective is to stabilize or improve bone mass and strength and prevent fractures. In patients who have already suffered osteoporotic fractures, reducing future falls and fractures, improving functional capacity, reducing pain and deformity, and improving quality of life are the main goals.

■ GENERAL APPROACH TO PREVENTION AND TREATMENT

A bone-healthy lifestyle should begin at birth and continue throughout life. Insuring adequate intakes of calcium and vitamin D along with other bone healthy lifestyle practices are the first steps in prevention and treatment. Prescription medication use for osteopenia (T-score -1 to -2.4) remains controversial. The National Osteoporosis Foundation recommends considering prescription therapy in any postmenopausal woman with a T-score less than -2.0 or less than -1.5 if they have one or more major osteoporosis risk factors.²⁷ Prescription medications, with bisphosphonates being the drug of choice, are recommended for men and women with osteoporosis (T-score of -2.5 or lower or presence of low-trauma fracture). Figure 93–3 provides an osteoporosis management algorithm that incorporates both nonpharmacologic and pharmacologic approaches.

■ NONPHARMACOLOGIC THERAPY

Nonpharmacologic therapy, referred to as bone-healthy lifestyle changes, includes diet, smoking cessation, exercise, fall prevention, and hip protectors.

Diet

④ Overall, a diet well balanced in nutrients and minerals is important for bone health. In addition, limiting intakes of caffeine, alcohol, sodium, cola, and other carbonated beverages.

Although results are conflicting, excessive caffeine consumption is associated with increased calcium excretion, increased rates of bone loss, and a modest increased risk for fracture.³⁷ Ideally, caffeine consumption should be limited to two servings or less per day. Moderate caffeine intake (two to four servings per day) should not be a concern if adequate calcium intake is achieved daily. For excessive caffeine use, intake should be decreased. Alcohol consumption in moderation is not associated with an increased risk for osteoporosis or fractures. Excessive alcohol intake can increase risk because of poor nutrition, impaired calcium and vitamin D metabolism, and an increased risk for falls. According to 2005 dietary guidelines, alcohol consumption should not exceed one drink per day for women and two drinks per day for men.³⁸

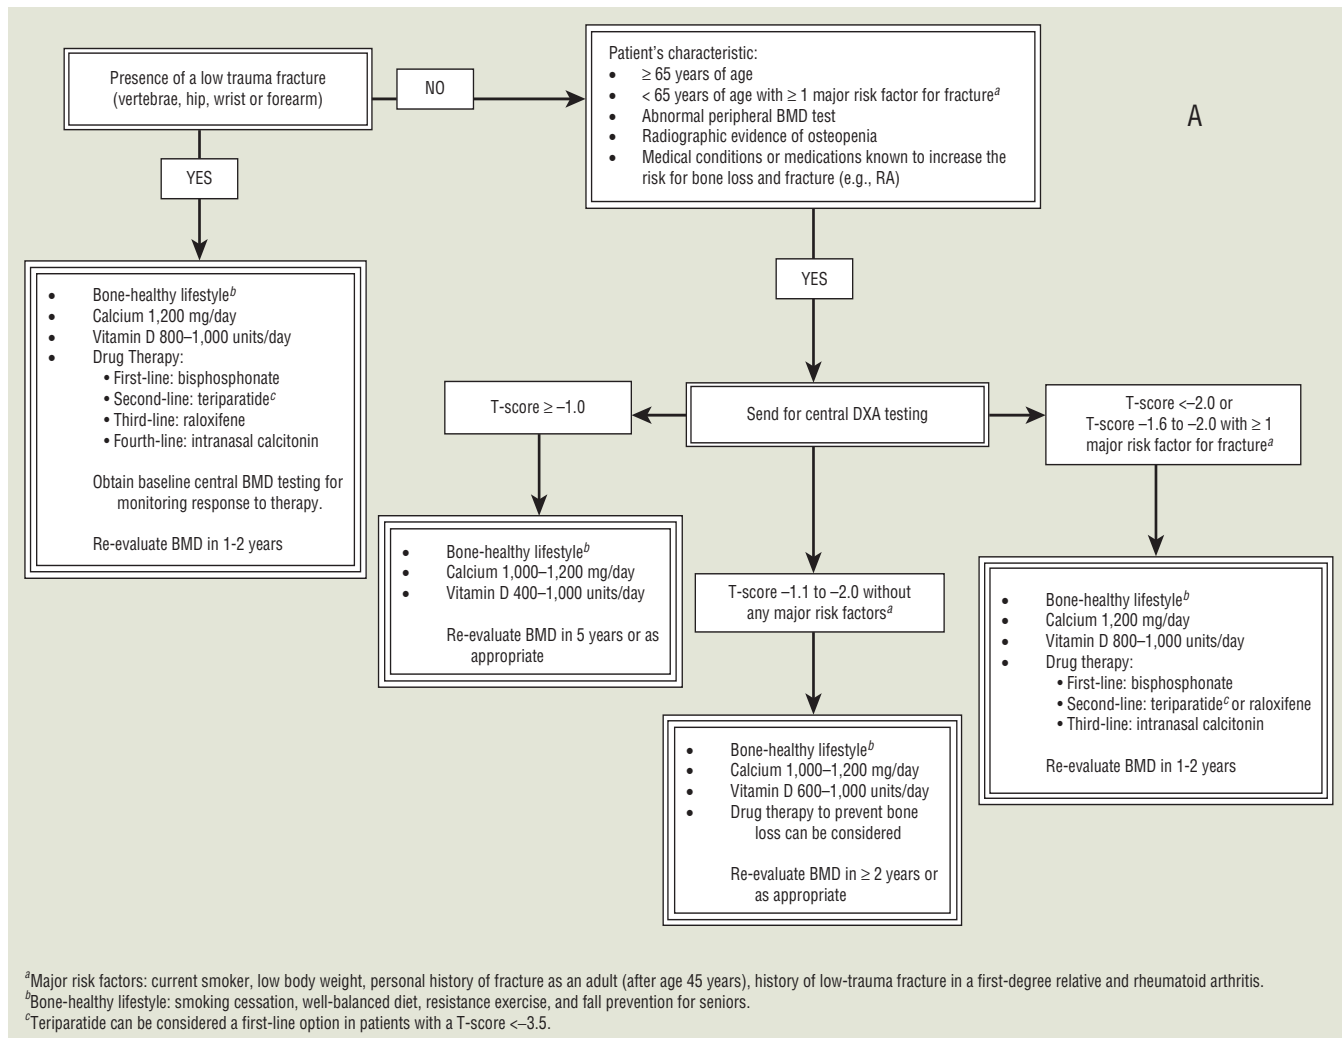

FIGURE 93-3. Algorithm for the management of osteoporosis in postmenopausal women (A) and men (B). (BMD, bone mineral density; DXA, dual-energy x-ray absorptiometry, RA, rheumatoid arthritis.)

Sodium intake increases calcium excretion.³⁹ In patients with low intakes of calcium, excessive sodium intake can lead to increased bone resorption and lower BMD. To minimize calcium loss secondary to increased sodium intake, an individual can consume higher amounts of daily calcium and potassium and decrease sodium intake to <2.4 g/day.

Consumption of cola beverages with or without caffeine is associated with decreased BMD and increased fracture risk; however, data are conflicting.⁴⁰ Caffeine and phosphoric acid content of cola beverages might cause bone loss by altering calcium balance. This effect is compounded by decreased milk consumption with a consequent reduction in calcium intake and simultaneous increased carbonated beverage intake in the United States.⁴¹

Calcium 4 5 Data clearly indicate that adequate calcium intake is necessary for the development of bone mass during growth and for its maintenance throughout life. Adequate calcium intake is an essential component of all osteoporosis prevention and treatment strategies.

Table 93-4 summarizes the recommended adequate intakes for calcium based on age. Achieving daily calcium requirements from calcium-containing foods, which also contain other essential nutrients, is preferred (Table 93-5). Some food sources are absorbed well but have low elemental calcium content (e.g., broccoli), or contain oxalic acid (e.g., spinach) or phytic acid (e.g., wheat bran) that bind calcium within the food and decrease its absorption.⁴² Approximately 25% of the U.S. population has some level of lactose intolerance, with

the incidence in Asian (80%) and African American (50%) populations being much higher than in whites (10%).⁴² For lactose-intolerant patients, lactose-reduced milk, lactose-free milk, yogurt with active cultures or Lactaid, along with other nondairy calcium-fortified products (e.g., orange juice, breakfast cereals, and energy bars) can be recommended.

Vitamin D 4 5 Table 93-4 lists the Institute of Medicine's adequate intakes for Vitamin D.⁴³ The National Osteoporosis Foundation guidelines recommend 800 to 1,000 units vitamin D daily for adults age 50 years and older.²⁷ Several experts believe at least 800 to 2,000 units of vitamin D daily are needed, especially in seniors.¹⁸ The three main sources of vitamin D are sunlight, diet, and supplements. Because few foods are naturally high or fortified with vitamin D (Table 93-6), most people, especially seniors, require supplementation.

Other Nutrients and Minerals Vitamin K is a cofactor for carboxylation (activation) of proteins, such as osteocalcin, which are involved in bone formation.^{18,39,44} Several studies have demonstrated that vitamin K deficiency can contribute to bone loss and an increased risk for fractures.⁴⁴ Data suggest that the current recommended adequate intakes for vitamin K might be too low for optimal bone health.⁴⁴ More data are needed before recommending routine supplementation.

Minimal to no data exist for other nutrients and minerals such as boron and magnesium.⁴⁵ Until more data are available, taking a

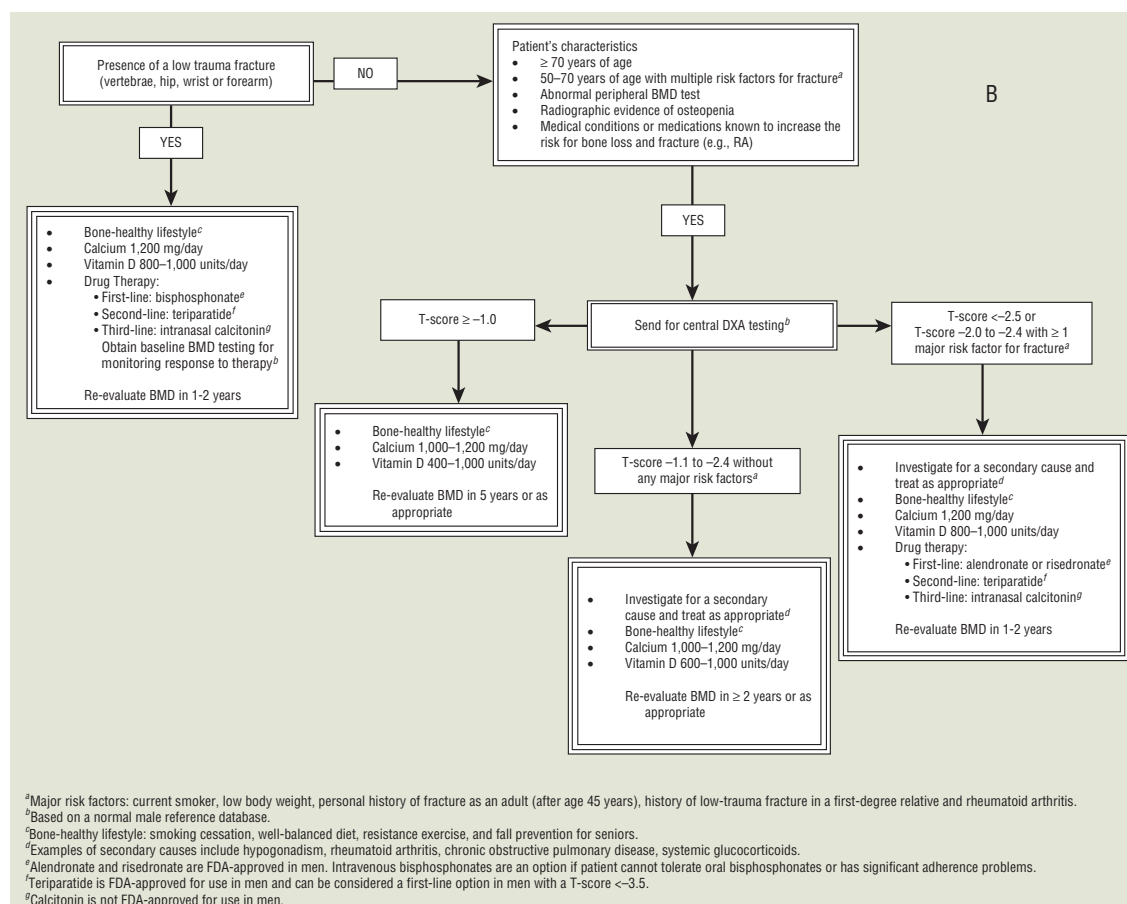

FIGURE 93-3. (Continued)

multivitamin once daily and consuming a healthy diet, following the United States Department of Agriculture food pyramid recommendations for daily fruit and vegetable intake, should provide an adequate intake of these vitamin and minerals for general bone health.

Protein Dietary protein represents a key nutrient for bone health.⁴⁶ High protein intakes (especially animal protein) were thought to be detrimental to bone health by increasing urinary calcium excretion. However, evidence suggests that low protein intakes increase osteoporosis risk and that higher protein intakes are protective against bone

loss and fractures. The increased calciuria seen with higher intakes of protein is more likely an indicator of an increased absorption of dietary calcium rather than increased bone resorption as proposed.

Dietary Soy Isoflavone phytoestrogens are plant-derived compounds that possess weak estrogenic agonist and antagonist effects. The most common source for isoflavone is dietary soy products. Genistein is the most abundant and biologically active isoflavone in soybeans. The evidence supporting a positive bone benefit from soy protein (isoflavone) intake is conflicting, with some positive data with larger isoflavone intakes (76 mg daily).⁴⁷ In the Chinese diet, higher soy protein intake was significantly associated with a lower risk of fractures, especially within 10 years of menopause and in women taking at least 21 mg isoflavone per day.⁴⁸ Since isoflavones are safe, patients can be encouraged to increase their intake, but true benefits on fracture are not clear.

Smoking Cessation

4 Counseling patients of all ages on smoking cessation can help to optimize peak bone mass, minimize bone loss, and ultimately reduce fracture risk. Cigarette smoking is an independent risk factor for osteoporosis and is associated with up to an 80% increased relative risk for hip fracture.⁴⁹ The effect is dose and duration dependent. A decrease in sex hormone concentrations, reduced intestinal calcium absorption, a direct toxic effect on osteoblasts, and detrimental effects of smoking on neurovascular function have been implicated for the negative bone effects.

Exercise

4 Physical activity or exercise is an important nonpharmacologic approach to preventing osteoporotic fractures. Exercise can decrease

TABLE 93-4 Calcium and Vitamin D Recommendations

Group and Ages	Institute of Medicine Adequate Intake	
	Elemental Calcium (mg) ^a	Vitamin D (units) ^{a,b}
Infants		
Birth to 6 months	210	200
6–12 months	270	200
Children		
1–3 years	500	200
4–8 years	800	200

^aU.S. Institute of Medicine of the National Academy of Sciences recommends no more than 2500 mg/day elemental calcium and 2000 units/day vitamin D.

^bMost experts believe the recommended Adequate Intakes for Vitamin D are too low.

TABLE 93-5 Elemental Calcium Content of Selected Foods and Beverages

Foods/Beverages	Elemental Calcium Content (mg) ^a
Milk (skim, low-fat, whole), 1 cup	276–309
Calcium-fortified soy milk, 1 cup	80–300
Calcium-fortified orange juice, 1 cup	300
Calcium-fortified cranberry juice, 1 cup	100
7UP Plus, 1 cup	100
Low-fat fruit yogurt, 1 cup	345
Frozen yogurt, 1 cup	180–240
Vanilla ice cream, 1 cup	176–200
Soft-serve vanilla ice cream, 1 cup	236
Swiss cheese, 1.5 oz.	336
Cheddar, mozzarella, or provolone cheese, 1.5 oz.	307–311
Ricotta cheese, ½ cup	255–335
Cottage cheese, 4 oz.	78–100
Fortified breakfast cereals	236–1,043
Fortified instant oatmeal	99–110
Figs, dried, 10	270
Collard greens, cooked, ½ cup	178
Broccoli, cooked, 1 cup	100–180
Soybeans, cooked, ½ cup	88–130
Okra, cooked, ½ cup	88
Bok choy, raw, 1 cup	160–250
Tofu, firm, ½ cup	253
Almonds, 1 oz.	75
Salmon, canned with bones, 3 oz.	170–210

^aFood labels are based on a RDA of 1,000 mg/day; multiply percentage on package by 10 (e.g., product containing 30% calcium = 300 mg).

Data from www.health.gov/dietaryguidelines/dga2005/document/html/appendixB.htm.

the risk of falls and fractures by improving muscle strength, coordination, balance, and mobility. Physical activity is especially important early in life as lack of exercise during growth can lead to suboptimal loading/straining, decreased stimulation of bone deposition, and a subsequently reduced peak bone mass. All patients who are medically fit should be encouraged to perform a moderate-intensity weight-bearing activity (e.g., walking, jogging, golf, stair climbing) for at least 30 minutes most days of the week and a resistance activity (e.g., weight machines, free weights, or elastic bands) at least twice per week for 20 to 30 minutes.^{3,27,38}

Fall Prevention

4 Because of the link between falls and fractures, homes should be made safe and potentially harmful medications eliminated.^{3,5} Table 93–7 provides solutions for commonly observed personal and home safety problems.⁵⁰ Medication profiles should be reviewed for any medications that can affect cognition and balance and potentially

TABLE 93-7 Personal and Home Fall Prevention Strategies

Lighting

Place switches/lamps at room entrances and at the bottom and top of stairs
Put in brighter light bulbs
Use nightlights, 100- to 200-watt bulbs
Keep a flashlight with fresh batteries by the bed for night use

Floors

Keep home environment neat and tidy; always keep objects off the floor
Remove low-lying or difficult-to-see objects
Remove throw rugs or use rugs with a nonslip backing
Remove all loose electrical and telephone wires

Bathrooms

Install elevated toilet seats
Install grab bars in bathtubs or showers
Apply nonskid strips, rubber mats, or decals to shower or bathtub floor
Place nonskid mats on bathroom floor
Install a seat in the bathtub or shower

Stairways (inside and outside the home)

Install cylindrical handrails on both sides of the stairs
Do not leave objects lying on the stairs
Fix any uneven or broken steps
Apply nonskid treads to steps

Furniture

Replace low furniture with higher or thicker furniture
Provide chairs with armrest support

Storage

Keep frequently used items at waist level
Use “reach” device to obtain objects

Personal safety

Watch out for small pets or children in home or outdoors
Use handrails when going up or down stairs
Wear shoes that grip well (nonskid rubber soles)
Always look where you are going (be cautious of uneven surfaces or icy spots)
Clean up spills immediately so you do not slip
Rise slowly from a seated position
Visit ophthalmologist annually (ensure adequate vision correction)
Exercise regularly to improve strength, balance, and coordination

Modified from reference 50. Also available in Spanish and Chinese.

increase fall risk and that are unneeded or can be replaced with a safer alternative. Maintenance of a regular exercise program, such as Tai Chi, should be recommended to improve body strength, balance, and agility.

Hip Protectors

External hip protectors are specialized undergarments designed to pad the area surrounding the hip decreasing the force of impact from a sideways fall. Conflicting results and poor adherence limit their use.^{5,51}

■ PHARMACOLOGIC THERAPY

Because nonpharmacologic interventions alone frequently are insufficient to prevent or treat osteoporosis, drug therapy is often necessary. Table 93–8 describes fracture and BMD effects and Table 93–9 describes important aspects of common osteoporosis medications. These medications should always be combined with a bone-healthy lifestyle.

Drug Treatments of First Choice

Currently, bisphosphonates are the prescription drug of choice with teriparatide, raloxifene, and calcitonin considered alternative agents. Duration of bisphosphonate therapy has not been defined, but safety data exist for periods of 7–10 years.⁵² Short-term (18 to 24 months) teriparatide is used for severe osteoporosis and then followed by bisphosphonate therapy. The algorithm (see Fig. 93–3) helps determine for whom drug therapy should be used. Osteoporosis prescrip-

tion medications in children and pre- and perimenopausal women are controversial and undergoing further investigation.

Published Guidelines and Treatment Protocols

Osteoporosis diagnosis and treatment guidelines exist but none are universally accepted. Two North American guidelines are evidence based: the 2003 update of the American Association of Clinical Endocrinologists evidence-based guidelines for prevention and treatment of postmenopausal osteoporosis and the 2002 Canadian osteoporosis guidelines for women, men, and special populations.^{33,53} The 2006 North American Menopause Society's position statement used both evidence and consensus to develop recommendations on the management of postmenopausal osteoporosis.⁵ In 2003, the National Osteoporosis Foundation updated its consensus guidelines for postmenopausal women.²⁷ The National Institutes of Health held an osteoporosis consensus conference in 2001 and published the findings, recommendations, and research needs.² Guidelines are being updated to reflect newer diagnostics (e.g., WHO fracture risk assessment), agents (e.g., teriparatide), and monitoring (e.g., biomarkers, osteonecrosis of the jaw). Subspecialty guidelines continue to be developed (e.g., osteoporosis and gastrointestinal [GI] diseases, rheumatology and glucocorticoid-induced osteoporosis). Based on these guidelines and newer information, an algorithm reflecting current suggested practice is presented (see Fig. 93–3). Even with guidelines and algorithms, many

patients are neither being evaluated nor receiving appropriate osteoporosis therapy.⁵⁴

Antiresorptive

Antiresorptive therapies include calcium, vitamin D, bisphosphonates, estrogen agonists/antagonists (known previously as selective estrogen receptor modulators or SERMs), and calcitonin.

Calcium Supplementation ⁵ Calcium imbalance can result from inadequate dietary intake, decreased fractional calcium absorption, or enhanced calcium excretion. Adequate calcium intake (see Table 93–4) is considered the minimal standard for osteoporosis prevention and treatment and should be combined with vitamin D and osteoporosis medications when needed. Supplemental calcium intake (Table 93–10) will be needed in the majority of people with or at risk for osteoporosis as survey data indicate that the average U.S. diet contains only 600 mg calcium per day.⁴²

Efficacy. Although calcium increases BMD, fracture prevention is minimal. More than 150 studies have evaluated calcium's effect on BMD with almost all trials and observational studies showing that higher calcium intake in children and adults produced greater increases or maintenance of BMD compared to BMD losses with placebo.¹⁷ Calcium's BMD effects are less than other antiresorptive and formation osteoporosis medications. If fracture prevention was documented, concomitant vitamin D therapy was usually given. Nonbone benefits of calcium intake include decreased

TABLE 93-9 Medications Used to Prevent and Treat Osteoporosis

Drug	Adult Dosage	Pharmacokinetics	Adverse Effects	Drug Interactions
Calcium	Adequate intake (Table 93–4) in divided doses	Absorption—predominantly active transport with some passive diffusion, fractional absorption 10%–60%, fecal elimination for the unabsorbed and renal elimination for the absorbed calcium	Constipation, gas, upset stomach, rare kidney stones	Carbonate salts—decreased absorption with proton pump inhibitors Decrease absorption of iron, tetracycline, quinolones, bisphosphonates, phenytoin, and fluoride when given concomitantly Might antagonize verapamil Might induce hypercalcemia with thiazide diuretics Fiber laxatives (variable), oxalates, phytates, and sulfates can decrease calcium absorption if given concomitantly (continued)

TABLE 93-9 Medications Used to Prevent and Treat Osteoporosis (continued)

Drug	Adult Dosage	Pharmacokinetics	Adverse Effects	Drug Interactions
D ₃ (cholecalciferol)	Adequate intake (Table 93-4); if malabsorption or multiple anticonvulsants might require higher doses (~ ≥4,000 or more units daily)	Hepatic metabolism to 25(OH) vitamin D and then renal metabolism to active compound 1,25(OH) ₂ vitamin D, other active and inactive metabolites	Hypercalcemia, (weakness, headache, somnolence, nausea, cardiac rhythm disturbance), hypercalciuria	Phenytoin, barbiturates, carbamazepine, rifampin increase vitamin D metabolism
D ₂ (ergocalciferol)	For vitamin D deficiency, 50,000 units once weekly or once monthly; dosed dependent on serum calcium			Cholestyramine, colestipol, orlistat, or mineral oil decrease vitamin D absorption
1,25(OH) ₂ vitamin D (calcitriol, Rocaltrol PO, Calcijex IV)	0.25–0.5 mcg orally or 1–2 mcg/mL intravenously daily for renal osteodystrophy, hypoparathyroidism, and refractory rickets			Might induce hypercalcemia with thiazide diuretics in hypoparathyroid patients
Oral bisphosphonates		Poorly absorbed—<1% decreasing to zero with food or beverage intake—long T _{1/2} (<10 years); renal elimination (of absorbed) and fecal elimination (unabsorbed)	Nausea; heartburn; GI pain, irritation, perforation, ulceration, and/or bleeding; transient flu-like illness; muscle pains; black box warning for rare osteonecrosis of the jaw	Do not coadminister with any other medication or supplements (including calcium and vitamin D)
Alendronate (Fosamax, Fosamax plus D)	5 mg daily, 35 mg weekly (prevention) 10 mg daily, 70 mg tablet, 70 mg tablet with vitamin D 2,800 or 5,600 units, or 75 mL liquid weekly (treatment)			
Risedronate (Actonel)	5 mg daily, 35 mg weekly, 75 mg on two consecutive days once monthly 150 mg monthly, 3 mg intravenous quarterly			
Intravenous bisphosphonates			Muscle pains, transient flu-like illness, redness or swelling at injection site, black-box warning for rare osteonecrosis of the jaw	
Ibandronate (Boniva)	5 mg intravenous infusion yearly			
Zoledronic acid ^a (Reclast)				
Mixed estrogen agonist/antagonist		Hepatic metabolism	Hot flushes, leg cramps, venous thromboembolism, peripheral edema, rare cataracts and gallbladder disease; black box warning for fatal stroke	None
Raloxifene (Evista)	60 mg daily		Rhinitis, epistaxis	None
Calcitonin (Miacalcin)	200 units intranasal daily, alternating nares every other day	Renal elimination 3% nasal availability		None
Teriparatide (1–34 units, Forteo)	20 mcg subcutaneously daily for up to 2 years	95% bioavailability T _{max} ~30 minutes T _{1/2} ~60 minutes Hepatic metabolism	Pain at injection site, nausea, dizziness, leg cramps, rare increase in uric acid, slightly increased calcium	None
Testosterone products		10% gel absorption (5 mg absorbed from 50 mg testosterone in 5 g of gel)	Weight gain, acne, hirsutism, dyslipidemia, hepatic consequences, gynecomastia, priapism, prostate disorders, testicular atrophy, sleep apnea, and skin reactions with patches	
Transdermal patch (Testoderm TTS, Androderm, Testim)	5 mg patch applied to arm, back, or thigh every evening (patches 2.5, 4, 5, & 6 mg) ^a			
Testoderm (R) with or without adhesive)	6 mg applied to scrotal skin every evening			
Gel (AndroGel 1%, Testim 1%)	5 gm gel applied to shoulder, upper arm, or abdomen every morning			
Buccal system (Striant 30 mg)	Place one system in gum area twice a day. Alternate sides of mouth. Do not crush or swallow			
Injection				
Cypionate (100 or 200 mg/mL) or enanthate (200 mg/mL) salt	200–300 mg IM every 2–3 weeks			
Methyltestosterone (for women)	1.25–2.5 mg with esterified estrogen			

GI, gastrointestinal; IM, intramuscular; T_{max}, time to maximum concentration; T_{1/2}, half life.^aNo abdomen patch placement for Testim; none of these patches can be applied to the genitals.

blood pressure, cholesterol, and colorectal cancer risk, the last being controversial.¹⁷

Adverse Events/Precautions. Calcium's most common adverse reaction, constipation, can first be treated with increased water intake, dietary fiber, and exercise. If still unresolved, smaller and more frequent administration or lower total daily dose can be tried. Calcium carbonate can create gas and cause stomach upset, which might resolve with calcium citrate, a product with fewer GI side effects.

Calcium rarely causes kidney stones. Some patients with a history of kidney stones can still ingest adequate amounts of calcium depending on the type of stones and/or will require increased fluid intake and decreased salt intake with their calcium supplementation.

Administration. Most children and adults of all ethnic backgrounds do not ingest sufficient (see Table 93–4) dietary calcium (see Table 93–5) and require supplements (see Table 93–10).^{17,55} To insure adequate calcium absorption, 25(OH) D concentrations should be maintained in the normal range. Because fractional calcium absorption is dose-limited, maximum single doses of 600 mg or less of elemental calcium are recommended. Calcium carbonate is the salt of choice as it contains the highest amount of elemental calcium and is the least expensive (see Table 93–10). Calcium carbonate tablets should be taken with meals to enhance absorption. Calcium citrate absorption is acid-independent and need not be administered with meals. Although tricalcium phosphate contains 39% calcium, calcium-phosphate complexes could limit overall calcium absorption compared to other products. This product might be helpful in the 10% of seniors with hypophos-

phatemia that cannot be resolved with increased dietary intake. Disintegration and dissolution rates vary significantly between products and lots. Products labeled “USP Verified” for United States Pharmacopeia, which guarantees the identity, strength, purity, and quality of the product, should be recommended. Oyster shell (other than the OsCal brand) or coral calcium should not be recommended because of concerns for high concentrations of lead and other heavy metals. “Bone designer” nonprescription products continue to be developed by combining calcium and vitamin D with other nutrients, some of which are associated with bone physiology (e.g., magnesium, manganese, boron, vitamin K).⁴⁵ Minimal BMD and no fracture data exist for these combination products. Because product labeling is confusing, patients might not realize they need 4 to 6 tablets per day to obtain adequate calcium intakes. These products are also more expensive. Combining too many vitamins and supplements might lead to upper-tolerable nutrient limits being exceeded and a concern for toxicities.

Vitamin D Supplementation **5** Vitamin D intake is critical for the prevention and treatment of osteoporosis because it maximizes intestinal calcium absorption. Given the safety, low cost, and other benefits of vitamin D, no patient should have an inadequate intake.

Efficacy. Two meta-analyses evaluated the efficacy of cholecalciferol with or without calcium supplementation on fracture risk and falls in seniors. Higher doses of vitamin D (700 to 800 units/day) demonstrated a significant 26% relative risk reduction in hip fractures, a 23% relative risk reduction in any nonvertebral fracture, and a 22% relative risk reduction in falls.^{36,56} While several studies have demonstrated a beneficial effect of vitamin D on fractures and falls, not all studies have demonstrated a beneficial effect.⁵⁶ Conflicting results between studies are thought to be a result of differences in vitamin D dosing, concomitant calcium administration, adherence, and baseline vitamin D status of subjects.

Vitamin D has other potential nonskeletal benefits. Improvement in muscle strength and cardiovascular function, decreased cancer risk (e.g., breast, colon, and prostate cancers), and positive immunomodulatory effects (e.g., multiple sclerosis, type 1 diabetes, rheumatoid arthritis) have been proposed.^{15,36}

Administration. Seniors and patients being treated for osteoporosis should take at minimum 800 units of vitamin D through food and supplementation with a goal to maintain their 25(OH) D concentration within the sufficient range.^{18,36} Cholecalciferol (vitamin D₃) is more efficient than ergocalciferol (vitamin D₂) at raising 25(OH) D concentrations and is the preferred form of vitamin D supplementation. Usual supplementation is with daily nonprescription vitamin D products (see Table 93–10). However, higher-dose prescription oral or intramuscular regimens administered weekly, monthly, or quarterly have been studied in seniors residing in the community or nursing home environments.⁵⁶ In patients with measured insufficient 25(OH) D concentrations, higher daily intakes of vitamin D may be needed. More than one multivitamin or large doses of cod liver oil daily are no longer advocated because of the risk of hypervitaminosis A, which increases bone loss. Because the half-life of vitamin D is about 1 month, approximately 3 months of therapy are required before a new steady state is achieved and a repeat 25(OH) D concentration can be obtained.¹⁶

Individuals with deficient concentrations of vitamin D are at risk for osteomalacia. Their management is discussed in Other Metabolic Bone Diseases below. In patients with disorders affecting vitamin D absorption (e.g., celiac disease, cystic fibrosis, or Crohn's disease), higher doses and more frequent monitoring. In patients with severe hepatic or renal disease, the activated form of vitamin D (calcitriol) might be more appropriate.

TABLE 93-10 Calcium and Vitamin D Product Selection

Product (% calcium) ^a	Elemental Calcium (mg)	Vitamin D (units)
Calcium carbonate ^b (40%)		
Trade and generic products	200–600	100–200
Mylanta Supreme liquid (5 mL)	160

Posture-D	600	125
Vitamin D ₃ (cholecalciferol)	0	400, 700, 800, or 1,000
Multivitamin (D ₃) ^c	40–250	400
Ergocalciferol (D ₂) ^e		
Liquid (1 mL)		8,000
Tablets/capsules		25,000 or 50,000
Intramuscular (1 mL)		500,000

^aMany products are adding magnesium, boron, zinc, copper, vitamin K, and/or manganese; sometimes adding “Plus” or “Ultra” to their name. These “bone designer” products are not listed here, see reference 45.

^bThere are many trade-name products for calcium carbonate (e.g., Calci-D, Caltrate, and Os-Cal). Only calcium carbonate alternative dosage forms (i.e., chewable, liquid, powder) are specifically listed.

^cContains vitamin K.

^dContains aspirin 81 mg.

^ePrescription products.

CLINICAL CONTROVERSY

Some experts believe that the upper tolerable limit for vitamin D should be raised and that the recommended daily allowance for vitamin D should be 2,000 units per day. This is the amount of vitamin D that would be needed for approximately 90% of the population to maintain 25(OH) D concentrations at ≥ 30 ng/mL with a low risk for toxicity.^{18,36}

Bisphosphonates ⑦ Bisphosphonates mimic pyrophosphate, an endogenous bone resorption inhibitor. Bisphosphonate antiresorptive activity results from blocking prenylation and inhibiting guanosine triphosphatase-signaling proteins, which lead to decreased osteoclast maturation, number, recruitment, bone adhesion, and life span. Their various R2 side chains produce different bone binding, persistence, and affinities; however, the resulting clinical significances are not clearly known.⁵⁷ All bisphosphonates become incorporated into bone, giving them long biologic half-lives of up to 10 years. Alendronate, risedronate, and oral ibandronate are currently FDA indicated for the prevention and treatment of postmenopausal osteoporosis (see Table 93–9). Intravenous ibandronate and zoledronic acid are indicated only for treatment of postmenopausal women. Risedronate and alendronate are also FDA indicated in male and glucocorticoid-induced osteoporosis. Clinical trials with ibandronate and zoledronic acid are ongoing for these indications.

Efficacy. Of the antiresorptive agents, bisphosphonates consistently provide the greatest fracture risk reductions and BMD increases (see Table 93–8). Fracture data trials used daily oral bisphosphonate or annual intravenous therapy, not weekly, monthly, or quarterly regimens.^{5,58,59} Although hip fracture reduction was not seen with daily oral ibandronate, the hip fracture incidence in the placebo group was low. Furthermore, not all studies for alendronate and risedronate have documented hip fracture prevention. Fracture reductions are demonstrated as early as 6 months,⁶⁰ with the greatest fracture reduction seen in patients with lower initial BMD and in those with the greatest BMD changes with therapy. (Note added in proof: Secondary fracture prevention has been documented after a hip fracture with annual intravenous zoledronic acid [Lyles KW, Colón-Emeric CS, Magaziner JS, et al. Zoledronic acid and clinical fractures and mortality after hip fracture. *N Engl J Med* 2007;357(18):1799-1809.]

BMD increases with bisphosphonates are dose dependent and greatest in the first 6 to 12 months of therapy. Small increases continue over time at the lumbar spine, but plateau after 2 to 5 years at the hip. After discontinuation, the increased BMD is sustained for a prolonged period of time that varies depending on the bisphosphonate used. Weekly alendronate and risedronate therapy produce equivalent BMD changes to their respective daily regimens. Weekly alendronate therapy increases BMD more than weekly risedronate therapy; however, there is no evidence that this difference would equate to greater fracture efficacy.⁶⁰ Monthly oral and quarterly intravenous ibandronate therapies produce greater BMD changes than daily therapy.⁶¹

The BMD increases with alendronate and risedronate in men are similar to postmenopausal women.⁶² Because of a lack of fracture data in men, bisphosphonates are only FDA indicated to increase BMD, not to reduce fracture risk in men.

CLINICAL CONTROVERSY

Women without evidence of a low-trauma fracture and who have responded well to alendronate therapy, with BMD increasing into the osteopenic range, are being considered for a “drug

holiday.” Patients are taken off their alendronate therapy and followed serially with bone turnover markers and central DXA BMD. Studies demonstrate prolonged suppression of bone turnover and maintenance of BMD in some women after discontinuation.⁶³ The impact of this practice on fracture risk and application to other bisphosphonates is unknown.

Adverse Events/Precautions. Bisphosphonate GI adverse effects are minimal if the medication is taken correctly. Weekly and monthly therapies have similar common but less-serious GI effects (perforation, ulceration, GI bleeding) than daily therapy. The GI event rates were not increased with concomitant nonsteroidal anti-inflammatory drug use. Patients should be encouraged to discuss GI complaints with a healthcare provider. Intravenous ibandronate and zoledronic acid can be used for patients with contraindications or intolerances to oral bisphosphonates.

The most common adverse effects of intravenous bisphosphonates include fever, flu-like symptoms, and local injection-site reactions.^{59,60}

Osteonecrosis of the jaw has been increasingly reported as a rare side effect of bisphosphonate therapy.⁶⁴ Most cases occur in patients who are receiving high-dose intravenous bisphosphonate therapy for multiple myeloma and metastatic carcinoma of the skeleton and after tooth extraction, mouth trauma, or oral surgery. Additional risk factors include advanced age and concomitant estrogen or glucocorticoid therapy. The incidence of osteonecrosis of the jaw in women taking alendronate has been estimated at 0.7 cases per 100,000 person-years of exposure.⁶⁵ Although the mechanism is incompletely understood, oversuppression of bone turnover is thought to play a primary role. Controversy exists about preventing and treating this condition. Routine dental care and good oral hygiene should be encouraged in anyone beginning bisphosphonate therapy. In addition, major dental work probably should be completed prior to beginning bisphosphonates if possible. There is no evidence that discontinuing bisphosphonate therapy prior to major dental work is beneficial. If osteonecrosis of the jaw develops, oral chlorhexidine washes, systemic antibiotics, and systemic analgesics are used based on severity.

Administration. Because bioavailability is very poor for bisphosphonates (<1% to 5%) and to minimize GI side effects, each oral dose should be taken with at least 6 ounces of plain tap water (not coffee, juice, mineral water, or milk) at least 30 (60 for ibandronate) minutes before consuming any food, supplement (including calcium and vitamin D), or medication. The weekly, raspberry flavored, oral solution only needs to be taken with 2 ounces of water and can be used for patients with swallowing difficulties (e.g., after stroke, tube feeding). The patient should also remain upright (i.e., either sitting or standing) for at least 30 minutes after alendronate and risedronate and 1 hour after ibandronate administration.

Before intravenous bisphosphonates are used, the patient's serum calcium level must be normal. The quarterly ibandronate injection comes as a prefilled syringe (3 mg/mL) kit with a butterfly needle. The injection is given intravenously over 15 to 30 seconds. The injection can also be diluted with dextrose 5% in water or normal saline and used with a syringe pump. Once-yearly administration of zoledronic acid should be infused over at least 15 minutes. Acetaminophen or ibuprofen can be given to decrease adverse effects.

Although these medications are effective, adherence is poor. In one study, oral bisphosphonate adherence for 1 year was only 58% to 61% with only approximately 20% continuing therapy for at least 1 year.⁶⁶ Most patients prefer once-weekly or once-monthly bisphosphonate administration to daily therapy. If a patient misses a weekly dose, they can take it the next day. If more than 1 day has lapsed, that dose is skipped until the next scheduled ingestion. If a

patient misses a monthly dose, they can take it up to 7 days before the next administration. For patients with adherence issues, the monthly e-mails or postcards sent by the ibandronate manufacturer might be helpful. Intravenous ibandronate could be used as replacements. Alendronate plus vitamin D can potentially help to ensure better adherence with vitamin D intake.

Mixed Estrogen Agonists/Antagonists 7 Raloxifene, a second-generation mixed estrogen agonist/antagonist (EAA) approved for prevention and treatment of postmenopausal osteoporosis, is an estrogen agonist on bone but an antagonist on the breast and uterus (see Table 93–9). Newer second-generation EAAs will be approved soon. Bazedoxifene (Viviant) received an approvable letter for the prevention of osteoporosis and lasofoxifene (Oporia) is under review.

Efficacy. Raloxifene decreases vertebral fractures and increases spine and hip BMD, but to a lesser extent than bisphosphonates (see Table 93–8).^{58,60} Eight-year data support long-term effects and safety. After raloxifene discontinuation, the medication effect is lost, with bone loss returning to age- or disease-related rates. For women with severe osteoporosis, particularly when hip fracture risk reduction is desired, a bisphosphonate is likely a better choice.

Raloxifene decreased invasive estrogen receptor positive breast cancer similarly to tamoxifen in the STAR (Study of Tamoxifen and Raloxifene) trial; however, tamoxifen had fewer (not significantly different) noninvasive breast cancer cases in women at high risk for breast cancer.⁶⁷ Raloxifene has an FDA-approved indication for invasive breast cancer risk reduction. Thus in a subset of women, this additional benefit might warrant raloxifene use for dual osteoporosis and breast cancer prevention.

Raloxifene causes some positive lipid effects (decreased total and low-density lipoprotein cholesterol, neutral effect on high-density lipoprotein cholesterol, slightly increased triglycerides); however, no reduction in cardiovascular effects was demonstrated in the RUTH (Raloxifene Use for the Heart)⁶⁸ or MORE-CORE (Multiple Outcomes with Raloxifene study and its continuation) trials.⁶⁹

Adverse Events/Precautions. Hot flashes occur with a greater likelihood in women recently finishing menopause or discontinuing estrogen therapy. Raloxifene rarely causes endometrial bleeding. Raloxifene is contraindicated for women with an active or past history of venous thromboembolic event. Therapy should be stopped if a patient anticipates extended immobility.

In large trials, no change in overall death, cardiovascular death, or overall stroke incidence was seen; however, a slight increase in fatal stroke was documented.⁶⁸ Women at high risk for a stroke or coronary events and those with known coronary artery disease, peripheral vascular disease, atrial fibrillation, or a prior history of cerebrovascular events might not be good candidates for this medication.

Administration. Similar to bisphosphonates, adherence and persistence problems exist. At 1 year, adherence was 54% and persistence was only 6%.⁶⁶

Calcitonin Calcitonin is released from the thyroid gland when serum calcium is elevated. Salmon calcitonin is more potent and longer lasting than the mammalian form. Calcitonin is FDA indicated for osteoporosis treatment for women who are at least 5 years past menopause (see Table 93–9). Although limited data document some benefits in men and concomitantly with glucocorticoids, these indications are not approved. Because efficacy is less robust than the other antiresorptive therapies, calcitonin is reserved as third-line treatment. Intermittent nasal regimens and an oral product are being explored.

Efficacy. Only vertebral fractures have been documented to decrease with intranasal calcitonin therapy (see Table 93–8).^{5,60} Calcitonin does not consistently affect hip BMD and does not decrease hip fracture risk.

Calcitonin might provide pain relief to some patients with acute vertebral fractures, about a 2.5-point change on a visual analog scale.⁷⁰ If used, calcitonin should be prescribed for short-term (4 weeks) treatment and should not be used in place of other more effective and less expensive analgesics nor should it preclude the use of more appropriate osteoporosis therapy.

Administration. Subcutaneous administration with 100 units daily is available but rarely used because of adverse effects and costs.

Estrogen Therapy Although estrogens are FDA indicated for prevention of osteoporosis, they should only be used short-term in women who need estrogen therapy for the management of menopausal symptoms such as hot flashes. The risks of estrogen therapy outweigh the bone benefits.⁶⁰ Even though the Women's Health Initiative trials only assessed one dose of conjugated equine estrogens, most clinicians extrapolate the results to all postmenopausal estrogen therapies until data indicate otherwise.

Efficacy. Estrogen with (HT)⁷¹ or without (ET)⁷² progestin therapy significantly decreases fracture risk (see Table 93–8).⁵ Increases in BMD are less than bisphosphonates or teriparatide, but greater than raloxifene and calcitonin. Oral and transdermal estrogens at equivalent doses and continuous or cyclic HT regimens have similar BMD effects. Effect on BMD is dose dependent with some benefit seen with lower estrogen doses. Fracture risk reduction has not been demonstrated with lower dose therapy. When ET or HT is discontinued, bone loss accelerates and fracture protection is lost.

Adverse Events/Precautions/Administration. The lowest effective dose of ET and HT should still be used for preventing and controlling menopausal symptoms with use discontinued with symptom abatement. A complete discussion of adverse events, precautions, and administration for all estrogen and estrogen and progestin combination products can be found in Chap. 85.

Testosterone 8 Decreased testosterone concentrations are seen with certain gonadal diseases, eating disorders, glucocorticoid therapy, oophorectomy, menopause, and andropause. Testosterone replacement is not approved for the prevention or treatment of osteoporosis.

Efficacy. A few studies of testosterone replacement in women have demonstrated increases in BMD.⁷³ Testosterone, in various salt forms, was associated with increased BMD in some studies when given to hypogonadal men and senior men with normal or mild hormonal deficiency.^{74,75} The impact of testosterone replacement on fracture risk in women and men have not been prospectively evaluated. Testosterone replacement should not be used solely for the prevention or treatment of osteoporosis, but might be beneficial to reduce bone loss in patients needing therapy for hypogonadal symptoms.

Adverse Events/Precautions. Patients using these products should be evaluated within 1 to 2 months of initiation and then every 3 to 6 months thereafter.⁷⁶ Testosterone and methyltestosterone are in pregnancy category X, indicating that the agents are contraindicated.

Administration. Testosterone products are schedule III drugs. The gel products can rub off and be absorbed by the patient's partner.

Thiazide Diuretics Thiazide diuretics increase urinary calcium reabsorption. Observational studies suggest that patients who receive thiazide diuretics have a greater bone mass, lower rates of bone loss, and fewer fractures.⁷⁷ Two prospective, controlled trials demonstrated small increases in bone mass over placebo. Prescribing thiazide diuretics solely for osteoporosis is not recommended but is a reasonable choice for the patient with osteoporosis who

requires a diuretic and for patients on glucocorticoids with greater than 300 mg of calcium excreted in the urine over 24 hours.

Anabolic Therapies

Currently teriparatide is the only available medication that increases bone formation.

Teriparatide Teriparatide is a recombinant product representing the first 34 amino acids in human PTH (see Table 93–9). Teriparatide increases bone formation, the bone remodeling rate, and osteoblast number and activity. Both bone mass and architecture are improved. Teriparatide is FDA indicated for postmenopausal women and men who are at high risk for fracture. Patients who have a history of osteoporotic fracture, multiple risk factors for fracture, very low bone density (e.g., T-score < –3.5), or have failed or are intolerant of previous bisphosphonate therapy are candidates for PTH therapy. Human PTH (1–84), PTH analog (1–31), oral PTH, and intranasal, transdermal, and once-weekly subcutaneous teriparatide administration are being investigated.

Efficacy. Teriparatide reduces fracture risk in postmenopausal women (see Table 93–8); however, no fracture data are available in men. Lumbar spine BMD increases are higher than any other osteoporosis therapy.^{60,78} Although wrist BMD is decreased, wrist fractures are not increased. Discontinuation of teriparatide therapy results in a decrease in BMD, although some antifracture efficacy appears to be maintained.⁷⁸ Sequential therapy with PTH followed by an antiresorptive agent (e.g., bisphosphonates) should be considered to maintain BMD gains.⁶⁰

Adverse Events/Precautions. Transient hypercalcemia rarely occurs. A trough serum calcium concentration is recommended 1 month after initiation of therapy. If high (>10.6 mg/mL), calcium intake should be decreased to 1,000 mg daily. If the serum calcium is still high, lowering the dose by 25% or switching to every-other-day calcium therapy can be tried.⁷⁸

Because of an increased incidence of osteosarcoma in rats, teriparatide contains a black box warning against use in patients at increased baseline risk for osteosarcoma (e.g., Paget's bone disease, unexplained elevations of alkaline phosphatase, pediatric patients, young adults with open epiphyses, or patients with prior radiation therapy involving the skeleton). In addition, teriparatide should not be used in patients with hypercalcemia, metabolic bone diseases other than osteoporosis, metastatic or skeletal cancers, or premenopausal women of child-bearing potential. Therapy is not recommended beyond 2 years because of a lack of efficacy and safety data.

Administration. Teriparatide is commercially available as a pre-filled 3-mL “pen” delivery device that administers subcutaneous injections in the thigh or abdominal area. The administration of the initial dose should take place with the patient either sitting or lying down in case orthostatic hypotension occurs. The patient should be reeducated with each refill. The pen must be kept refrigerated and can be used immediately after removing from the refrigerator. The pen must be discarded 28 days after the initial injection. Teriparatide is the most expensive antiosteoporosis therapy.

Combination Therapy

Greater increases in BMD have been demonstrated in some small studies of combination antiresorptive therapy in postmenopausal women.⁶⁰ Greater fracture risk reduction has not been demonstrated. Combination antiresorptive and anabolic therapies have been evaluated with conflicting results.⁷⁸ Greater increases in BMD were demonstrated when a less-potent antiresorptive agent, raloxifene or HT, was used with PTH, whereas a blunting of the BMD effect was seen when combination therapy included alendronate.

The effects of other bisphosphonates in combination with PTH are unknown. Because of lack of a clear benefit and potential for increased cost, side effects, and nonadherence, combination therapy is not recommended at this time.

Investigational Therapies

Besides the above mentioned investigational products, new drug classes are also being developed.

Denosumab Denosumab is a promising new antiresorptive agent with a unique mechanism of action. It is a fully human monoclonal antibody (immunoglobulin G₂) that binds to RANKL, blocking its ability to bind to its receptor activator of nuclear factor kappa B on the surface of osteoclast precursor cells and mature osteoclasts. Thus denosumab inhibits osteoclastogenesis and increases osteoclast apoptosis.^{79–81} In a phase II study, greater increases in total hip and distal radius BMD were demonstrated in the intermittent (every 3 to 6 months) denosumab subcutaneous groups compared to once-weekly alendronate.⁷⁹ Adverse effects were similar between all groups. The 60-mg subcutaneous injection every 6 months is being evaluated in a phase III trial of postmenopausal women with osteoporosis.

Other Investigational Drug Classes Additional new classes of medications are beginning to show promise.¹³ Although injectable OPG, a competitive inhibitor of RANKL, blocked osteoclastic differentiation and decreased bone resorption biomarkers in phases I and II, further development has ceased. Agents to enhance endogenous OPG, decrease RANKL production, or block RANKL binding to receptor activator of nuclear factor kappa B are being developed. Agents to block osteoclast attachment ($\alpha V \beta_3$ integrin receptor antagonists—preclinical), inhibit bone matrix degradation (cathepsin K inhibitors—phase I; nitroslated nonsteroidal antiinflammatory drugs—phase II), or change osteoclast cell structure (Src inhibitors—preclinical) have been effective in animal studies, and for some, in early human studies. Strontium ranelate and tibolone (Canada as well) are approved in Europe but most likely will not be marketed in the United States.

■ VERTEBROPLASTY AND KYPHOPLASTY

Sometimes patients with debilitating pain between 6 and 52 weeks after a vertebral fracture might undergo vertebroplasty or kyphoplasty during which bone cement is injected into the fractured vertebral space.⁸² The procedure stabilizes the damaged vertebrae and reduces pain in 70% to 95% of patients. Cement leakage into the spinal column can result in complicating nerve damage. Long-term benefits are unknown, but some vertebral fracturing around the cement has been documented.

SPECIAL POPULATIONS

Osteoporosis is a threat to all age groups and in some subgroups because of genetic abnormalities, diseases, and medications.

CHILDREN

Although rare, osteoporosis in children and adolescents can lead to significant pain, deformity, and chronic disability. The main causes of osteoporosis in children are secondary, such as chronic medications, genetic defects (e.g., osteogenesis imperfecta, cystic fibrosis), chromosomal defects (e.g., Turner's or Klinefelter's syndromes), endocrine disorders (e.g., growth hormone deficiency), malabsorptive or nutritional disorders (e.g., celiac sprue), malignancies, other chronic diseases (e.g., juvenile rheumatoid arthritis), and conditions associated with disuse (e.g., paralysis, muscular dystrophy).⁸³ Idiopathic juvenile

osteoporosis is a condition that can develop in previously healthy children and is only diagnosed after the exclusion of all other possible causes of osteoporosis. It can spontaneously resolve after 3–5 years, but sequelae can persist into adulthood. Although the pathogenesis is unknown, reduced osteoblastic bone formation mainly in trabecular regions appears to play a primary role.

The diagnosis and treatment of osteoporosis in children and adolescents is challenging. No guidelines or consensus recommendations exist. The International Society for Clinical Densitometry suggests that the diagnosis of osteoporosis in children (<20 years of age) should not be made on bone density results alone.³⁵ Central spine and total body DXA using an ethnic-matched reference database is recommended with a Z-score below –2.0 indicating low bone density.⁸³

After correcting any underlying causes (e.g., hypogonadism therapy, gluten free diet) and instituting a bone-healthy lifestyle, most experts recommend pharmacologic treatment when the Z-score is less than –2.0, with or without the presence of a low-trauma fracture.^{83,84}

Small studies, mostly evaluating the intravenous bisphosphonate pamidronate (cancer hypercalcemia therapy), have been promising.⁸⁵ Research with oral bisphosphonates is ongoing. A major concern with bisphosphonates is their effect on longitudinal bone growth and modeling; however, fracture healing, skeletal growth/maturation, or the appearance of growth plates does not appear to be impaired.⁸⁴ Teriparatide should not be used because of an increased risk for osteosarcoma.

PREMENOPAUSAL WOMEN

Because of increased accessibility to peripheral and central BMD testing, more premenopausal women are being screened for osteoporosis. The relationship between low bone density and future fracture risk in healthy premenopausal women is not well established nor is the efficacy and safety of pharmacologic therapy.^{86,87} Most premenopausal women with documented low bone density have an identifiable secondary cause (see Table 93–2). Approximately 15% of healthy premenopausal women will have low BMD as a normal variation of peak bone mass.^{11,87} Low peak bone mass is a major risk factor for postmenopausal osteoporosis and fractures, but it has thus far not predicted an increased risk for fractures in the premenopausal years.⁸⁷ This might be a result of better bone architecture contributing to better bone strength in younger women.³⁵

Routine bone density testing is not cost effective and should not be performed in healthy premenopausal women.³⁴ No evidence supports that identifying low bone density in healthy premenopausal women results in a better bone-healthy lifestyle compared to education alone. Nor does any evidence exist to support that pharmacologic treatment will reduce fracture risk in this population. Oral bisphosphonates and teriparatide are in pregnancy category C (zoledronic acid is category D) and are not recommended in women with childbearing capability. Long-term effects of bisphosphonates (>10 years) are unknown.

THE “OLDER” SENIOR

Age is an independent risk factor for osteoporosis and osteoporotic fractures, with the prevalence increasing dramatically with age. Seniors are living longer. The average additional life span for an 85-year-old was 6.8 years in 2003 and it is estimated that the number of people in the United States age 85 years and older will increase from 5.1 million in 2004 to 7.3 million by 2020. The number of “older” seniors with osteoporosis is on the rise and many do not realize they have the disease. According to National Health and Nutritional Examination Surveys data, only 12.1% and 9.7% of women and 1.3% and 1.6% of men ages 75 to 84 years and 85 years and older, respectively, reported they had osteoporosis.³ However, when tested,

32.5% and 50.5% of women and 6.4% and 13.7% of men, respectively, had the disease. Central DXA should be performed and is cost-effective in this population.⁸⁸ The United States Preventive Services Task Force estimated that only 75 women between 75 and 79 years of age would need to be screened to prevent one vertebral fracture and 143 would need to be screened to prevent one hip fracture.³⁴

Older seniors should practice a bone-healthy lifestyle, ingest adequate calcium and vitamin D, and implement measures to prevent falls (see Table 93–7). When deciding whether or not to use prescription medications in “older” seniors, the following factors need to be taken into consideration: remaining life span, ability to take and afford medications, cognitive function, GI disorders, polypharmacy, desire for more medications, and regimen complexity. Although efficacy and safety data are limited in the older senior, evidence consistently shows that those at highest risk for fracture benefit most from pharmacologic therapy.^{89–91}

GLUCOCORTICOID-INDUCED OSTEOPOROSIS

9 Glucocorticoids are the most common secondary cause of osteoporosis and the third most common cause of osteoporosis overall.⁹² Approximately 30% to 50% of patients taking chronic oral glucocorticoids will experience a fracture. Bone losses are rapid, with the greatest decrease occurring in the first 6 to 12 months of therapy. Low to medium doses of inhaled glucocorticoids have no appreciable effect on bone density and fracture risk.^{93,94} The impact of long-term, high-dose inhaled glucocorticoids needs further evaluation.

The pathophysiology of glucocorticoid-induced osteoporosis (GIO) is multifactorial. Glucocorticoids decrease bone formation through decreased proliferation and differentiation, and enhanced apoptosis of osteoblasts.⁹² They can interfere with the bone’s natural repair mechanism through increased apoptosis of osteocytes, the bone’s communication cells. Glucocorticoids increase bone resorption by increasing RANKL and decreasing OPG. They can reduce estrogen and testosterone concentrations and create a negative calcium balance by decreasing calcium absorption and increasing urinary calcium excretion.^{92,95} The underlying disease processes might also contribute negatively to bone metabolism.

Guidelines on the management of GIO are available from the American College of Rheumatology.^{95,96} A baseline BMD using central DXA is recommended for all patients starting on 5 mg or more daily of prednisone equivalent for at least 6 months. BMD testing should also be considered at baseline in patients being started on shorter durations of systemic glucocorticoids if they are at high risk for low bone mass and fractures based on risk factors (e.g., age >65 years, postmenopausal, current smoker, and personal history of a low trauma fracture as an adult). Because of the rapid loss of bone that can occur with oral glucocorticoid therapy, central DXA can be repeated every 6 to 12 months if needed. Patients using high-dose inhaled corticosteroids should be evaluated for osteopenia or osteoporosis.

All patients starting or receiving long-term systemic glucocorticoid therapy should receive at least 1,500 mg elemental calcium and 800 to 1,200 units of vitamin D daily, and practice a bone-healthy lifestyle. Both alendronate and risedronate have documented efficacy and are FDA indicated for GIO.⁹⁶ The American College of Rheumatology guidelines recommend all patients newly starting on systemic glucocorticoids (≥5 mg/day of prednisone equivalent) for an anticipated duration of at least 3 months should receive preventative bisphosphonate therapy. A more conservative approach might be considered in premenopausal women of child-bearing potential. Patients starting or receiving long-term glucocorticoid therapy with documented low bone density (T-score below –1.0) or evidence of a low trauma fracture should also receive bisphospho-

nate treatment. Teriparatide is the only anabolic therapy commercially available that increases bone formation. Teriparatide can be used if bisphosphonates are not tolerated or contraindicated. Testosterone replacement therapy should be considered in men, and high-dose hormonal oral contraceptives can be considered for premenopausal women with documented hypogonadism.

TRANSPLANTATION OSTEOPOROSIS

10 Patients undergoing solid-organ transplantation (e.g., kidney, lung, cardiac, and liver) have a high risk for osteoporosis and osteoporotic fractures.⁹⁷ Prior to transplantation, many patients have osteoporosis or low BMD because of osteoporosis risk factors (see Table 93–1) and negative bone effects from their underlying diseases (e.g., alcoholism, cachexia, impaired liver or kidney function, hypogonadism, and deconditioning). After transplantation, bone loss and fracture risk increase dramatically within the first 6 to 12 months, mainly as a consequence of high-dose systemic glucocorticoid exposure and the use of calcineurin inhibitors (e.g., cyclosporine).⁹⁷ Sometimes bone loss slows or improves within 1 year of transplant.

Before transplantation, patients should be evaluated for metabolic bone disease with lab tests and physical examination for secondary causes (see Table 93–2), radiographs for vertebral fractures, and central DXA.⁹⁷ Regardless of BMD results, patients should be counseled on a bone-healthy lifestyle and instructed to take 1,500 mg of elemental calcium and 800 to 1,200 units of vitamin D daily. Calcitriol (1,25-dihydroxyvitamin D) at a dose of 0.25 to 0.5 mcg daily might be needed for renal and/or liver dysfunction. Pretransplant patients with osteoporosis or a low trauma fracture, except patients with end-stage renal disease awaiting kidney transplantation, should be started on bisphosphonate therapy indefinitely. In patients with normal BMD prior to transplant, short-term bisphosphonate therapy (6 to 12 months) can be used to prevent bone loss after transplant. Parathyroid hormone has not been studied in the transplant population and is contraindicated in transplant patients with secondary hyperparathyroidism. Testosterone replacement might be considered for men, and high-dose hormonal oral contraceptives are options for premenopausal women with hypogonadism. Central DXA can be repeated as early as 6 to 12 months to evaluate bone loss and the effects of treatment.

CHRONIC KIDNEY DISEASE

Chronic kidney disease is defined as kidney damage for at least 3 months with or without a decrease in glomerular filtration rate (GFR) or a GFR less than 60 mL/min/1.73 m² for at least 3 months with or without kidney damage.⁹⁸ Most seniors have a GFR of less than 30 to 60 mL/min/1.73 m² without any kidney damage.⁹⁹ Consequently, to make osteoporosis treatment decisions, the origin of chronic kidney disease, either intrinsic kidney damage or aging needs to be determined. Patients with a GFR or creatinine clearance greater than 30 mL/min can be managed routinely (see Fig. 93–3). Bisphosphonates are not recommended for patients with creatinine clearances less than 30 or 35 mL/min because of potential drug accumulation. Based on large retrospective or pooled studies, oral bisphosphonates in patients with severe kidney impairment (creatinine clearance as low as 15 mL/min)¹⁰⁰ and teriparatide in patients with moderate kidney impairment (creatinine clearance 30 to 49 mL/min)¹⁰¹ appear safe and efficacious in patients with age-related declines in renal function.

Renal osteodystrophy describes a constellation of metabolic bone disorders that develop in patients with stages 4 and 5 chronic kidney disease (GFR <30 mL/min/1.73 m²) and end-stage renal disease as a consequence of intrinsic kidney damage. Bone biopsy is essential to

differentiate the different types of renal osteodystrophy from osteoporosis in this population. Antiresorptive therapies would be appropriate for the management of osteoporosis; however, they are contraindicated in patients with osteomalacia or adynamic bone and ineffective for osteitis fibrosa cystica. In patients with stage 5 chronic kidney disease (creatinine clearance below 15 mL/min) and documented osteoporosis, 50% of the oral bisphosphonate dose is frequently recommended.

GASTROINTESTINAL DISEASES

10 The three most common gastrointestinal disorders associated with increased osteoporosis risk are inflammatory bowel disease, celiac disease, and postgastrectomy states.¹⁰² Impaired absorption of key nutrients and minerals, chronic systemic glucocorticoid use and increased levels of inflammatory cytokines also are implicated. The prevalence of osteoporosis in patients with inflammatory bowel disease, Crohn's disease or ulcerative colitis is approximately 15%.¹⁰³ When glucocorticoids are used, the GIO prevention and treatment guidelines should be followed.^{95,96} The role of proinflammatory cytokines needs further investigation.

Celiac disease is an inherited autoimmune disorder in which the ingestion of the protein gluten triggers an immune reaction that damages the mucosal lining of the small intestine and leads to impaired nutrient absorption.¹⁰⁴ The incidence of celiac disease in the United States is estimated at 1 in 133, and at 1 in 22 for primary degree relatives. Patients newly diagnosed with celiac disease have an estimated prevalence of osteoporosis of approximately 28% at the spine and 15% at the hip. Long-term fracture risk is estimated to be double that of the general population. Impaired nutrient absorption, especially calcium and vitamin D, plays a central role in the bone loss requiring 25(OH) D monitoring. Celiac disease management requires a gluten-free diet, which can significantly increase BMD by approximately 5% within 1 year.¹⁰²

Patients undergoing total or partial gastrectomy are at high risk for the development of osteoporosis. The incidence of osteoporosis may be as high as 32% to 42% with a 30-year cumulative risk for fracture of 72% in women and 48% in men.¹⁰² Although the pathophysiology of bone disease postgastrectomy is unknown, reduced nutritional intake of protein might play a role. Bone density evaluation using central DXA should be considered in all patients who are more than 10 years postgastrectomy.

PHARMACOECONOMIC CONSIDERATIONS

The estimated burden for fractures in 2005 was \$17 billion and is expected to increase to \$25 billion by 2025.⁷ Consequently, determining who should be screened and treated for osteoporosis and fracture prevention is important. Various studies use different assumptions in their models. One study used the following mean annual costs for fractures; \$19,200 to \$25,300 for hip fracture; \$5,300 to \$6,800 for nonvertebral, nonhip fracture; and \$2,700 to \$3,000 for vertebral fractures.¹⁰⁵ Preventing osteoporosis in postmenopausal women with normal or osteopenic BMD is not cost-effective.¹⁰⁶ However, screening older women and only using a bisphosphonate for those with osteoporosis is cost-effective.⁸⁸ The cost per quality-adjusted life-year decreased from \$40,100 for women 65 to 74 years old to a cost savings for women 85 years and older. In seniors, bisphosphonates were found to produce the greatest quality-adjusted life-years gain at the lowest cost (i.e., 0.637; \$4,200), followed by PTH (0.0574; \$6,833), calcitonin (0.0348; \$5,761), and raloxifene (0.0339; \$5,676).¹⁰⁵ In this model, bisphosphonates had the greatest hip and nonvertebral, nonhip fracture reduction. Calcitonin was assumed to have better vertebral fracture

prevention than raloxifene, and both were assumed to have no hip or nonvertebral, nonhip prevention.

EVALUATION OF THERAPEUTIC OUTCOMES

Besides monitoring for efficacy and safety, adherence evaluation should also be conducted.

MONITORING OF THE PHARMACEUTICAL CARE PLAN

Central DXA BMD measurements can be obtained every 1 to 2 years for monitoring bone loss and treatment response. In patients with conditions associated with higher rates of bone loss (e.g., glucocorticoid use, after transplantation), more frequent monitoring might be warranted.

To minimize test variability, BMD testing must be performed on the same DXA machine and ideally with the same operator (technician). Any change in absolute BMD that exceeds the precision error of the machine at that site (approximately 3% spine and 4% hip) is considered clinically significant, and if below precision error, is considered a no response. Because changes in BMD do not entirely explain changes in fracture risk, many experts believe that decisions on whether or not to continue a particular therapy should not be based solely on BMD response.

Biochemical markers of bone turnover have been evaluated for use in monitoring early responses to drug therapy, especially for identifying therapy nonresponders or possibly promoting adherence. Bone resorption markers, with the first or second morning void for urinary N-terminal crosslinking telopeptide of type 1 collagen or morning for serum C-terminal crosslinking telopeptide of type 1 collagen, are typically performed after an overnight fast at baseline and repeated after 3 to 6 months of therapy. These parameters will decrease with effective therapy. Circadian variability, seasonal variations, food intake, and recent exercise can all impact results. As no consensus on result interpretation and high test variability exists, these tests are not yet considered routine.

PHARMACY SERVICES

Pharmacists play an important role in screening and monitoring for osteoporosis. Community pharmacy ultrasonography screenings identify patients who are at risk and, with pharmacist or other professional consultation, increase use of calcium and vitamin D, and physician referrals for osteoporosis.¹⁰⁷ (Note added in proof: This practice is financially sustainable in the community pharmacy setting [Liu Y, Nevins JC, Carruthers KM, et al. Osteoporosis risk screening for women in a community pharmacy. *J Am Pharm Assoc* 2007;47:521-526]). Patients should be frequently assessed for correct bisphosphonate ingestion. Specialty clinic practices have increased prevention and treatment of steroid-induced osteoporosis.¹⁰⁸ Hospital-based programs help increase the number of patients who, after a hip fracture, receive testing and treatment.

OTHER METABOLIC BONE DISEASES

Because of increased interest in bone diseases and newer medications, better therapies are being explored and developed for other bone diseases.

OSTEOMALACIA

Osteomalacia, meaning “soft bones,” is a condition seen in adults in which the bone is significantly undermineralized. Rickets is the

childhood equivalent of osteomalacia. The most common cause of osteomalacia is severe, prolonged vitamin D deficiency. Disorders that cause hypocalcemia or hypophosphatemia and, rarely, long-term anticonvulsant therapy can also cause osteomalacia. Phenytoin, phenobarbital, and carbamazepine are most commonly associated with severe vitamin D deficiency through cytochrome P450 system induction that increases vitamin D conversion to inactive metabolites. Oral doses of vitamin D₃ from 1,000 to 4,000 units per day might be needed to prevent vitamin D deficiency in patients on these medications.¹⁰⁹

Patients with osteomalacia present with pathologic fractures and/or deep bone pain or no obvious symptoms but low BMD.²² Patients with osteomalacia will have an extremely low 25(OH) D concentration (<10 ng/mL) and might have an elevated bone-specific alkaline phosphate and hypocalcemia. The treatment of osteomalacia caused by vitamin D deficiency is high-dose vitamin D replacement therapy. Prescription oral ergocalciferol 50,000 units once to twice weekly for at least 8 weeks is a regimen that is frequently used to raise vitamin D concentrations into the sufficient range. High-dose oral and intramuscular regimens have also been used. Once 25(OH) D concentrations are greater than 30 ng/mL, chronic maintenance vitamin D therapy can be instituted. Oral ergocalciferol 50,000 units once or twice a month or nonprescription cholecalciferol at least 1,000 units up to 2,000 units once daily are reasonable maintenance options.

PAGET'S DISEASE

Unlike osteoporosis, which is a systemic disorder affecting the entire skeleton, Paget's disease is a disorder of bone remodeling in discrete sections of bone. The main areas affected are the skull, spine, pelvis, femur, and tibia.¹¹⁰ The osteoclasts are abnormally large and have heightened activity, increasing bone turnover rate and affecting both bone resorption and formation. The accelerated bone formation does not allow for proper layering of collagen leading to disorganized or woven collagen. The disease is usually asymptomatic; however, patients can experience bone pain, fractures, skeletal deformities, and, rarely, malignant transformation into osteosarcoma.

Paget's disease tends to occur in adults older than age 55 years with a slight predominance in men and patients of north European ancestry. The disease affects approximately 1% of adults age 40 years and older.¹¹⁰ Various environmental and genetic factors cause Paget's disease with viral causes a controversial pathogenesis. Paget's disease is typically discovered because of an unexplained elevation in serum alkaline phosphatase. A bone scan can be performed to determine the extent of skeletal involvement.

Bisphosphonates are the drug of choice for managing Paget's disease because they work directly on osteoclasts to slow down bone turnover, allowing more time for proper bone formation.¹¹¹ Four regimens are FDA-indicated: risedronate 30-mg tablet orally once daily for 2 months; pamidronate 30-mg intravenous infusion for 3 days; alendronate 40-mg tablet orally once daily for 6 months; or a one-time intravenous infusion of 5 mg zoledronic acid. Zoledronic acid and risedronate regimens were compared in a head-to-head study, with zoledronic acid demonstrating a superior and more rapid therapeutic response.¹¹² Therapy can be repeated if symptoms return or serum alkaline phosphatase increases by 25% or more. Subcutaneous or intramuscular salmon calcitonin can be used if bisphosphonates therapy is contraindicated.

OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta is a genetic disorder characterized by low trabecular and cortical bone density.⁸³ Bone formation and mineralization are disturbed leading to impaired bone strength and an

increased risk for fractures. Up to seven different clinical types of this disease have been described, ranging in severity from mild disease with no major bone deformities (type I) to lethal in the perinatal period (type II).¹¹³ Nonpharmacologic management, mostly physical therapy, is the mainstay of therapy for osteogenesis imperfecta. Orthopedic surgery is sometimes needed to help stabilize the brittle bones. Observational studies and case reports suggested intravenous pamidronate for moderate to severe osteogenesis imperfecta can increase BMD, reduce bone pain, and decrease fracture incidence.⁸⁴ Oral bisphosphonates and teriparatide are being evaluated in clinical trials.

CONCLUSIONS

Osteoporosis is currently a public health priority with the prevalence of both the disease and fracture incidence expected to increase in the next 10 to 20 years. Osteoporosis prevention begins at birth and continues throughout life by practicing a bone-healthy lifestyle (adequate calcium and vitamin intake, exercise, no smoking, and minimal alcohol use). Generally osteoporosis occurs in postmenopausal women and senior men; however, the disease can occur in all ages as a result of secondary causes such as genetics, diseases, and medications. Portable ultrasonography machines can screen for osteoporosis but central bone densitometry is used for diagnosis and monitoring. Bisphosphonates are the drug of choice because they decrease hip, nonvertebral, and vertebral fractures, are relatively safe, and are affordable. Teriparatide is the only medication that can build bone; however, cost and subcutaneous administration limit its use. New agents and drug classes to prevent and treat osteoporosis show promise. As osteoporosis management becomes more streamlined for postmenopausal women, practitioners are now focusing on identifying other special populations at risk for osteoporosis (e.g., men, transplantation patients, glucocorticoid therapy, cancer therapies).

Because vitamin D insufficiency and deficiency are very common, adequate intake of vitamin D is essential for everyone, generally requiring nonprescription vitamin D supplementation. Osteomalacia is a disease of decreased bone mineralization. Eliminating or treating any underlying causes of osteomalacia is the first step. In most cases, pharmacologic doses of vitamin D are required.

ABBREVIATIONS

25(OH) D: calcidiol/25-hydroxyvitamin D

BMD: bone mineral density

DXA: dual-energy x-ray absorptiometry

EAA: estrogen agonist/antagonist

ET: estrogen therapy

GFR: glomerular filtration rate

GI: gastrointestinal

GIO: glucocorticoid-induced osteoporosis

HT: hormone therapy (estrogen plus progestin)

OPG: osteoprotegerin

PTH: parathyroid hormone

RANKL: receptor activator of nuclear factor-kappa B ligand

SERM: selective estrogen receptor modulator

WHO: World Health Organization

ARTHUR A. SCHUNA

KEY CONCEPTS

- 1 Rheumatoid arthritis is a systemic disease characterized by symmetrical inflammation of joints yet may involve other organ systems.
- 2 Control of inflammation is the key to slowing or preventing disease progression as well as managing symptoms.
- 3 Drug therapy should be only part of a comprehensive program for patient management which would also include physical therapy, exercise, and rest. Assistive devices and orthopedic surgery may be necessary in some patients.
- 4 Disease-modifying antirheumatic drugs (DMARDs) or biologic agents should be started within 3 months of the diagnosis of rheumatoid arthritis.
- 5 Nonsteroidal antiinflammatory drugs and/or corticosteroids should be considered adjunctive therapy early in the course of treatment and as needed if symptoms are not adequately controlled with DMARDs.
- 6 When DMARDs used singly are ineffective or not adequately effective, combination therapy with two or more DMARDs or a DMARD plus biologic agents may be used to induce a response.
- 7 Patients require careful monitoring for toxicity and therapeutic benefit for the duration of treatment.

Rheumatoid arthritis is the most common systemic inflammatory disease characterized by symmetrical joint involvement. Extraarticular involvement, including rheumatoid nodules, vasculitis, eye inflammation, neurologic dysfunction, cardiopulmonary disease, lymphadenopathy, and splenomegaly, can be manifestations of the disease. Although the usual disease course is chronic, some patients will enter a remission spontaneously.

EPIDEMIOLOGY

Rheumatoid arthritis is estimated to have a prevalence of 1% to 2% and does not have any racial predilections. It can occur at any age, with increasing prevalence up to the seventh decade of life. The disease is three times more common in women. In people ages 15 to 45 years, women predominate by a ratio of 6:1; the sex ratio is

approximately equal among patients in the first decade of life and in those older than age 60 years.

Epidemiologic data suggest that a genetic predisposition and exposure to unknown environmental factors may be necessary for expression of the disease. The major histocompatibility complex molecules, located on T lymphocytes, appear to have an important role in most patients with rheumatoid arthritis. These molecules can be characterized using human lymphocyte antigen (HLA) typing. A majority of patients with rheumatoid arthritis have HLA-DR4, HLA-DR1, or both antigens in the major histocompatibility complex region. Patients with HLA-DR4 antigen are 3.5 times more likely to develop rheumatoid arthritis than those patients who have other HLA-DR antigens.¹ Although the major histocompatibility complex region is important, it is not the sole determinant, because patients can have the disease without these HLA types. Rheumatoid arthritis is six times more common among dizygotic twins and nontwin children of parents with rheumatoid factor-positive, erosive rheumatoid arthritis when compared with children whose parents do not have the disease. If one of a pair of monozygotic twins is affected, the other twin has a 30 times greater risk of developing the disease.^{2,3}

PATHOPHYSIOLOGY

1 Chronic inflammation of the synovial tissue lining the joint capsule results in the proliferation of this tissue. The inflamed, proliferating synovium characteristic of rheumatoid arthritis is called *pannus*. This pannus invades the cartilage and eventually the bone surface, producing erosions of bone and cartilage and leading to destruction of the joint. The factors that initiate the inflammatory process are unknown.

The immune system is a complex network of checks and balances designed to discriminate self from non-self (foreign) tissues. It helps rid the body of infectious agents, tumor cells, and products associated with the breakdown of cells. In rheumatoid arthritis, this system no longer can differentiate self from non-self tissues and attacks the synovial tissue and other connective tissues.

The immune system has both humoral and cell-mediated functions (Fig. 94–1). The humoral component is necessary for the formation of antibodies. These antibodies are produced by plasma cells, which are derived from B lymphocytes. Most patients with rheumatoid arthritis form antibodies called *rheumatoid factors*. Rheumatoid factors have not been identified as pathogenic, nor does the quantity of these circulating antibodies always correlate with disease activity. Seropositive patients tend to have a more aggressive course of their illness than do seronegative patients. Immunoglobulins can activate the complement system. The complement system amplifies the immune response by encouraging chemotaxis, phagocytosis, and the release of lymphokines by mononuclear cells, which are then presented to T lymphocytes. The processed antigen is recognized by major histocompatibility complex proteins on the

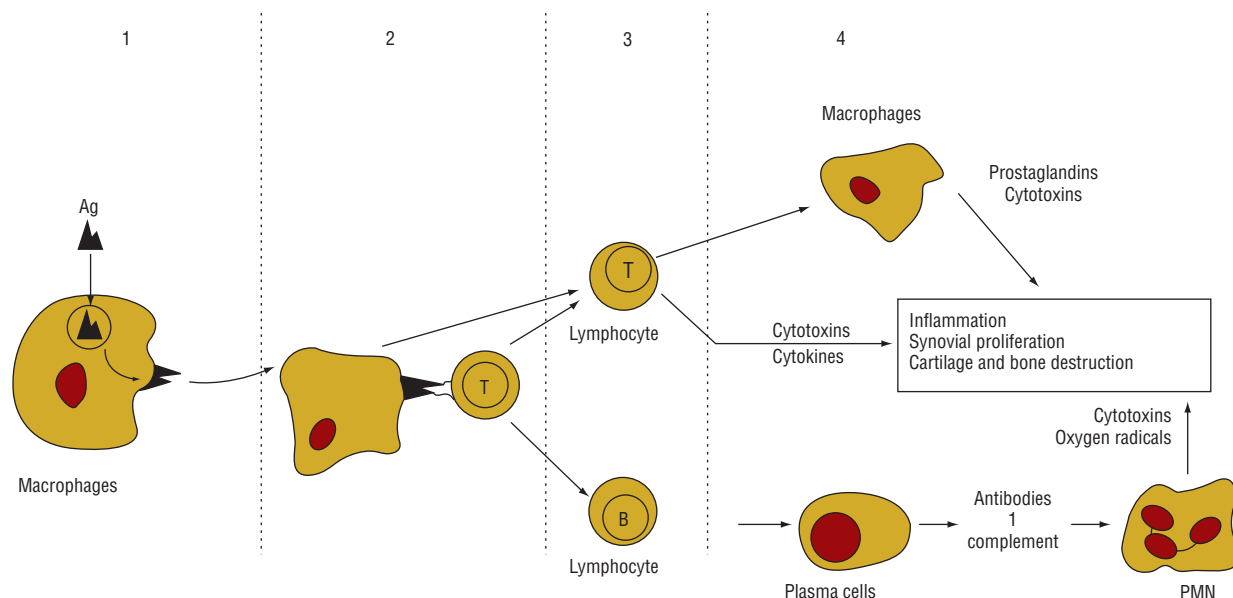

FIGURE 94-1. Pathogenesis of the inflammatory response. Phase 1: Antigen-presenting cell phagocytizes antigen. Phase 2: Antigen is presented to a T lymphocyte. The T lymphocyte attaches to antigen at the major histocompatibility complex portion of cell wall causing activation. Phase 3: An activated T cell stimulates T and B lymphocyte production, promoting inflammation. Phase 4: Activated T cells and macrophages release factors that promote tissue destruction, increase blood flow, and result in cellular invasion of synovial tissue and joint fluid. (Ag, antigen; PMN, polymorphonuclear leukocyte.)

lymphocyte, which activates it to stimulate the production of T and B cells. The proinflammatory cytokines tumor necrosis factor (TNF), interleukin (IL)-1 and IL-6 are key substances in the initiation and continuance of rheumatoid inflammation. Lymphocytes may be either B cells (derived from bone marrow) or T cells (derived from thymus tissue). T cells may be either CD4+ (T-helper) or CD8+ (cytotoxic or killer) T cells. There are two subtypes of T-helper cells, TH₁, which promote inflammation by producing interferon- γ , tumor necrosis factor, and interleukin-2, and TH₂, which produce the antiinflammatory cytokines IL-4, IL-5 and IL-10. CD8+ killer T cells have a regulatory effect on the immune process by suppressing activity of CD4+ cells through release of antiinflammatory cytokines and promoting apoptosis (cell death). Activated T cells produce cytotoxins, which are directly toxic to tissues, and cytokines, which stimulate further activation of inflammatory processes and attract cells to areas of inflammation. Macrophages are stimulated to release prostaglandins and cytotoxins.⁴

Although it has been suggested that T cells play a key role in the pathogenesis of rheumatoid arthritis, B cells clearly have an equally important role. Evidence for this importance may be found in the effectiveness of B-cell depletion using rituximab in controlling rheumatoid inflammation. Activated B cells produce plasma cells, which form antibodies. These antibodies in combination with complement result in the accumulation of polymorphonuclear leukocytes, which release cytotoxins, oxygen free radicals, and hydroxyl radicals that promote cellular damage to synovium and bone. B cells also produce cytokines that may alter the function of other immune cells, and they also have the ability to process antigens and act as antigen-presenting cells, which interact with T cells to activate the immune process.^{5,6}

In the synovial membrane, CD4+ T cells are abundant and communicate with macrophages, osteoclasts, fibroblasts and chondrocytes either through direct cell-cell interactions using cell surface receptors or through proinflammatory cytokines such as TNF- α , IL-1, and IL-6. These cells produce metalloproteinases and other cytotoxic substances, which lead to the erosion of bone and cartilage.^{1,7,8}

Vasoactive substances also play a role in the inflammatory process. Histamine, kinins, and prostaglandins are released at the site of

inflammation. These substances increase both blood flow to the site of inflammation and the permeability of blood vessels. These substances cause the edema, warmth, erythema, and pain associated with joint inflammation and make it easier for granulocytes to pass from blood vessels to the site of inflammation.

The end results of the chronic inflammatory changes are variable. Loss of cartilage may result in a loss of the joint space. The formation of chronic granulation or scar tissue can lead to loss of joint motion or bony fusion (called *ankylosis*). Laxity of tendon structures can result in a loss of support to the affected joint, leading to instability or subluxation. Tendon contractures also may occur, leading to chronic deformity.^{1,3,9,10}

CLINICAL PRESENTATION OF RHEUMATOID ARTHRITIS

Symptoms

- Joint pain and stiffness of more than 6 weeks' duration. May also experience fatigue, weakness, low-grade fever, loss of appetite. Muscle pain and afternoon fatigue may also be present. Joint deformity is generally seen late in the disease.

Signs

- Tenderness with warmth and swelling over affected joints usually involving hands and feet. Distribution of joint involvement is frequently symmetrical. Rheumatoid nodules may also be present.

Laboratory Tests

- Rheumatoid factor (RF) detectable in 60% to 70%.
- Anticyclic citrullinated peptide (anti-CCP) antibodies have similar sensitivity to RF (50% to 85%) but are more specific (90% to 95%) and are present earlier in the disease.
- Elevated erythrocyte sedimentation rate and C-reactive protein are markers for inflammation.
- Normocytic normochromic anemia is common as is thrombocytosis.

FIGURE 94-2. Patterns of joint involvement in rheumatoid arthritis and osteoarthritis.

Other Diagnostic Tests

- Joint fluid aspiration may show increased white blood cell counts without infection, crystals.
- Joint radiographs may show periarticular osteoporosis, joint space narrowing, or erosions.

The symptoms of rheumatoid arthritis usually develop insidiously over the course of several weeks to months. Prodromal symptoms include fatigue, weakness, low-grade fever, loss of appetite, and joint pain. Stiffness and muscle aches (myalgias) may precede the development of joint swelling (synovitis). Fatigue may be more of a problem in the afternoon. During disease flares, the onset of fatigue begins earlier in the day and subsides as disease activity lessens. Most commonly, joint involvement tends to be symmetrical; however, early in the disease some patients present with an asymmetrical pattern involving one or a few joints that eventually develops into the more classic presentation. Approximately 20% of patients develop an abrupt onset of their illness with fevers, polyarthritis, and constitutional symptoms (e.g., depression, anxiety, fatigue, anorexia, and weight loss).^{2,3}

No single test or physical finding can be used to make the diagnosis of rheumatoid arthritis. In early disease the diagnosis can be particularly challenging as radiographic findings are usually not found and rheumatoid factor test can be undetectable. Duration of joint pain and swelling and morning stiffness lasting more than 1 hour and involvement of three or more joints are important predictors of the development of persistent erosive rheumatoid arthritis.¹¹

JOINT INVOLVEMENT

The joints affected most frequently by rheumatoid arthritis are the small joints of the hands, wrists, and feet (Fig. 94-2). In addition, elbows, shoulders, hips, knees, and ankles may be involved. Patients usually experience joint stiffness that typically is worse in the morning. The duration of stiffness tends to be correlated directly with disease activity, usually exceeds 30 minutes, and may persist all day. Chronic inflammation with lack of an adequate exercise program results in loss of range of motion, atrophy of muscles, weakness, and deformity (Figs. 94-3 and 94-4).

On examination, the swelling of the joints may be visible or may be apparent only by palpation. The swelling feels soft and spongy because it is caused by proliferation of soft tissues or fluid accumulation within the joint capsule. The swollen joint may appear erythematous and feel warmer than nearby skin surfaces, especially early in the course of the disease. In contrast, the swelling associated with osteoarthritis usually is bony (caused by osteophytes) and infrequently is associated with signs of inflammation.

Involvement of the hands and wrists is common in rheumatoid arthritis. Hand involvement is manifested by pain, swelling, tenderness, and grip weakness during the acute phase and by subluxation, instability, deformity, and muscle atrophy in the chronic phase of the disease. Functional difficulties with clasp, grasp, and pinch alter both strength and fine motor movement.

Deformity of the hand may be seen with chronic inflammation. These changes may alter the mechanics of hand function reducing grip strength and making it difficult to perform usual daily activity.

Pain in the elbow and shoulder may be the result of true joint involving or inflammation of soft-tissue structures such as tendons

FIGURE 94-3. Deformities of rheumatoid arthritis, with marked ulnar deviation, swan-neck deformity, active synovitis, and nodules. (Reproduced with permission from Brunicaudi FC, Anderson DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE, Schwartz SI. *Schwartz's Principles of Surgery*. 8th ed, The McGraw-Hill Companies, 2005.)

FIGURE 94-4. A. Preoperative view of metacarpophalangeal joint in rheumatoid arthritis. B. Following resection arthroplasty. (Reproduced with permission from Skinner H, ed. *Current Diagnosis & Treatment in Orthopedics*, 4th ed. New York: McGraw-Hill, 2006:592.)

(tendonitis) or the bursa (bursitis). The knee also can be involved, with loss of cartilage, instability, and joint pain. Synovitis of the knee may cause the formation of a cyst behind the knee called a *popliteal* or *Baker cyst*. These cysts may become painful as they get tense, or they may rupture, producing a clinical picture similar to thrombophlebitis secondary to the release of inflammatory components into the area of the calf muscle. Chronic joint pain leads to muscle atrophy, which can result in a laxity of the ligamentous structures that support the knee, causing instability. Maintenance of an adequate range of motion of the knee is essential to normal gait.

Foot and ankle involvement in rheumatoid arthritis is common. The metatarsophalangeal joints are involved frequently in rheumatoid arthritis, making walking difficult. Subluxation of the metatarsal heads leads to “cock-up” or hammer toe deformities. Subluxation also may cause a flexion deformity at the proximal interphalangeal joint of the toe, leading to pressure necrosis of the skin over the joint secondary to irritation caused by shoes. Hallux valgus (lateral deviation of the digit) and bunion or callus formation may occur at the great toe. A widening of the foot occurs commonly with long-standing disease.

Involvement of the spine usually occurs in the cervical vertebrae; lumbar vertebral involvement is rare. Involvement of the first and second cervical vertebrae (C1–C2) can lead to instability of this joint. Patients with this problem are at a greater risk for spinal cord compression, although this complication is rare.

The temporomandibular joint (jaw) can be affected, resulting in malocclusion and difficulty in chewing food. Inflammation of cartilage in the chest can lead to chest wall pain. Hip pain may occur as a result of destructive changes in the hip joint, soft-tissue inflammation (e.g., bursitis), or referred pain from nerve entrapment at the lumbar vertebrae.

EXTRAARTICULAR INVOLVEMENT

Rheumatoid Nodules

Rheumatoid nodules occur in 20% of patients with rheumatoid arthritis. These nodules are seen most commonly on the extensor surfaces of the elbows, forearms, and hands but also may be seen on the feet and at other pressure points. They also may develop in the lung or pleural lining of the lung and, rarely, in the meninges. Rheumatoid nodules usually are asymptomatic and do not require any special intervention. Nodules are observed more commonly in patients with erosive disease.¹²

Vasculitis

Vasculitis usually is seen in patients with long-standing rheumatoid arthritis. Vasculitis may result in a wide variety of clinical presentations. Invasion of blood vessel walls by inflammatory cells results in an obliteration of the vessel, producing infarction of tissue distal to the area of involvement. Most commonly, small-vessel vasculitis produces infarcts near the ends of the fingers or toes, especially around the nail beds. These infarcts are usually of little consequence.

Vasculitis also may cause the breakdown of skin, especially in the lower extremities, producing ulcers that may be indistinguishable in appearance from stasis ulcers. However, these ulcers do not heal with the usual modes of treatment used for stasis ulcers. Involvement of larger vessels with vasculitis can result in life-threatening complications. Infarction of vessels supplying blood to nerves can cause irreversible motor deficits. Involvement of vessels supplying other organ systems can lead to visceral involvement and a polyarteritis nodosa-like illness. Aggressive treatment of the inflammatory

process is necessary in these patients. Fortunately, the more serious vasculitic picture is seen rarely.

Pulmonary Complications

Rheumatoid arthritis may involve the pleura of the lung, which is often asymptomatic, although pleural effusions may result. Pulmonary fibrosis also may develop as a result of rheumatoid involvement; smoking appears to increase the risk of this complication. Rheumatoid nodules may develop in lung tissue and appear similar to neoplasms on chest radiographs. Interstitial pneumonitis and arteritis are rare, potentially life-threatening complications of rheumatoid arthritis.

Ocular Manifestations

Ocular manifestations include keratoconjunctivitis sicca and inflammation of the sclera, episclera, and cornea. Atrophy of the lacrimal duct may result in a decrease in tear formation, causing dry and itchy eyes, termed *keratoconjunctivitis sicca*. When this is observed in association with rheumatoid arthritis, it is referred to as *Sjögren's syndrome*. Artificial tears may be used to relieve symptoms. The salivary glands may also be involved in Sjögren's syndrome. Inflammation of the superficial layers of the sclera (episcleritis) is generally self-limiting. Involvement of deeper tissues (scleritis) usually results in a more serious, painful, and chronic inflammation. Rheumatoid nodules may develop on the sclera.

Cardiac Involvement

The heart is sometimes affected by rheumatoid arthritis. Rheumatoid arthritis is associated with an increased risk of cardiovascular mortality. This risk appears to be higher in those with more active inflammation and is reduced with treatment, particularly with methotrexate.^{13,14} Pericarditis may occur, resulting in the accumulation of fluid. Although many patients show evidence of previous pericarditis at autopsy, the development of clinically evident pericarditis with tamponade is a rare complication. Cardiac conduction abnormalities and aortic valve incompetence, caused by aortic root dilation, may occur. Myocarditis is a rare complication of rheumatoid arthritis.

Felty's Syndrome

Rheumatoid arthritis in association with splenomegaly and neutropenia is known as *Felty's syndrome*. Thrombocytopenia also may be a manifestation of the syndrome. Patients with Felty's syndrome and severe leukopenia are more susceptible to infection. The decrease in granulocytes appears to be mediated by the immune system because splenectomy does not result in improvement of the patient.¹²

Other Complications

Lymphadenopathy may occur in patients with rheumatoid arthritis, particularly in nodes proximal to more actively involved joints. Renal involvement is rare but can be associated with treatment, including nonsteroidal antiinflammatory drugs (NSAIDs), gold salts, and penicillamine. Amyloidosis is a rare complication of longstanding rheumatoid arthritis. It appears to be more common in Europe than in the United States.

LABORATORY FINDINGS

Hematologic tests often reveal a mild to moderate anemia with normocytic, normochromic indices. The hematocrit may fall as low as 30%. The anemia is usually inversely related to inflammatory disease activity and is referred to as an *anemia of chronic disease*. This type of anemia does not respond to iron therapy and can

present a diagnostic dilemma because NSAIDs may induce gastritis and chronic blood loss, leading to iron-deficiency anemia. Laboratory tests useful in differentiating these anemias include stool guaiac (or other stool tests for occult blood), serum iron-to-iron-binding capacity ratio (decreased in iron deficiency), ferritin (decreased in iron deficiency), and mean corpuscular volume (more likely to be decreased in iron deficiency). Other causes of anemia also must be considered in the differential diagnosis (see Chap. 105).

Thrombocytosis is another common hematologic finding with active rheumatoid arthritis. Platelet counts rise and fall in direct correlation with disease activity in many patients. Thrombocytopenia may result from toxicity of gold salts, penicillamine, or immunosuppressive therapy. Thrombocytopenia also may be observed in Felty's syndrome or vasculitis.

Although leukopenia is associated with Felty's syndrome, it also may result from toxicity of methotrexate, gold, sulfasalazine, penicillamine, and immunosuppressive drugs. Leukocytosis is seen commonly as a result of corticosteroid treatment.

The erythrocyte sedimentation rate is usually elevated in patients with rheumatoid arthritis and other inflammatory diseases. This test is very nonspecific, and although the erythrocyte sedimentation rate usually falls as patients respond to therapy, there is a large variability among patients in response to treatment. C-reactive protein is another nonspecific marker for inflammatory arthritis when it is elevated. This protein is produced by the liver in response to certain cytokines.

Rheumatoid factor is present in 60% to 70% of patients with rheumatoid arthritis. The usual laboratory test for rheumatoid factor is an antibody specific for immunoglobulin (Ig) M rheumatoid factor. Patients with rheumatoid arthritis and a negative test for rheumatoid factor may have IgG or IgA rheumatoid factors, but tests for these are not routinely available. Rheumatoid factor tests may be reported positive at a specific serum dilution. Serum is diluted to a standard series of dilutions; the greatest dilution that yields a positive test result will be reported (e.g., rheumatoid factor positive at 1:640). Some laboratories quantify rheumatoid factor rather than using titers. Higher dilutional titers or serum concentrations of rheumatoid factors usually indicate a more severe disease, but like the erythrocyte sedimentation rate, the large interpatient variability makes this test unreliable as a means of assessing patient progress. Rheumatoid factor may be positive in patients without rheumatoid arthritis (Table 94-1).

Anticyclic citrullinated peptide antibody has similar sensitivity for rheumatoid arthritis, being found in 50% to 85% of patients with the disease, but is more specific (90% to 95%) and is detectable

TABLE 94-1 Diseases Associated with a Positive Rheumatoid Factor

Chronic active hepatitis
Sarcoidosis

very early in the disease. Many rheumatologists will do both tests in evaluating new patients.

Antinuclear antibodies are detected in 25% of patients with rheumatoid arthritis. These antibodies usually have a diffuse pattern of immunofluorescence. Tests for antibodies to double-stranded DNA (usually positive in systemic lupus erythematosus) are negative. Serum complement is usually normal, although complement concentrations of joint fluid often are depressed from consumption secondary to the inflammatory process. In patients with vasculitis, serum complement concentrations may be low.^{15,16}

Synovial fluid usually is turbid because of the large number of leukocytes in inflammatory fluid. White cell counts of 5,000 to 50,000/mm³ are not uncommon in inflamed joints. The fluid is usually less viscous than that in normal joints or in fluid associated with osteoarthritis. Glucose concentrations of joint fluid are normal or low compared with those in serum drawn at the same time as synovial aspirates. The decrease is not as profound as the decrease associated with joint infection or systemic lupus erythematosus.

Early radiographic manifestations of rheumatoid arthritis include soft-tissue swelling and osteoporosis near the joint (periarticular osteoporosis). Joint space narrowing occurs as a result of cartilage degradation. Erosions tend to occur later in the course of the disease and usually are seen first in the metacarpophalangeal and proximal interphalangeal joints of the hands and the metatarsophalangeal joints of the feet. Periodic joint radiographs are a useful way of evaluating disease progression.

Seronegative Inflammatory Arthritis

Although rheumatoid arthritis may have a negative rheumatoid factor titer, a number of other systemic inflammatory arthritic conditions exist including psoriatic arthritis, ankylosing spondylitis, and arthritis associated with inflammatory bowel disease. These conditions often tend to be less aggressive than what is typically seen with rheumatoid arthritis. Detailed discussion about these conditions is beyond the scope of this chapter, but further information may be found elsewhere.² Management principles are similar to those for rheumatoid arthritis.

TREATMENT

Rheumatoid Arthritis

■ DESIRED OUTCOME

② The primary objective is to improve or maintain functional status, thereby improving quality of life. Treatment of rheumatoid arthritis is a multifaceted approach that includes pharmacologic and nonpharmacologic therapies. Recent emphasis has been placed on aggressive treatment early in the disease course. The ultimate goal is to achieve complete disease remission, although this goal may be difficult to achieve in some patients. Additional goals of treatment include controlling disease activity and joint pain, maintaining the ability to function in daily activities or work, improving the quality of life, and slowing destructive joint changes.

■ NONPHARMACOLOGIC THERAPY

③ Rest, occupational therapy, physical therapy, use of assistive devices, weight reduction, and surgery are the most useful types of nonpharmacologic therapy used in patients with rheumatoid arthritis. Rest is an essential component of a nonpharmacologic treatment plan. It relieves stress on inflamed joints and prevents further joint destruction. Rest also aids in alleviation of pain. Too much rest and immobility, however, may lead to decreased range of motion and, ultimately, muscle atrophy and contractures.

Occupational and physical therapy can provide the patient with skills and exercises necessary to increase or maintain mobility. These disciplines also may provide patients with supportive and adaptive devices such as canes, walkers, and splints.

Other nonpharmacologic therapeutic options include weight loss and surgery. Weight reduction helps to alleviate inflamed joint stress. This should be instituted and monitored with close supervision of a healthcare professional. Tenosynovectomy, tendon repair, and joint replacements are surgical options for patients with rheumatoid arthritis. Such management is reserved for patients with severe disease.^{17,18}

■ PHARMACOLOGIC THERAPY

④ ⑤ A disease-modifying antirheumatic drug (DMARD) should be started within the first 3 months of symptom onset (Fig. 94–5).¹⁷ Early introduction of DMARDs results in a more favorable outcome.^{19–25} NSAIDs and/or corticosteroids may be used for symptomatic relief if needed. They provide relatively rapid improvement in symptoms compared with DMARDs, which may take weeks to months before benefit is seen; however, NSAIDs have no impact on disease progression and the long-term complication risk of corticosteroids make them less desirable.²⁴

Early treatment with DMARDs can reduce mortality. Patients with rheumatoid arthritis have increased mortality compared to people without the disease. In one trial, methotrexate reduced risk of mortality.¹³ Early treatment with DMARDs in patients followed for up to 10 years had mortality rates similar to patients without the disease.²⁶

DMARDs including biologic agents should be used in all patients except those with limited disease. DMARDs commonly used include methotrexate, hydroxychloroquine, sulfasalazine, and leflunomide. The biologic agents that have disease-modifying activity include the anti-TNF drugs (etanercept, infliximab, adalimumab), the IL-1 receptor antagonist anakinra, the costimulation modulator abatacept, and rituximab, which depletes peripheral B cells. Less frequently used are azathioprine, D-penicillamine, gold (including auranofin), minocycline, cyclosporine and cyclophosphamide. This is due to either less efficacy, high toxicity, or both. The order in which the first-line agents are used is not clearly defined, although methotrexate is often chosen because long-term data suggests superior outcomes with methotrexate than with other DMARDs and a lower cost than biologic agents. Leflunomide appears to have similar long-term efficacy as that of methotrexate.²⁷

The biologics have proven effective for patients who fail treatment with other DMARDs. Infliximab should be given in combina-

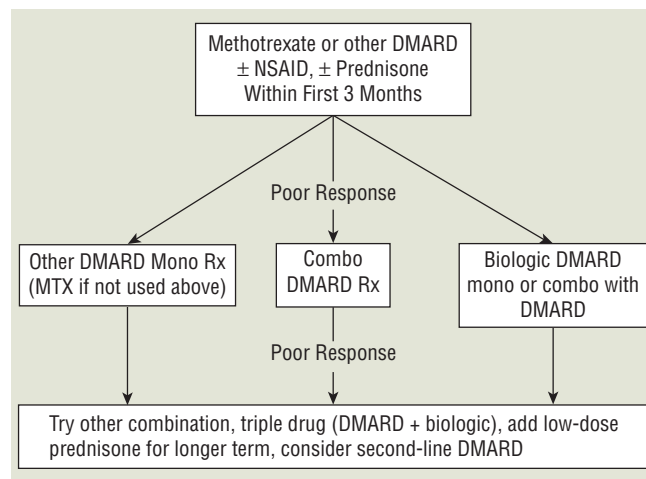

FIGURE 94-5. Algorithm for treatment of rheumatoid arthritis. (DMARD, disease-modifying antirheumatic drug; MTX, methotrexate; NSAID, non-steroidal antiinflammatory drug.)

TABLE 94-2 Usual Doses and Monitoring Parameters for Antirheumatic Drugs

Drug	Usual Dose	Initial	Maintenance
Nonsteroidal antiinflammatory drugs	See Table 95-2 in Chap. 95	Scr or BUN, CBC q 2–4 weeks p starting therapy × 1–2 months salicylates: serum salicylate levels if therapeutic dose & no response	Same as initial plus stool guaiac q 6–12 months
Methotrexate	Oral or IM: 7.5–15 mg q week	Baseline: AST, ALT, alk phos, alb, t. bili, hep B & C studies, CBC w/plt, Scr	CBC w/plt, AST, alb q 1–2 months
Leflunomide	Oral: 100 mg daily for 3 days then 10–20 mg daily or 10–20 mg daily without loading dose	Baseline: ALT, CBC with platelets	CBC with platelets and ALT monthly initially and then every 6–8 weeks
Hydroxychloroquine	Oral: 200–300 mg bid, after 1–2 months may ↓ to 200 mg bid or daily	Baseline: color fundus photography & automated central perimetric analysis	Ophthalmoscopy q 9–12 months and Amsler grid at home q 2 weeks
Sulfasalazine	Oral: 500 mg bid, then ↑ to 1 g bid max	Baseline: CBC w/plt, then q week × 1 month	Same as initial—q 1–2 months
Etanercept	50 mg SC weekly	Tuberculin skin test	None
Infliximab	3 mg/kg IV at 0, 2, 6 weeks then q 8 weeks	Tuberculin skin test	None
Adalimumab	40 mg SC q 2 weeks	Tuberculin skin test	None
Anakinra	100 mg SC daily	None	None
Rituximab	1,000 mg twice 2 weeks apart	None	None
Abatacept	<60 kg—500 mg 60–100 kg—750 mg >100 kg—1,000 mg	None	None
Auranofin	Oral: 3 mg daily to bid	Baseline: UA, CBC w/plt	Same as initial—q 1–2 months
Gold thiomalate	IM: 10 mg test dose, then weekly dosing 25–50 mg, after response may ↑ dosing interval	Baseline & until stable: UA, CBC w/plt preinjection	Same as initial—every other dose
Azathioprine	Oral: 50–150 mg daily	CBC w/plt, AST q 2 weeks × 1–2 months	Same as initial—q 1–2 months
D-Penicillamine	Oral: 125–250 mg daily, may ↑ by 125–250 mg q 1–2 months, max 750 mg daily	Baseline: UA, CBC w/plt, then q week × 1 month	Same as initial—q 1–2 months, but q 2 weeks if dose change
Cyclophosphamide	Oral: 1–2 mg/kg/day	UA, CBC w/plt q week × 1 month	Same as initial—q 2–4 weeks
Cyclosporine	Oral: 2.5 mg/kg/day	S _{cr} , blood pressure q month	Same as initial
Corticosteroids	Oral, IV, IM, IA, and soft-tissue injections: variable	glucose, blood pressure q 3–6 months	Same as initial

alb, albumin; alk phos, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; CBC, complete blood count; hep, hepatitis; IA, intraarticular; IM, intramuscular; IV, intravenous; p, after; plt, platelet; q, every; S_{cr}, serum creatinine; t. bili, total bilirubin; UA, urinalysis.

tion with methotrexate to prevent development of antibodies that may reduce drug efficacy or induce allergic reactions.

⑥ Combination therapy with two or more DMARDs may be effective when single-DMARD treatment is unsuccessful.^{24,28–34} The combinations of cyclosporine plus methotrexate and methotrexate plus sulfasalazine and hydroxychloroquine are particularly effective.³³ One study suggests that the initial combination therapy with either methotrexate, sulfasalazine plus prednisone, or infliximab plus methotrexate were superior to more conventional sequential monotherapy or step-up combinations of DMARDs in early rheumatoid arthritis.³⁰

Corticosteroids can be used in various ways. They are valuable in controlling symptoms before the onset of action of DMARDs. A burst

of corticosteroids can be used in acute flares. Continuous low doses may be adjuncts when DMARDs do not provide adequate disease control. Corticosteroids may be injected into joints and soft tissues to control local inflammation. Corticosteroids seldom should be used as monotherapy. There are data to suggest they have disease-modifying activity;^{35,36} however, it is preferable to avoid chronic use when possible to avoid long-term complications. NSAIDs and DMARDs have steroid-sparing properties that permit reductions of corticosteroid doses.

⑦ Tables 94–2, 94–3, and 94–4 provide monitoring parameters and dosing guidelines for DMARDs and NSAIDs used in rheumatoid arthritis.

TABLE 94-3 Clinical Monitoring of Drug Therapy in Rheumatoid Arthritis

Drug	Toxicities Requiring Monitoring	Symptoms to Inquire About ^a
NSAIDs and salicylates	GI ulceration and bleeding, renal damage	Blood in stool, black stool, dyspepsia, nausea/vomiting, weakness, dizziness, abdominal pain, edema, weight gain, SOB
Corticosteroids	Hypertension, hyperglycemia, osteoporosis ^b	Blood pressure if available, polyuria, polydipsia, edema, SOB, visual changes, weight gain, headaches, broken bones or bone pain
Azathioprine	Myelosuppression, hepatotoxicity, lymphoproliferative disorders	Symptoms of myelosuppression (extreme fatigue, easy bleeding or bruising, infection), jaundice
Gold (intramuscular or oral)	Myelosuppression, proteinuria, rash, stomatitis	Symptoms of myelosuppression, edema, rash, oral ulcers, diarrhea
Hydroxychloroquine	Macular damage, rash, diarrhea	Visual changes including a decrease in night or peripheral vision, rash, diarrhea
Methotrexate	Myelosuppression, hepatic fibrosis, cirrhosis, pulmonary infiltrates or fibrosis, stomatitis, rash	Symptoms of myelosuppression, SOB, nausea/vomiting, lymph node swelling, coughing, mouth sores, diarrhea, jaundice
Leflunomide	Hepatitis, GI distress, alopecia	Nausea/vomiting, gastritis, diarrhea, hair loss, jaundice
Penicillamine	Myelosuppression, proteinuria, stomatitis, rash, dysgeusia	Symptoms of myelosuppression, edema, rash, diarrhea, altered taste perception, oral ulcers
Sulfasalazine	Myelosuppression, rash	Symptoms of myelosuppression, photosensitivity, rash, nausea/vomiting
Etanercept, adalimumab, anakinra	Local injection-site reactions, infection	Symptoms of infection
Infliximab, rituximab, abatacept	Immune reactions, infection	Postinfusion reactions, symptoms of infection

GI, gastrointestinal; NSAIDs, nonsteroidal antiinflammatory drugs; SOB, shortness of breath.

^aAltered immune function increases infection which should be considered particularly in those patients taking azathioprine, methotrexate, and corticosteroids or other drugs as a symptom of myelosuppression.

^bOsteoporosis is unlikely to manifest itself early in treatment, but all patients should be taking appropriate steps to prevent bone loss.

From American College of Rheumatology Ad Hoc Committee on Clinical Guidelines. Guidelines for monitoring drug therapy in rheumatoid arthritis. *Arthritis Rheum* 1996;39:723–731.

TABLE 94-4 Dosage Regimens for Nonsteroidal Antiinflammatory Drugs

Drug	Recommended Antiinflammatory Total Daily Dosage		Dosing Schedule
	Adult	Children	
Aspirin	2.6–5.2 g	60–100 mg/kg	Four times daily
Celecoxib	200–400 mg	—	Daily to twice daily
Diclofenac	150–200 mg	—	Three times per day to four times daily Extended release—twice daily
Diflunisal	0.5–1.5 g	—	Twice daily
Etodolac	0.2–1.2 g (max. 20 mg/kg)	—	Twice daily to four times daily
Fenoprofen	0.9–3.0 g	—	Four times daily
Flurbiprofen	200–300 mg	—	Twice daily to four times daily
Ibuprofen	1.2–3.2 g	20–40 mg/kg	Three times per day to four times daily
Indomethacin	50–200 mg	2–4 mg/kg (max. 200 mg)	Twice daily to four times daily Extended release—daily
Meclofenamate	200–400 mg	—	Three times per day to four times per day
Meloxicam	7.5–15 mg	—	Daily
Nabumetone	1–2 g	—	Daily to twice daily
Naproxen	0.5–1.0 g	10 mg/kg	Twice daily Extended release—daily
Naproxen sodium	0.55–1.1 g	—	Twice daily
Nonacetylated salicylates	1.2–4.8 g	—	Twice daily to six times per day
Oxaprozin	0.6–1.8 g (max. 26 mg/kg)	—	Daily to three times a day
Piroxicam	10–20 mg	—	Daily
Sulindac	300–400 mg	—	Twice daily
Tolmetin	0.6–1.8 g	15–30 mg/kg	Twice daily to four times daily

Nonsteroidal Antiinflammatory Drugs

NSAIDs should seldom be used as monotherapy for rheumatoid arthritis because they do not alter the course of the disease; instead, they should be viewed as adjuncts to DMARD treatment. NSAIDs possess both analgesic and antiinflammatory properties and reduce stiffness associated with rheumatoid arthritis. NSAIDs mainly inhibit prostaglandin synthesis, which is only a small portion of the inflammatory cascade (see Fig. 94–1). For details on these agents see Chap. 95.

Methotrexate

Methotrexate is now considered the DMARD of choice by many rheumatologists for treating rheumatoid arthritis. In psoriatic arthritis it not only treats the joint symptoms but also improves the skin disease for most patients. Methotrexate is contraindicated in pregnant and nursing women. It is also contraindicated in patients with chronic liver disease, immunodeficiency, pleural or peritoneal effusions, leukopenia, thrombocytopenia, preexisting blood disorders, and a creatinine clearance of less than 40 mL/min.

Absorption of methotrexate is variable and averages approximately 70% of an oral dose. Methotrexate is 35% to 50% bound to albumin; it may be displaced by highly protein-bound drugs such as NSAIDs, but the clinical importance of this interaction is unknown. Methotrexate is extensively metabolized intracellularly to polyglutamated derivatives. It is excreted by the kidney, 80% unchanged, by glomerular filtration and active transport. Some methotrexate may be reabsorbed, but this transport process may be saturated even with low doses, resulting in increased renal clearance.

Methotrexate inhibits cytokine production, inhibits purine biosynthesis, and may stimulate release of adenosine, all of which may lead to its antiinflammatory properties. The drug has a fairly rapid onset of action; results may be seen as early as 2 to 3 weeks after starting therapy. Some 45% to 67% of patients remain on methotrexate therapy in studies ranging from 5 to 7 years.^{37,38} Methotrexate may be given intramuscularly, subcutaneously, or orally. Doses greater than 15 mg per week generally are given parenterally because of decreased oral bioavailability of larger doses.

The toxicities of methotrexate therapy are mainly gastrointestinal, hematologic, pulmonary, and hepatic. Stomatitis occurs in 3% to

10% of patients and may be painful or painless. Diarrhea, nausea, and vomiting may occur in up to 10% of patients. The most common hematologic toxicity is thrombocytopenia in 1% to 3% of patients. Leukopenia also may occur, but in a smaller number of patients. Although pulmonary fibrosis and pneumonitis can be severe adverse effects, they are rare.

Elevated liver enzymes may occur in up to 15% of patients; cirrhosis is rare. Liver function tests, aspartate aminotransferase or alanine aminotransferase, should be performed periodically. Methotrexate should be discontinued if these test values show sustained results greater than twice the upper limits of normal. An albumin blood level also should be checked periodically as a sign of liver toxicity because some patients may not have liver inflammation manifested by aspartate aminotransferase or alanine aminotransferase elevation. Liver biopsy is now recommended before beginning methotrexate therapy only for patients with a history of excessive alcohol use, ongoing hepatitis B or C infection, or recurring elevation of aspartate aminotransferase. Biopsies during methotrexate therapy are recommended only for patients who develop consistently abnormal liver function tests.¹⁷

Because the drug is teratogenic, patients should use contraception to avoid pregnancy and discontinue the drug if conception is planned.

Because it is a folic acid antagonist, methotrexate can induce a folic acid deficiency. This deficiency is thought to be partly responsible for methotrexate toxicity, and supplementation with folic acid does alleviate some adverse effects. Addition of folic acid to a methotrexate regimen for rheumatoid arthritis does not compromise drug efficacy.^{17,39–42}

Leflunomide

Leflunomide is a DMARD that inhibits pyrimidine synthesis, leading to a decrease in lymphocyte proliferation and modulation of inflammation. It is given as a loading dose of 100 mg daily for 3 days, followed by a maintenance dose of 20 mg daily. Lower doses may be used if patients have gastrointestinal intolerance, complain of hair loss, or have other signs of dose-related toxicity. The loading dose allows the patient to achieve a therapeutic response, usually

within the first month. The long elimination half-life of the drug (14 to 16 days) would require the patient to take the drug for several months to achieve steady state without a loading dose. Some rheumatologists prefer to begin with maintenance dosing as the loading dose may put the patient at risk for toxicity.

Leflunomide has efficacy similar to methotrexate for treating rheumatoid arthritis. The drug may cause liver toxicity and is contraindicated in patients with preexisting liver disease. Patients taking the drug should have alanine aminotransferase monitored monthly initially and periodically thereafter as long as they continue treatment. Leflunomide may cause bone marrow toxicity and complete blood count with platelets is recommended monthly for 6 months and then every 6 to 8 weeks thereafter.

The drug is teratogenic, and appropriate contraceptive measures are recommended to avoid pregnancy for all sexually active male and female patients who are taking leflunomide. If conception is desired, leflunomide must be discontinued. Because leflunomide undergoes enterohepatic circulation, the drug takes many months to drop to a plasma concentration considered safe during pregnancy (<0.02 mcg/mL). Cholestyramine may be used to rapidly clear the drug from plasma. In addition to pregnancy, cholestyramine use may be warranted to rapidly clear the drug in the event of severe toxicity.^{27,43–46}

Hydroxychloroquine

The pharmacokinetics of hydroxychloroquine are poorly understood. It is well absorbed orally and widely distributed to body tissues. Hydroxychloroquine is partially metabolized in the liver and is excreted by the kidney. The onset of action of hydroxychloroquine may be delayed up to 6 weeks, but the drug is considered a therapeutic failure only when 6 months of therapy without a response has elapsed.

The main advantage of hydroxychloroquine is the lack of myelosuppressive, hepatic, and renal toxicities that may be seen with other DMARDs, which simplifies monitoring. Short-term toxicities of hydroxychloroquine include gastrointestinal effects such as nausea, vomiting, and diarrhea, which can be managed by taking doses with food. Ocular toxicity includes accommodation defects, benign corneal deposits, blurred vision, scotomas (small areas of decreased or absent vision in the visual field), and night blindness. Although the risk of true retinopathy with hydroxychloroquine approaches zero, preretinopathy may occur in 2.7% of patients. All patients must understand the importance of adhering to hydroxychloroquine monitoring guidelines, as delineated in Table 94–2. Any visual change must be reported immediately. Dermatologic toxicities include rash, alopecia, and increased skin pigmentation; neurologic adverse effects such as headache, vertigo, and insomnia usually are mild.^{34,47,48}

Sulfasalazine

Sulfasalazine, a prodrug, is cleaved by bacteria in the colon into sulfapyridine and 5-aminosalicylic acid. It is believed that the sulfapyridine moiety is responsible for the agent's antirheumatic properties, although the exact mechanism of action is unknown. Once the colonic bacteria have cleaved sulfasalazine, sulfapyridine and 5-aminosalicylic acid are absorbed rapidly from the gastrointestinal tract. Sulfapyridine distributes rapidly throughout the body, but higher concentrations are found in certain tissues such as serous fluid, liver, and intestines. Both sulfasalazine and its metabolites are excreted in the urine. Antirheumatic effects should be seen in 2 months.

Use of sulfasalazine is often limited by its adverse effects. Gastrointestinal adverse effects such as nausea, vomiting, diarrhea, and anorexia are the most common. These can be minimized by initiating therapy with low doses and titrating gradually to higher doses, dividing the dose more evenly throughout the day, or using enteric-coated preparations. Rash, urticaria, and serum sickness-like reac-

tions can be managed with antihistamines and, if indicated, corticosteroids. If a hypersensitivity reaction occurs, therapy should be stopped immediately and another DMARD substituted. Sulfasalazine is associated with leukopenia, alopecia, stomatitis, and elevated hepatic enzymes. It also may cause the patient's urine and skin to turn a yellow-orange color, which is of no clinical consequence however; patients should be educated about this to avoid premature discontinuance.

Sulfasalazine's absorption can be decreased when antibiotics are used that destroy the colonic bacteria. Sulfasalazine also binds iron supplements in the gastrointestinal tract that can lead to a decreased absorption of sulfasalazine. The administration of these two agents should be separated temporally to avoid this interaction. Sulfasalazine can potentiate warfarin's effects by displacing it from protein-binding sites. Close monitoring of the patient's international normalized ratio is indicated.^{49,50}

Other Disease-Modifying Antirheumatic Drugs

Gold salts, azathioprine, D-penicillamine, cyclosporine, cyclophosphamide, and minocycline have all been used to treat rheumatoid arthritis. Although these drugs can be effective and they may be of value in certain clinical settings, they are used less frequently today because of toxicity, lack of long-term benefit, or both. Tables 94–2 and 94–3 provide dosing information and toxicity information.

Biologic Agents

Biologic agents are genetically engineered protein molecules that block the proinflammatory cytokines TNF- α (infliximab, etanercept, adalimumab) and IL-1 (anakinra), deplete peripheral B cells (rituximab), or bind to CD80/86 on T-cells to prevent the costimulation needed to fully activate T cells (abatacept). These drugs may be effective when other DMARDs fail to achieve adequate responses but are considerably more expensive to use. They have no toxicity that requires laboratory monitoring, but have a small increased risk for infection. There is an increased incidence of tuberculosis in patients treated with these agents. Tuberculin skin testing is recommended prior to treatment with these drugs.^{51–54} Patients with a history of significant tuberculosis exposure or recurrent infection may not be good candidates for these drugs. Those who develop infections while on biologic agents should at least temporarily discontinue them until the infection is cured. Additionally, congestive heart failure is a relative contraindication for infliximab and etanercept. Increased cardiac mortality has been seen in patients treated with infliximab and etanercept-associated heart failure exacerbations have been documented.^{46,55,56} It is postulated that TNF inhibitors may predispose patients to increased cancer risk as TNF plays a role in ridding the body of cancer cells. The reported incidence of malignancy is similar to that of patients with rheumatoid arthritis who are not on these drugs; however, long-term surveillance studies are lacking.^{57,58}

Etanercept Etanercept is a fusion protein consisting of two p75-soluble TNF receptors linked to an Fc fragment of human IgG₁. The drug binds to TNF, making it biologically inactive and preventing it from interacting with the cell-surface TNF receptors that would lead to cell activation.

The drug is given by subcutaneous injection, 50 mg once weekly or 25 mg twice weekly, usually through self-injections or administration by a caregiver. Aside from local injection-site reactions, adverse effects are rare. There are case reports of pancytopenia and neurologic demyelinating syndromes like multiple sclerosis associated with use of etanercept, but these are rare. Patients with multiple sclerosis should avoid use of this drug. The infection and congestive heart failure precautions are discussed above. No laboratory monitoring is required.

Most clinical trials have used etanercept in patients who failed DMARDs. Response was seen in 60% to 75% of patients. The drug has also been FDA approved for the treatment of juvenile rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis and moderate to severe psoriasis. Clinical trials have shown that it slows erosive disease progression to a greater degree than oral methotrexate therapy.^{59–67}

Infliximab Infliximab is a chimeric antibody combining portions of mouse and human IgG₁. An anti-TNF antibody was created by exposing mice to human TNF. The binding portion of that antibody was fused to a human constant-region IgG₁ to reduce the antigenicity of the foreign protein. This antibody, when injected in humans, binds to TNF and prevents its interaction with TNF receptors on inflammatory cells.

Infliximab is given by intravenous infusion at a dose of 3 mg/kg at 0, 2, and 6 weeks and then every 8 weeks. To prevent the formation of antibodies to this foreign protein, methotrexate should be given orally in doses typically used to treat rheumatoid arthritis for as long as the patient continues on infliximab. Antibodies develop in 7% to 15% of patients, which leads to a greater risk of infusion reactions and also may reduce the efficacy of the drug. Loss of response may be seen in patients with rheumatoid arthritis who have good initial response requiring increased doses or shorter intervals between doses to maintain response. Infusion reactions may occur in any patient treated with the drug. Both acute (within 24 hours of infusion) and delayed (24 hours to 14 days) reactions following infusion have been identified. An acute infusion reaction with symptoms including fever, chills, pruritus, and rash may occur during infusion or within 1 to 2 hours after giving the drug. Treatment includes slowing infusion rates and administering acetaminophen, diphenhydramine, or corticosteroids, depending on the severity of symptoms. Fortunately these reactions are rarely severe or anaphylactic in nature.⁶⁸ The drug may increase risk of infection as noted above. Autoantibodies and lupus-like syndrome also have been reported. In clinical trials, the combination of methotrexate plus infliximab halted progression of joint damage in patients and was superior to methotrexate monotherapy.^{63,69–71} In addition to rheumatoid arthritis, infliximab is indicated for the treatment of psoriatic arthritis and ankylosing spondylitis.^{69,72}

Adalimumab Adalimumab is a human IgG₁ antibody to TNF. Because it has no foreign protein components, it is less antigenic than infliximab. The drug is provided as either premixed syringes or injection pens containing 40 mg, which is administered by subcutaneous injection every 14 days. It has similar response rates to those seen with the other TNF inhibitors. Local injection-site reactions were the most common adverse reactions noted in clinical trials. It has the same precautions regarding tuberculosis and other infections as the other biologics. To date, congestive heart failure exacerbations have not been reported.^{73–78}

Interleukin-1 Receptor Antagonist Anakinra is an IL-1 receptor antagonist (IL-1ra) which is a naturally occurring antiinflammatory. By binding to IL-1 receptors on target cells, it prevents the interaction between IL-1 and the cell.

IL-1 is very important in the pathogenesis of rheumatoid arthritis. It stimulates release of chemotactic factors and adhesion molecules, and these promote migration of inflammatory leukocytes to tissues. It also causes release of factors known to dilate blood vessels and direct cytotoxins that produce connective tissue damage.

In a double-blind, placebo-controlled trial, IL-1ra 150 mg given by daily subcutaneous injection had a response rate of 43%, compared with 27% for placebo-treated patients. Less radiographic progression of joint damage was noted in those patients receiving IL-1ra. Injection-site reactions were the most common adverse effect noted. Infection risk and precautions are similar to those for the TNF inhibitors. Limited trials combining anakinra with anti-TNF therapy

failed to demonstrate better outcomes and increased infection risk and combination therapy is not recommended. When anakinra was added in patients who were not getting adequate response from methotrexate alone, nearly half of the patients had at least a 20% reduction in disease activity with the combination. The short half-life of the drug requires daily subcutaneous injections of 100 mg. Most rheumatologists feel anakinra has a less-robust response than the TNF inhibitors and reserve it for use in patients who fail these agents.^{79–83}

Abatacept Abatacept is a costimulation modulator approved for the treatment of rheumatoid arthritis in patients with moderate to severe disease who fail to achieve an adequate response from one or more DMARDs. By binding to CD80/CD86 receptors on antigen-presenting cells, abatacept inhibits interactions between the antigen-presenting cells and T cells, preventing the T cell from activating to promote the inflammatory process, which results in reductions in cytokines, T-cell proliferation, and other consequences of T-cell activation. Abatacept is a fusion protein made using the extracellular domain of human cytotoxic T-lymphocyte antigen 4 (the binding portion of the drug) and a fragment of the Fc domain of human IgG modified to prevent complement fixation. The drug is given by intravenous infusion based on patient weight (<60 kg: 500 mg; 60 to 100 kg: 750 mg; >100 kg: 1,000 mg) every 2 weeks for two doses after the initial dose and then every 4 weeks. The drug is well tolerated, with headache, nasopharyngitis, dizziness, cough, back pain, hypertension, dyspepsia, urinary tract infection, rash, and extremity pain reported more frequently in clinical trials. Infusion reactions were 50% more likely with abatacept than with placebo and there was a slightly higher rate of serious infections with active treatment.^{84,85} In patients who failed to achieve adequate responses with TNF- α inhibitors, half had a clinical response to abatacept.⁸⁶

Rituximab Rituximab is a monoclonal chimeric antibody consisting of mostly human protein with the antigen-binding region derived from a mouse antibody to CD20 protein found on the cell surface of mature B lymphocytes. The binding of rituximab to B cells results in nearly complete depletion of peripheral B cells, with a gradual recovery over several months. The prolonged effect on B cells results in a duration of action that allows for intermittent therapy which varies based on reactivation of arthritis symptoms. Rituximab is useful in patients who failed methotrexate or TNF inhibitors.^{87–90} Two infusions of 1,000 mg are given 2 weeks apart. Methylprednisolone 100 mg should be given 30 minutes prior to rituximab to reduce the incidence and severity of infusion reactions. Acetaminophen and antihistamines may also be of benefit in patients who have a history of reactions. Methotrexate should be given concurrently in the usual doses used for rheumatoid arthritis, as the combination has proved to provide the best therapeutic outcomes. Duration of benefit is variable after a course of rituximab and patients will need retreatment with reactivation of their disease. The drug is currently FDA approved for TNF inhibitor treatment failures.

Corticosteroids

Corticosteroids are used in rheumatoid arthritis for their antiinflammatory and immunosuppressive properties. They interfere with antigen presentation to T lymphocytes, inhibit prostaglandin and leukotriene synthesis, and inhibit neutrophil and monocyte superoxide radical generation. Corticosteroids also impair cell migration and cause redistribution of monocytes, lymphocytes, and neutrophils, thus blunting the inflammatory and autoimmune responses.

Oral corticosteroids are absorbed rapidly and completely from the gastrointestinal tract. They are metabolized and inactivated primarily by the liver and excreted in the urine. The elimination half-life of most corticosteroids is sufficiently long that once-daily dosing is possible.

Oral corticosteroids can be used in several ways. They can be used in bridging therapy, continuous low-dose therapy, and short-term high-dose bursts to control flares. Oral steroids (e.g., prednisone, methylprednisolone) can be used to control pain and synovitis while DMARDs are taking effect. This is termed *bridging therapy* and is often used in patients with debilitating symptoms when DMARD therapy is initiated. Patients with difficult-to-control disease may be placed on low-dose, long-term corticosteroid therapy to control their symptoms. Prednisone doses below 7.5 mg daily are well tolerated but are not devoid of the long-term adverse effects associated with corticosteroids. The lowest dose of corticosteroid that controls symptoms should be used to reduce adverse effects. Alternate-day dosing of low-dose oral corticosteroids usually is ineffective in rheumatoid arthritis; symptoms usually flare on days without medication. High-dose corticosteroid bursts often are used to suppress disease flares. High doses are sustained for several days until symptoms are controlled, followed by a taper to the lowest effective dose.

Corticosteroids also may be delivered by injection. The intramuscular route is preferable in patients with compliance problems. Long-acting depot forms of corticosteroids include triamcinolone acetonide, triamcinolone hexacetonide, and methylprednisolone acetate. This provides the patient with 2 to 6 weeks of symptomatic control. The depot effect provides a physiologic taper, avoiding withdrawal reaction associated with hypothalamic–pituitary axis suppression. Intravenous corticosteroids may be used to provide the patient with large amounts of drug during a steroid burst to control severe symptoms. Intraarticular injections of depot forms of corticosteroids can be useful in treating synovitis and pain when a small number of joints are affected. The onset and duration of symptomatic relief are similar to those of intramuscular injection. The intraarticular route often is preferred because it is associated with the fewest number of systemic adverse effects. If efficacious, intraarticular injections may be repeated every 3 months. No one joint should be injected more than two to three times per year because of the risk of accelerated joint destruction and atrophy of tendons. Soft tissues such as tendons and bursae also may be injected. This may help control the pain and inflammation associated with these structures. The onset and duration of symptomatic relief are similar to those of intramuscular and intraarticular injections.

The major limitation to the long-term use of corticosteroids is adverse effects. They include hypothalamic–pituitary–adrenal suppression, Cushing’s syndrome, osteoporosis, myopathies, glaucoma, cataracts, gastritis, hypertension, hirsutism, electrolyte imbalances, glucose intolerance, skin atrophy, and increased susceptibility to infections. To minimize these effects, use the lowest effective corticosteroid dose and limit the duration of use. Patients on long-term therapy should be given calcium and vitamin D to minimize bone loss. Alendronate is effective in preventing bone loss and might be considered prophylactically for patients when long-term corticosteroid is anticipated, particularly for patients who are at high risk (e.g., post-menopausal females, elderly) for bone loss.^{91,92} There is no evidence that corticosteroids alone increase the risk of gastrointestinal ulcerations, although they often have been implicated. Consequently, gastrointestinal protective measures usually are not indicated.^{93,94}

■ PHARMACOECONOMIC CONSIDERATIONS

The total cost of treating a patient with rheumatoid arthritis is estimated to be between \$7,500 and \$11,000 annually (1991 dollars). Of this, drugs account for roughly 10% of the total, excluding monitoring costs. These costs are approximately three times the cost of medical care for patients of similar age and gender without rheumatoid arthritis. However, if biologic agents are used, the cost of this drug therapy alone may be \$12,000 or more annually. The costs must be balanced against the high cost of disability on earning potential in these patients. Men with rheumatoid arthritis have average annual wages 50% lower than those of men of similar age

without rheumatoid arthritis. In women with the disease, average annual wages are only 25% of the wages of those women without the disease. The costs of disability make treatment worth the price if disability can be prevented or delayed and patients can continue to function as productive members of society.⁹⁵

CLINICAL CONTROVERSIES

1. The order of DMARD or biologic agent choice is not clearly defined.
2. Should combination DMARD be tried before biologic agents?
3. Even the best therapy available today does not completely eliminate all signs and symptoms of disease for most patients. How much treatment is enough?
4. Some patients show evidence of disease progression in spite of apparent control of clinical symptoms. How can these patients be identified and treatment course changed before progression occurs?

EVALUATION OF THERAPEUTIC OUTCOMES

The evaluation of therapeutic outcomes is based primarily on improvements of clinical signs and symptoms of rheumatoid arthritis. Clinical signs of improvement include a reduction in joint swelling, decreased warmth over actively involved joints, and decreased tenderness to joint palpation. Improvement in rheumatoid arthritis symptoms includes reduction in perceived joint pain and morning stiffness, longer time to onset of afternoon fatigue, and improvement in ability to perform activities of daily living. Improvement of activities of daily living may be assessed objectively using a Health Assessment Questionnaire score. Joint radiographs may be of some benefit in assessing the progression of the disease and should show little or no evidence of disease progression if treatment is effective.

Laboratory monitoring is of little value in monitoring individual patient response to therapy. Tables 94–2 and 94–3 provide monitoring of drug toxicity information. Routine monitoring of patients is essential to the safe use of these drugs. In addition, patients should be questioned about symptoms of the adverse effects outlined in the drug section of this chapter.

CONCLUSIONS

Rheumatoid arthritis is the most common inflammatory arthritis, affecting approximately 1% of the population. The disease is characterized by symmetrical swelling and stiffness of the involved joints. The stiffness is usually more prominent in the morning. Extraarticular features of rheumatoid arthritis include rheumatoid nodules, vasculitis, and ocular, cardiac, and pulmonary complications. The course of the disease is highly variable. Treatment is aimed at relieving pain and inflammation and maintaining and preserving joint function. Nondrug therapy, including exercise and adequate rest periods, should also be used early in the course of treatment. Early use of a DMARD or biologic agent results in better patient outcomes. Methotrexate, sulfasalazine, and hydroxychloroquine are often considered for initial therapy. Biologics have also been shown to be effective in these patients but may be considered second choice because of cost considerations; however, they are effective in patients who fail to achieve adequate response from older DMARDs. Combination DMARDs or biologics may be considered in those who fail adequate trials of single-agent therapy. Corticosteroids and NSAIDs may be useful adjuncts for treatment, but because of adverse effects and limited impact on long-term outcomes, they should not be considered as sole treatment for most patients.

ABBREVIATIONS

DMARD: disease-modifying antirheumatic drug
 HLA: human lymphocyte antigen
 Ig: immunoglobulin
 IL: interleukin
 NSAID: nonsteroidal antiinflammatory drug
 TNF- α : tumor necrosis factor α

LUCINDA M. BUYS AND MARY ELIZABETH ELLIOTT

KEY CONCEPTS

- 1 Approximately 46 million Americans have osteoarthritis (OA). OA prevalence increases with age, with women more commonly affected than men.
- 2 Contributors to OA are systemic (age, genetics, hormonal status, obesity, occupational or recreational activity) and/or local (injury, overloading of joints, muscle weakness, or joint deformity).
- 3 OA is primarily a disease of cartilage that reflects a failure of the chondrocyte to maintain proper balance between cartilage formation and destruction. This leads to loss of cartilage in the joint, local inflammation, pathologic changes in underlying bone, and further damage to cartilage triggered by the affected bone.
- 4 The most common symptom associated with OA is pain, which leads to decreased function and motion. Pain relief is the primary objective of medication therapy.
- 5 Manifestations of OA are local, affecting one or a few joints, usually the knees, hips, and hands. Osteophytes (bony proliferation of affected joints) are often found, in contrast to the soft-tissue swelling of rheumatoid arthritis.
- 6 Nonpharmacologic therapy is the foundation of the pharmaceutical care plan and should be initiated before or concurrently with pharmacologic therapy.
- 7 Based upon efficacy, safety, and cost considerations, scheduled acetaminophen, up to 4 g/day, should be tried initially for pain relief in OA. If this fails, a nonsteroidal antiinflammatory drug (NSAID) may be tried, if there are no contraindications.
- 8 Strategies to reduce NSAID-induced GI toxicity include the use of nonacetylated salicylates, COX-2 selective inhibitors, or the addition of misoprostol or a proton pump inhibitor. COX-2 selective inhibitors vary in their ability to prevent GI toxicity, and concomitant use of aspirin largely negates their gastroprotective effects.
- 9 COX-2 selective inhibitors can increase the risk of cardiovascular events. This may be a class effect, but the extent of this risk varies among COX-2 selective inhibitors, and traditional NSAIDs may also pose risks. This hazard, in addition to the GI toxicity possible with all NSAIDs, underscores the importance of using NSAIDs only as needed and after assessing the individual patient's risk.

- 10 NSAIDs are associated with GI, renal, cardiovascular, liver, and central nervous system toxicity. Monitoring with complete blood count, serum creatinine, and hepatic transaminase levels can be valuable in detecting potential toxicity.
- 11 Other agents useful in treating OA include topical NSAIDs or capsaicin, opioids, glucosamine and chondroitin in combination, and intraarticular injections of corticosteroids or hyaluronic acid.

Osteoarthritis (OA) is extremely common and poses tremendous personal, societal, and economic costs. Although OA has been defined in different ways, one definition created by a consensus panel reads

OA diseases are a result of both mechanical and biologic events that destabilize the normal coupling of degradation and synthesis of articular cartilage, chondrocytes, and extracellular matrix, and subchondral bone. Although they may be initiated by multiple factors, including genetic, developmental, metabolic, and traumatic, OA diseases involve all of the tissues of the diarthrodial joint. Ultimately, OA diseases are manifested by morphologic, biochemical, molecular, and biomechanical changes of both cells and matrix which lead to a softening, fibrillation, ulceration, loss of articular cartilage, sclerosis and eburnation of subchondral bone, osteophytes, and subchondral cysts, when clinically evident, OA diseases are characterized by joint pain, tenderness, limitation of movement, crepitus, occasional effusion, and variable degrees of inflammation without systemic effects.¹

This chapter first amplifies and clarifies the issues included in the above definition and summarizes the basics of OA diagnosis. It then focuses on pharmacologic and nonpharmacologic treatments currently in use for OA, as well as investigational agents. Because millions of persons take medications for OA, the overall risks posed by medications deserve thorough consideration, particularly by clinicians who treat and/or advise their patients on drug therapy for OA. This chapter examines the risks and benefits of OA treatments, with emphasis on those individuals who have the highest risk for adverse events, so as to help clinicians maximize benefit and reduce risks to their patients with OA.

EPIDEMIOLOGY

OA is the most prevalent of the rheumatic diseases and is responsible for enormous disability and loss of productivity.²⁻⁴ As the U.S. population continues to age, the economic impact of the lost productivity and the quality of life limitations from disability will become even more pronounced.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

PREVALENCE BY AGE, SEX, AND RACE

1 The prevalence of clinician-diagnosed arthritis is estimated at 46 million in the United States and is projected to increase to nearly 67 million by 2030, of which 25 million are expected to report arthritis-related activity limitations.⁵ The prevalence of OA is higher in older age groups than in younger groups. In those younger than age 45 years, about one-fifth have OA of the hands, whereas of those ages 75 to 79 years, 85% have OA of the hands. OA of the knee occurs in less than 0.1% of those ages 25 to 34 years, but in 10% to 20% of those ages 65 to 74 years.

OA severity also increases with age.²⁻⁴ In persons between 65 and 74 years of age, 33% have moderate to severe knee OA, and 50% have moderate to severe hip OA. Women are more often affected by OA, with older women being twice as likely as men to have OA of the knee and hands.³ Women are also more likely to have inflammatory OA of the proximal and distal interphalangeal joints of the hands, giving rise to the formation of Bouchard and Heberden nodes, respectively (Fig. 95-1). Knee OA appears to be twice as prevalent in black as opposed to white women. Chinese, East Indian, and Native American people have lower incidences of hip OA than do whites.

INCIDENCE

The overall incidence of hip or knee OA is approximately 200 per 100,000 person-years. Approximately one-half million symptomatic new cases of OA are estimated to occur annually in the United States.

ETIOLOGY

2 The etiology of OA is multifactorial. Many patients have more than one risk factor for the development of OA. The most common risk factors for the development of OA include obesity, previous occupation, participation in certain sports, history of joint trauma, and a genetic predisposition to OA. Patients with osteoarthritis are less likely to have osteoporosis because heavy individuals have higher bone density as a result of weight-bearing, but an increased risk of OA as a consequence of excessive joint loading.³

OBESITY

Increased body weight is strongly associated with hip, knee, and hand OA, and obesity is regarded as the number one preventable

FIGURE 95-1. Heberden nodes (distal interphalangeal joint) noted on all fingers and Bouchard nodes (proximal interphalangeal joint) noted on most fingers. (From Johnson BE. *Arthritis: Osteoarthritis, Gout and Rheumatoid Arthritis*. In: South-Paul JE, Matheny SC, Lewis EL, eds. *Current Diagnosis and Treatment in Family Medicine*. New York: McGraw-Hill; 2004, p. 266, p. 267.)

risk factor for OA.⁶⁻⁸ Obesity often precedes OA and contributes to its development, rather than occurring as a result of inactivity from joint pain. In a three-decade Framingham Study, the highest quintile of body mass was associated with a higher relative risk of knee OA (relative risk of 1.5 to 1.9 for men and 2.1 to 3.2 for women). Another study of 1,108 men in their twenties showed that a high body mass index was associated with later development of knee OA.⁸ The risk of developing OA increases by approximately 10% with each additional kilogram of weight, and in obese persons without OA, weight loss of even 5 kg decreases the risk of future knee OA by half. In addition to being a risk factor for OA, obesity is also a predictor for eventual prosthetic joint replacement.

OCCUPATION, SPORTS, AND TRAUMA

Those participating in activities involving repetitive motion or injury are at increased risk for developing OA.^{6,10} Workers exposed to repetitive stress of the hands or lower limbs (e.g., shipyard workers, carpenters, and agricultural workers) are at higher risk for OA of the stressed joints.

OA is associated with participation in activities such as wrestling, boxing, baseball pitching, cycling, and football, although recreational participants may not have the increased risk seen in the professional athlete. Risk for OA also depends on the type and intensity of physical activity. The Framingham Study showed that heavy physical activity increases knee OA risk, especially in the obese, whereas moderate or light activity does not.¹¹ Interestingly, long-distance runners are not at higher risk of developing OA.¹²

Age at injury does matter, because older individuals who damage ligaments tend to develop OA more rapidly than young people with a similar injury. However, trauma that occurs early in life is significant: The incidence of knee OA by age 65 years was more than doubled for men who sustained a knee injury in adolescence compared to those who had not.¹³

Quadriceps strength is also related to knee OA and disability. Quadriceps weakness, once thought to result from disuse atrophy in OA patients, may precede and contribute to the development of OA, possibly through decreased knee stability.¹⁴

GENETIC FACTORS

OA is a multifactorial disease in which many genes are considered to play a role. Genetics may play different roles in different types of arthritis.⁴ Heberden nodes are 10 times more prevalent in women than in men, for example, with a twofold higher risk if the woman's mother had them. Genetic links also have been shown with OA of the first metatarsophalangeal joint and with generalized OA. Twin studies indicate that OA can be attributed substantially to genetic factors (39% to 65%, 60%, and 70% for hand, hip, and spine OA, respectively).¹⁵

Genome-wide linkage studies (associating OA with a specific region out of the total human genome) also have been used to search for the genetic bases for OA.¹⁶ These studies have been carried out for persons with OA who were all from unrelated families. These studies, carried out in the United Kingdom (481 pedigrees), Finland (27 pedigrees), Iceland (329 pedigrees), and the United States (296 pedigrees) show that there are dozens of loci that may include OA-linked genes. Searches for candidate genes (known proteins that are plausibly connected to OA, such as structural proteins in cartilage, or proteins that regulate chondrocyte function, such as interleukins and other signaling molecules) within the identified loci has provided some promising clues. Variants in the interleukin-1 family (in interleukin-1, in an interleukin-1 receptor antagonist, and in the interleukin-1 receptor), in the interleukin-4 receptor, and in the secreted frizzled-related protein (involved in regulation of chondro-

genesis) all showed very significant associations with OA. Since then, one major collaborative research group used the more powerful technique of genome-wide association studies.¹⁶ This group identified the gene which codes for asporin, an extracellular matrix protein, as being significant in OA. This was true as well for the gene coding for calmodulin, an intracellular regulator that has a large number of physiologic roles, including expression of the gene for type II collagen. In vitro functional studies accompanying these genetic studies provided additional evidence of the importance of these genetic findings in OA.

Rapid progress in identifying and understanding the contributions of genetic variation to the development of OA is being made. Especially for relatively common alleles coding for proteins that regulate cartilage function, there is exciting potential for new drugs that affect these regulatory proteins so as to prevent, mitigate, or treat OA.

PATHOPHYSIOLOGY

OA falls into two major etiologic classes. *Primary (idiopathic) OA*, the most common type, has no identifiable cause. Subclasses of primary OA are *localized OA*, involving one or two sites, and *generalized OA*, affecting three or more sites. *Erosive osteoarthritis* is used to describe the presence of erosion and marked proliferation in the proximal and distal interphalangeal joints of the hands. *Secondary OA* is that associated with a known cause such as rheumatoid or another inflammatory arthritis, trauma, metabolic or endocrine disorders, and congenital factors.^{3,4,17,18}

Although OA was previously considered a wear-and-tear disease, increased knowledge about articular cartilage physiology has led to a more dynamic understanding of OA. Some changes in the OA joint may reflect compensatory processes to maintain function in the face of ongoing joint destruction. Not only biomechanical forces, but also inflammatory, biochemical, and immunologic factors are involved.^{17–19} To aid in understanding the pathophysiology of OA, a brief review of the biochemistry and function of normal cartilage and of the diarthrodial joint is provided.

NORMAL CARTILAGE

Function, Structure, and Composition of Cartilage

Articular cartilage is a unique substance, with viscoelastic properties that provide lubrication with motion, shock absorbency during rapid movements, and load support. In synovial joints, articular cartilage is found between the synovial cavity on one side, and a narrow layer of calcified tissue overlying subchondral bone, on the other side (Fig. 95–2).²⁰ The layer of cartilage is narrow, with medial femoral articular cartilage being approximately 2 to 3 mm thick in humans. Despite this, healthy articular cartilage in weight-bearing joints withstands millions of cycles of loading and unloading each

year. Another key feature of cartilage is that it is almost frictionless; for example, in comparison to articular cartilage, Teflon produces 20 times as much friction (has a 20-fold higher coefficient of sliding friction).²¹ Articular cartilage is also far superior to artificial joints in regard to friction.⁹ Articular cartilage enables movement in the joint, distributes load across joint tissues to prevent damage, and stabilizes the joint. Cartilage is easily compressed, losing up to 40% of its original height when a load is applied. Compression increases the area of contact and disperses force more evenly to underlying bone, tendons, ligaments, and muscles.

The robustness of articular cartilage, its extremely low coefficient of friction, its compressibility, and other exceptional features are a function of its unique structure. Cartilage is comprised of a complex, hydrophilic, extracellular matrix. It is approximately 75% to 85% water, 2% to 5% chondrocytes (the only cells in cartilage), and contains collagen proteins, smaller amounts of several other proteins, proteoglycans, and long hyaluronic acid molecules.²⁰ The proteoglycans combine with long hyaluronic acid molecules to form large complexes, which are located within a meshwork of collagen fibers. Five types of collagen are located in cartilage, approximately 95% being type II collagen.

The collagen network supports and holds together the extracellular matrix in which proteoglycan–hyaluronic complexes are held and in which chondrocytes are embedded. Cross-linking of type II collagen fibrils with other matrix proteins also provides tensile strength to cartilage and maintains its volume and shape. It is due to the hydrophilic and anionic nature of the proteoglycan–hyaluronate complexes in the collagen network that cartilage possesses the viscoelastic properties required for resiliency and load bearing.

Collagens also contribute to the function of joint cartilage in other ways, with orientation of collagen fibers being critical: superficial fibers are parallel to the surface, reducing friction and allowing forces to be dissipated; basal layer collagen fibers are perpendicular to the surface to anchor cartilage to the calcified zone or subchondral bony end plate.¹⁷

It is not clear exactly how biomechanical signals, such as stress, strain, or cyclic loading and unloading during walking, translate into biochemical signals which affect chondrocyte metabolism and cartilage turnover. Regulation of chondrocyte function and cartilage metabolism is complex.^{17–19} Insulin-like growth factor, epidermal growth factor, fibroblast growth factor, and other agents enhance chondrocyte proliferation and proteoglycan synthesis. By contrast, interleukin-1 and tumor necrosis factor- α promote enzymes that degrade matrix proteins and suppress proteoglycan and collagen synthesis in the extracellular matrix. In healthy adult cartilage, as opposed to OA or during development, anabolic and catabolic influences are in homeostatic balance, resulting in a low metabolic rate and very slow turnover of cartilage.^{9,20,22,23}

Finally, it is important to note that adult articular cartilage is avascular, with chondrocytes nourished by synovial fluid. With movement and cyclic loading and unloading of joints, nutrients

FIGURE 95-2. Characteristics of osteoarthritis in the diarthrodial joint. (Courtesy of Dr. D. Gotlieb.)

flow into the cartilage, whereas immobilization reduces nutrient supply. This is one of the reasons that normal physical activity is beneficial for joint health.

OSTEOARTHRITIC CARTILAGE

3 Important contributors to the development of OA are local mechanical influences, genetic factors, inflammation, and aberrant chondrocyte function leading to loss of articular cartilage. At a molecular level, OA pathophysiology involves the interplay of dozens, if not hundreds, of extracellular and intracellular molecules with roles including chondrocyte regulation, proteolytic degradation of cartilage components, and interactions between articular cartilage, underlying subchondral bone, and the joint synovium.

OA most commonly begins with damage to articular cartilage, through trauma or other injury, excess joint loading from obesity or other reasons, or instability or injury of the joint that causes abnormal loading.¹⁵ Although normal cartilage is in a state of slow turnover (see Normal Cartilage section), damage to cartilage dramatically increases the metabolic activity of chondrocytes. This leads to increased synthesis of matrix constituents, with swelling of cartilage. This hypertrophic phase is thought to represent a reparative response to damage, stimulated by the peptide annexin, parathyroid hormone-related protein, and other effectors.⁹ This hypertrophic response, however, does not restore the cartilage to normal, but instead is the first step in a process ultimately leading to further loss of cartilage.

Following the hypertrophic phase, there is increased turnover (increased collagen synthesis and destruction), but with destruction outpacing formation, with net loss of cartilage. Key players in this destruction are the matrix metalloproteinases (MMPs), specifically MMPs 1, 3, 13, and 28.⁹ In normal cartilage, activities of these enzymes are blocked by tissue inhibitors of metalloproteinases. In OA cartilage, however, there is increased expression and synthesis of MMPs, resulting in the MMP–tissue inhibitors of metalloproteinase balance tilting toward proteolysis. In addition, chondrocytes contribute to loss, secreting MMPs in response to inflammatory mediators present in OA (interleukin-1 and tumor necrosis factor- α). Also, chondrocytes in OA cartilage undergo apoptosis, likely as a result of induction of nitric oxide synthase and production of toxic metabolites.^{15,20} This leaves fewer chondrocytes to synthesize matrix components. In addition, OA chondrocytes are hyporesponsive to the anabolic stimulus transforming growth factor- β .²⁰ The net result of all of these processes is that there is a progressive cycle of cartilage destruction and loss of chondrocytes.

In addition to changes taking place in OA cartilage, there is also a role in OA for the subchondral bone adjacent to articular cartilage. Subchondral bone undergoes pathologic changes that may precede, coincide with, or follow damage to the articular cartilage. This damage to subchondral bone may play an essential role in allowing damage to articular cartilage to progress.^{9,18,24,25} In OA, subchondral bone releases vasoactive peptides and MMPs. Neovascularization and subsequent increased permeability of the adjacent cartilage also occurs and contributes further to cartilage loss.^{18,25}

Substantial loss of cartilage causes joint space narrowing and leads to a painful, deformed joint. Furthermore, the remaining cartilage softens and develops fibrillations (vertical clefts into the cartilage), and there is splitting, further loss of cartilage, and exposure of underlying bone.²⁶ As cartilage is destroyed and the adjacent subchondral bone undergoes pathologic changes, cartilage is eroded completely, leaving denuded subchondral bone, which becomes dense, smooth, and glistening (eburnation). A more brittle, stiffer bone results, with decreased weight-bearing ability and development of sclerosis and microfractures. New bone formations, or osteophytes also appear at joint margins distant from cartilage

destruction, and are thought to arise from local and humoral factors. There is direct evidence that osteophytes can help stabilize osteoarthritic joints.²⁷

Accompanying the changes in cartilage and subchondral bone, local inflammatory changes and pathologic changes can occur in the joint capsule and synovium. Infiltration of the synovium with T cells with T-helper type 1 phenotype occurs, as well as the appearance of immune complexes.¹⁵ Contributors to this inflammation may include crystals or cartilage shards in synovial fluid. With increased levels of interleukin-1, prostaglandin E₂, tumor necrosis factor- α , and nitric oxide observed in synovial fluid, these agents could also play a role.²⁷ With inflammatory changes in the synovium, effusions and synovial thickening occur.

4 The pain of OA is not related to the destruction of cartilage, but arises from the activation of nociceptive nerve endings within the joint by mechanical and chemical irritants.³ OA pain may result from distension of the synovial capsule by increased joint fluid, microfracture, periosteal irritation, or damage to ligaments, synovium, or the meniscus.

CLINICAL PRESENTATION

CLINICAL PRESENTATION OF OSTEOARTHRITIS

General

- The patient may have mild symptoms for months to years prior to seeking medical care; self-treatment is common for mild symptoms.
- Typical age at presentation is usually >50 years.

Symptoms

- Nearly all patients have pain in the affected joints, with the hands, knees, and hips being the most common locations.
- Pain is most commonly associated with motion, but pain in late disease can occur with rest.
- Joint stiffness resolves with motion; recurs with rest.

Signs

- Joint stiffness with or without joint enlargement.
- Crepitus, a crackling or grating sound heard with joint movement that is caused by irregularity of joint surfaces may be present.
- Limited range of motion that may be accompanied by joint instability.
- Late-stage disease is associated with joint deformity (Fig. 95–3).

Laboratory Tests

- There are no specific laboratory tests useful in the diagnosis.

Other Radiologic Tests—Plain Radiographic Films

- Joint space narrowing, appearance of osteophytes in moderate disease (Fig. 95–4).
- Abnormal alignment of joints and joint effusion in late disease.

DIAGNOSIS

5 The diagnosis of OA is made through history, physical examination, characteristic radiographic findings, and laboratory testing.^{3,24} The major diagnostic goals are (a) to discriminate between primary and secondary OA, and (b) to clarify the joints involved, severity of joint involvement, and response to prior therapies, providing a basis for a treatment plan. The American College of Rheumatology has published traditional diagnostic criteria and also “decision trees” for OA diagnosis.²⁴ As for all guidelines, the authors stress these are for

FIGURE 95-3. Physical findings of joint enlargement and genu varum of the knees. (Courtesy of Dr. D. Gotlieb.)

assisting the clinician rather than replacing clinical judgment. For example, traditional criteria are as follows: (a) For hip OA, a patient must have pain in the hip and at least two of the following three: an erythrocyte sedimentation rate <20 mm/h, femoral or acetabular osteophytes on radiography, or joint space narrowing on radiography. This provides a sensitivity of 89% and a specificity of 91%. (b) For knee OA, a patient must have pain at the knee and osteophytes on radiography plus one of the following: age older than 50 years, morning stiffness no more than 30 minutes, crepitus on motion, bony enlargement, bony tenderness, or palpable warmth. This provides a sensitivity of 95% and a specificity of 69%. The addition of laboratory or radiographic data further improves accuracy of diagnosis. Criteria for hand OA have also been published.

PROGNOSIS

The prognosis for patients with primary OA is variable and depends on the joint involved. If a weight-bearing joint or the spine is involved, considerable morbidity and disability are possible. In the case of secondary OA, the prognosis depends on the underlying cause. Treatment of OA may relieve pain or improve function, but does not reverse preexisting damage to the articular cartilage.

TREATMENT

Osteoarthritis

■ DESIRED OUTCOME

Management of the patient with OA begins with a diagnosis based on a careful history, physical examination, radiographic findings, and an assessment of the extent of joint involvement. Treatment should be tailored to each individual. Goals are (a) to educate the patient, caregivers, and relatives; (b) to relieve pain and stiffness; (c) to maintain or improve joint mobility; (d) to limit functional impairment; and (e) to maintain or improve quality of life.^{7,28–31}

■ GENERAL APPROACH TO TREATMENT

Treatment for each OA patient depends on the distribution and severity of joint involvement, comorbid disease states, concomitant medications, and allergies (Fig. 95–5). Management for all individuals with OA should begin with patient education, and physical and/or occupational therapy, and weight loss or assistive devices if appropriate.^{7,28–33}

FIGURE 95-4. Plain x-ray films of the knee demonstrating joint space narrowing. (From Johnson BE. *Arthritis: Osteoarthritis, Gout and Rheumatoid Arthritis*. In: South-Paul JE, Matheny SC, Lewis EL, eds. *Current Diagnosis and Treatment in Family Medicine*. New York: McGraw-Hill, 2004, p. 267.)

The primary objective of medication is to alleviate pain.^{28–32} Scheduled acetaminophen, up to 4 g/day, should be tried initially. If this is ineffective, nonsteroidal antiinflammatory drugs (NSAIDs) are prescribed, or possibly a cyclooxygenase (COX)-2 selective inhibitor (celecoxib) if warranted. Application of capsaicin or methylsalicylate topical creams over specific joints can sometimes be helpful adjuncts for pain control. Glucosamine and chondroitin in combination can be helpful for those with moderate to severe arthritis. Joint aspiration followed by glucocorticoid or hyaluronate injection can relieve pain, and is offered concomitantly with oral analgesics or after their lack of efficacy, depending on the practitioner's style. Opioid analgesics are a final medication to prescribe if other therapies are unsuccessful. When symptoms are intractable or there is significant loss of function, joint replacement may be appropriate if the patient is a surgical candidate.

Finally, for patients interested in clinical trials, investigational strategies with oral doxycycline, matrix metalloproteinase inhibitors, disease-modifying osteoarthritis drugs, or cartilage transplantations may be considered.

For management of patients with OA, the Third Canadian Consensus Conference Group recently summarized evidence-based recommendations (Table 95–1).³⁴ As for all guidelines, these are for assisting the clinician rather than replacing the clinician's judgment based on the patient, other evidence, and other recommendations. The American College of Rheumatology recommends acetaminophen as the drug of first choice. In patients with risk factors for GI complications, selection of a nonselective NSAID plus a proton pump inhibitor, or a COX-2 selective inhibitor plus a proton pump inhibitor is supported by much recent evidence, as described in this chapter.

■ NONPHARMACOLOGIC THERAPY

6 The first step in OA treatment is patient education about the disease process, the extent of OA, the prognosis, and treatment options. Education is paramount, in that OA is often seen as a “wear-and-tear” disease, an inevitable consequence of aging for which nothing helps. Even worse, patients may resort to the use of alternative but unproven medications or quackery. Patients should be warned about these and encouraged to access information from local or national units of the Arthritis Foundation.³⁵ The Arthritis Foundation provides literature about OA and OA medications and information about local clinics and agencies offering physical and economic assistance. The Arthritis Foundation also sponsors support groups and public education programs.

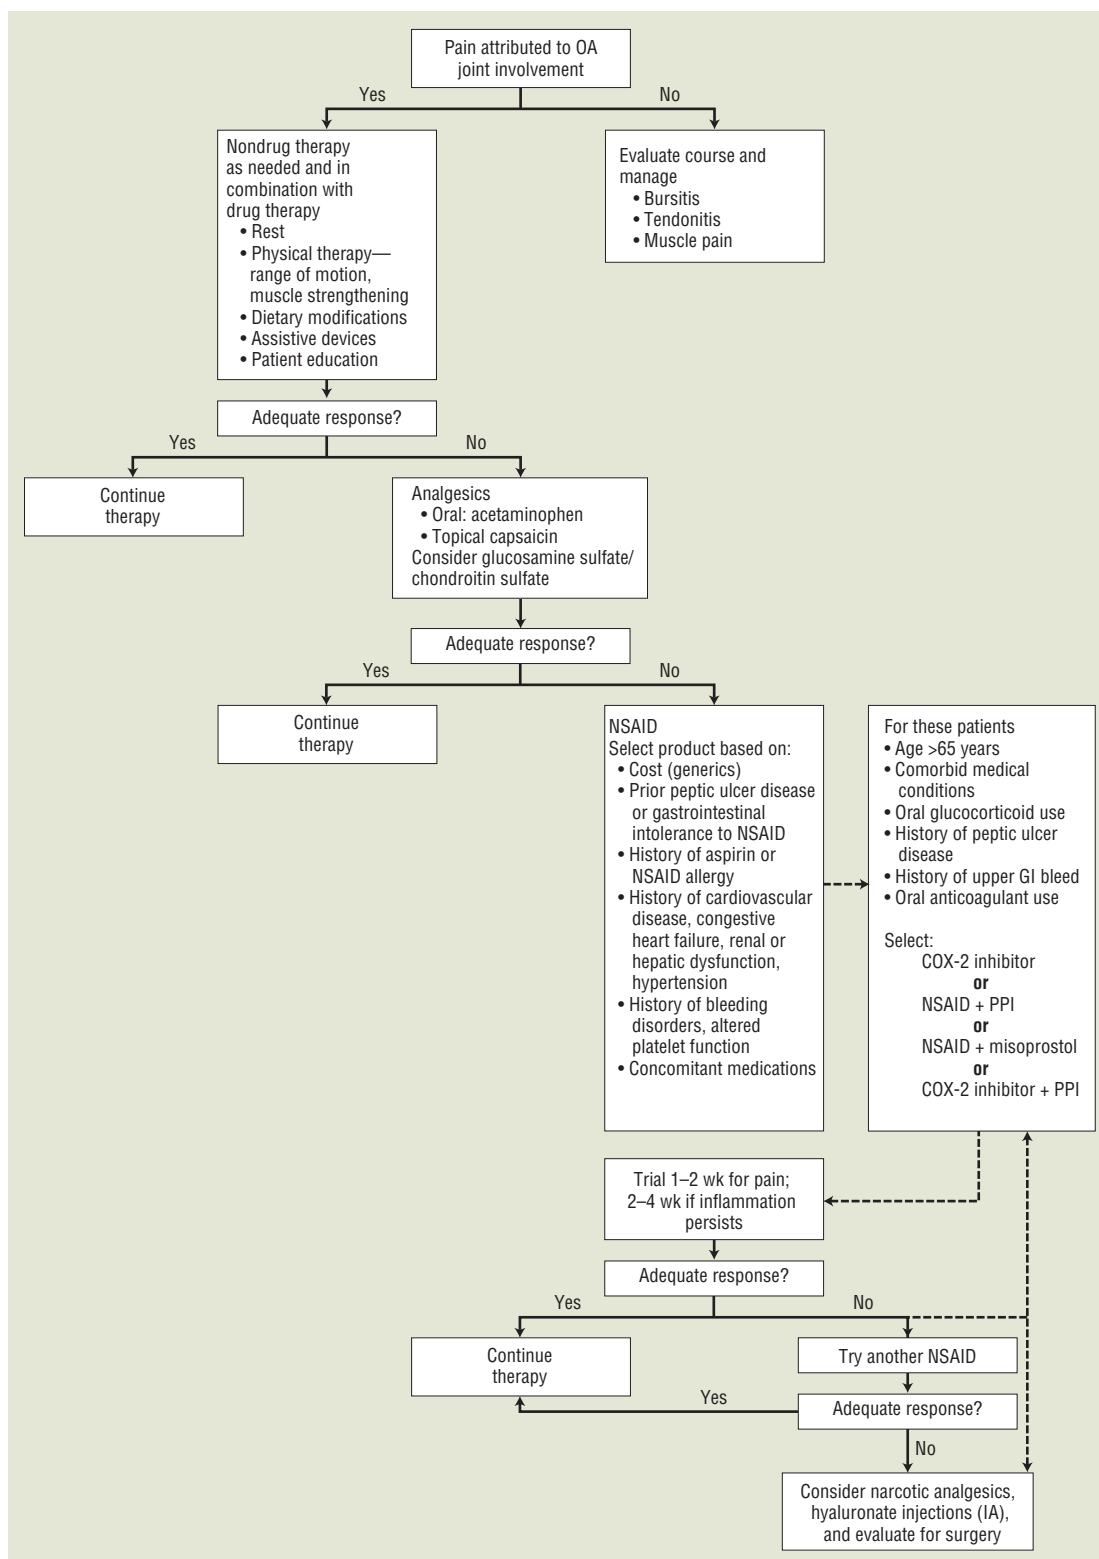

FIGURE 95-5. Treatment algorithm for osteoarthritis. (COX, cyclooxygenase; GI, gastrointestinal; IA, intraarticular; NSAID, nonsteroidal antiinflammatory drug; OA, osteoarthritis; PPI, proton pump inhibitor.)

The benefits of patient education have been documented in a variety of programs, including those using monthly telephone contact between trained volunteers and individuals with OA.² Volunteers speak with patients about symptoms, function, drugs, and clinic visits, resulting in improved pain and functional status at low cost. Likewise, OA patients participating in the program report decreases in joint pain and OA-related clinic visits, and improved physical activity and quality of life.

Diet

Excess weight increases the biomechanical load on weight-bearing joints and is the single best predictor of need for eventual joint replacement.^{4,8,33,36} Even a 5-kg weight loss can decrease the load on a weight-bearing joint. Weight loss is associated with decreased symptoms and disability, although results are variable.^{36,37} At least one randomized, controlled trial has demonstrated improvement in

TABLE 95-1 Summary of Recommendations for Osteoarthritis

Recommendation		Level of Evidence ^a	Grade of Recommendation ^b
1. Patient–physician communication	Patients should be fully informed about evolving information regarding the benefits and risks of their treatment options.	3	C
2. Indications	NSAIDs and coxibs are generally more effective and preferred by patients over acetaminophen, although a trial of the latter is warranted for some patients. Topical NSAID formulations may confer benefit in knee OA.	1	A
3. GI toxicity	In patients with risk factors for PUB, a coxib is still the antiinflammatory drug of choice, depending on the patient's cardiovascular risks. High-risk patients who must use nonselective NSAIDs should have a PPI.	1	A
4. Renal	Before starting an NSAID or coxib, determine renal status and creatinine clearance in patients older than 65 years and in those with comorbid conditions that may affect renal function. Advise patients that if they cannot eat or drink that day, they should withhold that day's dose of NSAID/coxib.	3	C
5. Hypertension	In patients receiving antihypertensive drugs, measure blood pressure within a few weeks after initiating NSAID/coxib therapy and monitor appropriately; drug doses may need adjustment.	4	D
6. Cardiovascular	Patients taking rofecoxib have been shown to have an increased risk of CV events. Current data suggest that this increased CV risk may be an effect of the NSAID/coxib class. Physicians and patients should weigh the benefits and risks of NSAID/coxib therapy.	1	A
7. Geriatric consideration	NSAIDs/coxibs should be used with caution in elderly patients, who are at the greatest risk for serious GI, renal, and CV side effects.	3	C
8. Pharmacoeconomics	Although the data are ambiguous, coxibs may be more cost-effective than traditional NSAID + proprietary PPI in high-risk patients.	3	C

CV, cardiovascular; GI, gastrointestinal; NSAID, nonsteroidal anti-inflammatory drug; OA, osteoarthritis; PPI, proton pump inhibitor; PUB, perforations, ulcers, and bleeds.

^aLevels of evidence: 1A, meta-analysis of randomized, controlled trial; 1B, at least one randomized, controlled trial; 2A, at least one controlled study without randomization; 3, descriptive studies, such as comparative, correlation, or case-control studies; 4, expert committee reports or opinions and/or clinical experience of respected authorities.

^bGrades of recommendation: A, Category 1 evidence; B, Category 2 evidence or extrapolated recommendation from Category 1 evidence; C, Category 3 evidence or extrapolated recommendation from Category 1 or 2 evidence; D, Category 4 evidence or extrapolated recommendation from Category 2 or 3 evidence.

pain and self-reported physical function using a combination of modest weight loss (5%) and exercise.³⁸ Although dietary intervention for overweight OA patients is reasonable, weight loss usually requires a motivated patient and a structured weight-loss program.

Physical and Occupational Therapy

Physical therapy—with heat or cold treatments and an exercise program—helps to maintain and restore joint range of motion and to reduce pain and muscle spasms. Warm baths or warm water soaks may decrease pain and stiffness. Heating pads should be used with caution, especially in the elderly. Patients should be warned not to fall asleep on the heat source or to lie on it for more than brief periods to avoid burns.

Exercise programs and quadriceps strengthening can improve physical functioning and can decrease disability, pain, and analgesic use by OA patients.^{2,38,39} Isometric exercise is preferred over isotonic exercise because the latter can aggravate affected joints. Exercises should be taught and then observed before the patient exercises at home, ideally three to four times daily. The patient should be instructed to decrease the number of repetitions if severe pain develops with exercise.

The decision about whether to encourage walking should be made on an individual basis. With weak or deconditioned muscles, the load is transmitted excessively to the joints, so weight-bearing activities can exacerbate symptoms. However, avoidance of activity by those with hip or knee OA leads to further deconditioning or weight gain. A program of patient education, muscle stretching and strengthening, and supervised walking can improve physical function and decrease pain in patients with knee OA.^{2,38,39} Referral to the physical and/or occupational therapist is especially helpful for patients with functional disabilities. The therapist can assess muscle strength and joint stability, and recommend exercises and methods of protecting the affected joint from excessive forces. The therapist can also provide assistive and orthotic devices, such as canes,

walkers, braces, heel cups, splints, or insoles for use during exercise or daily activities.

Surgery

Surgery can be recommended for OA patients with functional disability and/or severe pain unresponsive to conservative therapy. Criteria for total joint replacement (arthroplasty) of the knee were developed at an National Institutes of Health consensus conference.⁴⁰ Likewise, criteria for total hip replacement, as well as a summary of clinical outcomes resulting from this procedure have been published.⁴¹ These hip and knee replacement recommendations have been based on critical review of the literature as well as on expert opinion. For patients with advanced disease, a partial or total arthroplasty can relieve pain and improve motion, with the best outcomes after hip or knee arthroplasty.

Other surgical options are also available. Arthrodesis (joint fusion) can reduce pain but will restrict motion, and may be appropriate for smaller joints that are causing intractable pain. For patients with mild knee OA, an osteotomy (removal of bony tissue) may correct the misalignment of genu varum (“bowlegged” knees) or genu valgum (“knock-knees”). In addition, osteotomies of the pelvis or femur can ameliorate joint misalignment in hip OA, subsequently slowing progression of disease. Although knee arthroscopy or lavage have been recommended for short-term relief of pain, these procedures appear to be equivalent to sham surgery.³⁹ Experimental but potentially restorative approaches involve soft-tissue grafts, chondrocyte transplantation, gene therapy, and use of growth factors or artificial matrices.⁴² Cartilage-restoration approaches are investigational, and results regarding pain control and joint function have been mixed.

■ PHARMACOLOGIC THERAPY

Drug therapy in OA is targeted at relief of pain. OA is commonly seen in older individuals who have other medical conditions, and

OA treatment is often long-term. As such, a conservative approach to drug treatment, focusing on the needs of the individual patient, is warranted (see Fig. 95–5). For mild or moderate pain, topical analgesics or acetaminophen can be used. If these measures fail, or if there is inflammation, NSAIDs may be useful. Even when drug therapy is initiated, appropriate nondrug therapies should be continued and reinforced. Nondrug modalities are the cornerstone of OA management and may provide as much relief as drug therapy.

Acetaminophen

7 Place in Therapy The American College of Rheumatology recommends acetaminophen as first-line drug therapy for pain management in OA because of its relative safety, efficacy, and lower cost compared to NSAIDs.^{2,34,43} Pain relief with acetaminophen has been reported as similar to that obtained with aspirin, naproxen, ibuprofen, and other NSAIDs, although many patients respond better to NSAIDs.^{2,43,44} In addition to guidelines from the American College of Rheumatology, recommendations for OA management have been published by The European League Against Rheumatism, and a review of the evidence and suggestions for OA management have been formulated by rheumatology faculty in the Medical Research Council (UK) Environmental Epidemiology Unit.^{2,45,46} These guidelines stress the importance of acetaminophen as first-line drug therapy for OA.

Pharmacology and Mechanism of Action Acetaminophen is understood to act within the central nervous system by inhibiting synthesis of prostaglandins, agents that enhance pain sensations. Acetaminophen prevents prostaglandin synthesis by blocking the action of central cyclooxygenase. Acetaminophen is well absorbed after oral administration, with a bioavailability of 60% to 98%. It achieves peak concentrations within 1 to 2 hours, is inactivated in the liver by conjugation with sulfate or glucuronide, and its metabolites are renally excreted.

Efficacy Comparable relief of mild to moderate OA pain has been demonstrated for acetaminophen at 2.6 to 4 g/day, aspirin 650 mg four times daily, and NSAIDs, including ibuprofen at 1,200 or 2,400 mg daily, and naproxen 750 mg daily.^{2,43,47} Although studies have shown comparable efficacy for acetaminophen and NSAIDs, several others have reported that patients experience better pain control with NSAIDs than with acetaminophen.^{2,44,47} Patients with OA have been shown to prefer NSAIDs compared to acetaminophen in clinical trials, but when queried using a questionnaire that included considerations of side effects, NSAIDs were less preferred by patients.⁴⁸

Adverse Effects Although acetaminophen is one of the safest analgesics, its use carries some risks, primarily hepatotoxicity, and possibly renal toxicity with long-term use.^{2,7,43,49} With acetaminophen overdose, serious hepatotoxicity, including fatalities, have been well documented. (See Chap. 10 for treatment of acetaminophen overdose.) In a study of normal, healthy volunteers administered acetaminophen 4 g/day (1 g every 6 hours), alone or with concomitant opioid therapy, for 14 days, elevations of alanine aminotransferase at levels above three times the upper limits of normal were found in 31% to 44% of patients, depending on treatment group.⁵⁰ None of these participants had clinical symptoms of acute liver disease. Although the results of this study are not robust enough to alter the current standard dosing recommendations, it serves as an important reminder that the maximum dose of acetaminophen should be not be exceeded in any patient population, and that chronic use of even the maximum 4 g/day can affect the liver. Acetaminophen should be used cautiously in patients with liver disease or in those who abuse alcohol. Acute liver failure has been reported in patients taking less than 4 g/daily.⁵¹ The most common risk factor for liver failure in these patients was chronic alcohol intake. The FDA has recom-

mended that chronic alcohol users (three or more drinks daily) should be warned regarding an increased risk of liver damage or GI bleeding with acetaminophen. Other individuals do not appear to be at increased risk of GI bleeding.

The National Kidney Foundation strongly discourages the use of nonprescription combination analgesic products (e.g., acetaminophen and NSAIDs) because this is associated with an increased prevalence of renal failure.⁴⁹ Finally, patients should be warned about potential toxicity if they inadvertently ingest more than the recommended dose when using both nonprescription and prescription products containing acetaminophen.

Recent prospective cohort studies in women and in men have suggested that regular long-term use of acetaminophen is associated with development of hypertension, although the risk appears less for men.^{52,53} However, these studies were not designed to evaluate the effects of analgesics on the risk of developing hypertension, but were part of the Nurses' Health Study and Physicians' Health Study. Furthermore, patients taking analgesics for OA or other pain may have other risk factors for the development of hypertension, including advanced age, uncontrolled pain, use of other medications, obesity, and comorbid medical illness. Prospectively designed trials are needed to determine if the risk of developing hypertension is definitively linked to analgesic use, including acetaminophen.

Drug–Drug Interactions and Drug–Food Interactions Drug interactions with acetaminophen can occur; for example, isoniazid can increase the risk of hepatotoxicity. Chronic ingestion of maximal doses of acetaminophen may intensify the anticoagulant effect in patients taking warfarin; such individuals may need closer monitoring. Although food decreases the maximum serum concentration of acetaminophen by approximately half, the overall efficacy is unchanged.

Dosing and Administration When used for chronic OA, acetaminophen should be administered in a scheduled manner. It may be taken with or without food. Acetaminophen can be taken at 325 to 650 mg every 4 to 6 hours, but total dose must not exceed 4 g daily (see Adverse Effects above). If acetaminophen is used in the setting of chronic alcohol intake or in those with underlying disease, the duration should be limited and the dose should not exceed 2 g daily.

Nonsteroidal Antiinflammatory Drugs

Place in Therapy The American College of Rheumatology recommends consideration of NSAIDs for OA patients in whom acetaminophen is ineffective. NSAIDs have analgesic properties at lower doses and antiinflammatory effects at higher doses. NSAIDs all display comparable analgesic and antiinflammatory efficacy and are similarly beneficial in OA (Table 95–2).^{54,55}

Pharmacology and Mechanism of Action Blockade of prostaglandin synthesis by inhibiting cyclooxygenase enzymes (COX-1 and COX-2) is thought to account for the ability of NSAIDs to relieve pain and inflammation (Fig. 95–6).^{47,55–57} Because nonspecific NSAIDs and COX-2 selective inhibitors have similar efficacy, drug selection often depends on toxicity and cost. Increasing concern regarding safety of all NSAIDs, and particularly COX-2 selective inhibitors, has made patient safety paramount in drug selection. The next section will review the differences between nonspecific NSAIDs and COX-2 selective inhibitors.^{47,55–57}

Nonspecific NSAIDs and COX-2 Selective Inhibitors The COX-1 enzyme participates in “housekeeping” or routine physiologic functions such as generation of gastroprotective prostaglandins to promote gastric blood flow and bicarbonate generation (see Fig. 95–6).^{47,55–57} COX-1 is expressed constitutively not only in gastric mucosa, but also in vascular endothelial cells, platelets, and renal collecting tubules, so that COX-1–generated prostaglandins and

TABLE 95-2 Medications Commonly Used in the Treatment of Osteoarthritis

Medication	Dosage and Frequency	Maximum Dosage (mg/day)
Oral analgesics		
Acetaminophen	325–650 mg every 4–6 hours or 1 g three to four times/day	4,000
Tramadol	50–100 mg every 4–6 hours	400
Acetaminophen/codeine	300–1,000 mg/15–60 mg every 4 hours as needed	4,000 mg/360 mg ^a
Acetaminophen/oxycodone	325–650 mg/2.5–10 mg every 6 hours as needed	4,000 mg/40 mg ^a
Topical analgesics		
Capsaicin 0.025% or 0.075%	Apply to affected joint 3–4 times per day	—
Nutritional supplements		
Glucosamine HCl/chondroitin sulfate	500 mg/400 mg three times/day	1,500/1,200
Nonsteroidal antiinflammatory drugs (NSAIDs)		
Carboxylic acids		
Acetylated salicylates		
Aspirin, plain, buffered, or enteric-coated	325–650 mg every 4–6 hours for pain; antiinflammatory doses start at 3,600 mg/day in divided doses	3,600 ^b
Nonacetylated salicylates		
Salsalate	500–1,000 mg two to three times a day	3,000 ^b
Diflunisal	500–1,000 mg two times a day	1,500
Choline salicylate ^c	500–1,000 mg two to three times a day	3,000 ^c
Choline magnesium salicylate	500–1,000 mg two to three times a day	3,000 ^c
Acetic acids		
Etodolac	800–1,200 mg/day in divided doses	1,200
Diclofenac	100–150 mg/day in divided doses	200
Indomethacin	25 mg two to three times a day; 75 mg SR once daily	200; 150
Ketorolac ^d	10 mg every 4–6 hours	40
Nabumetone ^e	500–1,000 mg one to two times a day	2,000
Propionic acids		
Fenoprofen	300–600 mg three to four times a day	3,200
Flurbiprofen	200–300 mg/day in two to four divided doses	300
Ibuprofen	1,200–3,200 mg/day in three to four divided doses	3,200
Ketoprofen	150–300 mg/day in three to four divided doses	300
Naproxen	250–500 mg twice a day	1,500
Naproxen sodium	275–550 mg twice a day	1,375
Oxaprozin	600–1,200 mg daily	1,800
Fenamates		
Meclofenamate	200–400 mg/day in three to four divided doses	400
Mefenamic acid ^f	250 mg every 6 hours	1,000
Oxicams		
Piroxicam	10–20 mg daily	20
Meloxicam	7.5 mg daily	15
Coxibs		
Celecoxib	100 mg twice daily or 200 mg daily	200 (400 for RA)

RA, rheumatoid arthritis; SR, sustained release.

^aMaximum dosage in combination product limited by acetaminophen maximum of 4,000 mg/day.

^bMonitor serum salicylate levels over 3–3.6 g/day.

^cOnly available as a liquid; 870 mg salicylate/5 mL.

^dNot approved for treatment of osteoarthritis for more than 5 days.

^eNonorganic acid but metabolite is an acetic acid.

^fNot approved for treatment of osteoarthritis.

thromboxane also participate in hemostasis and renal blood flow. In contrast, the COX-2 enzyme is not as widely expressed in most body tissues, but is rapidly induced by inflammatory mediators, local injury, and cytokines, including interleukins, interferon, and tumor necrosis factor (see Fig. 95–6).^{47,55–57} Prostaglandins made by COX-2 contribute to pain sensations in OA and other conditions. Prostaglandins made by the COX-2 enzyme, including prostacyclin (prostaglandin I₂) are also implicated in some physiologic processes, including renal function, tissue repair, reproduction, and development.

Nonspecific NSAIDs block both COX-1 and COX-2 enzymes. In view of the above roles of the COX enzymes, COX-1 blockade that occurs with nonspecific NSAIDs is potentially undesirable and can lead to GI ulcers and increased bleeding risk by inhibiting platelet aggregation.^{47,55–58} Specific blockade of COX-2 activity could thus reduce prostaglandins, inflammation, and pain, without blocking effects of COX-1. This desirable quality led to development of specific COX-2 selective agents (“coxibs”). These agents are efficacious in relieving OA and other pain and some do have improved GI safety.

Celecoxib and rofecoxib were the first two COX-2 selective agents marketed and have been widely used for pain relief in OA and other conditions.

It is now appreciated that the COX-2 enzyme may play an important physiologic role in normal hemostasis. The COX-2 enzyme, found in blood vessel endothelial cells, leads to production of prostaglandin I₂ (prostacyclin), which has antithrombotic effects. The COX-1 found in platelets forms thromboxane A₂ a prothrombotic molecule. As far back as 1999, and continuing today, some researchers postulate that blocking COX-2 alone could upset the hemostatic balance, in favor of thromboxane A₂, with prothrombotic events possible.^{57,59} Although this explanation is plausible and is appealing in its simplicity, it has not been proven. Thus, whether the “prothrombotic imbalance” explanation accounts for the increased cardiovascular risk seen with COX-2 selective inhibitors is unknown.^{57,59,60}

Rofecoxib was withdrawn from the market in 2004 because of increased cardiovascular events, and celecoxib is less often used now and carries a black box warning for cardiovascular and GI risks, as

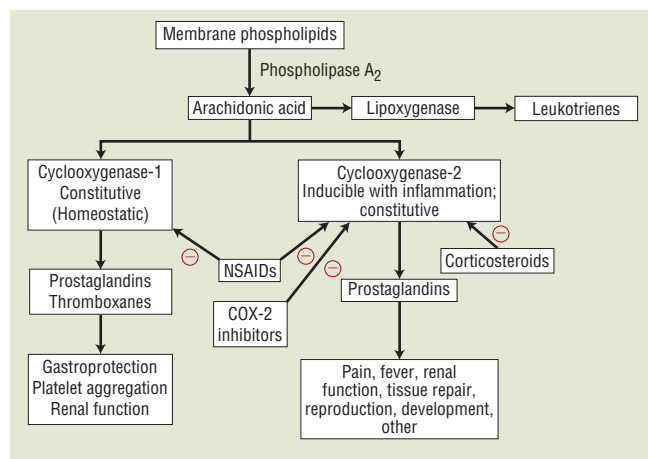

FIGURE 95-6. Pathway of synthesis for prostaglandins and leukotrienes. COX-1 and COX-2 are cyclooxygenase 1 and 2 enzymes. The minus (–) sign indicates inhibitory influence. Prostaglandins include PGE₂ and PGI₂, the latter also known as prostacyclin.

do other NSAIDs at this time. Although new coxibs are in development and some are in use in Canada and Europe, celecoxib is the only remaining coxib available in the United States.

Pharmacokinetics The various NSAIDs exhibit several pharmacokinetic similarities, including high oral availability, high protein binding, and absorption as active drugs (except for sulindac and nabumetone, which require hepatic conversion for activity). The most important difference in NSAIDs is a serum half-life ranging from 1 hour for tolmetin to 50 hours for piroxicam, impacting the frequency of dosing and, potentially, compliance with therapy.⁴⁷ Elimination of NSAIDs largely depends on hepatic inactivation, with a small fraction of active drug being renally excreted. NSAIDs penetrate joint fluid, reaching approximately 60% of blood levels.⁴⁷

Efficacy Prescription-strength NSAIDs are often prescribed for OA patients after treatment with acetaminophen proves ineffective or for patients with inflammatory OA.⁶¹ All NSAIDs and aspirin have similar analgesic and antiinflammatory effects, but these agents are only modestly more effective than acetaminophen.^{34,47,54,61,62} In evaluating efficacy in OA studies, commonly used end points include pain on the visual analog scale (0 to 100), and the patient's global assessment of disease activity and functional status, assessed using the Western Ontario and McMaster Universities Osteoarthritis Index questionnaire.⁶³ Because of differences among study designs and patient populations, comparisons between efficacies of treatments are best made within the same study.

A systematic review of studies of NSAIDs for OA found no evidence to support a definitive ranking of NSAID efficacy.⁶² However, individual patient response does differ among NSAIDs. The prescriber often relies on personal experience in choosing an NSAID. To assess efficacy in the individual patient, a trial that is adequate in time (2 to 3 weeks) and dose is needed. If the first trial fails, another NSAID in the same or another chemical class can be tried until an effective agent is found (see Table 95–2).^{34,47,54,61,62} Patients must understand this approach, appreciate the necessity of adherence to medication therapy throughout this trial period, and actively participate in assessment of drug efficacy. Combining two NSAIDs increases adverse effects without providing additional benefit.

COX-2 selective inhibitors demonstrate similar analgesic benefits to traditional NSAIDs and to each other.⁶⁴ Newer COX-2 selective inhibitors in development have also shown similar efficacy to traditional NSAIDs. Lumiracoxib 100 to 400 mg/day^{65–67} and etoricoxib 30 to 90 mg/day^{68–70} provided significant relief in OA compared to placebo and showed efficacy similar to other comparator

NSAIDs (ibuprofen 2,400 mg/day, naproxen 1,000 mg/day, or diclofenac 150 mg/day). The newer COX-2 selective inhibitors have also been compared to older COX-2 selective inhibitors: Etoricoxib 30 mg/day and celecoxib 200 mg/day were similarly efficacious in OA and superior to placebo.⁷¹ Lumiracoxib 100 to 200 mg/day was similarly efficacious as celecoxib 200 mg/day in treating OA.^{65,66,72}

Given that no proven efficacy differences exist among all traditional and COX-2 selective NSAIDs in OA, it is especially important that potential toxicities of these agents be rigorously examined. These safety issues are reviewed below.

8 Adverse Effects

Gastrointestinal Effects of Nonselective NSAIDs. The most common adverse effects of NSAIDs involve the GI tract, contributing to many treatment failures.⁵⁵ Minor complaints—nausea, dyspepsia, anorexia, abdominal pain, flatulence, and diarrhea—affect 10% to 60% of patients. To minimize these symptoms, NSAIDs should be taken with food or milk, except for enteric-coated products, which should *not* be taken with milk or antacids.

All NSAIDs have the potential to cause GI bleeding.⁵⁵ Un-ionized NSAIDs enter gastric mucosal cells, release hydrogen ions, and are concentrated (“ion trapped”) within cells, with cell death or damage. Gastric mucosal injury can also result from NSAID inhibition of gastroprotective prostaglandins.

The most common sites of GI injury are the gastric and duodenal mucosae.⁵⁵ The incidence of gastric ulcers with NSAID use is approximately 11% to 13%, and that for duodenal ulcers is 7% to 10%. Serious GI complications are associated with NSAIDs, including perforations, gastric outlet obstruction, and bleeding. These important GI complications occur in 1.5% to 4% of patients per year. NSAIDs are so widely used that these small percentages translate into substantial morbidity and mortality.^{2,55} Moreover, the risk increases to 9% per year for patients with the risk factors of advanced age, history of peptic ulcer or GI bleeding, or cardiovascular disease. Consequently, about 16,500 deaths are associated annually with NSAID use in rheumatoid arthritis or OA patients. A recent review that included a total of 1.3 million patients taking traditional NSAIDs for at least 2 months showed that 1 in 5 developed endoscopically evident ulcers, 1 in 70 had ulcer symptoms, 1 in 150 developed a GI tract perforation, and 1 in 1,200 died.³⁴

A key part of the clinician's decision regarding starting NSAID therapy for an OA patient is the patient's risk for GI toxicity. Increased GI risk is seen for those with a history of complicated ulcer (relative risk [RR] 13.5), use of multiple NSAIDs, including aspirin (RR = 9), use of high-dose NSAID (RR = 7), use of anticoagulant (RR = 6.4), age older than 70 years (RR = 5.6), and concomitant use of corticosteroids (RR = 2.2).³⁴

For patients taking NSAIDs, there is a poor correlation between GI ulceration and GI symptoms. The American College of Rheumatology recommends a complete blood count yearly to detect a silent bleeding ulcer characterized by an asymptomatic decline in hematocrit.⁷³ Fecal occult blood is an unreliable predictor of complications.

Medications are available for the treatment or prevention of ulcers in high-risk patients.^{2,74} Misoprostol protects against both gastric and duodenal NSAID-induced ulcers, and more importantly, their associated serious GI complications (perforations, gastric outlet obstruction, and bleeding).⁷⁴ Unfortunately, misoprostol frequently causes diarrhea and abdominal cramps. Because of its abortifacient properties, misoprostol is contraindicated in pregnancy and in women of childbearing age who are not maintaining adequate contraception. It must be dispensed in its original container, which carries a warning for these individuals. Misoprostol is also available in a combination product with diclofenac, which bears the same restrictions as misoprostol alone.

Other agents have been evaluated in attempts to prevent NSAID-induced gastropathy. Proton pump inhibitors (PPIs) appear to be

effective, although neither sucralfate or H_2 antagonists have been shown to be protective. In a recent meta-analysis that included 156 studies, misoprostol, COX-2 selective NSAIDs, and probably PPIs, were judged to significantly reduce the risk of symptomatic ulcers. Further work is required to strengthen the case for PPI's ability to reduce the risk of serious NSAID-induced GI complications. A new randomized, controlled trial has lent weight to this idea by showing that for persons who have experienced a prior GI bleed, the combination of a PPI with celecoxib substantially decreased the risk of future bleeding ulcers compared to celecoxib alone.⁷⁵

At present, use of either a COX-2 selective inhibitor, or an NSAID in combination with either a proton pump inhibitor or misoprostol is recommended for treatment of OA patients who are at high risk for GI complications by OA authorities in the United States, Canada, and Europe.^{24,34,45}

Gastrointestinal Effects of COX-2 Selective Inhibitors. Celecoxib, rofecoxib, and all COX-2 selective inhibitors studied to date have demonstrated fewer endoscopically observed ulcers compared to traditional NSAIDs. Such ulcers are relatively common with NSAIDs and are often asymptomatic. Data regarding the rare but serious GI complications of perforation, obstruction, or bleeding are more difficult to obtain as very large numbers of patients are required for such studies.

To evaluate the risk of serious GI complications with celecoxib, Celecoxib Long-term Arthritis Safety Study (CLASS) investigators used celecoxib (400 mg twice daily, or twice the highest FDA-approved dose) compared to diclofenac and ibuprofen at standard dose. Celecoxib use was reported to be associated with a reduced incidence for the combined end point of symptomatic ulcers and ulcer complications (perforations, gastric outlet obstruction, or bleeding) after 6 months.⁷⁶ However, this difference was not seen at 1 year and was not seen in patients taking aspirin. Furthermore, there was no reduction in the category of "perforations, gastric outlet obstruction, or bleeding" itself, but only if "symptomatic ulcers" were also included. Concerns have been raised by the FDA, which concluded that although there were trends favoring celecoxib, this drug did not show clear statistical superiority over nonspecific NSAIDs for clinically significant upper GI events.

In celecoxib's favor, its use was associated with decreased outpatient physician claims for upper GI symptoms compared with other prescription nonspecific NSAIDs. Celecoxib was also comparable to a combination of diclofenac and misoprostol in reducing the risk of recurrent GI bleeding in patients who had a prior GI bleed.⁷⁷ Celecoxib remains on the market and is an alternative to traditional NSAIDs for those at high risk for GI toxicity.

GI safety for rofecoxib was evaluated in the Vioxx Gastrointestinal Outcomes Research (VIGOR) study, where patients were randomized to receive rofecoxib 50 mg daily or naproxen 500 mg twice daily; use of concomitant aspirin was prohibited. Those randomized to rofecoxib experienced a 50% lower risk of serious GI events.⁷⁸ These findings led to its approval by the FDA, but rofecoxib was withdrawn from the worldwide market in 2004 because of increased risk of cardiovascular events, as discussed in Cardiovascular Inhibitors: Traditional NSAIDs section.

Lumiracoxib was evaluated in the Therapeutic Arthritis Research and Gastrointestinal Event Trial (TARGET), in which more than 18,000 patients were randomized to lumiracoxib 400 mg/day compared to naproxen 1,000 mg/day or ibuprofen 2,400 mg/day.⁷⁹ With lumiracoxib, there was a significant reduction in the risk of serious GI events (perforation, gastric outlet obstruction, bleeding) compared to naproxen (hazard ratio 0.34 [0.22 to 0.52], $P < 0.0001$ overall; hazard ratio 0.21 [95% confidence interval (CI) 0.12 to 0.37], $P < 0.0001$ in those not taking aspirin). However, in those taking aspirin, there was no difference in risk. Lumiracoxib is currently approved for use in Canada and the United Kingdom and is awaiting FDA approval.

Etoricoxib was evaluated in the Multinational Etoricoxib and Diclofenac Arthritis Long-term Program (MEDAL) study, in which more than 34,000 patients were randomized to etoricoxib 60 to 90 mg/day compared to diclofenac 150 mg/day.⁸⁰ With etoricoxib, there was a significant reduction in the risk of *clinical* GI events (perforation, gastric outlet obstruction, ulcers, bleeding) compared to diclofenac (hazard ratio 0.69, 95% CI 0.57 to 0.83; $P = 0.0001$). However, there was no advantage for etoricoxib when complicated GI events alone (perforation, gastric outlet obstruction, bleeding) were evaluated (hazard ratio 0.91, CI 0.67 to 1.24; $P = 0.561$). The interpretation was that there were significantly fewer upper gastrointestinal clinical events with etoricoxib than with diclofenac because of a decrease in uncomplicated events, but not in the more serious complicated events. Although etoricoxib is currently sold in 63 countries in Europe, Latin America, the Asia-Pacific region, and Middle East/North Africa, this drug received an FDA nonapproval letter on May 1, 2007. The FDA indicated further data was necessary to demonstrate a favorable risk-to-benefit ratio.

In summary, there is variable evidence that COX-2 inhibitors pose a decreased risk of GI toxicity compared to nonspecific NSAIDs, an especially important consideration when treating those at risk for clinically significant GI adverse effects. Proof that all COX-2 inhibitors are equally GI safe is lacking; this may reflect intrinsic differences among agents, or be a result of differences in study design, patient population, or concomitant medication use. Trends favor the GI safety of celecoxib, although GI complications were not convincingly decreased compared to traditional NSAIDs. Rofecoxib (since withdrawn) did decrease clinically significant GI complications. Lumiracoxib significantly decreases the risk of serious GI complications, although aspirin negates this advantage. Etoricoxib demonstrated some gastroprotection, but was not proven to decrease the number of serious GI complications (perforation, gastric outlet obstruction, and bleeding).

9 Cardiovascular Risk of COX-2 Inhibitors and Traditional NSAIDs.

In 2004, rofecoxib was withdrawn from the market after analysis of the Adenomatous Polyp Prevention on Vioxx (APPROVe) trial, where rofecoxib appeared to double the risk of cardiovascular events compared to placebo.⁸¹ Further concern about COX-2 selective inhibitors was raised when celecoxib use in the Adenoma Prevention with Celecoxib (APC) trial also increased cardiovascular risk.⁸² These observations raised questions about the cardiovascular safety of all COX-2 selective NSAIDs, and even about traditional NSAIDs. These concerns have triggered new FDA regulations and new labeling on all NSAIDs and have prompted meta-analyses of randomized controlled trials of COX-2 selective inhibitors and of NSAIDs.⁸³ Case control and cohort studies of patients using these agents have also examined cardiovascular risks involved with their use. As of this writing, much remains to be defined about these risks, regarding class effects, effect of dose and duration, and the population studied, but certain trends have taken shape.

The increased cardiovascular risk posed by rofecoxib was clearly demonstrated in the APPROVe trial, and the VIGOR trial also showed this risk.³⁴ For celecoxib, other data on cardiovascular risk, especially when used at the approved OA dose, is much less certain. The CLASS trial showed a small but not significantly increased risk. As noted above, the APC study did show increased risk, but this was for doses greater than 400 mg daily. The Prevention of Spontaneous Polyps (PreSAP) study, with celecoxib used at 400 mg/day, and the Alzheimer's Disease Antiinflammatory Prevention Trial (ADAPT) study, using 200 mg twice daily, did not show increased cardiovascular risk. More recently, in a meta-analysis of randomized trials including more than 100,000 patients, rofecoxib was shown to increase risk of arrhythmias, relative to placebo and to other NSAIDs, and also in comparison to celecoxib, which did not significantly increase arrhythmias.⁸⁴ Taken as a whole, these data suggested that although there might be a "class effect" of

coxibs (celecoxib and rofecoxib both posing risk), that this risk existed for rofecoxib at any dose, but to celecoxib when used at higher doses.³⁴

The cardiovascular safety of lumiracoxib was evaluated in the Therapeutic Arthritis Research and Gastrointestinal Event Trial (TARGET) study.⁸⁵ In this study of more than 18,000 patients, cardiovascular risk showed a nonsignificant increase relative to ibuprofen (but no increase relative to naproxen), and this increase was only seen in those not taking aspirin. One potential drawback to this study is that cardiovascular events were low (59 for lumiracoxib, 50 for ibuprofen). The cardiovascular safety of etoricoxib was evaluated in the MEDAL study.⁸⁶ In this study, more than 34,000 subjects were randomly assigned to etoricoxib (60 mg or 90 mg daily) or diclofenac (150 mg daily). Very similar rates for thrombotic cardiovascular events occurred for the etoricoxib group and for the diclofenac group (event rates of 1.24 and 1.30 per 100 patient-years, respectively, with a hazard ratio of 0.95 [95% CI 0.81 to 1.11]) for etoricoxib compared with diclofenac. The number of events in each arm was more than 300, which lends reassurance to the results. Despite these clear results, some investigators have indicated that diclofenac, having some COX-2 selectivity (almost as selective as celecoxib) should not be used as the comparator drug. Ibuprofen or naproxen are nonselective and may be better comparator drugs for determining if a COX-2 selective inhibitor possesses risk relative to nonspecific NSAIDs. Although the TARGET study for lumiracoxib and the MEDAL study for etoricoxib are somewhat reassuring, given the study limitations, further confirmation of their cardiovascular safety would be welcome.

In addition to controlled trials, analysis of cohort or case control studies can also contribute to information about risk, but such studies have confounders and do not necessarily produce consistent findings. Some studies have shown increased risk for coxibs and for nonspecific NSAIDs. Recently, in a systematic review of observational studies of COX-2 inhibitors and traditional NSAIDs, including an approximate 1 million patients, risk for cardiovascular events were calculated in comparison to nonusers or those with remote use of NSAIDs.⁸⁷ The summary relative risk was 1.33 (95% CI 1.00 to 1.79) for rofecoxib 25 mg/day, and 2.19 (95% CI 1.64 to 2.91) with more than 25 mg/day, with risk apparent within the first month of treatment. Celecoxib summary relative risk was 1.06 (95% CI 0.91 to 1.23) (but without enough information to dose stratify). Other summary relative risks were also reassuring, with naproxen at 0.97 (95% CI 0.87 to 1.07), piroxicam at 1.06 (95% CI 0.70 to 1.59), and ibuprofen at 1.07 (95% CI 0.97 to 1.18). Diclofenac, however, showed an increased summary relative risk of 1.40 (CI 1.16 to 1.70), which is concerning.⁸⁷

Taken together, the above data, both from controlled trials and from observational studies, confirm the increased cardiovascular risk seen with rofecoxib. Celecoxib 200 mg/day or even 400 mg/day does not appear to increase risk, but cardiovascular risk is likely increased with doses above 400 mg/day. Although studies with lumiracoxib and etoricoxib are somewhat reassuring and do not point to substantially increased cardiovascular risk, further work is needed on this issue. The balance of the evidence also suggests that, for the traditional NSAIDs which have been examined, with the exception of diclofenac, there is no significant or substantial increase in risk.⁶

CLINICAL CONTROVERSY

Controversy has arisen regarding both the gastroprotective effects of COX-2 selective inhibitors and the cardiovascular risk they may pose. Are all COX-2 selective inhibitors GI protective? Do they all pose cardiovascular risk? Is there a relationship between these two features for different coxibs? Although both rofecoxib and celecoxib are COX-2 selective inhibitors, rofecoxib demonstrated more robust reduction in GI complications. However, rofecoxib posed *greater* cardiovascular risk than celecoxib.

These differences may depend on the degree of selectivity of specific COX-2 inhibitors for COX-2 versus COX-1 enzymes. COX-2 selectivity is relative: Some traditional NSAIDs, such as diclofenac, possess some COX-2 selectivity, and even among the formally labeled COX-2 inhibitors, COX-2 selectivity varies. Interestingly, rofecoxib is more COX-2 selective than celecoxib. It is possible that rofecoxib's greater selectivity is responsible both for better GI protection *and* for increased cardiovascular risk. Such a connection is plausible, given the effects of COX-1 and COX-2 enzymes on the formation of thromboxane A₂ and prostacyclin. A highly selective COX-2 inhibitor may tilt the balance in favor of thromboxane A₂, thus promoting platelet aggregation (beneficial for preventing GI bleeds, but posing a prothrombotic risk to the cardiovascular system).

Several other COX-2 selective inhibitors are in development, and two key issues will be their degree of gastroprotection and what, if any, cardiovascular risk they pose. Further study will be needed to determine if one or more of these agents will be safe for the cardiovascular system and also gastroprotective, or whether the degree of gastroprotection is inextricably linked to the extent of cardiovascular risk for all COX-2 selective inhibitors.

Considerations for Patients at Risk for Both GI and Cardiovascular Events.

For those without increased GI or cardiovascular risk, a nonspecific NSAID is reasonable. For patients with elevated GI risk or cardiovascular risk who need treatment with an NSAID, careful consideration of risk and benefit is warranted.³⁴ Recommendations for those with increased GI risk but not on aspirin include consideration of a COX-2 selective inhibitor or a traditional NSAID taken with a PPI. For those taking regular low-dose aspirin for cardiovascular risk (with or without increased GI risk), a traditional NSAID taken with a PPI, or a COX-2 selective inhibitor taken with a PPI can be considered. Given the current concerns regarding cardiovascular risk with COX-2 selective inhibitors or possibly any NSAIDs, and continuing concern about GI events, treatment with the lowest dose possible for the shortest duration possible is warranted.

10 Other Toxicities Associated with NSAIDs. NSAIDs may cause kidney diseases, including acute renal insufficiency, tubulointerstitial nephropathy, hyperkalemia, and renal papillary necrosis.⁸⁸ Clinical features of these NSAID-induced renal syndromes include increased serum creatinine and blood urea nitrogen, hyperkalemia, elevated blood pressure, peripheral edema, and weight gain. Mechanisms of NSAID injury include direct toxicity, and inhibition of local prostaglandins that promote vasodilation of renal blood vessels and preserve renal blood flow. Patients at high risk are those with conditions associated with decreased renal blood flow or taking certain medications. Examples are those with chronic renal insufficiency, congestive heart failure, severe hepatic disease, nephrotic syndrome, advanced age, or taking diuretics, angiotensin-converting enzyme inhibitors, cyclosporine, or aminoglycosides (Fig. 95–7).

Close monitoring is advisable for high-risk patients taking an NSAID, with monitoring of serum creatinine at baseline and within 3 to 7 days of drug initiation. For those with impaired renal function, the National Kidney Foundation recommends acetaminophen as the drug of choice.⁴⁹

Coxibs can also pose renal risks, and there is neither evidence nor rationale why this class of drugs would be safer than nonspecific NSAIDs. In a meta-analysis of randomized trials of NSAIDs including more than 100,000 patients, rofecoxib was shown to significantly increase risk of renal toxicity in comparison to placebo, celecoxib, and nonspecific NSAIDs.⁸⁴ Although rofecoxib is now off the market, this study provides an important caution as new coxibs are approved: renal safety of coxibs may differ substantially. Keeping in mind that many OA patients may not be as healthy as trial participants, it is prudent to prescribe all coxibs and other NSAIDs with caution in patients who are at increased risk for renal dysfunction.⁸⁹

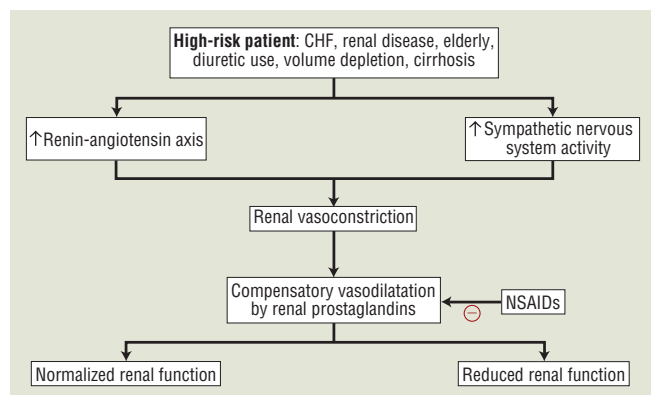

FIGURE 95-7. Mechanisms implicated in NSAID-induced renal injury. The minus (–) sign indicates inhibitory influence. (CHF, congestive heart failure; NSAIDs, nonsteroidal antiinflammatory drugs.)

Coxibs and NSAIDs uncommonly cause drug-induced hepatitis; the two NSAIDs most frequently implicated are diclofenac and sulindac. Patient monitoring should include periodic liver enzymes (aspartate aminotransferase and alanine aminotransferase), with cessation of therapy if these values exceed two to three times the normal range.

Other toxic effects of NSAIDs include hypersensitivity reactions, rash, and central nervous system complaints of drowsiness, dizziness, headaches, depression, confusion, and tinnitus.⁴⁷ Although NSAIDs are generally avoided in patients with asthma who are aspirin-intolerant, studies indicate that celecoxib is well tolerated in aspirin-sensitive asthma, providing a viable option for these patients.⁹⁰ Celecoxib is a sulfonamide and is thus contraindicated for those with sulfa allergies. However, some patients with sulfa allergies have shown no reaction to celecoxib, and in a meta-analysis including more than 11,000 patients, allergic reactions for those who did have sulfonamide allergies were similar in those taking celecoxib compared to those taking other NSAIDs.⁹¹

All nonspecific NSAIDs inhibit COX-1–dependent thromboxane production in platelets and thus increase bleeding risk. Importantly, aspirin inhibition is irreversible, and bleeding time requires 5 to 7 days to normalize after cessation of therapy, as new platelets enter the circulation. Other nonspecific NSAIDs inhibit thromboxane formation reversibly, with normalization of platelet function 1 to 3 days after the drug is stopped. The nonacetylated salicylate products and nabumetone, which have partial COX-2 selectivity, may be preferable to nonspecific NSAIDs.⁴⁷ COX-2 selective inhibitors do not block thromboxane synthesis and should pose even less bleeding risk. However, because warfarin and celecoxib are metabolized by the cytochrome P450 isoenzyme CYP2C9, patients receiving warfarin and COX-2 inhibitors should be followed closely.

Finally, NSAIDs should be used only with great caution and only if definitely necessary during pregnancy because of the risk to the fetus posed by the bleeding problems. In late pregnancy, all NSAIDs should be avoided because they may enhance premature closure of the ductus arteriosus. NSAIDs have a pregnancy risk factor of C/D (third trimester). Aspirin is also listed as C/D (D in third trimester if used at full dose). Acetaminophen has a pregnancy risk factor of B.

Drug-Drug and Drug-Food Interactions Important drug interactions with NSAIDs can be pharmacokinetic or pharmacodynamic in origin and have been reviewed.^{47,92} The most potentially serious interactions include the use of NSAIDs with lithium, warfarin, oral hypoglycemics, high-dose methotrexate, antihypertensives, angiotensin-converting enzyme inhibitors, β -blockers, and diuretics. Anticipation and careful monitoring often can prevent serious events when these drugs are used together.

Another recent drug interaction has been noted for those taking some NSAIDs and cardioprotective doses of aspirin. Ibuprofen, used at doses of 400 mg or more, may block aspirin's antiplatelet effect if it is taken prior to aspirin. Patients are advised to take a single dose of ibuprofen at least 30 minutes after taking aspirin, or they should take their aspirin at least 8 hours after taking ibuprofen.⁹³ It is possible that other nonselective NSAIDs, such as naproxen, also may cause such interactions. Acetaminophen does not appear to interfere with the antiplatelet effect of aspirin.

Specific drug interactions are also seen with coxibs. Celecoxib metabolism is primarily via CYP2C9.⁹² In clinical studies, increased celecoxib levels were seen with fluconazole administration. Cytochrome P450 inducers such as rifampin, carbamazepine, and phenytoin have the potential to reduce celecoxib levels. However, no clinically significant interactions have been documented with celecoxib and methotrexate, glyburide, ketoconazole, phenytoin, or tolbutamide. Because celecoxib inhibits CYP2D6, it has the potential to increase concentrations of a variety of agents, including antidepressants. Celecoxib increases lithium levels, as do other NSAIDs, thus caution is needed when using coxibs or NSAIDs with lithium.

Dosing and Administration Administration of NSAIDs must be tailored to the individual patient with OA. For the OA patient who has failed an adequate trial of acetaminophen, trial with an NSAID is warranted, if no contraindications exist. Selection of an NSAID depends on the prescriber's experience, medication cost, patient preference, allergies, toxicities, and adherence issues. Individual patient response differs among NSAIDs (see Table 95–2), so if an inadequate response is obtained with one NSAID, another NSAID may yet provide benefit.^{2,47,54}

Topical Therapies

11 Topical products can be used alone or in combination with oral analgesics or NSAIDs. Capsaicin, isolated from hot peppers, releases and ultimately depletes substance P from afferent nociceptive nerve fibers. Substance P has been implicated in the transmission of pain in arthritis, and capsaicin cream has been shown in four placebo-controlled studies to provide pain relief in OA when applied over affected joints.^{2,94} Data comparing topical capsaicin to other effective pharmacologic treatments for OA is lacking.

Adverse events associated with capsaicin are primarily local, with 1 in 3 patients experiencing burning, stinging, and/or erythema that usually subsides with repeated application. Some patients may experience coughing associated with application. Capsaicin is a nonprescription product available as a cream, gel, or lotion in concentrations ranging from 0.025% to 0.075%.

To be effective, capsaicin must be used regularly, and it may take up to 2 weeks to take effect. Although use is recommended four times a day, a twice-daily application may enhance long-term adherence and still provide adequate pain relief.⁹⁴ Patients should be warned not to get the cream in their eyes or mouth and to wash their hands after application. When patients were queried using an electronic questionnaire that considered possible toxicities of treatments, as well as route of administration and cost, capsaicin was the most preferred by patients, even when it was portrayed as being less effective than NSAIDs.⁴⁸

Topical diclofenac in a dimethyl sulfoxide (DMSO) carrier (Pennsaid) is a safe and effective treatment for pain associated with OA.⁹⁵ Pennsaid is available in Canada and other European countries and is currently under review at the FDA. The mechanism of action of topical NSAIDs is thought to be primarily by local inhibition of COX-2 enzymes. This mode of delivery minimizes systemic exposure and may decrease the risk of the serious adverse events associated with oral NSAIDs.

Although not well studied in a controlled setting, the use of topical rubefacients, containing methylsalicylate, trolamine salicylate, and other salicylates, may have modest, short-term efficacy in the treatment of acute pain associated with musculoskeletal conditions, including OA.⁹⁶ These agents act by providing topical counterirritation to the affected joint area, rather than by local inhibition of COX-2 enzymes. Chronic OA pain may respond less favorably than acute pain. Clinically significant adverse events are local skin reactions that occur rarely. There are no reports of systemic toxicity associated with topical rubefacients.

Glucosamine and Chondroitin

Interest in chondroitin and glucosamine was spurred initially by anecdotal reports of benefit in animals and humans, and by the ability of these substances to stimulate proteoglycan synthesis from articular cartilage in vitro. The excellent safety profile of these agents makes them especially appealing for use in those at high risk for adverse events, such as elderly patients, and in those with multiple morbidities. Recently, enthusiasm for these agents has waned somewhat as additional efficacy data has become available.^{97–99}

A meta-analysis of glucosamine and chondroitin had indicated that both agents had efficacy in reducing pain and improving mobility, and that glucosamine reduced joint space narrowing.⁹⁸ Use of glucosamine or chondroitin sulfate was associated with slower loss of cartilage than placebo in knees of OA patients.¹⁰⁰ Further support for the objective benefits of these compounds was seen in a followup survey carried out 5 years after completion of a 3-year study comparing glucosamine and placebo. This survey showed that rates of lower limb joint replacement were twofold higher in subjects given placebo, compared with subjects given glucosamine. In addition, subjects treated with glucosamine had lower rates of pain, joint space narrowing, and limitations of physical function.⁹⁹

In contrast to earlier reports, a recent large, well-controlled National Institutes of Health-sponsored study demonstrated no significant clinical response to glucosamine therapy alone, chondroitin therapy alone, or combination glucosamine–chondroitin therapy when compared to placebo across all patients.⁹⁷ In subgroup analyses, however, patients with moderate to severe knee pain showed a response to combination glucosamine–chondroitin therapy superior to placebo. This finding did not reach the predetermined threshold for pain reduction. The safety of the glucosamine and chondroitin therapy was similar to that of placebo.

The exact role of glucosamine, chondroitin, or a combination of the two products is still unclear. Because of the relative safety of these agents, a trial of glucosamine–chondroitin may be reasonable in patients considering alternatives to traditional OA treatments. Dosing should be at least 1,500 mg/day of glucosamine and 1,200 mg/day of chondroitin. The glucosamine component should be the sulfate salt rather than the hydrochloride salt, as nearly all positive efficacy studies used the better-absorbed sulfate salt. Glucosamine-related adverse events are generally mild and include gastrointestinal symptoms (gas, bloating, cramps). If made from shellfish, however, glucosamine should not be used in patients with shellfish allergies. The initial concerns regarding glucosamine-induced hyperglycemia had likely been overstated as later safety data in both healthy subjects and those with type 2 diabetes mellitus did not show significant elevations in blood glucose. Chondroitin is extremely well tolerated with the most common adverse effect being nausea. Depending on the source of chondroitin (cattle, pig, or shark), this compound could also pose risk to persons who are allergic to shark.

Because glucosamine and chondroitin are marketed in the United States as dietary supplements, neither the products nor their purity is adequately regulated by the FDA. The potential consequences related to the lack of regulatory oversight for these products can affect both efficacy and safety. Products containing less-than-

labeled doses can compromise efficacy, while those containing ingredients not included on the labeling can compromise safety. A variety of brand name and generic products are available.

Corticosteroids

Intraarticular glucocorticoid injections can provide excellent pain relief, particularly when a joint effusion is present.^{2,101} Aspiration of the effusion and injection of glucocorticoid are carried out aseptically, with examination of the aspirate recommended to exclude crystalline arthritis or infection. (This risk is low, however—approximately 1 in 50,000 procedures.) After injection, the patient should minimize activity and stress on the joint for several days. Initial pain relief may be seen within 24 to 72 hours after injection, with peak pain relief about 1 week after injection and lasting up to 4 to 8 weeks.

Several randomized, placebo-controlled, double-blind studies have shown that intraarticular corticosteroids are superior to placebo in alleviating knee pain and stiffness caused by OA.¹⁰¹ The branched esters of triamcinolone and methylprednisolone are preferred by practitioners because of the reduced solubility that allows the agents to remain in the joint space longer. There is no evidence of a clinically superior corticosteroid for intraarticular use, with equipotent doses of methylprednisolone acetate and triamcinolone hexacetonide having similar efficacy.¹⁰² Average doses for injection of large joints in adults are 10 to 20 mg of triamcinolone hexacetonide or 20 to 40 mg of methylprednisolone acetate. The therapy is generally limited to three or four injections per year because of the potential systemic effects of steroids, and because the need for more frequent injections indicates little response to the therapy.

Adverse events associated with intraarticular injection of corticosteroids can be local or systemic in nature. Systemic adverse events are the same as with any other systemic corticosteroid and can include hyperglycemia, edema, elevated blood pressure, dyspepsia, and, rarely, adrenal suppression with continuous, repeated injections. Local adverse effects can include infection in the affected joint, osteonecrosis, tendon rupture, and skin atrophy at the injection site. It has long been thought that intraarticular corticosteroids can hasten cartilage loss, but the potential risk of cartilage destruction with steroid injections has not been substantiated. The rate of cartilage loss tends to be similar between treated and control groups.

Systemic corticosteroid therapy is not recommended in OA, given the lack of proven benefit and the well-known adverse effects with long-term use.

Hyaluronate Injections

Agents containing hyaluronic acid (HA; sodium hyaluronate) are available for intraarticular injection for treatment of knee OA.^{103,104} High-molecular-weight HA is an important constituent of synovial fluid. Endogenous HA may also have antiinflammatory effects. Because the concentration and molecular size of synovial HA decrease in OA, administration of exogenous HA products has been studied, with the theory that this could reconstitute synovial fluid and reduce symptoms. In fact, HA injections temporarily and modestly increase viscosity. Although HA injections were reported to decrease pain, most studies were short-term and poorly controlled, and placebo injections also reduced OA pain dramatically. A study of patients who received two series of injections of HA demonstrated efficacy for 27 weeks after the first series of injections.¹⁰³

HA products are injected once weekly for either 3 or 5 weeks, depending on the specific agent administered. There are four commercially available preparations, Hyalgan (20 mg sodium hyaluronate/2 mL), Supartz (25 mg sodium hyaluronate/2.5 mL), (16 mg hyaluron polymers/2 mL), and Orthovisc (30 mg hyaluronan/2 mL). Hyalgan and Supartz are administered weekly for five injections, whereas Synvisc and Orthovisc are administered weekly for three injections.

One study has demonstrated that a series of three injections of Hyalgan was as effective as a longer series of six injections.¹⁰³ Injections are well tolerated, although acute joint swelling and local skin reactions, including rash, ecchymoses, and pruritus have been reported.

HA injections may be beneficial for patients with knee OA unresponsive to other therapies. These agents are expensive because the treatment includes both drug costs and administration costs. As a result, HA injections are often used after less-expensive therapies have demonstrated a lack of efficacy.

Opioid Analgesics

Low-dose opioid analgesics can be useful in patients who experience no relief with acetaminophen, NSAIDs, intraarticular injections, or topical therapy. These agents are particularly useful in patients who cannot take NSAIDs because of renal failure, and for patients in whom all other treatment options have failed and who are at high surgical risk, precluding joint arthroplasty. Low-dose opioids are the initial intervention, usually given in combination with acetaminophen.

Sustained-release compounds usually offer better pain control throughout the day, and are used when simple opioids are ineffective. A recent randomized, double-blind, placebo-controlled study showed that extended-release oxycodone (20 to 120 mg twice daily) was superior to placebo in reducing pain and improving both function and quality of life, although a high number of patients (36%) did not complete the study as a consequence of adverse events.¹⁰⁵ Nearly all (93%) patients in the oxycodone group experienced a typical opioid-related (nausea, somnolence, constipation, and dizziness) adverse event in this 90-day study. Although this is not an unexpected finding, it serves as a reminder to use opioids cautiously in elderly patients who may be more susceptible to adverse effects.

If pain is intolerable and limits activities of daily living, and the patient has sufficiently good cardiopulmonary health to undergo major surgery, joint replacement may be preferable to continued reliance on opioids.

Tramadol

Tramadol, with or without acetaminophen has modest analgesic effects in patients with OA when compared to placebo.¹⁰⁶ Tramadol is also modestly effective as add-on therapy in patients taking concomitant NSAIDs or COX-2 selective inhibitors.¹⁰⁷ As with opioid analgesics, tramadol may be helpful for patients who cannot take NSAIDs or COX-2 selective inhibitors. Tramadol should be initiated at a lower dose (100 mg per day) and may be titrated as needed for pain control to a dose of 200 mg per day. Tramadol is available in a combination tablet with acetaminophen and as a sustained-release tablet.

Opioid-like adverse effects such as nausea, vomiting, dizziness, constipation, headache, and somnolence are common with tramadol. These occur in 60% to 70% of treated patients, and 40% discontinue tramadol because of an adverse effect.¹⁰⁶ Although the frequency of adverse effects is high, the severity of adverse effects is less than with NSAIDs, as tramadol use is not associated with life-threatening gastrointestinal bleeding or with renal failure.

Novel Therapies and Disease-Modifying Drugs

Disease-modifying drugs are targeted not at pain relief but at preventing, retarding, or reversing damage to articular cartilage. Thus far, OA is a progressive disease that can only be treated symptomatically. Because of this, clinicians were very interested in the possible ability of chondroitin and/or glucosamine to slow joint damage, although those findings require further study (see Glucosamine and Chondroitin above).

New approaches to slow progression of OA are being investigated, but most products have been tested in animal models, and limited human data are available. One approach involves pharmacologic

agents that could mimic tissue inhibitors of metalloproteinases and thus potentially decrease cartilage destruction. Some studies have explored the use of tetracycline or doxycycline, which appear to inhibit metalloproteinases.¹⁰⁸ In knee OA, doxycycline has been seen to delay loss of articular cartilage (joint space narrowing) in humans when compared with placebo.¹⁰⁹ Other agents that act as inhibitors of metalloproteinase gene expression, are also under consideration in developing drugs to inhibit joint damage in OA.²¹

Another agent being studied is diacerein, an interleukin-1 β inhibitor. In a meta-analysis including a total of 2,069 OA patients, this agent decreased pain to a modest but statistically significant extent compared to placebo. In long-term studies, diacerein appeared to show a significant slowing of progression of joint space narrowing at the hip, but not at the knee.¹¹⁰

Aside from agents that may prevent disease progression, attempts to find new agents or methods to treat symptoms of OA are being made. There is recent interest in the potential of cyclooxygenase-inhibiting nitric oxide-donor compounds to relieve OA pain while sparing GI adverse effects. There are two lipid-based nontraditional therapies that have received some attention for treatment of symptoms related to OA; avocado/soy unsaponifiables and fish oil (particularly n-3 PUFA). Several short-term studies have demonstrated that the use of avocado/soy unsaponifiables at a dose of 300 mg to 600 mg daily led to decreases in the use of NSAIDs for pain control, but one long-term (2 years) study failed to replicate these results.¹¹¹ It is theorized that the oily fractions of avocado unsaponifiables decrease production of nitric oxide and stimulate production of plasminogen activator inhibitor-1 that can decrease MMPs. The n-3 PUFA fractions of fish oils have been shown to decrease proinflammatory cytokines, MMPs, and tumor necrosis factor- α in vitro. The administration of 1.6 to 3.2 g per day of eicosapentaenoic acid is an effective adjunct to the treatment of rheumatoid arthritis.¹¹² The role of n-3 PUFAs in the symptomatic treatment of OA is less-well defined, possibly owing to the differences in the pathophysiology between the two types of arthritis.

In addition to pharmacologic agents, acupuncture has been examined in OA. In a systematic analysis of 18 randomized, controlled trials of manual or electroacupuncture, 10 showed positive effects for acupuncture.¹¹³ However, in a recent, large, randomized, and well-controlled study, acupuncture was not seen to be any more effective than sham controls.¹¹⁴

CLINICAL CONTROVERSY

The role of herbal and supplement therapies in the treatment of OA is a source of continuing controversy. A variety of herbal therapies, including ginger, devil's claw, methylsulfonylmethane, flavonoids, willow bark, green tea polyphenols, bromelain, hyper-immune milk, and *Boswellia serrata* are purported to have efficacy in the treatment of pain associated with OA. Many patients encounter advertising and other publications in the lay press extolling the benefits of these products. Unfortunately, the lack of scientific trials evaluating these agents makes it difficult to determine their role in therapy. Key questions to be answered before recommendations about the safe use of these agents include the following: (a) Do these agents provide pain relief to a greater degree than placebo? (b) Are there safety issues? (c) Is the manufacturing process reliable? (d) Is it important to know the pharmacology, pharmacodynamics, and pharmacokinetics of these agents? Until additional efficacy and safety information becomes available, recommendations regarding the routine use of these products should be tempered by known drug safety data (if available) and other related safety issues, including costs of therapy, delays in seeking known, effective treatments, and potential exposure to products produced without standard manufacturing processes.

■ PHARMACOECONOMIC CONSIDERATIONS

There are substantial economic ramifications with OA, as the disease is extremely common, and OA ranks second in causes of disability in the United States.²⁻⁴

One of the highest costs associated with OA is hospitalization for joint replacement or for treatment of NSAID-related complications, particularly serious GI adverse events. To provide perspective on patient care costs for GI complications of NSAIDs, one study on more than 10,000 OA patients followed in a managed care setting showed that the mean annual cost of care per patient was \$543, with hospital costs accounting for 46%, medications 32%, and ambulatory care 22%.¹¹⁵ Consequently, intense focus has emerged on the cost-to-benefit ratio of medications to prevent ulcer complications, and the use of coxibs, which cause fewer ulcer complications.

For example, analysis of the cost-effectiveness of using NSAIDs or COX-2 selective inhibitors with or without concomitant PPI therapy in both high-risk and low-risk patients was reported, based on estimates of the risk of GI complications in these settings.¹¹⁶ The cost of avoiding one serious GI complication would be \$61,933 if all NSAID patients were given a PPI, but only \$4,355 if PPIs were limited to high-risk patients. In the same analysis, the cost of avoiding one serious GI complication would be \$62,467 if all NSAID patients were given a COX-2 selective inhibitor. The cost-effectiveness of an NSAID plus a PPI in high-risk patients has been demonstrated by others as well.¹¹⁷ Gastroprotective therapy or the use of COX-2 selective inhibitors in low-risk patients is not cost-effective because of the large number needed to treat to prevent serious events. Additionally, the use of COX-2 selective inhibitors to protect gastric mucosa in aspirin users is not cost-effective, because aspirin negates most, if not all, of the gastroprotective effects of these agents.^{116,117}

Pharmacoeconomic considerations for OA involve the selection of therapy for the initial treatment of patients with OA. Use of the nonprescription analgesic acetaminophen as initial therapy has greatly reduced medication costs in comparison with the use of NSAIDs, many of which are by prescription only. NSAID costs range from \$20 to \$120 per month, depending on the medication, daily dose, and regimen selected. As NSAIDs as a class are therapeutically similar, use of less-expensive NSAIDs, such as nonprescription ibuprofen or naproxen, may minimize the cost of medicine to the patient. More expensive NSAIDs can be prescribed if neither of these offers benefit after a 2-week trial at sufficient doses.

Nearly all elderly patients are eligible for prescription drug coverage through Medicare Part D insurance programs to assist with the costs of prescription medications for the treatment of OA. The use of nonformulary or noncovered medications can significantly reduce potential cost-savings to the patient. Careful attention to selection of appropriately covered medications will increase the affordability of medication for patients receiving drug therapy for OA.

EVALUATION OF THERAPEUTIC OUTCOMES

Pharmacotherapy monitoring in OA is patient-specific. It should be guided by aspects of disease that are most troubling to the patient, such as pain or decreased function, as well as the patient's risk of adverse effects. To monitor efficacy, the patient's baseline pain can be assessed with a visual analog scale, and range of motion for affected joints can be assessed, providing baseline measures to monitor the success of therapy. Baseline radiographs are helpful to document the extent of joint involvement and follow progression of disease with therapy. Additional tests of OA severity may include measurement of grip strength, 50-foot walking time, patient and physician global assessment of OA severity, and the Western Ontario and McMaster Universities Arthritis Index or Stanford Health Assessment Questionnaire to monitor ability to perform

activities of daily living. A decrease in the use of analgesics or NSAIDs would suggest a beneficial effect of nonpharmacologic interventions. Lastly, disease-specific quality of life is valuable in assessing clinical response to interventions.

Adverse events with acetaminophen are uncommon but are more problematic with NSAIDs, and avoiding toxicity requires individual attention. Each patient's GI, cardiovascular, renal, and other risks, as well as age and comorbidities, should be assessed. When assessing toxicity of therapy, patients should be asked first if they are having any "problems" with their medications. This open-ended question can be followed with more direct questions relating to the most common adverse effects associated with the respective medication. Symptoms of abdominal pain, heartburn, nausea, or change in stool color provide valuable clues to the presence of GI complications, although serious GI complications can occur without warning. Patients also should be monitored for the development of hypertension, weight gain, edema, skin rash, and central nervous system adverse effects such as headaches and drowsiness. Baseline serum creatinine, complete blood count, and serum transaminases are repeated at 6- to 12-month intervals to identify GI, renal, hepatic, and hematologic toxicities.

For patients receiving intraarticular corticosteroids, improvement should begin with 2 to 3 days and last 4 to 8 weeks. Patients should be advised about possible injection site reactions, as well as possible systemic effects, especially for those with hypertension or diabetes, as there is a potential for increased blood pressure or blood glucose (more likely for higher doses given more frequently). For patients receiving intraarticular hyaluronic acid, improvement can begin within 3 to 4 weeks and can last several months, and patients should be advised about possible injection-site reactions and allergic reactions. For patients receiving opioids or tramadol, relief from pain is expected to occur rapidly. Patients, especially if frail or elderly, should be monitored carefully and cautioned about sedation, dysphoria, nausea, risk of falls, constipation, and development of tolerance.

CONCLUSIONS

OA is a very common, slowly progressive disorder that affects diarthrodial joints and is characterized by progressive deterioration of articular cartilage, subchondral sclerosis, and osteophyte production. Clinical manifestations include gradual onset of joint pain, stiffness, and limitation of motion. The primary treatment goals are to reduce pain, maintain function, and prevent further destruction. An individualized approach based on education, rest, exercise, weight loss as needed, and analgesic medication can succeed in meeting these goals. Recommended drug treatment starts with acetaminophen ≤ 4 g/day and topical analgesics as needed. If acetaminophen is ineffective, NSAIDs may be used, often providing satisfactory relief of pain and stiffness. Individuals at increased risk for toxicity from NSAIDs, especially for GI, cardiovascular, or renal events, deserve special attention. Coxibs may have advantages in some OA patients, but their safety relative to other NSAIDs and their role in OA remain in a state of flux. Glucosamine-chondroitin may be useful in moderate to severe arthritis and is safe. Experimental therapy aimed at preventing the progression of OA requires further clinical investigation before entering widespread clinical use.

KEY CONCEPTS

- 1 Asymptomatic hyperuricemia does not require treatment.
- 2 Acute gouty arthritis may be treated effectively with short courses of high-dose nonacetylated nonsteroidal antiinflammatory drugs (NSAIDs).
- 3 Colchicine is highly effective at relieving acute attacks of gout but has the lowest benefit-to-toxicity ratio of the available pharmacotherapy for gout. When employed, it should only be used orally.
- 4 Individuals with contraindications to NSAIDs (e.g., active peptic ulcer disease, severe renal impairment, uncompensated congestive heart failure, or history of hypersensitivity) or colchicine, or who do not respond to these therapies may be treated with corticosteroids.
- 5 Uric acid nephrolithiasis should be treated with adequate hydration (2 to 3 L/day), a daytime urine-alkalinizing agent, and 60 to 80 mEq/day of potassium bicarbonate or potassium citrate.
- 6 Treatment with urate-lowering drugs to reduce risk of recurrent attacks of gouty arthritis is considered cost-effective in patients having two or more attacks of gout per year.
- 7 Allopurinol is efficacious for prophylaxis of recurrent gout attacks in both underexcretors and overproducers of uric acid. Start with a low dose (100 mg/day) after the acute attack has resolved, and titrate by 100 mg/day at 1-week intervals until the goal serum urate of <6 mg/dL is achieved. Many clinicians give colchicine (0.5 mg twice daily) during the first 3 months of therapy, to minimize the risk of acute attacks that may occur during initiation of uric acid-lowering therapy. Allopurinol should be discontinued if rash develops or liver function tests become abnormal.
- 8 Uricosuric agents should be avoided in patients with renal impairment (a creatinine clearance below 50 mL/min), a history of renal calculi, or overproduction of uric acid.
- 9 Patients with hyperuricemia or gout should be evaluated for signs of cardiovascular disease and appropriate risk reduction measures (weight loss, reduction of alcohol intake, control of blood pressure) undertaken.

The term *gout* describes a heterogeneous clinical spectrum of diseases including elevated serum urate (hyperuricemia), recurrent attacks of acute arthritis associated with monosodium urate crystals in synovial fluid leukocytes, deposits of monosodium urate crystals (tophi) in tissues in and around joints, interstitial renal disease, and uric acid nephrolithiasis.¹

The core metabolic disorder of gout is hyperuricemia, defined physiochemically as serum supersaturated with monosodium urate. At 37°C (98.6°F), serum urate concentrations above (or around) 7 mg/dL begin to exceed the limit of solubility for monosodium urate.¹ For determination of the risk of gout, hyperuricemia is defined statistically as serum urate concentrations greater than two standard deviations above the population means for age-and-sex-matched healthy populations, usually 7.0 mg/dL for men and 6.0 mg/dL for women.^{1,2} Although hyperuricemia is fundamental to the development of gout, the mere presence of hyperuricemia itself is often an asymptomatic condition.

EPIDEMIOLOGY

Gout has been referred to as both the “king of diseases” and the “disease of kings.”¹ Since ancient times, it has often been associated with affluent societies and lifestyles of overindulgence, gluttony, and intemperance.³ The incidence and prevalence of gout continue to increase in Western industrialized countries, but the disease is not limited strictly to populations with a high standard of living.^{3–5} Recent epidemiologic data indicate that the prevalence of gout is also increasing in less-industrialized Eastern countries.^{6,7} Numerous factors may explain the rising prevalence of gout, including increased longevity, dietary habits, and increasing prevalence of obesity and the metabolic syndrome.⁴

There is a direct correlation between serum uric acid concentration and both the incidence and prevalence of gout. Population studies have shown that serum urate concentration correlates with increasing age, serum creatinine, blood urea nitrogen, male gender, blood pressure, body weight, and alcohol intake.⁸ In several epidemiologic studies, the incidence of gout is consistently higher in individuals who are obese, or who consume large amounts of alcohol, or who consume higher amounts of meat or fish.^{9–12}

The 5-year cumulative risk of gout in patients with serum urate <7 mg/dL is 0.6%, compared with a risk of 30.5% for those with urate levels >10 mg/dL.¹³ Although serum urate levels are the single most important risk factor for the development of gout, hyperuricemia and gout are not always concurrently present.¹⁴ Sustained elevation of serum urate is virtually essential for the development of gout; however, hyperuricemia does not always lead to gout, and most patients with hyperuricemia remain asymptomatic.² Conversely, acute gouty arthritis can occur in the presence of normal serum uric acid concentrations.¹⁵

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

Gout affects men about seven to nine times more often than women.¹⁶ The incidence of gout increases with age, peaking at 30 to 50 years of age, with an annual incidence ranging from 1 in 1,000 for men ages 40 to 44 years and 1.8 in 1,000 for those ages 55 to 64 years.¹² The lowest rates of gout are observed in young women, approximately 0.8 cases per 10,000 patient-years.¹⁷ Serum uric acid levels in women approach those of men once menopause has occurred; thus, in older age groups the gender gap narrows, and approximately half of newly diagnosed cases of gout are found in women.^{2,5} Gout in men younger than 30 years of age, or in premenopausal women may indicate an inherited enzyme defect or the presence of renal disease.¹⁸ Although no genetic marker has been isolated for gout, the familial nature of gout strongly suggests an interaction between genetic and environmental factors.

ETIOLOGY AND PATHOPHYSIOLOGY

In humans, uric acid is the end product of the degradation of purines. Because uric acid serves no known physiologic purpose, it is regarded as a waste product.¹⁹ Normal uric acid levels are near the limits of urate solubility, because of the delicate balance that exists between the amount of urate produced and excreted.²⁰ Humans have higher uric acid levels than other mammals because they do not express the enzyme uricase, which converts uric acid to the more soluble allantoin.^{3,21}

Gout occurs exclusively in humans in whom a miscible pool of uric acid exists. Under normal conditions, the amount of accumulated uric acid is about 1,200 mg in men and about 600 mg in women. The size of the urate pool is increased severalfold in individuals with gout. This excess accumulation may result from either overproduction or underexcretion of uric acid. Several conditions are associated with either decreased renal clearance or an overproduction of uric acid, leading to hyperuricemia. Table 96–1 lists some of these conditions.

OVERPRODUCTION OF URIC ACID

The purines from which uric acid is produced originate from three sources: dietary purine, conversion of tissue nucleic acid to purine nucleotides, and de novo synthesis of purine bases. The purines derived from these three sources enter a common metabolic pathway leading to the production of either nucleic acid or uric acid. Under normal circumstances, uric acid may accumulate excessively if production exceeds excretion. The average human produces about 600 to 800 mg of uric acid each day. Dietary purines play an unimportant role in the generation of hyperuricemia in the absence of some derangement in purine metabolism or elimination. However, diet modifications are important in patients with such problems who develop symptomatic hyperuricemia.

TABLE 96-1 Conditions Associated with Hyperuricemia	
Primary gout	Obesity
Diabetic ketoacidosis	Sarcoidosis
Myeloproliferative disorders	Congestive heart failure
Lactic acidosis	Renal dysfunction
Lymphoproliferative disorders	Down syndrome
Starvation	Lead toxicity
Chronic hemolytic anemia	Hyperparathyroidism
Toxemia of pregnancy	Acute alcoholism
Pernicious anemia	Hypoparathyroidism
Glycogen storage disease type 1	Acromegaly
Psoriasis	Hypothyroidism
Hypoxanthine-guanine phosphoribosyl-transferase deficiency	Phosphoribosylpyrophosphate synthetase overactivity
Polycythemia vera	Berylliosis
Renal transplantation	

Several enzyme systems regulate purine metabolism. Abnormalities in these regulatory systems can result in overproduction of uric acid.²² Uric acid also may be overproduced as a consequence of increased breakdown of tissue nucleic acids and excessive rates of cell turnover, as with myeloproliferative and lymphoproliferative disorders, polycythemia vera, psoriasis, and some types of anemias. Cytotoxic medications used to treat these disorders can also result in overproduction of uric acid secondary to lysis and breakdown of cellular matter.²³

Two enzyme abnormalities resulting in an overproduction of uric acid have been well described (Fig. 96–1). The first is an increase in the activity of phosphoribosyl pyrophosphate (PRPP) synthetase, which leads to an increased concentration of PRPP. PRPP is a key determinant of purine synthesis and thus uric acid production. The second is a deficiency of hypoxanthine-guanine phosphoribosyl-transferase (HGPRT). HGPRT is responsible for the conversion of guanine to guanylic acid and hypoxanthine to inosinic acid. These two conversions require PRPP as the cosubstrate and are important reuse reactions involved in the synthesis of nucleic acids. A deficiency in the HGPRT enzyme leads to increased metabolism of guanine and hypoxanthine to uric acid, and more PRPP to interact with glutamine in the first step of the purine pathway.²⁴ Complete absence of HGPRT results in the childhood Lesch-Nyhan syndrome, characterized by choreoathetosis, spasticity, mental retardation, and markedly excessive production of uric acid. A partial deficiency of the enzyme may be responsible for marked hyperuricemia in otherwise normal, healthy individuals.

UNDEREXCRETION OF URIC ACID

The vast majority of patients (80% to 90%) with gout have a relative decrease in the renal excretion of uric acid for an unknown reason (primary idiopathic hyperuricemia).² Normally, uric acid does not accumulate as long as uric acid production is balanced with elimination. Uric acid is eliminated in two ways. About two-thirds of the uric acid produced each day is excreted in the urine. The rest is eliminated through the gastrointestinal tract after enzymatic degradation by colonic bacteria.

A decline in the urinary excretion of uric acid to a level below the rate of production leads to hyperuricemia and an increased miscible

pool of sodium urate. Almost all the urate in plasma is freely filtered across the glomerulus. The concentration of uric acid appearing in the urine is determined by multiple renal tubular transport processes in addition to the filtered load. Evidence favors a four-component model including glomerular filtration, tubular reabsorption, tubular secretion, and postsecretory reabsorption.

Approximately 90% of filtered uric acid is reabsorbed in the proximal tubule, probably by both active and passive transport mechanisms. There is a close linkage between proximal tubular sodium reabsorption and uric acid reabsorption, so conditions that enhance sodium reabsorption (e.g., dehydration) also lead to increased uric acid reabsorption. The exact site of tubular secretion of uric acid has not been determined; this too appears to involve an active transport process. Postsecretory reabsorption occurs somewhere distal to the secretory site. Table 96-2 lists the drugs that decrease renal clearance of uric acid through modification of filtered load or one of the tubular transport processes. By enhancing renal urate reabsorption, insulin resistance is also associated with gout.²⁵

The pathophysiologic approach to the evaluation of hyperuricemia requires determining whether the patient is overproducing or underexcreting uric acid. This can be accomplished by placing the patient on a purine-free diet for 3 to 5 days and then measuring the amount of uric acid excreted in the urine in 24 hours. As it is very difficult in clinical practice to maintain someone on a purine-free diet for several days, this test is done infrequently in clinical practice. Nevertheless, when it is performed, individuals who excrete more than 600 mg on a purine-free diet may be considered overproducers. Hyperuricemic individuals who excrete less than 600 mg of uric acid per 24 hours on a purine-free diet may be classified as underexcretors of uric acid. However, on a regular diet, excretion of greater than 1,000 mg per 24 hours reflects overproduction; less than this is probably normal.

CLINICAL PRESENTATION

1 Gout is a disease diagnosed by symptoms rather than laboratory tests of uric acid. In fact, asymptomatic hyperuricemia discovered incidentally generally requires no therapy because many individuals with hyperuricemia will never have an attack of gout. Nevertheless, these patients should still be encouraged to implement lifestyle measures to reduce serum urate.

CLINICAL PRESENTATION OF ACUTE GOUTY ARTHRITIS

General

Gout classically presents as an acute inflammatory monoarthritis. The first metatarsophalangeal joint is often involved ("podagra"), but any joint of the lower extremity can be affected and occasionally gout will present as a monoarthritis of the wrist or finger. The spectrum of gout also includes nephrolithiasis, gouty nephropathy, and aggregated deposits of sodium urate (tophi) in cartilage, tendons, synovial membranes, and elsewhere (Fig. 96-2).

Signs and Symptoms

Fever; intense pain, erythema, warmth, swelling, and inflammation of involved joints

Laboratory Tests

Elevated serum uric acid levels; leukocytosis

FIGURE 96-2. Acute gout attack of the first metatarsophalangeal joint. (From Imboden J, Hellmann DB, Stone JH. *Current Rheumatology Diagnosis & Treatment*, 2d ed. New York: McGraw-Hill, 2004:316.)

Other Diagnostic Tests

- Observation of monosodium urate crystals in synovial fluid or a tophus (Fig. 96-3)
- In patients with long-standing gout, radiographs may show asymmetric swelling within a joint or subcortical cysts without erosions

ACUTE GOUTY ARTHRITIS

Acute attacks of gouty arthritis are characterized by rapid onset of excruciating pain, swelling, and inflammation. The attack typically is monarticular at first, most often affecting the first metatarsophalangeal joint (great toe) and then, in order of frequency, the insteps, ankles, heels, knees, wrists, fingers, and elbows. In one-half of initial attacks, the first metatarsophalangeal joint is affected, a condition known as *podagra*. Up to 90% of patients with gout will experience attacks in the great toe at some point in the course of their disease.¹⁹

Atypical presentations of gout also occur. In elderly patients, gout can present as a chronic polyarticular arthritis that can be confused with rheumatoid arthritis or osteoarthritis.⁴ Additionally, the onset of gout may be less dramatic than the typical acute attack and have fewer clinical findings. Multiple small joints in the hands may be involved, especially in elderly women.^{2,19} Table 96-3 summarizes the different clinical manifestations of gout.

The predilection of acute gout for peripheral joints of the lower extremity is probably related to the low temperature of these joints combined with high intraarticular urate concentration. Synovial effusions are likely to occur transiently in weight-bearing joints in

FIGURE 96-3. Urate crystal ingested by a polymorphonuclear leukocyte in synovial fluid. (From Imboden J, Hellmann DB, Stone JH. *Current Rheumatology Diagnosis & Treatment*, 2d ed. New York: McGraw-Hill, 2004:317.)

TABLE 96-3 Clinical Manifestations of Gout	
Classic acute gout ("podagra")	Monoarticular arthritis Frequently attacks the first metatarsophalangeal joint although other joints of the lower extremities are also frequently involved Affected joint is swollen, erythematous, and tender
Interval or intercritical gout	Asymptomatic period between attacks
Tophaceous gout	Deposits of monosodium urate crystals in soft tissues Complications include soft-tissue damage, deformity, joint destruction, and nerve compression syndromes such as carpal tunnel syndrome
Atypical gout	Polyarthritis affecting any joint, upper or lower extremity May be confused with rheumatoid arthritis or osteoarthritis
Renal effects	Nephrolithiasis Acute and chronic gouty nephropathy

the course of a day with routine activity. At night, water is reabsorbed from the joint space, leaving behind a supersaturated solution of monosodium urate, which can precipitate attacks of acute arthritis. Attacks generally begin at night with the patient awakened from sleep by excruciating pain.

The development of crystal-induced inflammation involves a number of chemical mediators causing vasodilation, increased vascular permeability, complement activation, and chemotactic activity for polymorphonuclear leukocytes.²⁶ Phagocytosis of urate crystals by the leukocytes results in rapid lysis of cells and a discharge of lysosomal and proteolytic enzymes into the cytoplasm. The ensuing inflammatory reaction is associated with intense joint pain, erythema, warmth, and swelling. Fever is common, as is leukocytosis. Untreated attacks may last from 3 to 14 days before spontaneous recovery.

Although acute attacks of gouty arthritis may occur without apparent provocation, a number of conditions may precipitate an attack. These include stress, trauma, alcohol ingestion, infection, surgery, rapid lowering of serum uric acid by ingestion of uric acid-lowering agents, and ingestion of certain drugs known to elevate serum uric acid concentrations (see Table 96–2). Other crystal-induced arthropathies that may resemble gout on clinical presentation are caused by calcium pyrophosphate dihydrate crystals (pseudogout) and calcium hydroxyapatite crystals, which are associated with calcific periartthritis, tendinitis, and arthritis.^{27,28}

Acute flares of gouty arthritis may occur infrequently, although with time the period between attacks may shorten if appropriate measures to correct hyperuricemia are not undertaken.¹⁹ Later in the disease, tophaceous deposits of monosodium urate crystals in the skin or subcutaneous tissues may be found. These tophi can be anywhere but are often found on the hands, wrists, elbows, or knees. It is estimated to take 10 or more years for tophi to develop.¹⁹

Diagnostic Evaluation

Table 96–4 lists the differential diagnosis of an acute monoarthritis.²⁹ A definitive diagnosis of gout requires aspiration of synovial fluid from the affected joint and identification of intracellular crystals of monosodium urate monohydrate in synovial fluid leukocytes.^{2,30} Identification of monosodium urate crystals is highly dependent on the experience of the observer. Crystals are needle shaped and when examined under polarizing light microscopy they are strongly negatively birefringent. Crystals can be observed in synovial fluid during asymptomatic periods.³¹ If an affected joint is tapped, the resulting synovial fluid may have white cells and appear purulent. Such findings should always raise the question of infection. If any clinical features of infection are present, such as high fever, elevated white blood cell count, multiple joints affected, or an identified source of infection, proper diagnosis and treatment are critical. Patients with

TABLE 96-4 Differential Diagnosis of Acute Monoarthritis

2. Palindromic rheumatism	
3. Seronegative inflammatory arthritis	
4. Trauma or hemarthrosis	
5. Septic arthritis	
6. Cellulitis	
7. Type II dyslipidemia	
8. Unrelated hyperuricemia (as in psoriasis, hypertension) when joint pain is not caused by gout	

gout can have septic arthritis. Diabetes, alcohol abuse, and advanced age increase the likelihood of septic arthritis.

In lieu of obtaining a synovial fluid sample from an affected joint to inspect for urate crystals, the clinical triad of inflammatory monoarthritis, elevated serum uric acid level, and response to colchicine can be used to diagnose gout. However, this approach has limitations, including a failure to recognize atypical gout presentations and the fact that serum uric acid levels can be normal or even low during an acute gout attack.^{13,32} In addition, use of colchicine as a diagnostic tool for gout is limited by lack of sensitivity and specificity for the disease. Other conditions such as psoriatic arthritis, sarcoidosis, and Mediterranean fever can respond to colchicine therapy. Table 96–5 shows the American College of Rheumatology classification criteria for an acute gouty arthritis attack.³³

In patients with long-standing gout, radiographs may show punched-out marginal erosions and secondary osteoarthritic changes; however, in an acute first attack radiographs will be unremarkable.^{14,29,34} Alternatively, the presence of chondrocalcinosis on radiographs may indicate pseudogout. Some studies have recently looked at the use of magnetic resonance imaging and computed tomography for imaging gout; however, this is not currently considered part of normal practice.

URIC ACID NEPHROLITHIASIS

Clinicians should be suspicious of hyperuricemic states in patients who present with kidney stones, as nephrolithiasis occurs in 10% to 25% of patients with gout.³⁵ The frequency of urolithiasis depends on serum uric acid concentrations, acidity of the urine, and urinary uric acid concentration. Typically, patients with uric acid nephrolithiasis have a urinary pH of less than 6.0. Uric acid has a negative logarithm of the acid ionization constant of 5.5. Therefore when the urine is acidic, uric acid exists primarily in the unionized, less-soluble form. At a urine pH of 5.0, urine is saturated at a uric acid level of 15 mg/dL. When the urine pH is 7.0, the solubility of uric acid in urine is increased to 200 mg/dL.¹ In patients with uric

^aThe combination of crystals, tophi, and/or six or more criteria is highly suggestive of gout. Data from Wallace SL, Robinson H, Masi AT, et al. Preliminary criteria for the classification of the acute arthritis of primary gout. *Arthritis Rheum* 1977; 20:895–900.

acid nephrolithiasis, urinary pH typically is less than 6.0 and frequently less than 5.5. When an acidic urine is saturated with uric acid, spontaneous precipitation of stones may occur.

Other factors that predispose individuals to uric acid nephrolithiasis include excessive urinary excretion of uric acid and a highly concentrated urine. The risk of renal calculi approaches 50% in individuals whose renal excretion of uric acid exceeds 1100 mg/day. In addition to pure uric acid stones, hyperuricosuric individuals are at increased risk for mixed uric acid–calcium oxalate stones and pure calcium oxalate stones. Uric acid stones are usually small, round, and radiolucent. Uric acid stones containing calcium are radiopaque.³⁵

GOUTY NEPHROPATHY

There are two types of gouty nephropathy: acute uric acid nephropathy and chronic urate nephropathy.³⁶ In acute uric acid nephropathy, acute renal failure occurs as a result of blockage of urine flow secondary to massive precipitation of uric acid crystals in the collecting ducts and ureters. This syndrome is a well-recognized complication in patients with myeloproliferative or lymphoproliferative disorders and is a result of massive malignant cell turnover, particularly after initiation of chemotherapy.

Chronic urate nephropathy is caused by the long-term deposition of urate crystals in the renal parenchyma. Microtophi may form, with a surrounding giant cell inflammatory reaction. A decrease in the kidneys' ability to concentrate urine and the presence of proteinuria may be the earliest pathophysiologic disturbances. Hypertension and nephrosclerosis are common associated findings. Although renal failure occurs in a higher percentage of gouty patients than expected, it is not clear that hyperuricemia per se has a harmful effect on the kidneys. The chronic renal impairment seen in individuals with gout may result largely from the concurrence of hypertension, diabetes mellitus, and atherosclerosis.

TOPHACEOUS GOUT

Tophi (urate deposits) are uncommon in the general population of gouty subjects and are a late complication of hyperuricemia. The most common sites of tophaceous deposits in patients with recurrent acute gouty arthritis are the base of the great toe, helix of the ear, olecranon bursae, Achilles tendon, knees, wrists, and hands (Fig. 96-4).² Eventually, even the hips, shoulders, and spine may be affected. In addition to causing obvious deformities, tophi may damage surrounding soft tissue, cause joint destruction and pain, and even lead to nerve compression syndromes including carpal tunnel syndrome.

FIGURE 96-4. Tophaceous gout with subcutaneous nodule almost breaking through the skin. (From South-Paul JE, Matheny SC, Lewis EL. *Current Diagnosis & Treatment in Family Medicine*. New York: McGraw-Hill, 2004:275.)

TREATMENT

Gout and Hyperuricemia

The goals in the treatment of gout are to terminate the acute attack, prevent recurrent attacks of gouty arthritis, prevent complications associated with chronic deposition of urate crystals in tissues, and prevent or reverse features commonly associated with the illness including obesity, elevated triglycerides, and hypertension.¹ This can be accomplished through a combination of nonpharmacologic and pharmacologic methods. Table 96-6 summarizes the available pharmacotherapy for gout.

■ ACUTE GOUTY ARTHRITIS

2 In most patients without contraindications, acute attacks of gouty arthritis may be treated successfully with short courses of high-dose nonsteroidal antiinflammatory drugs (NSAIDs) (Fig. 96-5).³⁷

Nonsteroidal Antiinflammatory Drugs

Nonsteroidal antiinflammatory drugs are the mainstay of therapy for acute attacks of gouty arthritis because of their excellent efficacy and minimal toxicity with short-term use. Indomethacin has been historically favored as the NSAID of choice for acute gout flares, but there is little evidence to support one NSAID as more efficacious than another, and three (indomethacin, naproxen, and sulindac) have actual United States Food and Drug Administration (FDA)-approved labeling for this indication, among several that have been studied (see Table 96-6).² The most important determinant of therapeutic success with NSAIDs appears not to be which one is chosen, but rather how soon it is initiated.¹⁸ Therapy should be initiated with maximum dosages at the onset of symptoms and continued for 24 hours after complete resolution of an acute attack, then tapered quickly over 2 to 3 days.³⁰ Resolution of an acute attack for most patients generally occurs within 5 to 8 days after initiating therapy.

All NSAIDs have the potential to cause similar adverse effects. The most common areas affected include the gastrointestinal system (gastritis, bleeding, and perforation), kidneys (renal papillary necrosis, reduced creatinine clearance), cardiovascular system (sodium and fluid retention, increased blood pressure), and central nervous system (impaired cognitive function, headache, dizziness). Caution should be exercised when using NSAIDs in individuals with a history of peptic ulcer disease, congestive heart failure, uncontrolled hypertension, renal insufficiency, coronary artery disease, or if they are receiving anticoagulants concurrently. Patients with active peptic ulcer disease, uncompensated congestive heart failure, severe renal impairment, or a history of hypersensitivity to aspirin or other NSAIDs should not be prescribed an NSAID.

Although the risk for gastric ulceration and bleeding is relatively small with short-term therapy normally employed when treating acute gout flares, consideration should be given to administering a proton pump inhibitor to protect from NSAID-induced gastric problems in elderly patients and in others who are at risk for these complications (e.g., presence of multiple comorbidities, alcoholism, previous history of ulcer, or concurrent anticoagulant use).^{38,39} The efficacy and safety of selective cyclooxygenase-2 inhibitors have not been assessed in patients with gouty arthritis, but they are more costly than older NSAIDs and unlikely to result in fewer gastrointestinal complications because of the short courses of therapy routinely used to treat acute attacks.

Colchicine

3 Colchicine is an antimitotic drug that is highly effective at relieving acute attacks of gout but has the lowest benefit/toxicity

TABLE 96-6 Pharmacotherapy of Acute and Chronic Gout

Therapeutic Agent	Typical Regimen	Considerations
Acute gout		
NSAIDs		
Etodolac	300 mg twice daily	Avoid in patients with peptic ulcer disease, active bleeding. May cause renal dysfunction, gastritis (worse with concurrent aspirin), fluid retention, hypertension. Use caution in congestive heart failure. Consider coadministration with a proton pump inhibitor in patients at risk for gastrointestinal bleeding.
Fenoprofen	300–600 mg three times per day to four times per day	
Ibuprofen	800 mg four times per day	
Indomethacin ^a	25–50 mg four times per day initially for 3 days, then taper to twice daily for 4–7 days	
Ketoprofen	75 mg four times per day	
Naproxen ^a	500 mg twice daily initially for 3 days, then 250–500 mg daily for 4–7 days	Dose reduction necessary in patients with renal insufficiency. Dose-dependent gastrointestinal side effects (diarrhea, nausea, vomiting). Intravenous dosing not recommended because of toxicities.
Piroxicam	20 mg daily or divided twice daily	
Sulindac ^a	200 mg twice daily for 7–10 days	
Oral colchicine	0.5–0.6 mg q hour until side effects occur or maximum dosage of 8 mg is reached	
Corticosteroids		
Oral	30–60 mg prednisone-equivalent daily × 3–5 days, then taper in 5-mg decrements spread over 10–14 days until discontinuation	Use with caution in diabetics. Avoid long-term use. May cause fluid retention, impaired wound healing. Intraarticular administration is preferred for monoarticular involvement; avoid use if joint sepsis is not excluded.
Intramuscular	Triamcinolone acetone 60 mg IM once, or methylprednisolone 100–150 mg/day × 1–2 days	
Intraarticular	Triamcinolone acetone 10–40 mg (large joints), 5–20 mg (small joints)	Repeat injections (every 6–8 hours for 2–3 days) may be needed. Requires intact pituitary–adrenal axis. Less effective in patients receiving long-term oral corticosteroid therapy.
Corticotropin	25 USP units subcutaneously for acute small-joint monoarticular gout; 40 USP units IM or IV for larger joints or polyarticular involvement	
Intercritical gout		
NSAIDs		
Oral colchicine	Lowest effective dosage	NSAID gastropathy; see above. Reversible axonal neuromyopathy and rhabdomyolysis.
Xanthine oxidase inhibitor	0.6–1.2 mg daily to every other day	
Allopurinol	50–300 mg daily	Can be used in both urate overproduction and urate underexcretion. Side effects include rash, gastrointestinal symptoms, potential for fatal hypersensitivity syndrome. Dose reduction necessary in patients with renal insufficiency.
Uricosurics		
Probenecid	250 mg twice daily, titrated up to 500–2,000 mg/day (target serum urate <6 mg/dL)	Useful in urate underexcretion. Avoid in patients with history of urolithiasis.
Sulfinpyrazone	50 mg twice daily, titrated to 100–400 mg/day (target serum urate <6 mg/dL)	

IM, intramuscular; IV, intravenous; NSAID, nonsteroidal antiinflammatory drug.

^aFDA approved for treatment of acute gouty arthritis.

ratio of the available pharmacotherapy for gout.⁴⁰ When begun within the first 24 hours of an acute attack, colchicine produces a response in two-thirds of patients within hours of administration.⁴¹ If the initiation of colchicine is delayed longer than 48 hours after the onset of acute symptoms, the probability of success with the drug diminishes substantially. Although it is a highly effective therapy, oral colchicine can cause dose-dependent gastrointestinal adverse effects, including nausea, vomiting, and diarrhea, in 50% to 80% of patients before the relief of the attack.² Other important nongastrointestinal adverse effects include neutropenia and axonal neuromyopathy, which may be worsened in patients taking other myopathic drugs such as β -hydroxy- β -methylglutaryl-coenzyme A reductase inhibitors, or in those with renal insufficiency.^{19,22}

As a consequence of the high incidence of adverse effects and the low benefit-to-toxicity ratio, colchicine is used less often than NSAIDs in the United States.¹⁹ Colchicine should be reserved for patients with intolerance or contraindications to NSAID use, or in whom ineffective relief with NSAIDs is obtained. Colchicine should not be used concurrently with macrolide antibiotics, particularly clarithromycin, because biliary excretion of colchicine may be reduced leading to increased plasma levels of colchicine.⁴² Deaths caused by agranulocytosis are attributed to this interaction.^{43–45}

Colchicine is available in both oral and parenteral formulations. It is usually dosed orally with 1 mg initially, followed by 0.5 mg every 1 hour until the joint symptoms subside, until the patient develops abdominal discomfort or diarrhea, or until a total dose of 8 mg has been administered. In patients with renal dysfunction (creatinine

clearances of 10 to 50 mL/min) or hepatic dysfunction, there is no specific recommendation for adjustment of the dose of colchicine in an acute attack; however, the dose of oral colchicine should be reduced to no more than 0.6 mg daily to every other day when used as prophylaxis following an acute attack. Colchicine is contraindicated in patients with blood dyscrasias, severe cardiac or gastrointestinal disease, hepatic failure, and severe renal disease (creatinine clearance <10 mL/min).

Intravenous colchicine is associated with serious adverse effects, including bone marrow suppression, tissue necrosis from local extravasation, disseminated intravascular coagulation, hepatocellular toxicity, and renal failure. As safer alternatives exist, intravenous colchicine should generally be avoided. Intravenous colchicine is not dialyzable, and exceeding the recommended maximum cumulative dose of 2 to 4 mg during a course of therapy has resulted in fatalities.⁴⁶ If rare or unusual circumstances necessitate using colchicine parenterally, it should be overseen by experienced clinicians. Recommended guidelines suggest a dose of 2 mg diluted in 10 to 20 mL of normal saline administered slowly over 10 to 20 minutes in a secure free-flowing intravenous line to avoid extravasation, followed by two additional doses of 1 mg each at 6-hour intervals, with the total dose not exceeding 4 mg.⁴⁷ After a full intravenous course, patients should not receive colchicine from any route for at least 7 days.

Corticosteroids

4 Corticosteroids may be used to treat acute attacks of gouty arthritis, but they are reserved primarily for patients with a contra-

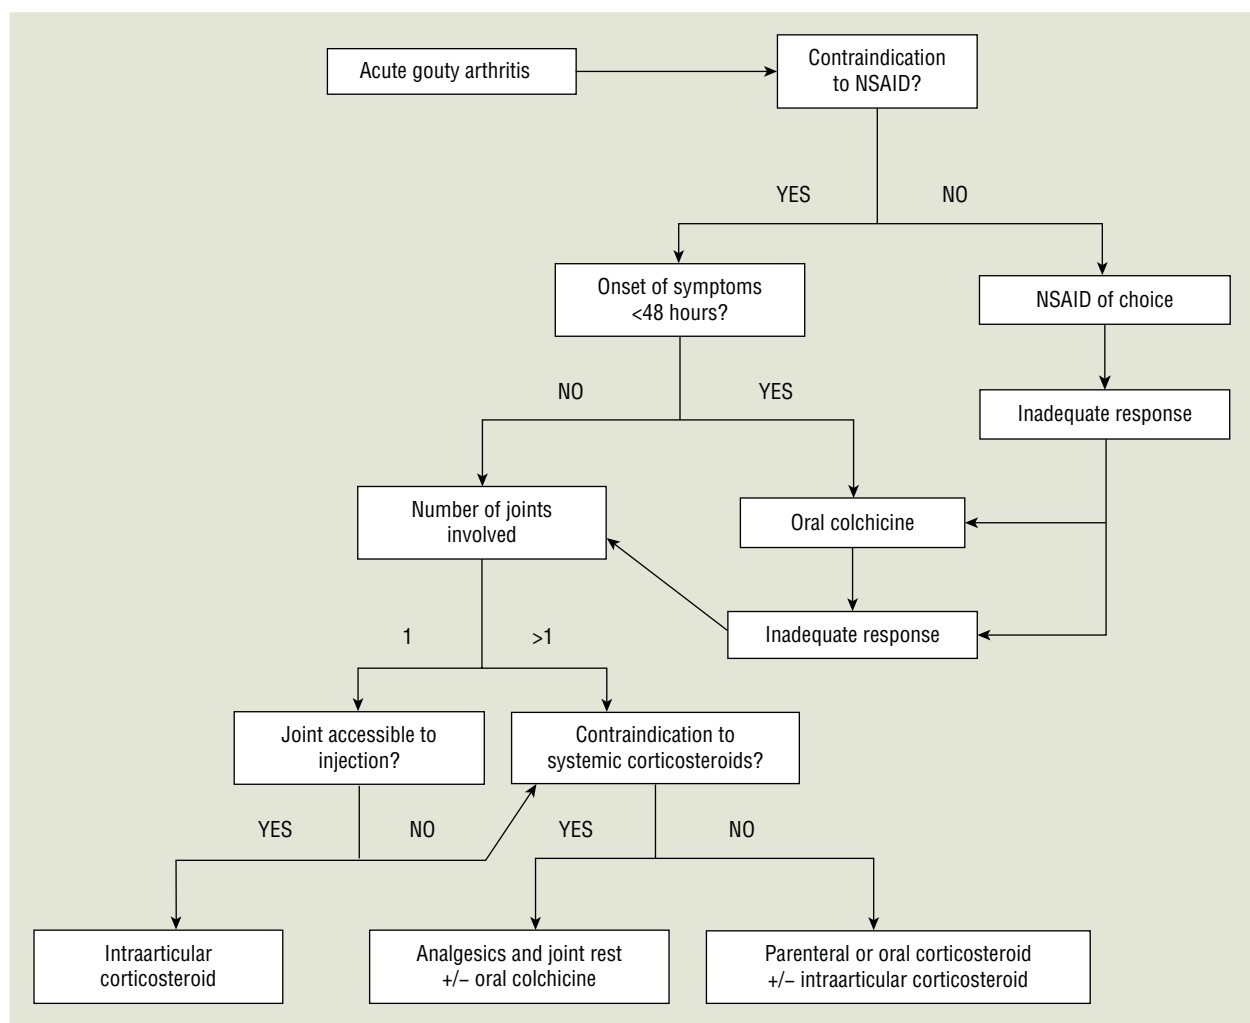

FIGURE 96-5. Treatment algorithm for acute gouty arthritis. (NSAID, nonsteroidal antiinflammatory drug.)

indication or who are unresponsive to NSAID or colchicine therapy.² Patients with polyarticular involvement may also benefit from corticosteroids. They can be used either systemically or by intraarticular injection. Oral corticosteroids may be administered in doses of 30 to 60 mg of prednisone-equivalent for 3 to 5 days in patients with multiple-joint involvement.² Because rebound attacks may occur upon steroid withdrawal, the dose should be tapered gradually in 5-mg decrements spread over 10 to 14 days and then discontinued. Intraarticular administration of triamcinolone acetonide in a dose of 20 to 40 mg may be useful in treating acute gout limited to one or two joints.⁴⁸ Injection should be done under aseptic technique in a joint determined not to be infected. A single intramuscular injection of a long-acting corticosteroid, such as methylprednisolone, can be used as an alternative to the oral route if patients are unable to take oral therapy.² If not contraindicated, low-dose colchicine can be used as adjunctive therapy to injectable corticosteroids to prevent rebound flare-ups.

Corticosteroids can have a number of adverse effects, and should be used with caution in patients with diabetes as they can increase blood sugar. In addition, patients with a history of gastrointestinal problems, bleeding disorders, cardiovascular disease, and psychiatric disorders should be monitored closely. Long-term corticosteroid use should be avoided because of the risk for osteoporosis, hypothalamic-pituitary axis suppression, cataracts, and muscle deconditioning that can occur with their use.

Corticotropin, or adrenocorticotrophic hormone (ACTH), which stimulates the adrenal cortex to produce cortisol and corticosterone, can be administered in acute gout. Doses of 40 to 80 USP units are

given intramuscularly every 6 to 8 hours for 2 to 3 days, and then discontinued. Studies with ACTH are limited, but it appears to provide similar efficacy to systemic antiinflammatory doses of corticosteroids.⁴⁹ When administered alone or in combination with colchicine, ACTH may provide earlier efficacy compared with indomethacin but with fewer adverse effects.⁵⁰ Unfortunately, ACTH is often difficult to obtain in the United States as a result of manufacturing problems. Because the studies have several limitations, the regimen should be considered only as an alternative, especially in patients with comorbidities where other regimens are contraindicated.⁵¹ Examples of patients where ACTH has been used safely when other first-line gout therapies were contraindicated include those with congestive heart failure, chronic renal failure, and history of gastrointestinal bleeding.⁵²

Nonpharmacologic Therapies

Gout is influenced by several dietary factors, including obesity, alcohol intake, hyperlipidemia, and insulin resistance syndrome.⁵³ Because of the elevated risk for development of gout that exists with hyperuricemia, even the asymptomatic patient should receive interventions directed toward modifying or correcting some of these underlying contributors.

Patients suffering from acute gouty arthritis should be advised to reduce their dietary intake of saturated fats and meats high in purines (e.g., organ meats).⁵⁴ Some consideration may be given to a rigid purine-free diet, although they may only be moderately effective in lowering serum uric acid levels and they can rarely be sustained for long periods of time.⁵³ Because of the increased risk of developing

nephrolithiasis, clinicians should counsel patients with gout to increase fluid intake and decrease salt consumption.⁵⁵ In addition, joint rest for 1 to 2 days should be encouraged, and local application of ice may be beneficial.^{53,56} Joint exercise and application of heat to the affected area should be avoided, as they can worsen the condition.

Weight loss through caloric restriction and exercise should be promoted in all patients with gout or asymptomatic hyperuricemia, and may enhance renal excretion of urate.⁵⁷ Restriction of alcohol intake is of great importance, as alcohol consumption is closely correlated with gout symptoms.¹⁰ Acute ingestions of alcohol cause lactic acidemia, which reduces renal urate excretion, whereas long-term alcohol intake promotes production of purines as a by-product of the conversion of acetate to acetyl coenzyme A in the metabolism of alcohol.⁵³

The presence of gout should not be a contraindication to the use of thiazide diuretics in hypertensive patients, although clinicians should be aware that diuretics are independent risk factors for gout and can increase serum uric acid levels.¹¹ It may be important to avoid using diuretics if other agents can be used to control blood pressure, particularly if the patient has had frequent gout attacks or continues to have an elevated serum uric acid level despite appropriate gout therapy.

■ NEPHROLITHIASIS

5 The medical management of uric acid nephrolithiasis includes hydration sufficient to maintain a urine volume of 2 to 3 L/day, alkalization of urine, avoidance of purine-rich foods, moderation of protein intake, and reduction of urinary uric acid excretion.

Maintenance of a 24-hour urine volume of 2 to 3 L with an adequate intake of fluids is desirable for all gouty patients, but especially for those with excessive (>1 g/day) uric acid excretion. Alkalinizing agents should be used with the objective of making the urine less acidic. Urine pH should be maintained at 6 to 6.5. In this pH range, up to 85% of uric acid will be in the form of the soluble urate ion.

Reduction of urine acidity is usually accomplished by the administration of potassium bicarbonate or potassium citrate 60 to 80 mEq/day.^{58,59} Administration of alkali via sodium salts is a less desirable option for two reasons. First, the sodium-induced volume expansion will increase sodium excretion and can secondarily cause hypercalcemia because calcium passively follows the reabsorption of sodium in the proximal tubule and loop of Henle. In the presence of uric acid, the resultant hypercalcemia can lead to calcium oxalate stone formation. Secondly, one must keep in mind that older patients with uric acid kidney stones also may have hypertension, congestive heart failure, or renal insufficiency, and obviously should not be overloaded with alkalinizing sodium salts or unlimited fluid intake. Acetazolamide, a carbonic anhydrase inhibitor, produces rapid and effective urinary alkalization and sometimes is used in conjunction with alkali therapy. When a 250-mg dose of acetazolamide is given at bedtime, the excretion of an acidic urine in the early morning hours is avoided. The usual tachyphylaxis (rapid tolerance) to this drug is obviated by a daily repletion dose of bicarbonate.

Since the advent of allopurinol, a low-purine, low-protein diet in the patient with uric acid nephrolithiasis is no longer as critical as it once was; however, it is still advisable to instruct the patient to avoid foods rich in purine and to limit protein to no more than 90 g/day. Such a diet is still palatable and reduces appreciably the amount of uric acid in the urine.

The mainstay of drug therapy for recurrent uric acid nephrolithiasis is allopurinol. It is effective in reducing both serum and urinary uric acid levels, thus preventing the formation of calculi. Allopurinol is also recommended as prophylactic treatment in patients who will receive cytotoxic agents for the treatment of lymphoma or leukemia. The marked increase in uric acid production associated with cytotoxicity of a neoplasm predisposes a patient to the development of uric acid nephrolithiasis.

■ PROPHYLACTIC THERAPY OF INTERCRITICAL GOUT

6 After the first attack of acute gouty arthritis or after the passage of the first renal stone, a decision to institute prophylactic therapy must be entertained. The decision to institute pharmacotherapy for prevention of gout attacks should carefully balance risk and benefit. Prophylactic therapy has been found to be cost-effective if patients have two or more attacks per year, even if the serum uric acid concentration is normal or only minimally elevated.^{60,61}

If the first episode was mild and responded promptly to treatment, the patient's serum urate concentration was elevated only minimally, and the 24-hour urinary uric acid excretion was not excessive (<1,000 mg/24 hours on a regular diet), then prophylactic treatment can be withheld. Some patients never have a second attack or a second stone. Others may not experience a second gouty episode for 5 to 10 years. Consequently, a wait-and-see approach seems justified in patients who meet these conditions.⁶²

On the other hand, if the patient had a severe attack of gouty arthritis, a complicated course of uric acid nephrolithiasis, a substantially elevated serum uric acid level (>10 mg/dL), or a 24-hour urinary excretion of uric acid of more than 1,000 mg, then prophylactic treatment should be instituted immediately after resolution of the acute episode. Patients with tophi should also be administered prophylactic therapy. When implemented, urate-lowering therapy should not commence during an acute attack, but 6 to 8 weeks after resolution.¹⁴

Prophylactic therapy with low-dose oral colchicine, 0.5 to 0.6 mg twice daily, may be effective in preventing recurrent arthritis in patients with no evidence of visible tophi and a normal or slightly elevated serum urate concentration. Patients do not become resistant to or tolerant of daily colchicine, and if they sense the beginning of an acute attack, they should increase the dose to 1 mg every 2 hours; in most instances the attack will abort after 1 or 2 mg of colchicine. If the serum urate concentration is within the normal range and the patient has been symptom-free for 1 year, maintenance colchicine may be discontinued. The patient should be advised, however, that discontinuation of the treatment program may be followed by an exacerbation of acute gouty arthritis.

Patients with a history of recurrent acute gouty arthritis and a significantly elevated serum uric acid concentration probably are best managed with uric acid-lowering therapy. The goal of initiating urate-lowering therapies is to achieve and maintain a serum uric acid concentration of less than 6 mg/dL, and preferably below 5 mg/dL.^{22,62} Reduction of the serum urate concentration can be accomplished pharmacologically by decreasing the synthesis of uric acid (xanthine oxidase inhibitors), or by increasing the renal excretion of uric acid (uricosurics). Colchicine at a dose of 0.5 mg twice daily is sometimes administered during the first 6 to 12 months of antihyperuricemic therapy to minimize the risk of acute attacks that may occur during initiation of uric acid-lowering therapy.

Xanthine Oxidase Inhibitor

7 Currently, allopurinol is the only drug approved in the United States for use in inhibiting uric acid synthesis. Because allopurinol is efficacious for prophylaxis of recurrent gout attacks in both under-excretors and overproducers of uric acid, it is the most widely prescribed agent for the long-term management of gout.⁴⁸ Both allopurinol and its major metabolite, oxypurinol, are xanthine oxidase inhibitors and thus impair the conversion of hypoxanthine to xanthine and xanthine to uric acid. Allopurinol also lowers the intracellular concentration of PRPP.

Allopurinol lowers uric acid levels in a dose-dependent manner. Because of the long half-life of its metabolite, allopurinol can be given once daily. It is typically initiated at a dose of 100 mg/day, and titrated

by 100 mg/day at 1-week intervals to achieve a serum uric acid level of 6 mg/dL or less, which will promote shrinkage of tophi.⁶³ Serum uric acid levels can be checked approximately 1 week after initiating or modifying the dose of allopurinol. Typical doses of 100 to 300 mg/day are used, although tophaceous gout may require doses of 400 to 600 mg/day and the maximum recommended dose of allopurinol is 800 mg/day. Allopurinol should be considered for long-term use when prescribed, as intermittent administration has been found to be less effective in controlling gouty attacks.⁶⁴

Although allopurinol is the most effective urate-lowering agent available, up to 5% of patients are unable to tolerate it because of adverse effects, and long-term persistence with allopurinol therapy may be less than optimal.⁶⁵ Mild adverse effects such as skin rash, leukopenia, gastrointestinal problems, headache, and urticaria can occur with allopurinol administration. More severe adverse reactions including severe rash (toxic epidermal necrolysis, erythema multiforme, or exfoliative dermatitis), hepatitis, interstitial nephritis, and eosinophilia reportedly occur in approximately 2% of patients, and are associated with a 20% mortality.^{22,66} This “allopurinol hypersensitivity syndrome” is dose related (200 to 400 mg/daily) and occurs more commonly in the presence of renal insufficiency.⁶⁶ The dose of allopurinol should be reduced in patients with renal insufficiency (200 mg/day for creatinine clearance of 60 mL/min, and 100 mg/day for creatinine clearance of 30 mL/min). However, some evidence exists that allopurinol can be safely used at higher doses than traditionally recommended in patients with renal impairment.⁶⁷

CLINICAL CONTROVERSY

To reduce the risk of developing the allopurinol hypersensitivity syndrome, some experts believe that the dose of allopurinol should be adjusted based on the patient's creatinine clearance.

A desensitization protocol (Table 96-7) is recommended for gout patients who have experienced maculopapular eruptions or mild rashes on allopurinol.⁶⁸ In addition, it is recommended for patients with gout and renal insufficiency (where uricosurics are contraindicated), gout caused by urate overproduction, intolerance or allergic reactions to uricosuric agents, and malignancy-associated hyperuricemia.^{22,68} Unfortunately, not all patients are successfully able to be desensitized, and desensitization should not be attempted in patients who have previously experienced the allopurinol hypersensitivity syndrome.⁶⁹

Uricosuric Drugs

Uricosuric drugs increase the renal clearance of uric acid by inhibiting postsecretory renal proximal tubular reabsorption of uric acid. The drugs used most widely to increase uric acid excretion are probenecid and sulfapyrazone. Several other uricosuric drugs are available in Europe, but they have not been approved for use in the United States.

TABLE 96-7 Protocol for Desensitizing Patients Unable to Tolerate Allopurinol

Daily Allopurinol Dose	Preparation	Days
50 mcg	0.25 mL (1 mg/5 mL)	1–3
100 mcg	0.5 mL (1 mg/5 mL)	4–6
200 mcg	1 mL (1 mg/5 mL)	7–9
500 mcg	2.5 mL (1 mg/5 mL)	10–12
1 mg	5 mL (1 mg/5 mL)	13–15
5 mg	2.5 mL (10 mg/5 mL)	16–18
10 mg	5 mL (10 mg/5 mL)	19–21
25 mg	12.5 mL (10 mg/5 mL)	22–24
50 mg	1/2 of 100-mg tablet	25–27
100 mg	100-mg tablet	28 and beyond

Therapy with uricosuric drugs should be started at a low dose to avoid marked uricosuria and possible stone formation. They should be used only in patients with documented underexcretion of urate (less than 800 mg in 24 hours on a regular diet, or 600 mg on a purine-restricted diet). The maintenance of adequate urine flow and alkalization of the urine during the first several days of uricosuric therapy further diminish the possibility of uric acid stone formation. Probenecid is given initially at a dose of 250 mg twice a day for 1 to 2 weeks and then 500 mg twice a day for 2 weeks. Thereafter the daily dose is increased by 500-mg increments every 1 to 2 weeks until satisfactory control is achieved or a maximum dose of 2 g is reached. The initial dose of sulfapyrazone is 50 mg twice a day for 3 to 4 days and then 100 mg twice a day, increasing the daily dose by 100-mg increments each week up to 800 mg/day.

The major adverse effects associated with uricosuric therapy are gastrointestinal irritation, rash and hypersensitivity, precipitation of acute gouty arthritis, and stone formation. Of the two agents, probenecid is the most frequently used uricosuric as sulfapyrazone is associated with more severe adverse effects. A disadvantage of uricosurics is that salicylates may interfere with this mechanism and result in treatment failure;²² however, low-doses (325 mg/day or less) of enteric-coated aspirin may be used cautiously.⁷⁰ In addition, probenecid can inhibit the tubular secretion of other organic acids; thus, increased plasma concentrations of penicillins, cephalosporins, sulfonamides, and indomethacin can occur. Because it is chemically related to phenylbutazone, sulfapyrazone can act as an antiplatelet agent and should be used with great caution in anticoagulated patients, or those with peptic ulcer disease.

8 Uricosuric drugs are contraindicated in patients who are allergic to them and in patients with impaired renal function (a creatinine clearance <50 mL/min), a history of renal calculi, and in patients who are overproducers of uric acid; for such patients, allopurinol should be used.

Miscellaneous Agents

Several other medications have been effective in gout. Benzbromarone is a uricosuric that is efficacious in patients with renal insufficiency, but it is not available in the United States.² Oxypurinol, a metabolite of allopurinol, is not commercially available in the United States, but can be obtained through the manufacturer on a compassionate basis.⁵³ Several newer medications, such as uric acid oxidase (uricase), and febuxostat, are currently under investigation and may offer additional options in the future.^{4,53} Of these agents, febuxostat has demonstrated superior efficacy to allopurinol in reducing serum urate, but had an increase in rebound gout flares.⁷¹ It has received an approvable letter from the United States FDA, pending completion of a currently ongoing phase III clinical trial. A recombinant form of uricase (rasburicase) is currently available and indicated for use in the management of hyperuricemia in children with leukemia, lymphoma, or solid-tumor malignancies who are likely to experience tumor lysis syndrome. The efficacy of rasburicase has not been assessed outside of the oncology setting in adults with acute gouty arthritis.

Lipid-lowering agents, in particular fenofibrate, can also be prescribed for patients with gout. Although dyslipidemia is common in gout patients, the fibrates are believed to exert their effects as an ancillary benefit by increasing the clearance of hypoxanthine, and xanthine, leading to a sustained reduction in serum urate. Reductions of 20% to 30% in urate levels are observed with fenofibrate use.^{72,73} Importantly, fenofibrate does not appear to not cause an acute gout flare when initiated, and is well tolerated overall.^{74,75}

Losartan, an angiotensin II receptor antagonist, has also demonstrated benefit in reducing serum urate independent of angiotensin receptor antagonism.⁷⁶ Losartan inhibits renal tubular reabsorption of uric acid and increases urinary excretion, and this effect seems to be a unique property of losartan that is not shared with other

angiotensin II receptor antagonists.⁷⁷ In addition, it alkalinizes the urine, which helps reduce the risk for stone formation.

■ ASYMPTOMATIC HYPERURICEMIA

Questions are often raised regarding the indications for drug therapy for asymptomatic hyperuricemia. The purported benefits from treatment include prevention of acute gouty arthritis, tophi formation, nephrolithiasis, and chronic urate nephropathy. The first three complications are easily controlled should they develop; therefore antihyperuricemic therapy is not warranted to prevent these conditions. The prevention of urate nephropathy might be a stronger indication because it is irreversible even with proper treatment. Available data indicate, however, that gouty nephropathy is extremely rare in the absence of clinical gout, and evidence that elevation of uric acid by itself may cause renal disease is weak and inconclusive.¹⁸ As discussed previously, renal impairment is very rare in the absence of concurrent hypertension and atherosclerosis. In addition, it is unclear whether uric acid-lowering therapy protects renal function in such individuals. Thus, the routine treatment of asymptomatic hyperuricemia on the grounds of reducing renal complications is presently not recommended.

The relationship between elevated serum urate and cardiovascular disease is controversial. In observational studies, hyperuricemia has been shown to be a risk factor for ischemic heart disease.^{78–81} However, as hyperuricemia is also associated with other known risk factors for cardiovascular disease, such as diabetes mellitus, dyslipidemia, and hypertension, the individual contribution of hyperuricemia on the risk for cardiovascular disease is difficult to separate from these associated factors. No studies have examined whether drug treatment of asymptomatic hyperuricemia is protective against coronary artery disease, and the available data at this time do not justify routine therapy for patients with asymptomatic hyperuricemia for this indication.

CLINICAL CONTROVERSY

Although asymptomatic hyperuricemia is not generally treated, some clinicians have begun recommending treatment to reduce the risk of coronary artery disease. Hyperuricemia is associated with both hypertension and coronary artery disease, and patients with elevated uric acid levels and hypertension may have an increased risk of cardiovascular morbidity and mortality.

■ PHARMACOECONOMIC CONSIDERATIONS

Assuming patients with asymptomatic hyperuricemia are not treated with pharmacologic therapy, pharmacoeconomic considerations apply only to the management of the acute and chronic clinical manifestations of gout.

In a cost-effectiveness analysis in patients with nontophaceous recurrent gouty arthritis, urate-lowering therapy was found to reduce costs if patients experienced two or more recurrent attacks per year.⁶⁰ Generic allopurinol was associated with a lower incremental cost-effectiveness ratio than were either probenecid or sulfinpyrazone.

In the case of chronic tophaceous gout, a need to continue long-term therapy with a urate-lowering drug clearly exists. Allopurinol generally is less expensive than uricosuric therapy and may be more effective. Comparative trials are lacking. For severe cases, combination therapy may be indicated. Many clinicians will add colchicine to the regimen to reduce the likelihood of precipitating acute gouty arthritis, but this does not appear to be a cost-effective measure.

■ EVALUATION OF THERAPEUTIC OUTCOMES

Followup of the gout sufferer depends on the frequency of attacks and on the medications used to treat symptoms. For a patient who is

experiencing a first attack of gout, long-term therapy is generally not indicated. As mentioned previously, most experts agree that treatment should be started only after two or three attacks of gout, because the treatment is long-term and relatively expensive, the drugs used are potentially toxic, and adherence in patients without symptoms is generally poor.^{61,65} Patients having a first attack should be educated about the likelihood of recurrence and what to do if another attack occurs. Approximately 60% of patients have a second attack within the first year, and 78% have a second attack within 2 years. Only 7% of patients do not have a recurrence within a 10-year period.⁸²

Baseline blood work for patients receiving hypouricemic medications chronically should include renal function (serum creatinine, blood urea nitrogen), liver enzymes (aspartate aminotransferase, alanine aminotransferase), complete blood count, and electrolytes. There is generally no need to recheck these laboratory parameters for patients undergoing acute therapy with an NSAID or colchicine of limited duration. However, in patients requiring long-term therapy or prophylaxis, they should be rechecked every 6 to 12 months, or as clinically indicated. In patients without evident tophi, consideration can be given to discontinuing long-term therapy 6 to 12 months after normal serum urate levels are obtained.

For patients suspected of having an acute attack of gouty arthritis, it is reasonable to check a serum uric acid level, particularly if it is not the first attack and a decision is to be made regarding initiation of prophylactic therapy. However, clinicians should be mindful that acute gouty arthritis can occur in the presence of normal serum uric acid concentrations.¹⁵ Repeat serum uric acid levels do not need to be routinely monitored in patients, with the exception of during the titration phase of allopurinol to achieve a goal serum urate of <6 mg/dL.⁸³

⑨ Because of comorbidity with diabetes mellitus, lipid abnormalities, hypertension, and stroke, elevated uric acid levels or gout should prompt evaluations for signs of cardiovascular disease and the need for appropriate risk reduction measures.³⁷ Additionally, clinicians should look for a possible correctable cause of hyperuricemia, such as medications (e.g., thiazide diuretics, niacin, cyclosporine), obesity, malignancy, and alcohol abuse. Patients should be encouraged to exercise, lose weight, reduce alcohol intake, and control blood pressure and have periodic followup to address these conditions.

CONCLUSIONS

Hyperuricemia may lead to acute arthritis, chronic gout, or kidney stones, or to no sequelae at all. Asymptomatic hyperuricemia need not be treated, although lifestyle modifications (e.g., weight loss, reduction of alcohol intake, control of blood pressure) should be encouraged to help reduce serum urate and overall cardiovascular health.

Acute gouty arthritis responds well to short courses of NSAIDs to treat the underlying inflammatory condition. Colchicine is also highly effective, but has the lowest benefit-to-toxicity ratio of the available pharmacotherapy for acute gouty arthritis. If contraindications to NSAIDs or colchicine exist, or there is lack of response to these agents, or polyarticular involvement is noted, intraarticular or oral corticosteroids may be used. The management of uric acid nephrolithiasis includes hydration and alkalinization of the urine. Prevention of recurrent gouty arthritis or recurrent nephrolithiasis and treatment of chronic gout require hypouricemic therapy with either a uricosuric drug or allopurinol. Allopurinol is effective in both underexcretors and overproducers of uric acid, making it the hypouricemic drug of choice in most patients with gout.

ABBREVIATIONS

ACTH: adrenocorticotrophic hormone

HGPRT: hypoxanthine guanine phosphoribosyl transferase

NSAID: nonsteroidal antiinflammatory drug

PRPP: phosphoribosyl pyrophosphate (synthetase)

SECTION 13

OPHTHALMIC AND OTOLARYNGOLOGIC DISORDERS

CHAPTER

97

Glaucoma

RICHARD G. FISCELLA, TIMOTHY S. LESAR, AND DEEPAK P. EDWARD

KEY CONCEPTS

- 1 Primary open-angle glaucoma (POAG) or ocular hypertension (ocular hypertension) is more prevalent than closed- or narrow-angle glaucoma.
- 2 In any form of glaucoma, reduction of intraocular pressure (IOP) is essential.
- 3 IOP is a very important risk factor for glaucoma, but the most important considerations are progression of glaucomatous changes in the back of the eye (optic disk and nerve fiber layer) and visual field changes when diagnosing and monitoring for POAG or ocular hypertension.
- 4 Optic nerve changes often occur before visual field changes are exhibited.
- 5 Recent studies demonstrate that reduction in IOP prevents progression or even onset of glaucoma.
- 6 Newer medications simplify treatment regimens for patients. Prostaglandin analogs are considered the most potent topical medications for reducing IOP and flattening diurnal variations in intraocular pressure.
- 7 Local adverse events are common with topical glaucoma medications, but patient education and reinforcing adherence are essential to prevent glaucoma progression.

The glaucomas are a group of ocular disorders that lead to an optic neuropathy characterized by changes in the optic nerve head (optic disk) that is associated with loss of visual sensitivity and field. Increased intraocular pressure (IOP), a traditional diagnostic criterion for glaucoma, is thought to play an important role in the pathogenesis of glaucoma, but is no longer a diagnostic criterion for glaucoma.^{1–10} Two major types of glaucoma have been identified:

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

open angle and closed angle. Open-angle glaucoma accounts for the great majority of cases. Either type can be a primary inherited disorder, congenital, or secondary to disease, trauma, or drugs, and can lead to serious complications.^{11–16} Both primary and secondary glaucomas may be caused by a combination of open-angle and closed-angle mechanisms (Table 97–1).

BASIC CONCEPTS

AQUEOUS HUMOR DYNAMICS AND INTRAOCULAR PRESSURE

An understanding of IOP and aqueous humor dynamics will assist the reader in understanding the drug therapy of glaucoma.^{1,2,17–19}

Aqueous humor is formed in the ciliary body and its epithelium (Figs. 97–1 and 97–2) through both filtration and secretion. Because ultrafiltration depends on pressure gradients, blood pressure and IOP changes influence aqueous humor formation. Osmotic gradients produced by active secretion of sodium and bicarbonate, and possibly other solutes such as ascorbate from the ciliary body epithelial cells into the aqueous humor, result in movement of water from the pool of ciliary stromal ultrafiltrate into the posterior chamber, forming aqueous humor. Carbonic anhydrase (primarily isoenzyme type II), α - and β -adrenergic receptors, and sodium- and potassium-activated adenosine triphosphatases are found on the ciliary epithelium and appear to be involved in this secretion of the solutes sodium and bicarbonate.

Receptor systems controlling aqueous inflow have not been elucidated fully. Pharmacologic studies suggest that β -adrenergic agents increase inflow, whereas α_2 -adrenergic blocking, α -adrenergic blocking, β -adrenergic blocking, dopamine-blocking, carbonic, anhydrase-inhibiting, and adenylate cyclase-stimulating agents decrease aqueous inflow. Aqueous humor produced by the ciliary body is secreted into the posterior chamber at a rate of approximately 2 to 3 $\mu\text{L}/\text{min}$. The pressure in the posterior chamber produced by the constant inflow pushes the aqueous humor between the iris and lens and through the pupil into the anterior chamber of the eye (see Fig. 97–2).^{1,2,17–22}

Aqueous humor in the anterior chamber leaves the eye by two routes: (a) filtration through the trabecular meshwork (conventional outflow) to the Schlemm canal (80% to 85%) and (b) through the

TABLE 97-1 General Classification of Glaucoma

ciliary body and the suprachoroidal space (uveoscleral outflow or unconventional outflow). Cholinergic agents such as pilocarpine increase outflow by physically opening the meshwork pores secondary to ciliary muscle contraction. The uveoscleral outflow of aqueous humor is also increased by prostaglandin analogs, and β - and α_2 -adrenergic agonists. Constant inflow of aqueous humor from the ciliary body and resistance to outflow result in an IOP great enough to produce an outflow rate equal to the inflow rate (see Fig. 97-2).

The median IOP measured in large populations is 15.5 ± 2.5 mm Hg; however, the distribution of pressures around the mean is skewed to the right (toward higher readings). IOP is not constant and changes with pulse, blood pressure, forced expiration or coughing, neck compression, and posture. IOP is measured by tonometry: indentation tonometry, applanation tonometry, or a noncontact method using an air pulse. These methods may result in slightly different pressure readings. IOPs consistently greater than 21 mm Hg are found in 5% to 8% of the general population. The incidence increases with age, such that “abnormal” (i.e., >22 mm Hg) IOP is found in 15% of those 70 to 75 years of age. Intermittently high IOP (>40 mm Hg) is found in patients with closed-angle glaucoma (CAG). The increased IOP in all types of glaucoma results from the decreased facility for aqueous humor outflow through the trabecular meshwork. Aqueous humor production in primary open-angle glaucoma (POAG) is normal.^{1,2,17-19}

IOP demonstrates considerable circadian variation (often referred to as *diurnal* IOP or the IOP during the daily 24-hour cycle)

**FIGURE 97-1.** Anatomy of the eye.

primarily because of changes in the rate of aqueous humor formation. This circadian variation results in a minimum IOP at approximately 6 PM and a maximum IOP at awakening, although some studies suggest that both healthy and glaucoma patients may have their highest IOP at night after falling asleep.²⁰ Low systemic blood pressure in conjunction with high IOPs (decreased ocular perfusion pressure) at night can result in optic nerve head damage.²⁰ Generally, the circadian IOP variation is usually less than 3 to 4 mm Hg; however, it may be greater in patients with glaucoma. This circadian variation and the poor relationship of IOP with visual loss make measurement of IOP a poor screening test for glaucoma.

Although increased IOP within any range is associated with a higher risk of glaucomatous damage, it is both an insensitive and nonspecific diagnostic and monitoring tool. Of individuals with IOP between 21 and 30 mm Hg, only 0.5% to 1% per year will develop optic disk changes and visual field loss (i.e., glaucoma) over 5 to 15 years. However, more subtle retinal damage, such as alteration of color vision or decreased contrast sensitivity, occurs in a higher

**FIGURE 97-2.** Anterior chamber of the eye and aqueous humor flow.

FIGURE 97-3. Normal fundus of the eye and optic disk and cup.

percentage of patients with IOPs greater than 21 mm Hg, and the incidence of visual field defects increases to as high as 28% in individuals with IOPs above 30 mm Hg. For a given abnormal IOP, the incidence of glaucoma increases with age. In patients with preexisting optic nerve damage, the worse the existing damage, the more sensitive the eye is to a given IOP. As many as 20% to 30% of patients with glaucomatous visual field loss have an IOP of less than 21 mm Hg (called *normal-tension glaucoma*, referring to the normal IOP). Thus the absolute IOP is a less-precise predictor of optic nerve damage. More direct measurements of therapeutic outcome, such as optic disk examination and visual-field evaluation, also must be used as monitors of disease progression.^{1-7,17-24} Taking the above factors into consideration, glaucoma medications that provide maximal reduction of IOP over 24 hours and have minimal influence on blood pressure may be advantageous in treating glaucoma patients.

OPTIC DISK AND VISUAL FIELDS

The optic disk is the portion of the optic nerve ophthalmoscopically visible as it leaves the eye. It consists of approximately 1 million retinal ganglion nerve cell axons, blood vessels, and supporting connective tissue structures (lamina cribrosa). The small depression within the disk is termed the *cup* (Fig. 97-3). A normal physiologic cup does not extend beyond the optic nerve rim and has a varying diameter of less than one-third to one-half that of the disk (cup-to-disk ratio: 0.33 to 0.5). Table 97-2 lists the common alterations of

TABLE 97-2 Optic Disk and Visual Field Findings

Optic disk

Cup-to-disk ratio >0.5
 Progressive increase in cup size
 Cup-to-disk ratio asymmetry >0.2
 Vertical elongation of the cup
 Excavation of the cup
 Increased exposure of lamina cribrosa
 Pallor of the cup
 Splinter hemorrhages
 Cupping to edge of disk
 Notching of the cup (usually superior or inferior)
 Nerve fiber defects

Visual field findings

General peripheral field constriction
 Isolated scotomas (blind spots)
 Nasal visual field depression ("nasal step")
 Enlargement of blind spot
 Large arc-like scotomas
 Reduced contrast sensitivity
 Reduced peripheral acuity
 Altered color vision

the optic disk found in glaucoma. These disk changes result from optic nerve axonal degeneration and remodeling of the supporting structures. As the nerve axons die, the cup becomes larger in relation to the whole disk. A loss of retinal nerve fiber layer visibility might be visualized in glaucoma patients with detectable visual field loss. This pattern of changes is consistent with visual field losses and loss of visual sensitivity seen in glaucoma.^{1,2,17-24}

Determination of the visual field allows assessment of optic nerve damage and is an important monitoring parameter in treatment. However, visual field changes lag behind optic disk changes, and a loss of 25% to 35% of retinal ganglion cells is usually required before detectable visual field defects are noted. The peripheral visual field is measured using a visual field instrument called a *perimeter*. Characteristic visual field loss occurs in glaucoma (Fig. 97-4; see also Table

FIGURE 97-4. Schematic of the progression of visual field loss in glaucoma.

97–2), but loss of central visual acuity usually does not occur until late in the disease. Other indicators, such as color vision changes and contrast sensitivity, may allow earlier and more sensitive detection of glaucomatous changes.^{1,2}

GENETICS

Glaucoma is often inherited as a complex multifactorial disease, but it can also be inherited as a mendelian autosomal-dominant or autosomal-recessive trait form. The common age-related adult-onset glaucoma, like POAG, although containing heritability of some significance, is more complex and is influenced by environmental factors. Genetic studies have more clearly defined the underlying molecular events responsible for the mendelian forms of the disease. However, the chromosome locations identified may play some factor in the more complex forms. A number of major gene loci associated with POAG have been identified. The molecular mechanism of how mutations in any of these genes result in increased IOP with loss of visual field has not been elucidated. The future of genetic studies in glaucoma will include discovery of new glaucoma genes, determination of clinical phenotypes associated with these genes and mutations, understanding how environmental factors interact, and developing a database that can be used for further testing. It is hoped that improved understanding of the genetic origins of POAG will lead to new diagnostic tools and therapies that target the underlying causes of the disease.^{1,2,25,26}

EPIDEMIOLOGY OF OPEN-ANGLE GLAUCOMA

① Open-angle glaucoma is the second leading cause of blindness, affecting up to 3 million individuals in the United States and up to 60.5 million individuals worldwide by 2010. It is estimated that by 2010, 135,000 persons in the United States, and about 4.5 million in the world, will have bilateral blindness. The prevalence rate varies with age, race, diagnostic criteria, and other factors. In the United States, open-angle glaucoma occurs in 1.5% of the population older than 30 years of age, 1.3% of whites and 3.5% of blacks. The incidence of open-angle glaucoma increases with increasing age. The incidence of the disease in patients 80 years of age is 3% in whites and 5% to 8% in blacks.

ETIOLOGY OF OPEN-ANGLE GLAUCOMA

② The specific cause of glaucomatous optic neuropathy is presently unknown. Previously, increased IOP was considered to be the sole cause of the damage; however, it is now recognized that IOP is only one of many factors associated with the development and progression of glaucoma.^{1–10} Increased susceptibility of the optic nerve to ischemia, a reduced or dysregulated blood flow, excitotoxicity, autoimmune reactions, and other abnormal physiologic processes are likely additional contributory factors. The final outcome of these processes is believed to be apoptosis of the retinal ganglion cells, which results in axonal degeneration, and finally permanent loss of vision.^{11–16} Interestingly enough, there appears to be a fair amount of similarity between neuronal cell death by apoptosis in Alzheimer's disease and glaucoma.¹³ Indeed, open-angle glaucoma may represent a number of distinct diseases or conditions that simply manifest the same symptoms. Susceptibility to visual loss at a given IOP varies considerably; some patients do not demonstrate damage at high IOPs, whereas other patients have progressive visual field loss despite an IOP in the normal range (normal-tension glaucoma).

Although IOP poorly predicts which patients will have visual field loss, the risk of visual field loss clearly increases with increasing IOP within any range. In fact, recent studies demonstrate that lowering IOP, no matter what the pretreatment IOP, reduces the risk of glaucomatous progression or may even prevent the onset to early glaucoma in patients with ocular hypertension.^{3–7}

The mechanism by which a certain level of IOP increases the susceptibility of a given eye to nerve damage remains controversial. Multiple mechanisms are likely to be operative in a spectrum of combinations to produce the death of retinal ganglion cells and their axons in glaucoma. Pressure-sensitive astrocytes and other cells in the optic disk supportive matrix may produce changes and remodeling of the disk, resulting in axonal death. Vasogenic theories suggest that optic nerve damage results from insufficient blood flow to the retina secondary to the increased perfusion pressure required in the eye, dysregulated perfusion, or vessel wall abnormalities, and results in degeneration of axonal fibers of the retina. Another theory suggests that the IOP may disrupt axoplasmal flow at the optic disk.

Recently, focus on the mechanisms of the retinal ganglion cell apoptosis and the role of excessive glutamate and nitric oxide found in glaucoma patients has broadened the focus of drug therapy research to include evaluation of agents that act as neuroprotectants.^{12–15} Such agents may be particularly useful in patients with normal-pressure glaucoma, in whom pressure-independent factors may play a relatively larger role in disease progression. These agents would target risk factors and underlying pathophysiologic mechanisms of disease other than IOP.^{11–16}

PATHOPHYSIOLOGY OF OPEN-ANGLE GLAUCOMA

③ As stated previously, optic nerve damage in POAG can occur at a wide range of intraocular pressures, and the rate of progression is highly variable. Patients may exhibit pressures in the 20 to 30 mm Hg range for years before any disease progression is noticed in the optic disk or visual fields. That is why open-angle glaucoma is often referred to as the “sneak thief of sight.”

CLINICAL PRESENTATION OF GLAUCOMA

General

- Glaucoma can be detected in otherwise asymptomatic patients, or patients can present with characteristic symptoms, especially vision loss. POAG is a chronic, slowly progressive disease found primarily in patients older than 50 years of age, whereas CAG is more typically associated with symptomatic acute episodes.

Symptoms

- POAG: None until substantial visual field loss occurs.
- CAG: Nonsymptomatic or prodromal symptoms (blurred or hazy vision with halos around lights that is caused by a hazy, edematous cornea, and occasionally headache) may be present. Acute episodes produce symptoms associated with a cloudy, edematous cornea, ocular pain or discomfort, nausea, vomiting, abdominal pain, and diaphoresis.

Signs

- POAG: Disk changes and visual field loss (see Table 97–2); IOP can be normal or elevated (>21 mm Hg).
- CAG: Hyperemic conjunctiva, cloudy cornea, shallow anterior chamber, and occasionally an edematous and hyperemic optic disk; IOP is generally elevated markedly (40 to 90 mm Hg) when symptoms are present.

Laboratory Tests

- None

Other Diagnostic Tests

- Emerging tests include optical coherence tomography, retinal nerve fiber analyzers, and confocal scanning laser tomography of the optic nerve.

CLINICAL PRESENTATION OF OPEN-ANGLE GLAUCOMA

POAG is a bilateral, genetically determined disorder constituting 60% to 70% of all glaucomas and 90% to 95% of primary glaucomas (see Clinical Presentation of Glaucoma above). An increased IOP is not required for diagnosis of POAG. Symptoms do not present until substantial visual field constriction occurs. Central visual acuity typically is maintained, even in the late stages of the disease. Even though POAG is a bilateral disease, it may have greater progression and severity in one eye.

④ Detection and diagnosis involve evaluation of the optic disk and retinal nerve fiber layer, assessment of the visual fields, and measurement of IOP. The presence of characteristic disk changes and visual field loss with or without increased IOP confirms the diagnosis of glaucoma. Typical disk changes and field loss occurring at an IOP of less than 21 mm Hg account for 20% to 30% of patients and are referred to as *normal-tension glaucoma*. Elevated IOP (>21 mm Hg) without disk changes or visual field loss is observed in 5% to 7% of individuals (known as *glaucoma suspects*) and is referred to as *ocular hypertension*. New technologies such as optical coherence tomography, retinal nerve fiber analyzers, or confocal scanning laser tomography of the optic nerve head may allow early identification of signs of glaucomatous retinal changes in ocular hypertensives, thus allowing for earlier initiation of therapy.^{1-3,17}

Secondary open-angle glaucoma has many causes, including exfoliation syndrome, pigmentary glaucoma, systemic diseases, trauma, surgery, ocular inflammatory diseases, and medications. A system for classifying secondary glaucomas into pretrabecular, trabecular, and posttrabecular forms has been proposed. This classification allows drug therapy to be chosen on the basis of the pathogenic mechanism involved. In pretrabecular forms, a normal meshwork is covered that does not permit aqueous humor outflow. Trabecular forms of secondary glaucoma result from either an alteration of meshwork or an accumulation of material in the intertrabecular spaces. The posttrabecular forms result primarily from disorders causing increased episcleral venous blood pressure.^{1,2,15-17}

PROGNOSIS OF OPEN-ANGLE GLAUCOMA

⑤ In most cases of POAG, the overall prognosis is excellent when it is discovered early and treated adequately. Even patients with advanced visual field loss can have continued visual field loss reduced if the IOP is maintained at low enough pressures (often <10 to 12 mm Hg). Progression of visual field loss still occurs in 8% to 20% of patients despite reaching standard therapy IOP goals. However, in untreated patients and in those who fail to achieve target IOP reduction, up to 80% have continued visual field loss. Estimates of progression to bilateral blindness in treated patients range from 4% to 22%. Thus the keys to medical treatment of POAG are an effective, well-tolerated drug regimen, close monitoring of therapy, and adherence. Medications will control IOP successfully in 60% to 80% of patients over a 5-year period. Availability of newer, highly effective, well-tolerated agents may improve the prognosis further.^{1,2,5,17-19,23-28}

EPIDEMIOLOGY OF CLOSED-ANGLE GLAUCOMA

The incidence of closed-angle glaucoma varies by ethnic group, with a higher incidence in individuals of Inuit, Chinese, and Asian-Indian descent. Incidence rates of 1% to 4% have been reported in these populations.^{1,2}

ETIOLOGY OF CLOSED-ANGLE GLAUCOMA (ANGLE-CLOSURE GLAUCOMA)

Primary CAG accounts for 5% or less of primary glaucomas; however, when CAG occurs, it may need to be treated as an emergency to avoid visual loss. CAG results from mechanical blockage of the (usually normal) trabecular meshwork by the peripheral iris. Partial or complete blockage of the meshwork occurs intermittently, resulting in extreme fluctuations between normal IOP with no symptoms, and very high IOP with symptoms of acute CAG. Between attacks of CAG, the IOP is usually normal unless the patient has concomitant open-angle glaucoma or nonreversible blockage of the meshwork with synechiae (“creeping” angle closure) that develops over time in the narrow-angle eye. Primary CAG occurs in patients with inherited shallow anterior chambers, which produce a narrow angle between the cornea and iris or tight contact between the iris and lens (pupillary block). The presence of a narrow angle is determined mainly by visualization of the angle by gonioscopy. Other tests for CAG involve provocation of an angle-closure-induced IOP increase. These tests, which attempt to produce angle closure through mydriasis (darkroom test or mydriasis test), or gravity (prone test), are rarely performed in the clinical setting.

Two major types of classic, reversible primary CAG have been described: CAG with pupillary block and CAG without pupillary block. CAG with pupillary block results when the iris is in firm contact with the lens. This produces a relative block of aqueous flow through the pupil to the anterior chamber (pupillary block), resulting in a bowing forward of the iris, which blocks the trabecular meshwork. CAG with pupillary block occurs most commonly when the pupil is in middilation. In this position, the combination of pupillary block and relaxed iris allows the greatest bowing of the iris; however, angle closure may occur during miosis or mydriasis.

CAG can occur without significant pupillary block in patients with an abnormality called a *plateau iris*. The ciliary processes in these cases are situated anteriorly, which indent the iris forward and cause closure of the trabecular meshwork, especially during mydriasis. The mydriasis produced by anticholinergic drugs or any other drug results in precipitation of both types of CAG glaucoma, whereas drug-induced miosis may produce pupillary block.

PATHOPHYSIOLOGY OF CLOSED-ANGLE GLAUCOMA

The mechanism of IOP elevation in CAG is clearer than that of POAG. In CAG, a physical blockage of trabecular meshwork is present. In many cases, single or multiple episodes of excessively high IOP (>40 mm Hg) result in optic nerve damage. Very high IOP (>60 mm Hg) may result in permanent loss of visual field within a matter of hours to days.

One type of CAG, known as “creeping” angle closure, occurs in patients with narrow angles in which the iris adheres to the trabecular meshwork and may result in continuously increased IOP in ranges more similar to those of POAG, and the clinical behavior is similar to POAG, with individuals differing in the degree and rapidity of visual loss from any given elevated IOP.¹

CLINICAL PRESENTATION OF CLOSED-ANGLE GLAUCOMA

Patients with untreated CAG typically experience intermittent nonsymptomatic or prodromal symptoms brought on by precipitating events (see Clinical Presentation of Glaucoma above). Increased IOP during such prodromal episodes is not great enough or long enough to produce the other symptoms of a full-blown

TABLE 97-3 Drugs That May Induce or Potentiate Increased Intraocular Pressure

Open-angle glaucoma
Ophthalmic corticosteroids (high risk)
Systemic corticosteroids
Nasal/inhaled corticosteroids
Fenoldopam
Ophthalmic anticholinergics
Succinylcholine
Vasodilators (low risk)
Cimetidine (low risk)
Closed-angle glaucoma
Topical anticholinergics
Topical sympathomimetics
Systemic anticholinergics
Heterocyclic antidepressants
Low-potency phenothiazines
Antihistamines
Ipratropium
Benzodiazepines (low risk)
Theophylline (low risk)
Vasodilators (low risk)
Systemic sympathomimetics (low risk)
Central nervous system stimulants (low risk)
Serotonin selective reuptake inhibitors
Imipramine
Venlafaxine
Topiramate
Tetracyclines (low risk)
Carbonic anhydrase inhibitors (low risk)
Monoamine oxidase inhibitors (low risk)
Topical cholinergics (low risk)

attack. Such prodromal attacks last 1 to 2 hours, at which time pupillary block is broken by further mydriasis or miosis; or when miosis or mydriasis occurs in patients with plateau iris. The rate at which IOP increases may be a determinant of when full-blown symptoms occur. Visual fields demonstrate generalized constriction or typical glaucomatous defects. In prolonged attacks, total loss of vision may occur if the IOP is high enough. Tonometry reveals IOPs as high as 40 to 90 mm Hg. Patients who have developed adhesions between the iris and meshwork (anterior synechiae) may have chronic IOP elevation with intermittent spikes of high IOP when angle closure occurs.

DRUG-INDUCED GLAUCOMA

A number of medications are associated with increased IOP or carry labeling that cautions against use of the medication in glaucoma patients. The potential for a medication to produce or worsen glaucoma depends on the type of glaucoma and whether or not the patient is treated adequately.²⁵

Patients with treated, controlled POAG are at minimal risk of induction of an increase in IOP by systemic medications with anticholinergic properties or vasodilators; however, in patients with untreated glaucoma or uncontrolled POAG, the potential of these medications to increase IOP should be considered. Topical anticholinergic agents used to produce mydriasis may result in an increase in IOP. Potent anticholinergic agents such as atropine or homatropine are most likely to increase IOP. Weaker anticholinergics, such as tropicamide, that produce less cycloplegia are less likely to increase IOP and are favored, along with phenylephrine, when mydriasis is desired in POAG patients. Inhaled, nasal, topical, or systemic glucocorticoids may increase IOP in both normal individuals and patients with POAG.

Patients with POAG appear to be particularly susceptible to glucocorticoid-induced increases in IOP. Glucocorticoids reduce

the facility of aqueous humor outflow through the trabecular meshwork. The decreased facility of outflow appears to result from the accumulation of extracellular material blocking the trabecular channels. The potential of a glucocorticoid to increase IOP is related to its antiinflammatory potency and intraocular penetration. Thus patients should be treated with the lowest potency and dose and for the shortest time possible when steroids are indicated.

In patients predisposed to CAG (i.e., narrow anterior chambers), angle closure may be produced by any drug that causes mydriasis (e.g., anticholinergics). A wide range of sulfa compounds cause idiosyncratic reactions that result in anterior choroidal effusions with anterior movement of the iris and lens, resulting in angle closure. The topical use of anticholinergics or sympathomimetic agents most likely will result in angle closure. Systemic and inhaled anticholinergic and sympathomimetic agents also must be used with caution in such patients. As discussed previously, potent miotic agents such as echothiophate may produce angle closure by increasing pupillary block. Table 97–3 lists the drugs associated with potentiation of glaucoma.

TREATMENT

Ocular Hypertension

Treatment of the patient with possible glaucoma (ocular hypertension; i.e., patients with IOP >22 mm Hg) is less controversial than it was in the past, with the recent results of the Ocular Hypertensive Treatment Study (OHTS).³ The OHTS helped to identify risk factors for treatment. Patients with intraocular pressures higher than 25 mm Hg, vertical cup-to-disk ratio of more than 0.5, and central corneal thickness of less than 555 micrometers are at greater risk for developing glaucoma. Risk factors such as family history of glaucoma, black ethnicity, severe myopia, and patients with only one eye must also be taken into consideration when deciding which individuals need treatment.

Patients without risk factors typically are not treated and are monitored for the development of glaucomatous changes. Patients with significant risk factors usually are treated with a well-tolerated topical agent such as a β -blocking agent, an α_2 -agonist (brimonidine), a topical carbonic anhydrase inhibitor (CAI), or a prostaglandin analog, depending on individual patient characteristics. Optimally, therapy is initiated in one eye to assess efficacy and tolerance. Use of second- or third-line agents (e.g., pilocarpine or dipivefrin) when first-line agents fail to reduce IOP depends on the risk-to-benefit assessment of each patient. The cost, inconvenience, and frequent adverse effects of combination therapies, anticholinesterase inhibitors, and oral CAIs result in an unfavorable risk-to-benefit ratio in patients with possible glaucoma.²⁹

The goal of therapy is to lower the IOP to a level associated with a decreased risk of optic nerve damage, usually at least a 20%, if not a 25% to 30%, decrease from the baseline IOP. Greater decreases may be required in high-risk patients or those with higher initial IOPs. Drug therapy should be monitored by measurement of IOP, examination of the optic disk, assessment of the visual fields, and evaluation of the patient for drug adverse effects and compliance with therapy. Patients who are unresponsive to or intolerant of a drug should be switched to an alternative agent rather than given an additional drug. Many clinicians prefer to discontinue all medications in patients who fail to respond adequately to simple topical therapy, closely monitor for development of disk changes or visual field loss, and treat again when such changes occur.^{1,2,17–19,29}

More recently risk calculators have been suggested as a means of determining who are at greatest risk in developing glaucoma. It is hoped that with future improvement in such calculators, one would

be able to tailor treatment to those at greatest risk for developing glaucoma.

TREATMENT

Open-Angle Glaucoma

All patients with elevated IOP and characteristic optic disk changes and/or visual field defects not caused by other factors (i.e., glaucoma by definition) should be treated. Recent findings that 1 in 5 patients with “normal” IOP and glaucomatous retinal nerve findings (i.e., normal-tension glaucoma) do not have progression of visual field loss if left untreated have prompted recommendations to monitor normal-tension glaucoma patients without immediate threat of loss

of central vision, and treat only when progression is documented. Some controversy exists as to whether the initial therapy of glaucoma should be surgical trabeculectomy (filtering procedure), argon laser trabeculectomy, or medical therapy.^{1,2,17,18} Presently, drug therapy remains the most common initial treatment modality. Drug therapy of patients with documented glaucomatous change with either elevated or normal IOP is initiated in a stepwise manner (Fig. 97-5), starting with lower concentrations of a single, well-tolerated topical agent. The goal of therapy is to prevent further visual loss. A “target” IOP is chosen based on a patient baseline IOP and the amount of existing visual field loss. Typically, an initial target IOP reduction of 30% is desired. Greater reductions may be desired in patients with very high baseline IOPs or advanced visual field loss. Patients with normal baseline IOPs (normal-tension glaucoma) may have target IOPs of less than 10 to 12 mm Hg.

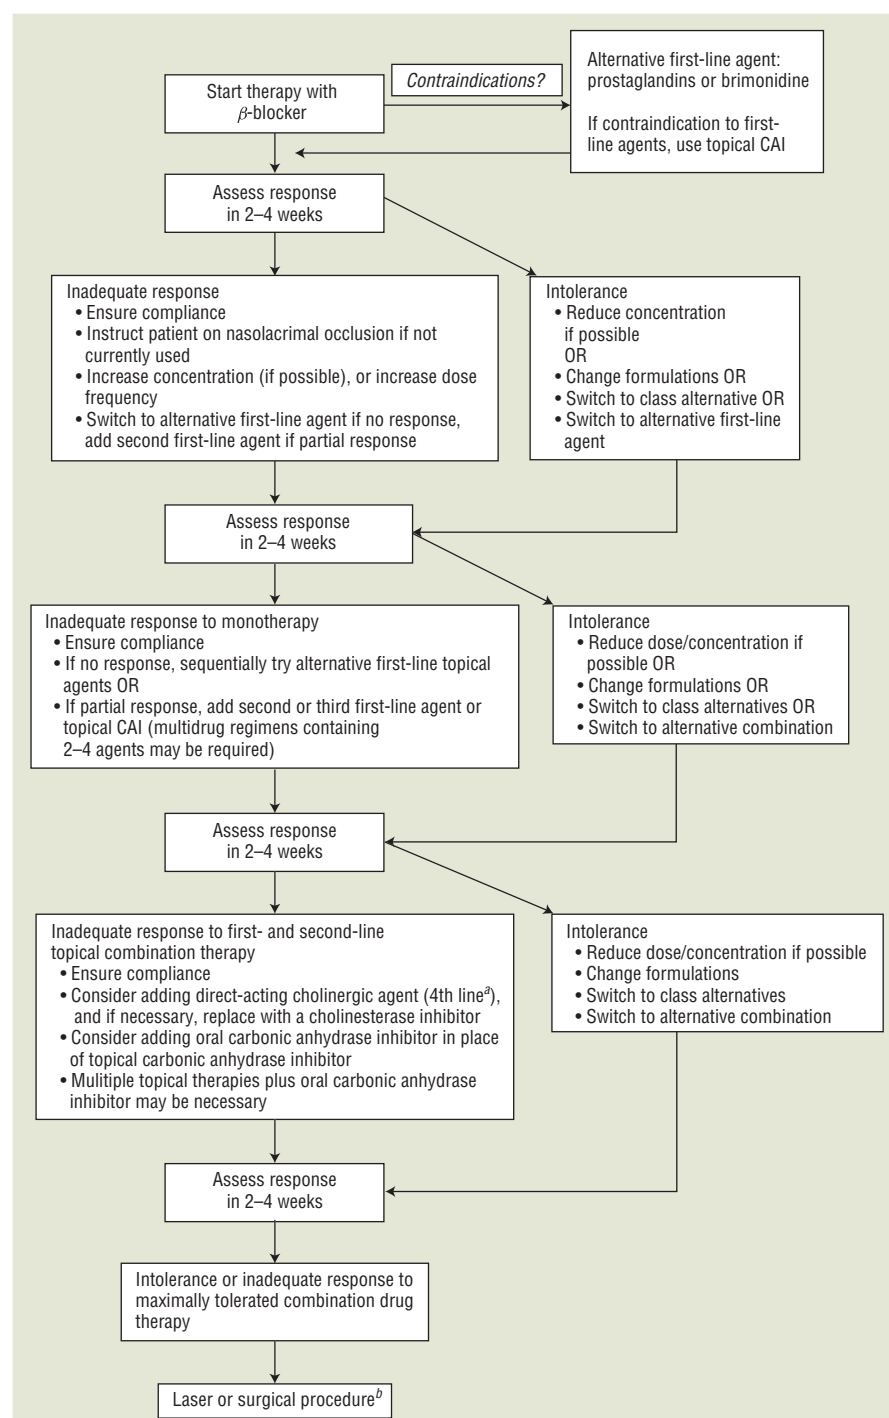

FIGURE 97-5. Algorithm for the pharmacotherapy of open-angle glaucoma. ^aFourth-line agents not commonly used any longer. ^bMost clinicians believe laser procedure should be performed earlier (e.g., after three-drug maximum, poorly adherent patient). (CAI, carbonic anhydrase inhibitor.)

CLINICAL CONTROVERSY

How much should the IOP be reduced in patients who may have POAG? Although the major clinical trial (OHTS³) required a 20% reduction in IOP for patients with ocular hypertension, many clinicians believe a further lowering of IOP may be more beneficial in preventing the progression of ocular hypertension to glaucoma. The American Academy of Ophthalmology Preferred Practice Guidelines suggest 20% to 30% IOP lowering. It remains to be seen if a more aggressive approach earlier in the treatment of the POAG suspect would be more beneficial.

■ PHARMACOTHERAPEUTIC APPROACH

6 Medications most commonly used to treat glaucoma are the nonselective β -blockers, the prostaglandin analogs (latanoprost, travoprost, and bimatoprost), brimonidine (an α_2 -agonist), and the fixed combination product of timolol and dorzolamide.^{21–22}

Before 1996, a β -blocker was used provided no contraindications existed, because this class of drugs has a long history of successful use, providing a combination of clinical efficacy and tolerability. The newer agents, in particular the prostaglandin analogs, brimonidine, and topical CAIs, are also considered suitable first-line therapy or alternative initial therapy in patients with contraindications to or other concerns with β -blockers (see Fig. 97–5). Pilocarpine and dipivefrin are used as third-line therapies because of their increased frequency of adverse effects or reduced efficacy.

Therapy optimally is started as a single agent in one eye (except in patients with very high IOP or advanced visual field loss) to evaluate drug efficacy and tolerance. Monitoring of therapy should be individualized: Initial response to therapy is typically done 4 to 6 weeks after the medication is started. A monocular trial of medication is recommended when possible. Once IOPs reach acceptable levels, the IOP is monitored every 3 to 4 months (more frequently after any change in drug therapy).

Visual fields and disk changes are typically monitored annually or earlier if the glaucoma is unstable or there is suspicion of disease worsening. Patients should always be questioned regarding adherence to and tolerance of prescribed therapy. Initial IOP response does not predict long-term IOP control. Using more than one drop per dose does not improve response, but increases the likelihood of adverse effects and the cost of therapy. When using more than one medication, separation of drop instillation of each agent by at least 5 to 10 minutes is suggested to provide optimal ocular contact for each agent.

The value of an agent with which the patient has shown a drop in IOP following an initial response can be measured by discontinuing the medication completely and determining if an increase in IOP occurs. Patients responding to but intolerant of initial therapy may be switched to another drug or to an alternative dosage form of the same medication. For patients failing to respond to the highest tolerated concentrations of an initial drug, a switch to an alternative agent after 1 day of concurrent therapy should be considered. Alternatively, if only a partial response occurs, addition of another topical drug to be used in combination is a possibility. A number of drugs or drug combinations may need to be tried before an effective and well-tolerated regimen is identified. Because of the frequency of adverse effects, carbachol, topical cholinesterase inhibitors, and oral CAIs are considered last-line agents to be used in patients who fail less-toxic combination topical therapy.

CLINICAL CONTROVERSY

The American Academy of Ophthalmology has not designated any agent as the drug of choice for initiation of glaucoma

treatment. In recent years, many clinicians have used the prostaglandin analogs because they are dosed once daily and achieve the best pressure reduction. However, others believe that even though the β -blockers are less potent in reducing IOP, they should still be used as initial agents because they are dosed once or twice daily and are available as generic products, and thus are more cost-effective.

■ NONPHARMACOLOGIC THERAPY: LASER AND SURGICAL PROCEDURES

When drug therapy fails, is not tolerated, or is excessively complicated, surgical procedures such as laser trabeculoplasty (argon or selective) or a surgical trabeculectomy (filtering procedure) may be performed to improve outflow. Laser trabeculoplasty is usually an intermediate step between drug therapy and trabeculectomy. Procedures with higher complication rates, such as those involving placement of draining tubes or destruction of the ciliary body (cyclodestruction), may be required when other methods fail (see Fig. 97–2).^{1,2,25}

Surgical methods for reduction of IOP involve the creation of a channel through which aqueous humor can flow from the anterior chamber to the subconjunctival space (filtering bleb), where it is reabsorbed by the vasculature. A major reason for failure of the procedure is healing and scarring of the site.

Modification of the healing process to maintain patency is possible with the use of antiproliferative agents. The antiproliferative agents 5-fluorouracil and mitomycin C are used in patients undergoing glaucoma-filtering surgery to improve success rates by reducing fibroblast proliferation and consequent scarring. Although used most commonly in patients with increased risk for suboptimal surgical outcome (after cataract surgery and a previous failed filtering procedure), use of these agents also improves success in low-risk patients.^{30–33}

TREATMENT

Closed-Angle Glaucoma

The goal of initial therapy for acute CAG with high IOP is rapid reduction of the IOP to preserve vision and to avoid surgical or laser iridectomy on a hypertensive, congested eye. Iridectomy (laser or surgical) is the definitive treatment of CAG; it produces a hole in the iris that permits aqueous humor flow to move directly from the posterior chamber to the anterior chamber, opening up the block at the trabecular meshwork. Drug therapy of an acute attack typically involves administration of pilocarpine, hyperosmotic agents, and a secretory inhibitor (a β -blocker, α_2 -agonist, prostaglandin $F_2\alpha$ analog, or a topical or systemic CAI). With miosis produced by pilocarpine, the peripheral iris is pulled away from the meshwork. Although traditionally the drug of choice, pilocarpine used as initial therapy is controversial. Miotics may worsen angle closure by increasing pupillary block and producing anterior movement of the lens because of drug-induced accommodation.

At IOPs greater than 60 mm Hg, the iris may be ischemic and unresponsive to miotics; as the pressure drops and the iris responds, miosis occurs. During this time, the urge to use excessive amounts of pilocarpine must be resisted. The dose of pilocarpine commonly used is a 1% or 2% solution instilled every 5 minutes for two or three doses and then every 4 to 6 hours. However, many practitioners withhold application of pilocarpine until the IOP has been reduced by other agents, and then apply a single drop of 1% to 2% pilocarpine to produce miosis. In either case, the unaffected contralateral eye should be treated with the miotic every 6 hours to prevent development of angle closure. An osmotic agent also commonly is administered because these drugs produce the most rapid decrease

in IOP. Oral glycerin 1 to 2 g/kg can be used if an oral agent is tolerated; if not, intravenous mannitol 1 to 2 g/kg should be used. Osmotic agents reduce IOP by withdrawing water from the eye secondary to the osmotic gradient between the blood and the eyes. These drugs are among the first-line agents in the short-term treatment of CAG or other forms of acute very high IOP elevations. Topical corticosteroids often are used to reduce the ocular inflammation and reduce the development of synechiae in CAG eyes. In classic CAG, once the IOP is controlled, pilocarpine may be given every 6 hours until iridectomy is performed. Patients failing therapy altogether will require an emergency iridectomy.

Peripheral iridectomy essentially “cures” primary CAG without significant synechiae. Long-term drug therapy is not used unless

IOP remains high because of the presence of synechiae blocking the trabecular meshwork or concurrent POAG. In such cases, the pharmacotherapeutic approach is essentially identical to that for the POAG patient, or laser or surgical procedures are performed.^{1,2}

PHARMACOLOGIC AGENTS USED IN GLAUCOMA

β -BLOCKING DRUGS

The topical β -blocking agents are one of the most commonly used antiglaucoma medications (Table 97–4). β -Blockers lower IOP by

TABLE 97-4 Topical Drugs Used in the Treatment of Open-Angle Glaucoma

Drug	Pharmacologic Properties	Common Brand Names	Dose Form	Strength (%)	Usual Dose ^a	Mechanism of Action	
β-Adrenergic blocking agents							
Betaxolol	Relative β_1 -selective	Generic	Solution	0.5	1 drop twice a day	All reduce aqueous production of ciliary body	
		Betoptic-S	Suspension	0.25	1 drop twice a day		
Carteolol	Nonselective, intrinsic sympathomimetic activity	Generic	Solution	1	1 drop twice a day		
Levobunolol	Nonselective	Betagan	Solution	0.25, 0.5	1 drop twice a day		
Metipranolol	Nonselective	OptiPranolol	Solution	0.3	1 drop twice a day		
Timolol	Nonselective	Timoptic, Betimol, Istalol	Solution	0.25, 0.5	1 drop every day—one to two times a day		
		Timoptic-XE	Gelling solution	0.25, 0.5	1 drop every day ^a		
Nonspecific adrenergic agonists							
Dipivefrin	Prodrug	Propine	Solution	0.1	1 drop twice a day	Increased aqueous humor outflow	
α_2-Adrenergic agonists							
Apraclonidine	Specific α_2 -agonists	Iopidine	Solution	0.5, 1	1 drop two to three times a day	Both reduce aqueous humor production; brimonidine known to also increase uveoscleral outflow	
Brimonidine		Alphagan P	Solution	0.15, 0.1	1 drop two to three times a day		
Cholinergic agonists direct acting							
Carbachol	Irreversible	Carboptic, Isopto Carbachol	Solution	1.5, 3	1 drop two to three times a day	All increase aqueous humor outflow through trabecular meshwork	
Pilocarpine	Irreversible	Isopto Carpine, Pilocar	Solution	0.25, 0.5, 1, 2, 4, 6, 8, 10	1 drop two to three times a day 1 drop four times a day		
		Pilopine HS	Gel	4	Every 24 h at bedtime		
Cholinesterase inhibitors							
Echothiophate		Phospholine Iodide	Solution	0.125	Once or twice a day		
Carbonic anhydrase inhibitors							
Topical							
Brinzolamide	Carbonic anhydrase type II inhibition	Azopt	Suspension	1	Two to three times a day	All reduce aqueous humor production of ciliary body	
Dorzolamide		Trusopt	Solution	2	Two to three times a day		
Systemic							
Acetazolamide		Generic	Tablet	125 mg, 250 mg	125–250 mg two to four times a day		
			Injection	500 mg/vial	250–500 mg		
		Diamox Sequels	Capsule	500 mg	500 mg twice a day		
Methazolamide		Generic	Tablet	25 mg, 50 mg	25–50 mg two to three times a day		
Prostaglandin analogs							
Latanoprost	Prostaglandin F _{2α} analog	Xalatan	Solution	0.005	1 drop every night	Increases aqueous uveoscleral outflow and to a lesser extent trabecular outflow	
Bimatoprost	Prostamide analog	Lumigan	Solution	0.03	1 drop every night		
Travoprost		Travatan, Travatan Z	Solution	0.004	1 drop every night		
Combinations							
Timolol-dorzolamide		Cosopt	Solution	Timolol 0.5% dorzolamide 2%	1 drop twice daily		
Timolol-brimonidine		Combigan	Solution	Timolol 0.5% brimonide 0.2%	1 drop twice daily		

^aUse of nasolacrimal occlusion will increase number of patients successfully treated with longer dosage intervals.

20% to 30% with a minimum of local ocular adverse effects. These are commonly one of the agents of first choice in treating POAG if no contraindications exist.^{1,2,17–19,34–36}

The β -blocking agents produce ocular hypotensive effects by decreasing the production of aqueous humor by the ciliary body without producing substantial effects on aqueous humor outflow facility. The mechanism by which β -blockers decrease aqueous humor inflow remains controversial, but it is most frequently attributed to β_2 -adrenergic receptor blockade in the ciliary body.

Five ophthalmic β -blockers are presently available: timolol, levobunolol, metipranolol, carteolol, and betaxolol. Timolol, levobunolol, and metipranolol are nonspecific β -blocking agents, whereas betaxolol is a relatively β_1 -selective agent. Carteolol is a nonspecific blocker with intrinsic sympathomimetic activity. Despite differences in potency, selectivity, lipophilicity, and intrinsic sympathomimetic activity, the five agents reduce IOP to a similar degree, although betaxolol has been reported to produce somewhat less lowering of IOP than timolol and levobunolol. Levobunolol may be more effective than timolol and betaxolol in reducing postcataract surgery IOP increases. Levobunolol solution is more effective in controlling IOP than other agents when given as aqueous solutions on a once-daily schedule (up to 70% of patients). Timolol in the form of a gel-forming solution (Timoptic-XE) provides equivalent IOP control with once-daily administration when compared with the same concentration of the aqueous solution administered twice daily. The choice of a specific β -blocking agent generally is based on differences in adverse effect potential, individual patient response, and cost. Long-term treatment with topical β -blockers results in tachyphylaxis in 20% to 25% of patients. The mean IOP reduction from baseline may be smaller in patients receiving topical β -blockers with concurrent systemic β -blockers.²⁹

Local adverse effects with β -blockers usually are tolerable, although stinging on application occurs commonly, particularly with betaxolol solution (less with betaxolol suspension) and metipranolol. Other local effects include dry eyes, corneal anesthesia, blepharitis, blurred vision, and, rarely, conjunctivitis, uveitis, and keratitis. Some local reactions may be a result of preservatives used in the commercially available products. Switching from one agent to another or switching the type of formulation may improve tolerance in patients experiencing local adverse effects.

Systemic effects are the most important adverse effects of β -blockers. Drug absorbed systemically may produce decreased heart rate, reduced blood pressure, negative inotropic effects, conduction defects, bronchospasm, central nervous system effects, and alteration of serum lipids, and may block the symptoms of hypoglycemia. The β_1 -specific agents betaxolol and possibly carteolol (as a consequence of intrinsic sympathomimetic activity) are less likely to produce the systemic adverse effects caused by β -adrenergic blockade, such as the cardiac effects and bronchospasm, but a real risk still exists. The use of timolol as a gel-forming liquid or betaxolol as a suspension allows for administration of less drug per day, and therefore reduces the chance for systemic adverse effects compared with the aqueous solutions.

Because of their systemic adverse effects, all ophthalmic β -blockers should be used with caution in patients with pulmonary diseases, sinus bradycardia, second- or third-degree heart block, congestive heart failure, atherosclerosis, diabetes, and myasthenia gravis, as well as in patients receiving oral β -blocker therapy. Use of nasolacrimal occlusion (NLO; see Patient Education below for description) technique during administration reduces the risk or severity of systemic adverse effects, as well as optimizes response. Overall, β -adrenergic blocking agents are well tolerated by most patients, and most potential problems can be avoided by appropriate patient evaluation, drug choice, and monitoring of drug therapy.

In patients failing or having an inadequate response to single-drug therapy with a β -blocking agent, the addition of a CAI, parasympathomimetic agent, prostaglandin analog, or an α_2 -adrenergic receptor agonist usually will result in additional IOP reduction. Epinephrine or dipivefrin added to a β -blocking agent (particularly nonspecific β -blockers) usually results in only minimal additional IOP reduction.^{1–3,17–19,29}

α_2 -ADRENERGIC AGONISTS

Brimonidine and the less lipid-soluble and less receptor-selective apraclonidine are α_2 -adrenergic agonists structurally similar to clonidine. Apraclonidine is indicated and brimonidine is effective for prevention or control of postoperative or postlaser treatment increases in IOP. Brimonidine is considered a first-line or adjunctive agent in the therapy of POAG, and apraclonidine is seen as a second-line or adjunctive therapy. Use of apraclonidine has fallen dramatically because of a high incidence of loss of control of IOP (tachyphylaxis) and a more severe and prevalent ocular allergy rate.

α_2 -Agonists reduce IOP by decreasing the rate of aqueous humor production (some increase in uveoscleral outflow also occurs with brimonidine). The drugs reduce IOP by 18% to 27% at peak (2 to 5 hours) and by 10% at 8 to 12 hours. Comparative trials demonstrate a reduction in IOP similar to that obtained with 0.5% timolol. Use of brimonidine 0.2% every 8 to 12 hours appears to provide maximum IOP-lowering effects in long-term use. Use of NLO (see Patient Education, below) may improve response and allow the longer dosing frequency (i.e., every 12 hours). Combinations of α_2 -agonists with β -blockers, prostaglandin analogs, or CAIs produce additional IOP reduction.

An allergic-type reaction characterized by lid edema, eye discomfort, foreign-object sensation, itching, and hyperemia occurs in approximately 30% of patients with apraclonidine. Brimonidine produces this adverse effect in up to 8% of patients. This reaction commonly necessitates drug discontinuation. Systemic adverse effects with brimonidine include dizziness, fatigue, somnolence, dry mouth, and possibly a slight reduction in blood pressure and pulse. α_2 -Agonists should be used with caution in patients with cardiovascular diseases, renal compromise, cerebrovascular disease, and diabetes, as well as in those taking antihypertensives and other cardiovascular drugs, monoamine oxidase inhibitors, and tricyclic antidepressants.

Brimonidine is also contraindicated in infants because of apneic spells and hypotensive reactions. In terms of overall efficacy and tolerability, brimonidine approximates that achieved with β -blockers.^{1,2,17–19,29}

Brimonidine-purite 0.15% or 0.1% is a formulation of brimonidine in a lower concentration than the original product, that contains a less-toxic preservative than the most commonly employed benzalkonium chloride. The newer formulations are as effective as the original because the more neutral pH of brimonidine-purite (0.15% pH 7.2; 0.1% pH 7.7) allows for higher concentrations of brimonidine in the aqueous humor with a similar reduction in IOP and a reduced incidence of ocular allergy.²⁹

The combination product timolol 0.5%/brimonidine 0.2% (Combigan) may provide additional IOP lowering than either agent alone. A new treatment option, this product is marketed in solution that is dosed twice daily.

CLINICAL CONTROVERSY

Many animal trials demonstrate that brimonidine has excellent neuroprotective properties.^{12–15} Some clinicians believe that one of the major advantages of using brimonidine lies in its potential neuroprotective properties. However, neuroprotection has not been demonstrated in human trials.

PROSTAGLANDIN ANALOGS

The prostaglandin analogs, including latanoprost, travoprost, and bimatoprost, reduce IOP by increasing the uveoscleral and, to a lesser extent, trabecular outflow of aqueous humor. Some differences in receptor sites and mechanisms of action may exist between the two prostaglandins (latanoprost and travoprost), the prostamide (bimatoprost). Bimatoprost may be slightly more effective in lowering IOP, getting a larger percentage of patients to lower IOPs, and in patients unresponsive to latanoprost.^{29,37–39}

Reduction in IOP with once-daily doses of prostaglandin $F_2\alpha$ analogs (a 25% to 35% reduction) is often greater than that seen with timolol 0.5% twice daily. In addition, nocturnal control of IOP is improved compared with timolol. Interestingly, administration of prostaglandin $F_2\alpha$ analogs twice daily may reduce the IOP comparably to once-daily dosing. The drugs are administered at nighttime, although they are probably as effective if given in the morning.

Prostaglandin analogs are well tolerated and produce fewer systemic adverse effects than timolol. Local ocular tolerance generally is good, but ocular reactions such as punctate corneal erosions and conjunctival hyperemia do occur. Local intolerance occurs in 10% to 25% of patients with these agents.

With prostaglandin analogs, altered iris pigmentation occurs in 15% to 30% of patients, particularly those with mixed-color irises (blue-brown, green-brown, blue-gray-brown, or yellow-brown eyes), which become more brown in color over 3 to 12 months. The change in iris pigmentation will often appear within 2 years, and long-term consequences of this pigment change appear to be mostly cosmetic but irreversible upon discontinuation. Hypertrichosis is fairly common and reverses upon discontinuation of the drug. Hyperpigmentation around the lids and lashes has also been reported and appears to reverse upon discontinuation.

These agents are associated with uveitis, and caution is recommended in patients with ocular inflammatory conditions. Cystoid macular edema also has been reported. Cases of worsening of herpetic keratitis have been reported.

Prostaglandin analogs can be used in combination with other antiglaucoma agents for additional IOP control because of their unique mechanism of action. Given their excellent efficacy and side-effect profile, prostaglandin analogs provide effective monotherapy or adjunctive therapy in patients who are not responding to or tolerating other agents. Many glaucoma experts have advocated the use of prostaglandin analogs as first-line therapy in POAG. Long-term studies of these agents are ongoing, but they appear to be safe, efficacious, and well tolerated in glaucoma therapy.^{17–19,29,37,38}

CARBONIC ANHYDRASE INHIBITORS

Topical Agents

CAIs reduce IOP by decreasing ciliary body aqueous humor secretion. CAIs appear to inhibit aqueous production by blocking active secretion of sodium and bicarbonate ions from the ciliary body to the aqueous humor.^{1,2,29} Topical CAIs such as dorzolamide and brinzolamide are well tolerated and are indicated for monotherapy or adjunctive therapy of open-angle glaucoma and ocular hypertension. Relatively specific inhibitors of carbonic anhydrase enzyme II such as dorzolamide and brinzolamide reduce IOP by 15% to 26%.

Topical CAIs generally are well tolerated. Local adverse effects include transient burning and stinging, ocular discomfort and transient blurred vision, tearing, and, rarely, conjunctivitis, lid reactions, and photophobia. A superficial punctate keratitis occurs in 10% to 15% of patients. Brinzolamide produces more blurry vision but is less stinging than dorzolamide. Systemic adverse effects are unusual despite the accumulation of drug in red blood cells. Because of their favorable adverse-effect profile, topical CAIs pro-

vide a useful alternative agent for monotherapy or adjunctive therapy in patients with inadequate response to or who are unable to use other agents. The drugs may add additional IOP reduction in patients using other single or multiple topical agents. The usual dose of a topical CAI is 1 drop every 8 to 12 hours. Administration every 12 hours produces somewhat less IOP reduction than administration every 8 hours. Use of NLO should optimize response to CAI given at any interval.^{1,2,17–19,29,34,36} The combination product timolol 0.5% and dorzolamide 2% (Cosopt) is dosed twice daily and produces equivalent IOP lowering to each product dosed separately.

Systemic Agents

Systemic CAIs are indicated in patients failing to respond to or tolerate maximum topical therapy. Systemic and topical CAIs should not be used in combination because no data exist concerning improved IOP reduction, and the risk for systemic adverse effects is increased. Oral CAIs reduce aqueous humor inflow by 40% to 60% and IOP by 25% to 40%. The available systemic CAIs (see Table 97–4) produce equivalent IOP reduction but differ in potency, adverse effects, dosage forms, and duration of action. Despite their excellent effects on elevated IOP of any etiology, the systemic CAIs frequently produce intolerable adverse effects. As a result, CAIs are considered third-line agents in the treatment of POAG and often used for short-term administration to lower IOP.

On average, only 30% to 60% of patients are able to tolerate oral CAI therapy for prolonged periods. Intolerance to CAI therapy results most commonly from a symptom complex attributable to systemic acidosis and including malaise, fatigue, anorexia, nausea, weight loss, altered taste, depression, and decreased libido. Other adverse effects include renal calculi, increased uric acid, blood dyscrasias, diuresis, and myopia. Elderly patients do not tolerate CAIs as well as younger patients. The available CAIs produce the same spectrum of adverse effects; however, the drugs differ in the frequency and severity of the adverse effects listed.

CAIs should be used with caution in patients with sulfa allergies (all CAIs, topical or systemic, contain sulfonamide moieties), sickle cell disease, respiratory acidosis, pulmonary disorders, renal calculi, electrolyte imbalance, hepatic disease, renal disease, diabetes mellitus, or Addison's disease. Concurrent use of a CAI and a diuretic may rapidly produce hypokalemia. High-dose salicylate therapy may increase the acidosis produced by CAIs, whereas the acidosis produced by CAIs may increase the toxicity of salicylates.^{1,2,17–19,21,29,34,35}

PARASYMPATHOMIMETIC AGENTS

The parasympathomimetic (cholinergic) agents reduce IOP by increasing aqueous humor trabecular outflow. The increase in outflow is a result of physically pulling open the trabecular meshwork secondary to ciliary muscle contraction, thereby reducing resistance to outflow. These agents may reduce uveoscleral outflow. Cholinergics agents work well to decrease IOP, but their use as primary or even adjunctive agents in the treatment of glaucoma has decreased significantly because of local ocular adverse effects and/or frequent dosing requirements.

Pilocarpine, the parasympathomimetic agent of choice in POAG, is available as an ophthalmic solution, an ocular insert, and a hydrophilic polymer gel (see Table 97–4). Pilocarpine produces similar (20% to 30%) reductions in IOP as those seen with β -blocking agents. Pilocarpine in POAG or “glaucoma suspects” is initiated as 0.5% or 1% solution, 1 drop three to four times daily. The use of NLO improves response and reduces the need for an every-6-hour dosing frequency. The use of 1 drop of 2% pilocarpine every 6 to 12 hours and NLO provides optimal response in many patients. Both drug concentration and frequency may be increased if IOP reduction is inadequate. Patients with darkly pigmented eyes

frequently require higher concentrations of pilocarpine than do patients with lightly pigmented eyes. Concentrations of pilocarpine above 4% rarely improve IOP control in patients, other than those patients with darkly pigmented eyes.

Pilocarpine 4% gel (Pilopine HS) once daily is equivalent to treatment with pilocarpine solution 4% four times daily or timolol 0.5% twice daily. When using every-24-hour dosing of pilocarpine gel, the adequacy of IOP control late in the dosing interval should be confirmed. Ocular adverse effects of pilocarpine include miosis, which decreases night vision and vision in patients with central cataracts. Visual field constriction may be seen secondary to miosis and should be considered when evaluating visual field changes in a glaucoma patient. Pilocarpine ciliary muscle contraction produces accommodative spasm, particularly in young patients still able to accommodate (presbyopic). Pilocarpine also may produce frontal headache, brow ache, periorbital pain, eyelid twitching, and conjunctival irritation or injection early in therapy, which tends to decrease in severity over 3 to 5 weeks of continued therapy.

Cholinergics produce a breakdown of the blood-aqueous humor barrier and may result in a worsening of an ocular inflammatory reaction or condition. Systemic cholinergic adverse effects of pilocarpine—such as diaphoresis, nausea, vomiting, diarrhea, cramping, urinary frequency, bronchospasm, and heart block—are rare but may be seen in patients who are using products with high pilocarpine concentrations (6% to 8%), or in those patients who are using such products overzealously in treatment of acute-angle closure. Other adverse effects associated with direct-acting miotics include retinal tears or detachment, allergic reaction, permanent miosis, cataracts, precipitation of CAG, and, rarely, miotic cysts of the pupillary margin.

Carbachol is a potent direct-acting miotic agent; its duration of action is longer than that of pilocarpine (8 to 10 hours) because of resistance to hydrolysis by cholinesterases. This drug also may act as a weak inhibitor of cholinesterase. Patients with an inadequate response to or intolerance of pilocarpine as a result of ocular irritation or allergy frequently do well on carbachol. The ocular and systemic adverse effects of carbachol are similar to but more frequent, constant, and severe than those of pilocarpine.^{1,2,17–19,29,34,35} Clinical use of carbachol is limited and may not be commercially available in the near future.

The cholinesterase inhibitors used most commonly in the treatment of POAG are the long-acting, relatively irreversible agents demecarium and echothiophate (limited commercial availability; see Table 97–4). These agents are potent inhibitors of pseudocholinesterase, but they also inhibit true cholinesterase. Because of the serious ocular and systemic toxic effects of these agents, the cholinesterase inhibitors are reserved primarily for patients who are either not responding to or are intolerant of other therapy. Because of their cataractogenic properties, most ophthalmologists use these agents only in patients without lenses (aphakia) and in patients with artificial lenses (pseudophakia). The ocular and periocular parasympathomimetic adverse effects are more common and more severe than with pilocarpine or carbachol.

In addition to the parasympathomimetic effects, the cholinesterase inhibitors may produce severe fibrous iritis (particularly with the irreversible inhibitors), synechiae, iris cysts, conjunctival thickening, occlusion of the nasolacrimal ducts, and cataracts. The inhibition of systemic pseudocholinesterase by these agents decreases the rate of succinylcholine hydrolysis, resulting in prolonged muscle paralysis. Cholinesterase inhibitors should be discontinued at least 2 weeks before procedures in which succinylcholine is used.

The role of cholinesterase inhibitors in glaucoma is limited by the frequency and potential toxicity of these agents. In phakic patients, cholinesterase inhibitors should be administered only if intolerance or failure results with other antiglaucoma medications. Cholinester-

ase inhibitors have been shown to provide additional IOP-lowering effects when used with β -blockers, CAIs, and sympathomimetic (adrenergic) agents. As with all agents for glaucoma, therapy should be initiated with lower concentrations of these agents. A once-daily administration frequency should be used in most patients unless very high IOP is present.

Use of NLO likely improves response and reduces systemic adverse effects and should be performed by all patients administering cholinesterase inhibitors. These agents should be used with caution in patients with asthma, retinal detachments, narrow angles, bradycardia, hypotension, heart failure, Down's syndrome, epilepsy, parkinsonism, peptic ulcer, and ocular inflammation, as well as in those receiving cholinesterase inhibitor therapy for myasthenia gravis or exposure to carbamate or organophosphate insecticides and pesticides.^{1,2,17–19,29,34,35}

EPINEPHRINE AND DIPIVEFRIN

The mechanism of action by which epinephrine lowers IOP has not been fully elucidated; however, a β_2 -receptor-mediated increase in outflow facility through the trabecular meshwork and the uveoscleral route appears to be the primary mechanism. Compared with β -blockers or miotics, epinephrine and dipivefrin reduce IOP less. With the advent of the better tolerated and more efficacious agents to treat glaucoma, the clinical use of epinephrines has decreased dramatically.

Epinephrine is not commercially available anymore. Use of the prodrug of epinephrine, dipivefrin, allows use of lower concentrations secondary to improved intraocular absorption (10- to 15-fold higher). The 0.1% dipivefrin produces equivalent IOP reduction to 1% to 2% epinephrine. Consequently, dipivefrin may be tolerated by patients who are unable to tolerate epinephrine solutions, and it is often chosen over other epinephrine products when this class of drugs is indicated.

A factor limiting the usefulness of epinephrine was the high frequency of local ocular adverse effects. Tearing, burning, ocular discomfort, brow ache, conjunctival hyperemia, punctate keratopathy, allergic blepharoconjunctivitis, rare loss of eyelashes, stenosis of the nasolacrimal duct, and blurred vision may occur. Prolonged use (>1 year) may result in deposition of pigment (adrenochrome) in the conjunctiva and cornea. Pigment also may deposit in soft contact lenses, turning them black. These adverse effects occur less frequently with dipivefrin. Epinephrine may produce mydriasis (particularly when combined with a β -blocker) and may precipitate acute CAG in patients with narrow anterior chambers. A transient increase in IOP may occur with initial therapy, particularly in patients not using other antiglaucoma medications. A relative contraindication to the use of dipivefrin is aphakia (i.e., after cataract removal) or lens dislocation because of the development of swelling of the macular portion of the retina. The edema is dose dependent and disappears with drug discontinuation.

Systemic adverse effects of epinephrine include headache, faintness, increased blood pressure, tachycardia, arrhythmias, tremor, pallor, anxiety, and increased perspiration. Epinephrine should be used with caution in patients with cardiovascular diseases, cerebrovascular diseases, aphakia, CAG, hyperthyroidism, and diabetes mellitus, as well as in patients undergoing anesthesia with halogenated hydrocarbon anesthetics. Using NLO with epinephrine and dipivefrin will improve therapeutic response and reduce the risk of systemic adverse effects.^{1,2,17–19,29,34,35}

FUTURE DRUG THERAPIES

It is hoped that new agents, improved formulations, and novel approaches to the reduction of IOP and other methods of preven-

tion of glaucomatous visual field loss will provide more effective and better-tolerated therapies. Agents that are neuroprotective and act through mechanisms other than IOP reduction are likely to be part of glaucoma therapy in the future.^{13–15,40}

EVALUATION OF THERAPEUTIC OUTCOMES

The ultimate goal of drug therapy in the patient with glaucoma is to preserve visual function through reduction of IOP to a level at which no further optic nerve damage occurs. Because of the poor relationship between IOP and optic nerve damage, no specific target IOP exists. Indeed, drugs used to treat glaucoma may act in part to halt visual field loss through mechanisms separate from or in addition to IOP reduction, such as improvements in retinal or choroidal blood flow. Often a 25% to 30% reduction is desired, but greater reductions (40% to 50%) may be desired in patients with initially high IOPs. For patients with glaucoma, an IOP of less than 21 mm Hg generally is desired, with progressively lower target pressures needed for greater levels of glaucomatous damage. Even lower IOPs (possibly even below 10 mm Hg) are required in patients with very advanced disease, those showing continued damage at higher IOPs, and those with normal-tension glaucoma and pretreatment pressures in the low to middle teens. The IOP considered acceptable for a patient is often a balance of desired IOP and acceptable treatment-related toxicity and patient quality of life.

PATIENT EDUCATION

7 An important consideration in patients failing to respond to drug therapy is adherence. Poor adherence or nonadherence occurs in 25% to 60% of glaucoma patients.

A large percentage of patients also fail to use topical ophthalmic drugs correctly. Patients should be taught the following procedure:

1. Wash and dry the hands; shake the bottle if it contains a suspension.
2. With a forefinger, pull down the outer portion of the lower eyelid to form a “pocket” to receive the drop.
3. Grasp the dropper bottle between the thumb and fingers with the hand braced against the cheek or nose and the head held upward.
4. Place the dropper over the eye while looking at the tip of the bottle; then look up and place a single drop in the eye.
5. The lids should be closed (but not squeezed or rubbed) for 1 to 3 minutes after instillation. This increases the ocular availability of the drug.
6. Recap bottle and store as instructed.

Note that many patients are physically unable to administer their own eyedrops without assistance. NLO also should be used to improve ocular bioavailability and reduce systemic absorption.^{1,2,17–19,29,34,35} The patient induces NLO for 1 to 3 minutes by closing the eyes and placing the index finger over the nasolacrimal drainage system in the inner corner of the eye. This maneuver, as well as eyelid closure itself, decreases nasolacrimal drainage of drug, thereby decreasing the amount of drug available for systemic absorption by the nasopharyngeal mucosa. The use of NLO may improve drug response significantly, reduce adverse effects, and allow less frequent dosing intervals and the use of lower drug concentrations.

Use of more than 1 drop per dose increases costs, does not improve response significantly, and may increase adverse effects. When two drugs are to be administered, instillations should be separated by at least 3 to 5 minutes (preferably 10 minutes) to prevent the drug administered first from being washed out. The patient should be taught not to touch the dropper bottle tip with eye, hands, or any surface.

Adherence to glaucoma therapy commonly is inadequate, and it always should be considered as a possible cause of drug therapy failure. Assessment of adherence by healthcare providers generally is poor, so all patients should be encouraged continually to administer prescribed therapy diligently as instructed. To improve adherence, the patient, family, and care providers should be fully informed of the expectations of therapy and the need to continue therapy despite a lack of symptoms. Possible adverse effects of the medication and ways to reduce them should be discussed. Adherence will be improved by good communication, close monitoring, and use of well-tolerated and convenient drug regimens.^{1,2,17–19,29}

CONCLUSIONS

The glaucomas are a group of primary and secondary diseases, the management of which presents a considerable challenge to the clinician. Successful therapy requires rational use of antiglaucoma medications and patient adherence to the selected regimen, combined with conscientious monitoring for adverse effects and disease progression. The reward for successful therapy is considerable—the maintenance of vision. The overview of the clinical findings, pathology, and drug therapy presented in this chapter provides the clinician with the fundamentals necessary to understand and treat glaucoma.

ABBREVIATIONS

- CAG: closed-angle glaucoma
 CAI: carbonic anhydrase inhibitor
 IOP: intraocular pressure
 NLO: nasolacrimal occlusion
 OHTS: Ocular Hypertensive Treatment Study
 POAG: primary open-angle glaucoma

KEY CONCEPTS

- 1 Allergic rhinitis is a common disease. Treatment is justified in most cases because of the potential for complications.
- 2 Because an immediate immune response to allergens results in release of inflammatory mediators that cause allergic rhinitis symptoms, patients must understand the rationale for the proper timing and administration of prophylactic regimens.
- 3 Proven therapies include avoidance of allergens and pharmacologic management with antihistamines, topical and systemic decongestants, topical steroids, cromolyn sodium, and immunotherapy.
- 4 Immunotherapy can be highly successful, offering long-term benefits, but expense, potential risks, and a major time commitment makes proper patient selection critical.

Allergic rhinitis involves inflammation of the nasal mucous membrane. In a sensitized individual, allergic rhinitis occurs when inhaled allergenic materials contact mucous membranes and elicit a specific response mediated by immunoglobulin E (IgE). This acute response involves the release of inflammatory mediators and is characterized by sneezing, nasal itching, and watery rhinorrhea, often associated with nasal congestion. Itching of the throat, eyes, and ears frequently accompanies allergic rhinitis.

Allergic rhinitis may be regarded as seasonal allergic rhinitis, commonly known as hay fever, or perennial allergic rhinitis (increasingly called “intermittent” and “persistent”). Seasonal rhinitis occurs in response to specific allergens usually present at predictable times of the year, during plants’ blooming seasons (typically the spring or fall). Seasonal allergens include pollen from trees, grasses, and weeds. Perennial allergic rhinitis is a year-round disease caused by nonseasonal allergens, such as house-dust mites, animal dander, and molds, or multiple allergic sensitivities. It typically results in more subtle, chronic symptoms. Many patients have a combination of these two types of allergic rhinitis, with symptoms year-round and seasonal exacerbations. About one-third to one-half of sufferers have recognizable seasonal disease with the remainder having perennial or a combination of both.¹

EPIDEMIOLOGY AND ETIOLOGY

- 1 Allergic rhinitis is one of the most common medical disorders found in humans. Prevalence in the United States is estimated

between 8.8% and 16%, with some believing the percentage to be higher.^{2,3} It ranks as the sixth most prevalent chronic illness in the United States.¹ Patients are limited in their ability to carry out normal daily functions; higher levels of general fatigue, mental fatigue, anxiety, and depressive disorders are seen.^{4,5}

In addition, the impact of allergic rhinitis goes well beyond these central nervous system issues. Allergic rhinitis is associated with several other serious medical conditions, including asthma, chronic rhinosinusitis, otitis media, nasal polyposis, respiratory infections, and orthodontic malocclusions.

PREDISPOSING FACTORS

The development of allergic rhinitis is determined by genetics, allergen exposure, and the presence of other risk factors. A family history of allergic rhinitis, atopic dermatitis, or asthma suggests that rhinitis is allergic. The risk of developing allergic disease is approximately 50% for children with one atopic parent and 66% for those with two allergic parents.³

Allergen exposure is another necessary factor. For allergic rhinitis to occur, an individual must be exposed over time to a protein that elicits the allergic response in that individual. Many potential sufferers never develop symptoms because they do not come into contact with the allergen that would produce symptoms in them.

Evidence suggests microbial exposure in the first years of life could help prevent allergic disease by stimulating a nonatopic immune response.⁶ Farm children are exposed to higher concentrations of endotoxin, derived from cell walls of gram-negative bacteria, in stables and in dust around the farmhouse. Consumption of nonpasteurized farm milk may cause further exposure. This concept has led to the idea that allergic disease could be prevented by proactively increasing exposure to harmless bacteria early in life (see Alternative Treatment Options below). This could explain why positive skin tests indicating allergen sensitization have been observed more frequently in people in higher socioeconomic classes and in people who live in suburban areas.⁷

Other predisposing factors include an elevated serum IgE (>100 international units/mL) before the age of 6 years, eczema, and heavy exposure to secondhand cigarette smoke.⁸

ALLERGENS

Allergens that produce seasonal rhinitis include protein components of airborne pollen grains, often enzymes, from a variety of trees, grasses, and weeds. Ragweed and grass pollen are the most common offenders in the United States; however, this varies with the geographic region. In general, tree pollens cause symptoms in the spring, grass pollens cause symptoms in the late spring and summer, and weed pollens are the culprits from late summer to early fall. Patients who are hypersensitive to all three may have overlapping problem periods, and may be described as having perennial rhinitis, when

Learning objectives, review questions,
and other resources can be found at
www.pharmacotherapyonline.com.

they are actually experiencing prolonged seasonal rhinitis. For this reason and the fact that most patients with seasonal problems are sensitive to at least some of the perennial allergens, many allergists are less often distinguishing between the two types of allergic rhinitis. To complicate matters further, the antigenic components of many grasses—including fescue, Kentucky bluegrass, orchard, redtop, and timothy—are similar, resulting in cross-allergenicity. By contrast, most trees that produce many of the offending airborne pollens produce antigenically distinct pollens. These trees include ash, beech, birch, cedar, hickory, maple, oak, poplar, and sycamore. Flowering plants that depend on insect pollination do not cause allergic rhinitis.

Mold spores are also important, but less common allergens. Various spores are present year-round; however, mold growth on decaying vegetation increases seasonally. Just walking through uncut fields or raking leaves can increase exposure. Thus mold spores can be responsible for both perennial and seasonal allergies.

Indoor allergens are always present. Most important among these are house-dust mite fecal proteins, animal dander, cockroaches, and certain mold species. Dust mite levels are on the rise, possibly as a result of the construction of energy-efficient homes and offices with reduced ventilation and increased humidity, use of wall-to-wall carpeting, and the popularity of cool water detergents and cold-water washing.³

PATHOPHYSIOLOGY

Knowledge of nasal physiology aids in the understanding of allergic rhinitis. The nose performs three “air conditioning” functions to prepare incoming gases and their contents for the lungs. During the fraction of a second that air is in the nose, it is heated, humidified, and cleaned. The cleaning process plays a role in the development of allergic rhinitis. As the air passes through the nose, the turbulence throws particulate matter against a mucous blanket. The rhythmic movements of the nasal cilia cause the mucous blanket to move posteriorly at approximately 9 mm/min, where it is eventually swallowed; thus trapped foreign particles are removed via the gastrointestinal tract and do not reach the lungs.

The vascular tissue in the nose is erectile. Stimulation of sympathetic fibers causes vasoconstriction, reduction in erectile tissue size, and airway widening. Parasympathetic stimulation causes vasodilation, an increase in erectile tissue size, and airway narrowing.

Located in the nasal mucosa are the mast cells, which participate in the regulation of nasal patency by releasing such mediators as histamine. These are described below.

IMMUNE RESPONSE TO ALLERGENS

2 Allergic reactions in the nose are mediated by antigen-antibody responses, during which allergens interact with specific IgE molecules bound to nasal mast cells and basophils. In allergic people, these cells are increased in both number and reactivity. During inhalation, airborne allergens enter the nose and are processed by lymphocytes, which produce antigen-specific IgE, thereby sensitizing genetically predisposed hosts to those agents. Upon nasal reexposure, IgE bound to mast cells interacts with airborne allergen, triggering release of inflammatory mediators (Fig. 98–1).⁹

Both immediate and late-phase reactions are observed after allergen exposure. The immediate reaction occurs within seconds to minutes, resulting in the rapid release of preformed mediators and newly generated mediators from the arachidonic acid cascade as the mast cell membrane is disturbed (Table 98–1). These mediators of immediate hypersensitivity include histamine, leukotrienes C₄, D₄, E₄, prostaglandin D₂, tryptase, and kinins.⁹ In addition, the mast cell has been found to be a source of several cytokines that probably are relevant to the chronicity of the mucosal inflammation that charac-

FIGURE 98-1. Allergen sensitization and the allergic response. *A.* Exposure to antigen stimulates IgE production and sensitization of mast cells with antigen-specific IgE antibodies. *B.* Subsequent exposure to the same antigen produces an allergic reaction when mast cell mediators are released.

terizes allergic rhinitis.¹⁰ Sensory nerve stimulation produces itching, and sneezing occurs via reflex stimulation of efferent vagal pathways. Neuropeptides substance P and calcitonin gene-related peptide from nonadrenergic, noncholinergic nerves affect vascular engorgement directly and via modulation of sympathetic tone. Histamine produces rhinorrhea, itching, sneezing, and obstruction, with the obstruction only partially blocked by H₁- or H₂-blocking agents.¹¹ Nasal obstruction is also caused by kinins, prostaglandin D₂, and leukotrienes C₄/D₄. Kinins, when directly administered, produce pain rather than itching.¹² These inflammatory mediators also produce vasodilation, increased vascular permeability, and production of nasal secretions.¹³

Four to 8 hours after the initial exposure to an allergen, a late-phase reaction occurs in 50% of allergic rhinitis patients.¹⁴ This response, thought to be caused by cytokines released primarily by mast cells and thymus-derived helper lymphocytes, is characterized by profound infiltration and activation of migrating cells. This inflammatory response likely is responsible for the persistent, chronic symptoms of allergic rhinitis, including nasal congestion. The inflamed mucosa becomes hyperresponsive, a state characterized by exacerbation of nasal reactions to nonspecific or irritant triggers. In this state, the patient also reacts to increasingly lower amounts of the same allergen.¹⁵

CLINICAL PRESENTATION

SYMPTOMS AND DIAGNOSIS

The patient with allergic rhinitis typically complains of clear rhinorrhea, paroxysms of sneezing, nasal congestion, postnasal drip, and pruritic eyes, ears, nose, or palate. Symptoms of allergic conjunctivitis are associated more frequently with seasonal than perennial allergic rhinitis, because a majority of the perennial allergens, such as dust mites and molds, are indoors, where air velocity is too low for substantial deposition of allergenic particles on the conjunctivae. However, with heavy exposure from animal or mold allergens, allergic conjunctivitis can be pronounced.

Symptoms secondary to the late-phase reaction, predominantly nasal congestion, begin 3 to 5 hours after antigen exposure and peak at 12 to 24 hours. Subsequent symptoms, both allergic and irritant, are elicited more easily because of the priming effect. For instance, a ragweed-sensitive patient, when exposed to ragweed pollen out of season, responds with modest symptoms and may be very tolerant of irritants such as air pollution or tobacco smoke. During the ragweed season, however, when the nasal mucosa is already inflamed, exposure to small doses of pollen or to irritants to which the patient is usually tolerant elicits a response clinically indistinguishable from the patient's allergy.

Allergic rhinitis is distinguished from other causes of rhinitis by a thorough history, physical examination, and certain diagnostic tests. The medical history consists of a careful description of symptoms, environmental factors and exposures, results of previous therapy, use of other medications, previous nasal injuries, previous nasal or sinus surgery, family history, and the presence of other medical problems and medications. Historical identification of specific causative allergens may be difficult. For example, a reaction induced by mowing the lawn may not be caused by grass pollens, but by the disturbance of various weeds, molds, or other plants in the lawn. With perennial allergic rhinitis, the cause–effect and temporal relationships are less clear, making the diagnosis more difficult, especially with such covert allergens as house-dust mites and molds.

In children, physical examination may reveal allergic shiners, a transverse nasal crease caused by repeated rubbing of the nose, and adenoidal breathing. Pale, bluish, edematous nasal turbinates coated with thin, clear secretions are characteristic of a purely allergic reaction. Tearing, conjunctival injection and edema, and periorbital swelling may be present. Physical findings are generally less clear-cut in adults.

Nasal scrapings will provide a representative sample of cells infiltrating the nasal mucosa and can be helpful in supporting the diagnosis.¹⁶ Microscopic examination of the nasal smear from an allergic individual typically will show numerous eosinophils. The blood eosinophil count may be elevated in allergic rhinitis, but it is nonspecific and has limited usefulness.¹⁷

Allergy testing can help determine whether a patient's rhinitis is caused by an allergic response to allergens. Immediate-type hypersensitivity skin tests are used for the diagnosis of allergic rhinitis. These include skin tests performed by the percutaneous route, where the diluted allergen is pricked or scratched into the skin surface, or by the intradermal route, where a small volume (0.01 to 0.05 mL) of diluted allergen is injected between the layers of skin. Percutaneous tests are more commonly performed and are safer and more generally accepted, with intradermal tests reserved for patients requiring confirmation in special circumstances.

In percutaneous testing, a positive control (histamine) and a negative control are essential for correct interpretation. After 15 minutes of the application of the allergen, the site is examined for a positive reaction (defined as a wheal-and-flare reaction). Because correct testing is done with extremely minute doses, undetectable by nonsensitized individuals, this reaction is evidence of the presence of mast cell-bound IgE specific to the allergen tested. Many, but not all, common allergens are available as standardized allergenic extracts.

Antihistamines and a few other medications interfere with the wheal-and-flare reaction. First-generation antihistamines should be stopped 3 to 5 days before testing, and second-generation, nonsedating antihistamines should be stopped for 10 days.¹⁸ Medications with antihistamine properties (e.g., sympathomimetic agents, phenothiazines, and tricyclic antidepressants) and H₂-receptor antagonists (e.g., cimetidine, ranitidine, and famotidine) should be discontinued before skin testing.

The radioallergosorbent test (RAST) was the first commonly used method for detecting IgE antibodies in the blood that are specific for a given allergen. Several other quantitative assays that include a reference curve calculated against standardized IgE are available.¹⁹ These tests are highly specific but less sensitive than percutaneous tests.

COMPLICATIONS

1 Not only is allergic rhinitis aggravating, it also frequently leads to further complications, particularly if the patient does not receive adequate treatment. Symptoms of untreated rhinitis may lead to disturbed sleep, chronic malaise, fatigue, and poor work or school performance. Patients often are plagued by loss of smell or taste, with sinusitis or polyps underlying many cases of allergy-related hyposmia. Postnasal drip with cough, hoarseness, and even vocal polyps also can be bothersome.

The role of allergic rhinitis in the development of acute otitis media or chronic middle ear effusion is often less clear. Children with allergic rhinitis appear to be at greater risk of these conditions because of nasal obstruction, insufflation of nasal secretions into the middle ear via eustachian tube obstruction, and negative middle ear pressure. Hearing problems in children related to middle ear effusion may lead to delayed development of language in young children or to school problems in older children.

Structural facial and dental problems can result from chronic allergic rhinitis.^{20,21} The chronic edema and venous stasis may contribute to the development of a high-arched, V-shaped palate. Mouth

breathing caused by nasal obstruction can be responsible for dental malocclusion and orthodontic problems. Constant upward rubbing of the nose (allergic salute) can cause a transverse crease across the lower nose; nasal congestion often leads to venous pooling and dark circles under the eyes known as *allergic shiners*.

Allergic rhinitis is clearly a risk factor for asthma. As many as 78% of asthma patients have nasal symptoms, whereas approximately 38% of allergic rhinitis patients have asthma.³ Asthma is more common in those with perennial than seasonal allergic rhinitis, and it is less likely to be “outgrown” when associated with allergic rhinitis.²²

Recurrent and chronic sinusitis are relatively common complications of allergic rhinitis. The structure of the mucus blanket breaks down, with decreased water production by serous glands, leaving hair cells trapped in the thicker mucus layer. This greatly reduces the clearance of trapped bacteria and offers ideal breeding grounds for the bacteria. Nasal polyps are less common but nonetheless bothersome; they require specific therapy but may improve with management of the underlying allergic state. Epistaxis also can be a problem; it is related to mucosal hyperemia and inflammation.

TREATMENT

Allergic Rhinitis

■ DESIRED OUTCOME

The therapeutic goal for patients with allergic rhinitis is to minimize or prevent symptoms. This goal should be accomplished with no or minimal adverse medication effects and reasonable medication expenses. The patient should be able to maintain a normal lifestyle, including participating in outdoor activities, yard work, and playing with pets as desired.

■ GENERAL APPROACH TO TREATMENT

3 Once the causative allergens and the specific symptoms are identified, management consists of three possible approaches: (a) allergen avoidance, (b) pharmacotherapy for prevention or treatment of symptoms, and (c) specific immunotherapy. The pharmacotherapy for symptoms approach includes several options that are based on patient-specific information (Table 98–2). Figure 98–2 depicts an algorithm for treatment options.

■ AVOIDANCE

Avoidance of offending allergens is the most direct method of preventing allergic rhinitis, but it is often the most difficult to

accomplish, especially for perennial allergens. Mold growth can be reduced by maintaining household humidity below 50% and removing obvious growth with bleach or disinfectant. Patients sensitive to animals will benefit most by removing pets from the home; however, most animal lovers are reluctant to comply with this approach. Cats may be more of a problem than dogs. Cat allergen is so prevalent and persistent in the air that up to 25% of cat-free houses contain detectable cat allergen.²³ Washing cats weekly may reduce allergens but studies are inconclusive.²⁴ Some dogs display more profuse antigens than do others; clinically, a sensitized person may tolerate one animal better than another.

Efforts to eliminate dust mites should be rigorous, particularly in the bedroom. Exposure to dust mites can be reduced by encasing mattresses and pillows with impermeable covers and washing bed linens in hot water. Washable area rugs are preferable to wall-to-wall carpeting. Acaricide treatment of carpets denatures the dust mite allergen, but must be done repeatedly, resulting in inconvenience and expense. Atopic infants who are exposed to high levels of dust mites are at increased risk for developing asthma.²⁵ Environmental control of these allergens may be helpful in forestalling further rhinitis and preventing later asthma.

Older central air-filtration systems for houses were expensive and minimally effective. High-efficiency particulate air (HEPA) filters have minimal effect on the dust mite allergens because these allergens are heavy and heavily charged electrically and are not typically floating in the air in the first place. These filters are effective in removing lightweight airborne particulates, including pollens, mold spores, and cat allergen, thus reducing allergic respiratory symptoms.²⁶

Patients with seasonal allergic rhinitis should keep windows closed and minimize time spent outdoors during pollen seasons. Immediate hair washing and change of clothes are recommended upon returning indoors. Use of fans that direct outside air into the house should be avoided. Filter masks can be worn while gardening or mowing the lawn. Table 98–3 summarizes recommendations for environmental control.

The few clinical trials on the effectiveness of avoidance measures are inconclusive.²⁴ These measures are intended to be a part of a comprehensive treatment strategy that will likely include pharmacotherapy and in selected cases, immunotherapy.

■ PHARMACOLOGIC THERAPY

First-line therapeutic modalities for treating allergic rhinitis are directed at relief of symptoms (see Table 98–2). Antihistamines and decongestants (both oral and topical) generally are used first in treating allergic rhinitis with medications. Several options in these two categories are available without a prescription, but patients will

TABLE 98-2 Pharmacotherapeutic Options for Allergic Rhinitis		
Medication Class	Symptoms Controlled	Comments
Antihistamines		
Systemic	Sneezing, rhinorrhea, itching, conjunctivitis	For seasonal allergic rhinitis, begin treatment before allergen exposure. Nonsedating agents should be tried first. If ineffective or too expensive for the patient, the older agents may be used. For perennial allergic rhinitis, use an intranasal steroid as an alternative to or in combination with systemic antihistamines.
Ophthalmic	Conjunctivitis	Logical addition to nasal steroids if ocular symptoms are present.
Intranasal	Sneezing, rhinorrhea, nasal pruritus	Option for seasonal allergic rhinitis. Warn patients of potential drowsiness.
Decongestants		
Systemic	Nasal congestion	Only needed when nasal congestion is present.
Topical	Nasal congestion	Only needed when nasal congestion is present. Do not exceed 3–5 days.
Intranasal corticosteroids	Sneezing, rhinorrhea, itching, nasal congestion	For seasonal allergic rhinitis, an option when congestion is present. Must begin therapy before allergen exposure. Excellent choice for perennial rhinitis.
Mast cell stabilizers	See comments	Prevents symptoms; therefore, for seasonal allergic rhinitis, use before offending allergen's season starts. For perennial rhinitis, improvement may not be seen for up to 1 month.
Intranasal anticholinergics	Rhinorrhea	Reserve for use when above therapies fail or cannot be tolerated.

Note: Level of evidence for each of these treatment options is Level I: strong evidence from at least one published systematic review of multiple, well-designed, randomized clinical trials.

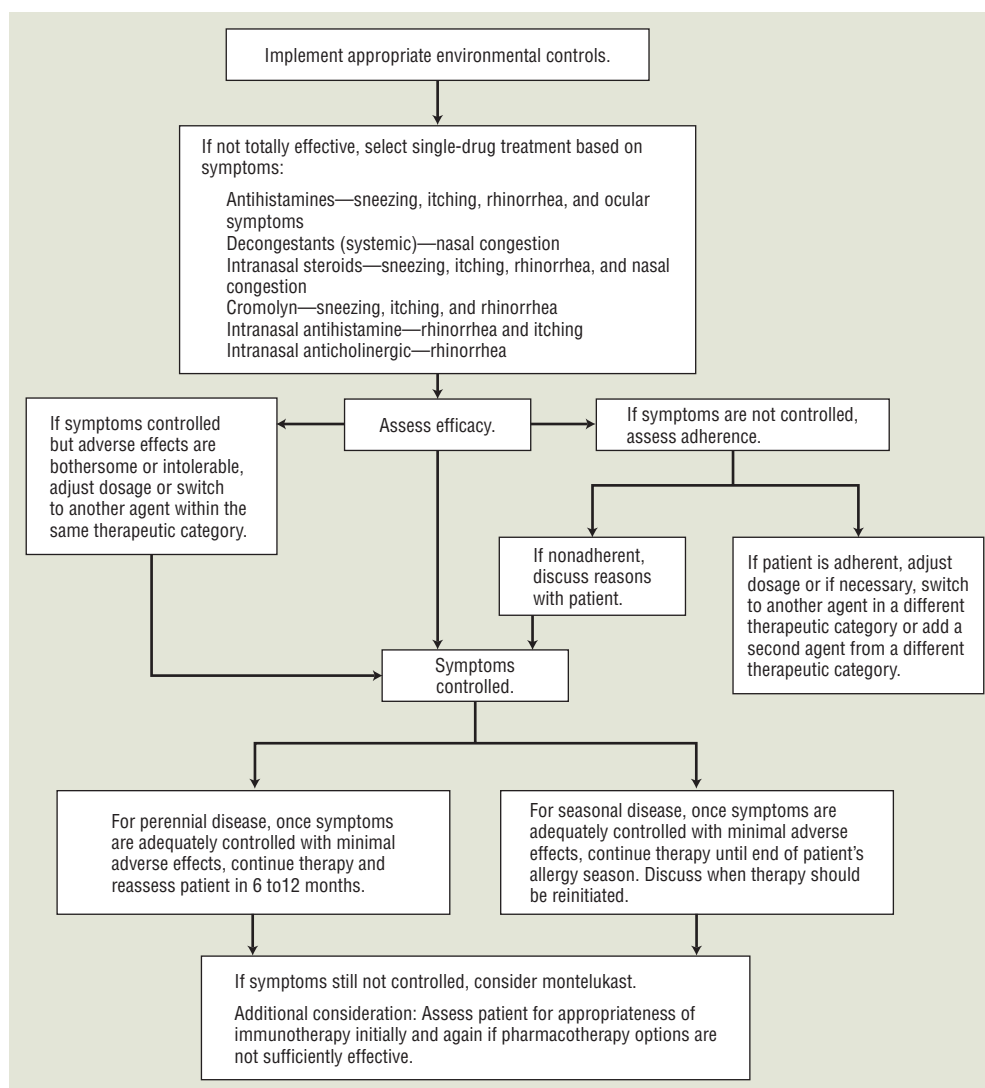

FIGURE 98-2. Treatment algorithm for allergic rhinitis.

need sound advice to make appropriate choices. Knowledge of pathophysiology and the inflammatory state has led to prophylactic therapy for more severe disease using agents such as cromolyn and topical steroids. However, in attempting to assess the evidence supporting any particular therapy, clinicians have difficulty interpreting the medical literature for a variety of reasons, including lack of uniformity in the research methodologies, inappropriate drug controls, and failure to identify types of rhinitis in study subjects (perennial versus seasonal and allergic versus nonallergic).

Antihistamines

Histamine (H_1)-receptor antagonists are competitive antagonists to histamine. They bind to H_1 receptors without activating them, preventing histamine binding and action. Newer antihistamines may also affect components of the inflammatory response such as histamine release, generation of adhesion molecules, and influx of inflammatory cells. Although it was once thought that the older antihistamines had no antiinflammatory action, some were shown to have these effects as early as the 1950s.²⁷ Antihistamines are available in oral, ophthalmic, and intranasal dosage forms.

The oral antihistamines are the most commonly used and can be divided into two major categories: nonselective (first generation) and peripherally selective (second generation). Nonselective agents are commonly referred to as *sedating antihistamines*, and peripherally selective agents are referred to as *nonsedating antihistamines*. These

generalizing terms can be misleading. Individual agents should be judged on their specific characteristics because variation within these broad categories exists. Also, the nonsedating claim is only valid when the newer agents are used at recommended doses.²⁸ This is of particular concern as some of these antihistamines are now available without a prescription. The mechanism for sedation is not well understood, but its central effect depends on the drugs' ability to cross the blood-brain barrier. Most older antihistamines are lipid-soluble and cross this barrier easily. The peripherally selective agents have little or no central or autonomic nervous system effects. Table 98-4 lists common antihistamines, their chemical classifications, their relative potential for causing sedation, and their relative anticholinergic effects.

Antihistamines are much more effective in preventing the actions of histamines than in reversing these actions once they have taken place. Reversal of symptoms is largely caused by the anticholinergic properties of these drugs. This activity is responsible for the drying effect of antihistamines, which reduces the problem of nasal, salivary, and lacrimal gland hypersecretion. Antihistamines antagonize increased capillary permeability, wheal-and-flare formation, and itching.

In general, the antihistamines are well absorbed, have large volumes of distribution, and are metabolized by the liver. Serum half-lives vary considerably between patients. Also, the therapeutic effects of these agents are more prolonged than might be predicted by their half-lives.

Drowsiness is usually the chief complaint of patients who take antihistamines. It can interfere with a patient's ability to drive a car or

Adapted from reference 3.

operate machinery and may interfere with the patient's ability to function adequately at the workplace. Remember that these problems can also be a reflection of the disease itself. For this reason, many recommend the use of peripherally selective agents as first-line treatment for any patient who is at high risk for the development of adverse events. This includes patients with renal or hepatic impairment, those with small weights (for whom adult doses may provide larger-than-recommended doses on a milligram-per-kilogram basis), patients with preexisting central nervous system or cardiac disorders, patients who require higher doses, and patients who have shown a tendency to overuse nonprescription or prescription medications.²⁷

The sedative effects of antihistamines can be useful in patients who suffer from sleeplessness caused by the symptoms of allergic rhinitis. In these patients, a bedtime dose may prove beneficial. However, they may cause residual daytime sedation, decreased alertness, and performance impairment.²⁴

The logic of preferentially using the newer agents is not clear cut. A recent meta-analysis of performance-impairment trials did not show a clear and consistent distinction between diphenhydramine and the peripherally selective agents.²⁹ Another study showed that tolerance to sedation secondary to diphenhydramine developed by day 4 of treatment, becoming indistinguishable from placebo,³⁰ but sedation must be distinguished from impairment, as the two are not equivalent.

Anticholinergic (drying) effects contribute to the agents' therapeutic efficacy, but they also cause most adverse effects. Dry mouth, difficulty in voiding urine, constipation, and potential cardiovascular effects may be troublesome. Keep in mind that the differences may be small. Patients with a predisposition to urinary retention (e.g., older men and those on concurrent anticholinergic therapy) should use antihistamines with caution. Caution also should be

used in patients with increased intraocular pressure, hyperthyroidism, and cardiovascular disease.

Other adverse effects of oral antihistamines include loss of appetite (and paradoxically, weight gain with increased appetite), nausea, vomiting, and epigastric distress.

Antihistamines are only fully effective when taken approximately 1 to 2 hours before anticipated exposure to the offending allergen. If tolerance develops to the therapeutic effect, a change to an agent in a different chemical class is usually effective.

Patients should be counseled about the proper use of antihistamines. Adverse effects, especially drowsiness, should be emphasized. Patients should be warned against taking other central nervous system depressants, including the use of alcohol. Patients should be told not to take a double dose when a dose is missed. Taking the antihistamine with meals or at least a full glass of water will help prevent gastrointestinal adverse effects such as nausea, vomiting, and epigastric distress. Patients should check with their healthcare professional and read labels before taking nonprescription medications. Many cold products and sleep aids contain antihistamines. Patients should be instructed not to use more than one antihistamine at a time. Table 98-5 lists the recommended dosages of the commonly used agents with their prescription status.

Many patients respond to and tolerate the older agents quite well. Because many of the older agents are available generically, they are much less expensive. Patient cost for many of the older nonprescription agents is less than \$5 for a 30-day supply, compared with more than \$20 for some of the nonprescription selective agents, and more than \$70 dollars for the selective prescription-only products. Although cost is a concern, patient safety should be the first consideration. Interestingly, the most frequently recommended nonprescription antihistamine to adults by pharmacists was diphenhydramine.³² This may be because of diphenhydramine's use as a sleep aid. With the heavy promotion of competing brands of nonprescription loratadine, this ranking may soon change. Loratadine in combination with pseudoephedrine did show up in the same survey as the top pharmacists' pick in the "adult multisymptom allergy" category.

TABLE 98-5 Oral Dosages of Commonly Used Oral Antihistamines and Decongestants

		Dosage and Interval ^a	
Medication	Availability	Adults	Children
Nonselective (first-generation) antihistamines			
Chlorpheniramine maleate, plain ^b	OTC	4 mg every 6 h	6–12 y: 2 mg every 6 h 2–5 y: 1 mg every 6 h
Chlorpheniramine maleate, sustained-release	OTC	8–12 mg daily at bedtime or 8–12 mg every 8 h	6–12 y: 8 mg at bedtime <6 y: Not recommended
Clemastine fumarate ^b	OTC	1.34 mg every 8 h	6–12 y: 0.67 mg every 12 h
Diphenhydramine hydrochloride ^b	OTC	25–50 mg every 8 h	5 mg/kg per day divided every 8 h (up to 25 mg per dose)
Peripherally selective (second-generation) antihistamines			
Loratadine ^b	OTC	10 mg once daily	6–12 y: 10 mg once daily 2–5 y: 5 mg once daily
Fexofenadine	Rx	60 mg twice daily or 180 mg once daily	6–11 y: 30 mg twice daily
Cetirizine ^b	OTC	5–10 mg once daily	>6 y: 5 mg once daily Infants 6–11 mo ^c

^aDosage adjustment may be needed in renal/hepatic dysfunction. Refer to manufacturers' prescribing information.

^bAvailable in liquid form.

^c0.25 mg/kg orally demonstrated to be safe.³¹

^dControlled-release product available: 240 mg once daily (60-mg immediate-release with 180-mg controlled-release).

^eSee text regarding nonprescription requirements.

^fPhenylephrine has replaced pseudoephedrine in many nonprescription antihistamine–decongestant combination products. Read product labels carefully.

For seasonal allergic rhinitis, an intranasal antihistamine, azelastine, is available. Azelastine has been used successfully in patients who did not respond to loratadine.³³ Using the nasal route offers an alternative to switching to another oral antihistamine. Patient satisfaction has been varied because while the product produces rapid symptom relief, patients complain of drying effects, headache, and diminished effectiveness over time. Patients should be warned of the medication's potential to produce drowsiness, as its systemic availability is approximately 40%.³⁴

Allergic conjunctivitis, often associated with allergic rhinitis, can be treated with an ophthalmic antihistamine such as levocabastine. Because systemic antihistamines usually are also effective for allergic conjunctivitis, levocabastine is a logical addition to nasal steroids when ocular symptoms occur, and is an acceptable approach in patients whose only symptoms involve the eyes or to add for those whose symptoms persist on oral treatment.

CLINICAL CONTROVERSY

Although many clinicians strongly prefer a peripherally selective agent as the first antihistamine choice, economic considerations still result in the first-line choice of the less expensive and more sedating products by some prescription plans and clinicians.

Decongestants

Topical and systemic decongestants are sympathomimetic agents that act on adrenergic receptors in the nasal mucosa, producing vasoconstriction. Decongestants shrink swollen mucosa and improve ventilation. When nasal congestion is part of the clinical picture, decongestants work well in combination with antihistamines.

TOPICAL DECONGESTANTS

Topical decongestants are applied directly to swollen nasal mucosa via drops or sprays. Table 98–6 lists the common topical decongestants

and their durations of action. The use of these agents results in little or no systemic absorption.

Because these agents are extremely effective and are available to patients without a prescription, they are widely used. However, prolonged use of these agents (for more than 3 to 5 days) can result in a condition known as *rhinitis medicamentosa*, or *rebound vasodilation*, with even more severe congestion. Patients who develop this condition use increasingly more spray more often with less response. Although the methods used to treat this “addiction” have not been studied formally, several are used commonly. Abrupt cessation works, but it is difficult because of rebound congestion that may leave the patient congested for several days or weeks. Sleeping may become difficult. Nasal steroids have been used successfully, but they take several days to work. Weaning the patient off topical decongestants can be accomplished by decreasing the dosing frequency or the concentration over several weeks. Combining the weaning process with nasal steroids may prove useful. Ultimately, the success of any plan depends on the patient's resolve and clear understanding of the importance of stopping the drug to end the problem.

Other adverse effects of topical decongestants include burning, stinging, sneezing, and dryness of the nasal mucosa.

Patients should be counseled on the use of topical decongestants to prevent rhinitis medicamentosa. Patients should be instructed to

TABLE 98-6 Duration of Action of Topical Decongestants

Medication	Duration (h)
Short acting	
Phenylephrine hydrochloride	Up to 4
Intermediate acting	
Naphazoline hydrochloride	4–6
Tetrahydrozoline hydrochloride	
Long acting	
Oxymetazoline hydrochloride	Up to 12
Xylometazoline hydrochloride	

use as small a dose as possible as infrequently as possible and only when absolutely necessary (e.g., at bedtime to aid in falling asleep). Duration of therapy always should be limited to 3 to 5 days.

Systemic Decongestants

Oral decongestants are not as effective on an immediate basis as the topical agents, but their effects sometimes last longer and they cause less local irritation. Also, rhinitis medicamentosa is not a problem with oral agents. The most commonly used agent is pseudoephedrine. Table 98–5 lists the usual doses for the regular and sustained-release versions. The use of phenylephrine is increasing as a result of new regulations related to pseudoephedrine described below.

Concerns of safety have greatly limited the systemic decongestant options. Recently, new legal requirements for the sale of pseudoephedrine were put into place to combat the misuse of the drug as a component in making methamphetamine. Pseudoephedrine must now be sold behind the counter and the monthly amount a patient can purchase is limited. Until this new requirement, pseudoephedrine was the most frequently used systemic decongestant and it was considered the safest. Doses of 180 mg have been shown to produce no measurable change in blood pressure or heart rate.³⁵ In higher doses (210 to 240 mg), pseudoephedrine has raised both blood pressure and heart rate.³⁶ Pseudoephedrine can cause mild central nervous system stimulation, even at therapeutic doses. Stroke, related to use of oral decongestants such as pseudoephedrine, can occur in patients with hypertension and/or vasospasm.³⁷ Although stroke complications seem to be associated with higher-than-recommended doses, there is also a stroke risk when these agents are taken properly. Severe hypertensive reactions can occur when pseudoephedrine is given concomitantly with monoamine oxidase inhibitors.³⁸ Hypertensive patients should, unless absolutely necessary, avoid systemic decongestants.

Combination Products

Numerous products combine an antihistamine with a decongestant. The combination is rational because of the different mechanisms of action. Both nonselective and peripherally selective antihistamines are available in such combinations. As mentioned previously, patients should read labels to avoid therapeutic duplication. Consideration should be given to whether the patient is always congested before recommending these combinations.

NASAL STEROIDS

Nasal steroids are an excellent choice for treating perennial rhinitis, and can be useful in seasonal rhinitis, especially if begun in advance of symptoms. Nasal steroids appear to be effective with minimal adverse effects. Some believe that nasal steroids should be recommended as initial therapy over antihistamines because of their high level of efficacy when used properly and along with avoidance of allergens.³⁹ Multiple mechanisms are involved with the effects of nasal steroids on the nasal mucosa: reducing inflammation by reducing mediator release, suppressing neutrophil chemotaxis, reducing intracellular edema, causing mild vasoconstriction, and inhibiting mast cell-mediated late-phase reactions.⁴⁰ Table 98–7 lists the available nasal steroids and their usual doses.

Topical steroids produce only minor adverse effects, most commonly sneezing, stinging, headache, and epistaxis. Despite concerns about safety of systemic steroids, nasal steroids have been found to have no significant association with hypothalamic–pituitary axis suppression, cataract formation, glaucoma, or bone mineral density changes in the doses used for allergic rhinitis. Growth suppression remains a question with some evidence showing that nasal steroids with higher bioavailability (e.g., beclomethasone) may have a greater growth suppression effect than less bioavailable agents.⁴¹ These

TABLE 98-7 Dosage of Nasal Steroids

Medication	Dosage and Interval
Beclomethasone dipropionate, monohydrate	>12 y: 1–2 inhalations (42–84 mcg) twice daily in each nostril 6–12 y: 1 inhalation per nostril (42 mcg) twice daily to start
Budesonide	>6 y: 2 sprays (64 mcg) per nostril in am and pm or 4 sprays per nostril in am (maximum: 256 mcg)
Flunisolide	Adults: 2 sprays (50 mcg) per nostril twice daily (maximum: 400 mcg) Children: 1 spray per nostril three times a day
Fluticasone	Adults: 2 sprays (100 mcg) per nostril once daily; after a few days decrease to 1 spray per nostril Children >4 y and adolescents: 1 spray per nostril once daily (maximum: 200 mcg/day)
Mometasone furoate	>12 y: 2 sprays (100 mcg) per nostril once daily
Triamcinolone acetanide	>12 y: 2 sprays (110 mcg) per nostril once daily (maximum: 440 mcg/day)

findings require more study. Most likely, all currently available nasal steroids are safe in the majority of patients and their clinical benefits outweigh any small growth suppressive effect. Other concerns include local infections with *Candida albicans*, which occur rarely.

The therapeutic benefits of topical steroids are not immediate and they are not decongestants. Patients need to understand this to ensure cooperation and continuation of therapy. Some patients notice improvement in a few days, but peak responses may not be observed for 2 to 3 weeks. Once a response is achieved the dosage may be reduced. Blocked nasal passages should be cleared with a decongestant or saline irrigation before administration to ensure adequate penetration of the spray. Patients should be advised to avoid sneezing or blowing their noses for at least 10 minutes after administration. Topical steroids should not be used in patients with nasal septum ulcers or recent nasal surgery or trauma.

One additional benefit of nasal steroids in treating allergic rhinitis in individuals with asthma and upper airway conditions is that they may confer some protection against exacerbations of asthma, leading to fewer emergency room visits. The overall relative risk for an emergency visit among asthma patients who received intranasal steroids was 0.7.⁴² No effect was seen in patients receiving antihistamines.

OTHER INHALANT MEDICATIONS

Cromolyn sodium and ipratropium bromide offer two additional approaches for treating allergic rhinitis. Cromolyn sodium is a mast cell stabilizer. Increased interest in this product has resulted from it becoming available without a prescription. Ipratropium bromide is an anticholinergic agent useful in perennial allergic rhinitis.

Cromolyn sodium nasal spray is used for the symptomatic prevention and treatment of allergic rhinitis. It curtails antigen-triggered mast cell degranulation and release of the mediators of allergic reactions, including histamine. Cromolyn sodium has no direct antihistaminic, anticholinergic, or antiinflammatory properties. Similarly to topical steroids, the most common adverse effects—sneezing and nasal stinging—result from local irritation. The dose in adults and children at least 2 years of age is one spray in each nostril three to four times per day at regular intervals every 4 to 6 hours. Cromolyn sodium must cover the entire nasal lining; therefore patients should be instructed to clear nasal passages before administration. Inhaling gently through the nose during administration aids in this process. Dosing must be repeated at 6-hour intervals to maintain the effect.

For seasonal rhinitis, treatment with cromolyn sodium should be initiated just before the usual start of the offending allergen’s season and continued throughout the season. In perennial rhinitis, the effects may not be seen for 2 to 4 weeks; therefore antihistamines or decongestants may be needed during this initial phase of therapy. As

cromolyn sodium begins to work, the need for these medications should decrease.

Ipratropium nasal spray is an anticholinergic agent that exhibits antisecretory properties when applied locally. It provides symptomatic relief of rhinorrhea associated with allergic and other forms of chronic rhinitis. The 0.03% solution is given as two sprays (42 mcg) two to three times daily. The optimal dose should be determined based on the specific patient's symptoms and response. Adverse effects are mild, with the most common being headache, nosebleeds, and nasal dryness.

■ IMMUNOTHERAPY

4 The first report of the successful use of grass pollen extract injections to treat allergic rhinitis was published in 1911 by Noon.⁴³ The therapy was first called *desensitization*; however, this did not seem appropriate because skin reactivity sometimes remained. The name was later changed to *hyposensitization*. Although this term is still used today, *immunotherapy* is used more commonly and is less confusing.

Immunotherapy is the slow, gradual process of injecting increasing doses of antigens responsible for eliciting allergic symptoms into a patient with the hope of inducing tolerance to the allergen when natural exposure occurs. Several mechanisms have been proposed to explain the beneficial effects of immunotherapy, including: induction of IgG blocking antibodies, reduction in specific IgE (long-term), reduced recruitment of effector cells, altered T-cell cytokine balance (a shift from T-helper type 1 to T-helper type 2), T-cell anergy, and induction of regulatory T cells.⁴⁴

Immunotherapy is expensive, has significant potential risks, and requires a major time commitment from the patient. For these reasons, it should be considered only in a select group of patients. Candidates for immunotherapy should have significant symptoms unsuccessfully controlled by avoidance and pharmacotherapy, or stand to achieve more benefit in other significant ways, such as with asthma. Immunotherapy may postpone the onset of asthma or possibly even prevent it.⁴⁵ Patients who are unable to tolerate the adverse effects of properly managed drug therapy also should be considered. Patients must be committed to the necessary regular office visits required to complete this course of therapy over several years.

The effectiveness of immunotherapy for seasonal allergic rhinitis appears to be better than that seen with perennial rhinitis, in part because it is more difficult to determine which allergen is responsible for perennial symptoms, and it is more often due to multiple sensitizations. Effectiveness has been shown in a number of clinical studies using a variety of pollen extracts, even in patients with severe disease resistant to pharmacotherapy.⁴⁴ Specific immunotherapy for house-dust mites has had good results in appropriately selected patients, while several studies have described marked improvement in patients with allergy to cats. Data indicate that in some patients 3 years of immunotherapy may be sufficient to give lasting benefit.⁴⁶ However, many require longer treatment.

The selection of antigens should be based on patient history and skin test results. Numerous regimens for administration of selected allergens have been suggested. In the beginning, very dilute solutions are given initially one to two times per week. The concentration is increased until the maximum tolerated dose is achieved. This maintenance dose is continued every 2 to 6 weeks, depending on clinical response. In light of the present understanding of the immunologic results of immunotherapy, it should be given year-round rather than seasonally.

Adverse reactions can occur with immunotherapy and range from mild to life-threatening. Among the most common are mild local reactions, consisting of induration and swelling at the site of the injection. These may be immediate or delayed. Other more serious reactions (e.g., generalized urticaria, bronchospasm, laryngospasm, and vascular collapse) occur rarely; deaths can result from anaphylactic reactions. Severe reactions are treated with epineph-

TABLE 98-8 Dosage Regimens for Montelukast in Treatment of Allergic Rhinitis

Age	Dosage ^a
Adults and adolescents >15 years	One 10-mg tablet daily
Children 6–14 years	One 5-mg chewable tablet daily
Children 2–5 years	One 4-mg chewable tablet or oral granule packet daily

^aThe timing of drug administration can be individualized. If the patient has combined asthma and seasonal allergic rhinitis, the dose should be given in the evening.

rine as well as other modalities recommended for anaphylaxis. Because of this potential risk, immunotherapy must not be given without adequate direct observation in a medical facility.

Several patient types have been identified as poor candidates for immunotherapy, including patients with any medical condition that would compromise the ability to tolerate an anaphylactic-type reaction, patients with impaired immune systems, and patients with a history of nonadherence to therapy.⁴⁷

■ ALTERNATIVE TREATMENT OPTIONS

Montelukast is the first leukotriene receptor antagonist that has received approved labeling for the treatment of seasonal allergic rhinitis. Leukotriene receptor antagonists inhibit the cysteinyl leukotriene receptor. The cysteinyl leukotrienes are among the inflammatory mediators released from mast cells. Montelukast is effective alone or in combination with an antihistamine.⁴⁸ Table 98–8 lists dosage regimens. Although this class represents a therapeutic alternative, studies published to date show them to be no more effective than peripherally selective antihistamines and less effective than intranasal steroids, but when combined with antihistamines, more effective than the antihistamine alone.⁴⁹

CLINICAL CONTROVERSY

The exact role of montelukast in treating allergic rhinitis remains to be defined. Although expensive, it may be advantageous in men with significant prostatic hypertrophy who cannot tolerate antihistamines and in patients who have difficulty stopping antihistamines a week before skin testing.

The development of monoclonal antibodies directed against the binding site of IgE provides an additional way to treat allergic respiratory diseases. Omalizumab, a recombinant humanized anti-IgE monoclonal antibody, is the first to show efficacy in allergic rhinitis.⁵⁰ The actual mechanism of how this agent is thought to work is quite complex.⁵¹ Anti-IgE antibodies bind to the site on the IgE molecule that recognizes the IgE receptor, thereby preventing the IgE molecule from binding to mast cells or basophils. The half-life of IgE antibodies on the mast cell surface is about 6 weeks, and as the antibodies turn over, they become available for binding to anti-IgE antibodies. Thus by giving repeated doses of omalizumab, the number of IgE antibodies on the mast cell surface can be significantly reduced over time. These new IgE molecules are not eliminated, but remain in circulation as small immune complexes. IgE receptor numbers on basophils and mast cells may be decreased as a result of down regulation. Because of the extremely expensive nature of this therapy, omalizumab's role strictly limited to severe allergic asthma.

CLINICAL CONTROVERSY

Omalizumab may offer significant long-term benefits to allergic rhinitis patients, but it may prove to be too expensive to gain widespread acceptance.

As mentioned earlier in this chapter, microbial exposure in the early years of life could help prevent allergic disease by favoring a nonatopic immune response.⁶ This concept was further studied by administering *Lactobacillus rhamnosus* prenatally to mothers who had at least one first-degree relative or partner with atopic disease (eczema, allergic rhinitis, or asthma) and postnatally for 6 months to their infants.⁵² However, their use may be limited to treatment or prevention of childhood eczema as available evidence shows little benefit in allergic airway diseases.⁵³

Other avenues for treating allergic rhinitis include Chinese herbal medicine and acupuncture. Although study designs and the small number of patients included have been questioned, these treatments deserve further study.⁵⁴

PHARMACOECONOMIC CONSIDERATIONS

The economic impact of allergic rhinitis is enormous. The direct costs have grown significantly over the past few years because of the increasing use of peripherally selective antihistamines and nasal steroids. The most recent detailed review estimated expenditures of \$3.4 billion annually in the United States, with the majority of this cost attributed to prescription medications and outpatient visits.⁵⁵ Of prescribed medications, 51% were peripherally selective antihistamines, 25% intranasal steroids, and 5% were older antihistamines. A total of 58% of patients received one or more agents. The mean prescription medication expenditure was \$103 per patient for those on Medicaid, \$155 for patients with private insurance, and \$69 for patients with no insurance. Indirect costs related to missed school or workdays and loss of productivity may approach the amount for the direct costs.⁵⁶ These figures do not include expenditures for nonprescription medications. With various brands and generic equivalents of nonprescription nonsedating products being heavily marketed to consumers, one would guess that usage of these agents would greatly increase. Direct-to-consumer advertising for prescription-only allergic rhinitis treatment options has also increased significantly. How this will affect the prescription market is unknown.
