Pharmacotherapy

A Pathophysiologic Approach

seventh edition

Pharmacotherapy

A Pathophysiologic Approach

Seventh Edition

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Pharmacotherapy

A Pathophysiologic Approach

Seventh Edition

Joseph T. DiPiro, PharmD, FCCP

Executive Dean and Professor, South Carolina
College of Pharmacy, University of South Carolina, Columbia, South Carolina
and Medical University of South Carolina, Charleston, South Carolina

Robert L. Talbert, PharmD, FCCP, BCPS, CLS

SmithKline Professor, College of Pharmacy, University of Texas at Austin,
Professor, Department of Medicine, University of Texas Health
Science Center at San Antonio, San Antonio, Texas

Gary C. Yee, PharmD, FCCP, BCOP

Professor, Department of Pharmacy Practice,
College of Pharmacy, University of Nebraska Medical Center,
Omaha, Nebraska

Gary R. Matzke, PharmD, FCP, FCCP

Professor of Pharmacy and Pharmaceutics and Associate
Dean for Clinical Research and Public Policy, School of Pharmacy,
Professor of Internal Medicine, Nephrology Division, School of Medicine,
Virginia Commonwealth University, Richmond, Virginia

Barbara G. Wells, PharmD, FASHP, FCCP, BCPP

Dean and Professor, Executive Director of the Research Institute
of Pharmaceutical Sciences, School of Pharmacy,
The University of Mississippi, Oxford, Mississippi

L. Michael Posey, BPharm

Editorial Director, Periodicals Department, American Pharmacists Association,
Washington, D.C.

DEDICATION

To our patients, who have challenged and inspired us
and given meaning to all our endeavors.

To practitioners, who continue to improve patient health outcomes
and thereby serve as role models for their colleagues and students
while clinging tenaciously to the highest standards of practice.

To our mentors, whose vision provided educational and training
programs that encouraged our professional growth and challenged us
to be innovators in our patient care, research, and education.

To our faculty colleagues for their efforts and support for our mission
to provide a comprehensive and challenging educational
foundation for the pharmacists of the future.

And finally to our families for the time that they have sacrificed
so that this seventh edition would become a reality.

IN MEMORIAM

Mario M. Zeolla (1974–2007) earned his Bachelor of Science and Doctor of Pharmacy degrees from the Albany College of Pharmacy, completed a Community Pharmacy Residency at the University of Maryland School of Pharmacy, and was a Board Certified Pharmacotherapy Specialist. In his brief but productive career as a pharmacy practitioner and educator at the Albany College of Pharmacy, Dr. Zeolla quickly rose to the rank of Associate Professor in the Department of Pharmacy Practice. In addition, he was the Patient Care Pharmacist at Eckerd (and later Brooks) Pharmacy in Loudonville, New York, where he developed innovative community-based clinical pharmacy services. He was an author in previous editions of *Pharmacotherapy: A Pathophysiologic Approach* and published several scholarly papers related to community pharmacy practice and dietary supplements/herbal therapies. Dr. Zeolla was considered one of the brightest stars on the Albany College of Pharmacy faculty and a passionate advocate for pharmacy. He was a popular teacher, trusted advisor, and beloved peer.

CONTENTS

Contributors.....	xiii
Foreword	xxvii
Foreword to the First Edition.....	xxix
Preface.....	xxxi

SECTION 1

Foundation Issues

Section Editor: L. Michael Posey

1. Pharmacoeconomics: Principles, Methods, and Applications 	1
<i>Lisa A. Sanchez</i>	
2. Health Outcomes and Quality of Life 	3
<i>Stephen Joel Coons</i>	
3. Evidence-Based Medicine 	5
<i>Elaine Chiquette and L. Michael Posey</i>	
4. Documentation of Pharmacy Services 	7
<i>George E. MacKinnon, III and Neil J. MacKinnon</i>	
5. Clinical Pharmacokinetics and Pharmacodynamics	9
<i>Larry A. Bauer</i>	
6. Pharmacogenetics	31
<i>Larisa H. Cavallari and Y. W. Francis Lam</i>	
7. Pediatrics	47
<i>Milap C. Nahata and Carol Taketomo</i>	
8. Geriatrics	57
<i>Catherine I. Starner, Shelly L. Gray, David R. P. Guay, Emily R. Hajjar, Steven M. Handler, and Joseph T. Hanlon</i>	
9. Pharmacoepidemiology 	67
<i>Andy Stergachis, Thomas K. Hazlet, and Denise Boudreau</i>	
10. Clinical Toxicology	69
<i>Peter A. Chyka</i>	

11. Emergency Preparedness: Identification and Management of Biological Exposures 	91
<i>Colleen M. Terriff, Jason E. Brouillard, Lisa T. Costanigro, and Jessica S. Gruber</i>	
12. Emergency Preparedness: Identification and Management of Chemical and Radiological Exposures 	93
<i>Greene Shepherd and Richard B. Schwartz</i>	

SECTION 2

Cardiovascular Disorders

Section Editor: Robert L. Talbert

13. Cardiovascular Testing	95
<i>Robert Chilton and Robert L. Talbert</i>	
14. Cardiopulmonary Arrest	123
<i>Jeffrey F. Barletta and Jeffrey L. Wilt</i>	
15. Hypertension	139
<i>Joseph J. Saseen and Eric J. MacLaughlin</i>	
16. Heart Failure.....	173
<i>Robert B. Parker, Jo E. Rodgers, and Larisa H. Cavallari</i>	
17. Ischemic Heart Disease	217
<i>Robert L. Talbert</i>	
18. Acute Coronary Syndromes	249
<i>Sarah A. Spinler and Simon de Denus</i>	
19. The Arrhythmias	279
<i>Cynthia A. Sanoski, Marieke Dekker Schoen, and Jerry L. Bauman</i>	
20. Diastolic Heart Failure and the Cardiomyopathies	315
<i>Jean M. Nappi and Robert L. Page, II</i>	
21. Venous Thromboembolism	331
<i>Stuart T. Haines, Daniel M. Witt, and Edith A. Nutescu</i>	
22. Stroke.....	373
<i>Susan C. Fagan and David C. Hess</i>	

- 23.** Hyperlipidemia 385
Robert L. Talbert
- 24.** Peripheral Arterial Disease 409
Barbara J. Hoeben and Robert L. Talbert
- 25.** Use of Vasopressors and Inotropes
in the Pharmacotherapy of Shock 417
Robert MacLaren, Maria I. Rudis, and Joseph F. Dasta
- 26.** Hypovolemic Shock 441
Brian L. Erstad

SECTION 3

Respiratory Disorders

Section Editor: Robert L. Talbert

- 27.** Introduction to Pulmonary Function Testing. 455
Jay I. Peters and Stephanie M. Levine
- 28.** Asthma 463
H. William Kelly and Christine A. Sorkness
- 29.** Chronic Obstructive Pulmonary Disease. 495
Dennis M. Williams and Sharya V. Bourdet
- 30.** Pulmonary Hypertension  519
Robert L. Talbert, Rebecca Boudreaux, and Rebecca L. Owens
- 31.** Drug-Induced Pulmonary Diseases 521
*Hengameh H. Raissy, Michelle Harkins,
and Patricia L. Marshik*
- 32.** Cystic Fibrosis. 535
Gary Milavetz

SECTION 4

Gastrointestinal Disorders

Section Editor: Joseph T. DiPiro

- 33.** Evaluation of the Gastrointestinal Tract 547
Keith M. Olsen, Marie A. Chisholm, and Mark W. Jackson
- 34.** Gastroesophageal Reflux Disease 555
Dianne B. Williams and Robert R. Schade
- 35.** Peptic Ulcer Disease. 569
Rosemary R. Berardi and Lynda S. Welage
- 36.** Inflammatory Bowel Disease. 589
Brian A. Hemstreet and Joseph T. DiPiro
- 37.** Nausea and Vomiting 607
Cecily V. DiPiro

- 38.** Diarrhea, Constipation, and Irritable
Bowel Syndrome 617
William J. Spruill and William E. Wade
- 39.** Portal Hypertension and Cirrhosis 633
*Julie M. Sease, Edward G. Timm,
and James J. Stragand*
- 40.** Drug-Induced Liver Disease. 651
William R. Kirchain and Rondall E. Allen
- 41.** Pancreatitis. 659
Rosemary R. Berardi and Patricia A. Montgomery
- 42.** Viral Hepatitis 675
*Paulina Deming, Renee-Claude Mercier,
and Manjunath P. Pai*
- 43.** Drug Therapy Individualization in Patients
with Hepatic Disease or Genetic Alterations
in Drug Metabolizing Activity 693
Y. W. Francis Lam

SECTION 5

Renal Disorders

Section Editor: Gary R. Matzke

- 44.** Quantification of Renal Function 705
Thomas C. Dowling
- 45.** Acute Renal Failure. 723
William Dager and Anne P. Spencer
- 46.** Chronic Kidney Disease:
Progression-Modifying Therapies 745
Melanie S. Joy, Abhijit Kshirsagar, and Nora Franceschini
- 47.** Chronic Kidney Disease:
Management of Complications 765
Joanna Q. Hudson
- 48.** Hemodialysis and Peritoneal Dialysis  793
Edward F. Foote and Harold J. Manley
- 49.** Drug-Induced Kidney Disease. 795
Thomas D. Nolin and Jonathan Himmelfarb
- 50.** Glomerulonephritis. 811
Alan H. Lau
- 51.** Drug Therapy Individualization for
Patients with Renal Insufficiency. 833
Gary R. Matzke and Reginald F. Frye
- 52.** Disorders of Sodium and Water Homeostasis 845
James D. Coyle and Melanie S. Joy

- 53.** Disorders of Calcium and Phosphorus Homeostasis 861
Amy Barton Pai, Mark Rohrscheib, and Melanie S. Joy
- 54.** Disorders of Potassium and Magnesium Homeostasis 877
Donald F. Brophy and Todd W. B. Gehr
- 55.** Acid–Base Disorders 889
John W. Devlin, Gary R. Matzke, and Paul M. Palevsky

SECTION 6

Neurologic Disorders

Section Editor: Barbara G. Wells

- 56.** Evaluation of Neurologic Illness 909
Susan C. Fagan and Fenwick T. Nichols
- 57.** Multiple Sclerosis 913
Jacquelyn L. Bainbridge and John R. Corboy
- 58.** Epilepsy. 927
Susan J. Rogers and Jose E. Cavazos
- 59.** Status Epilepticus. 953
Stephanie J. Phelps, Collin A. Hovinga, and James W. Wheless
- 60.** Acute Management of the Brain Injury Patient . . . 965
Bradley A. Boucher and Shelly D. Timmons
- 61.** Parkinson's Disease 977
Jack J. Chen, Merlin V. Nelson, and David M. Swope
- 62.** Pain Management 989
Terry J. Baumann and Jennifer Strickland
- 63.** Headache Disorders 1005
Deborah S. Minor and Marion R. Wofford

SECTION 7

Psychiatric Disorders

Section Editor: Barbara G. Wells

- 64.** Evaluation of Psychiatric Illness 1021
Patricia A. Marken, Mark E. Schneiderhan, and Stuart Munro
- 65.** Childhood Disorders. 1029
Julie Ann Dopheide, Jane Tran Tesoro, and Michael Malkin

- 66.** Eating Disorders 1041
Steven C. Stoner
- 67.** Alzheimer's Disease 1051
Patricia W. Slatum, Russell H. Swerdlow, and Angela Massey Hill
- 68.** Substance-Related Disorders: Overview and Depressants, Stimulants, and Hallucinogens. . . . 1067
Paul L. Doering and Lisa A. Boothby
- 69.** Substance-Related Disorders: Alcohol, Nicotine, and Caffeine 1083
Paul L. Doering, W. Klugh Kennedy, and Lisa A. Boothby
- 70.** Schizophrenia 1099
M. Lynn Crismon, Tami R. Argo, and Peter F. Buckley
- 71.** Depressive Disorders 1123
Christian J. Teter, Judith C. Kando, Barbara G. Wells, and Peggy E. Hayes
- 72.** Bipolar Disorder 1141
Shannon J. Drayton and Benjamin L. Weinstein
- 73.** Anxiety Disorders I: Generalized Anxiety, Panic, and Social Anxiety Disorders. 1161
Cynthia K. Kirkwood and Sarah T. Melton
- 74.** Anxiety Disorders II: Posttraumatic Stress Disorder and Obsessive-Compulsive Disorder 1179
Cynthia K. Kirkwood, Eugene H. Makela, and Barbara G. Wells
- 75.** Sleep Disorders. 1191
John M. Dopp and Bradley G. Phillips
- 76.** Developmental Disabilities  1203
Nancy Brahm, Jerry McKee, and Robert C. Brown

SECTION 8

Endocrinologic Disorders

Section Editor: Robert L. Talbert

- 77.** Diabetes Mellitus 1205
Curtis L. Triplitt, Charles A. Reasner, II, and William L. Isley
- 78.** Thyroid Disorders 1243
Steven I. Sherman and Robert L. Talbert
- 79.** Adrenal Gland Disorders. 1265
John G. Gums and Shawn Anderson
- 80.** Pituitary Gland Disorders 1281
Amy Heck Sheehan, Jack A. Yanovski, and Karim Anton Calis

SECTION 9

Gynecologic Disorders

Section Editor: Barbara G. Wells

- 81.** Pregnancy and Lactation:
Therapeutic Considerations 1297
*Denise L. Walbrandt Pigarelli, Connie K. Kraus,
and Beth E. Potter*
- 82.** Contraception.....1313
Lori M. Dickerson, Sarah P. Shrader, and Vanessa A. Diaz
- 83.** Menstruation-Related Disorders 1329
Elena M. Umland, Lara C. Weinstein, and Edward Buchanan
- 84.** Endometriosis.....1345
Deborah A. Sturpe
- 85.** Hormone Therapy in Women 1351
*Sophia N. Kalantaridou, Susan R. Davis, and
Karim Anton Calis*

SECTION 10

Urologic Disorders

Section Editor: L. Michael Posey

- 86.** Erectile Dysfunction.....1369
Mary Lee
- 87.** Management of Benign
Prostatic Hyperplasia 1387
Mary Lee
- 88.** Urinary Incontinence.....1399
*Eric S. Rovner, Jean Wyman, Thomas Lackner,
and David Guay*

SECTION 11

Immunologic Disorders

Section Editor: Gary C. Yee

- 89.** Function and Evaluation of the
Immune System 1417
Philip D. Hall and Nicole A. Weimert
- 90.** Systemic Lupus Erythematosus and Other
Collagen-Vascular Diseases 1431
Jeffrey C. Delafuente and Kimberly A. Cappuzzo
- 91.** Allergic and Pseudoallergic Drug Reactions 1447
Joseph T. DiPiro
- 92.** Solid-Organ Transplantation 1459
Kristine S. Schonder and Heather J. Johnson

SECTION 12

Rheumatologic Disorders

Section Editor: L. Michael Posey

- 93.** Osteoporosis and Other Metabolic
Bone Diseases..... 1483
Mary Beth O'Connell and Sheryl F. Vondracek
- 94.** Rheumatoid Arthritis 1505
Arthur A. Schuna
- 95.** Osteoarthritis..... 1519
Lucinda M. Buys and Mary Elizabeth Elliott
- 96.** Gout and Hyperuricemia 1539
Michael E. Ernst, Elizabeth C. Clark, and David W. Hawkins

SECTION 13

Ophthalmic and Otolaryngologic Disorders

Section Editor: L. Michael Posey

- 97.** Glaucoma..... 1551
Richard G. Fiscella, Timothy S. Lesar, and Deepak P. Edward
- 98.** Allergic Rhinitis..... 1565
J. Russell May and Philip H. Smith

SECTION 14

Dermatologic Disorders

Section Editor: L. Michael Posey

- 99.** Dermatologic Drug Reactions and
Self-Treatable Skin Disorders..... 1577
Nina H. Cheigh
- 100.** Acne Vulgaris..... 1591
*Dennis P. West, Amy Loyd, Kimberly A. Bauer, Lee E. West,
Laura Scuderi, and Giuseppe Micali*
- 101.** Psoriasis 1603
*Dennis P. West, Amy Loyd, Lee E. West, Kimberly A. Bauer,
Maria Letizia Musumeci, and Giuseppe Micali*
- 102.** Atopic Dermatitis 1619
Nina H. Cheigh

SECTION 15

Hematologic Disorders

Section Editor: Gary C. Yee

- 103.** Hematopoiesis..... 1627
William P. Petros and Michael Craig

- 104.** Anemias 1639
Beata A. Ineck, Barbara J. Mason, and William L. Lyons
- 105.** Coagulation Disorders 1665
Betsy Bickert Poon and Char Witmer
- 106.** Sickle Cell Disease 1685
C. Y. Jennifer Chan and Reginald H. Moore
- 107.** Drug-Induced Hematologic Disorders 1701
Dale H. Whitby and Thomas E. Johns

SECTION 16

Infectious Diseases

Section Editor: Joseph T. DiPiro

- 108.** Laboratory Tests to Direct Antimicrobial Pharmacotherapy 1715
Michael J. Rybak and Jeffrey R. Aeschlimann
- 109.** Antimicrobial Regimen Selection 1731
David S. Burgess
- 110.** Central Nervous System Infections 1743
Isaac F. Mitropoulos, Elizabeth D. Hermesen, Jeremy A. Schafer, and John C. Rotschafer
- 111.** Lower Respiratory Tract Infections 1761
Mark L. Glover and Michael D. Reed
- 112.** Upper Respiratory Tract Infections 1779
Yasmin Khaliq, Sarah Forgie, and George Zhanel
- 113.** Influenza 1791
Elizabeth D. Hermesen and Mark E. Rupp
- 114.** Skin and Soft-Tissue Infections 1801
Douglas N. Fish, Susan L. Pendland, and Larry H. Danziger
- 115.** Infective Endocarditis 1821
Michael A. Crouch and Angie Veverka
- 116.** Tuberculosis 1839
Charles A. Peloquin
- 117.** Gastrointestinal Infections and Enterotoxigenic Poisonings 1857
Steven Martin and Rose Jung
- 118.** Intraabdominal Infections 1875
Joseph T. DiPiro and Thomas R. Howdieshell
- 119.** Parasitic Diseases 1887
J. V. Anandan
- 120.** Urinary Tract Infections and Prostatitis 1899
Elizabeth A. Coyle and Randall A. Prince
- 121.** Sexually Transmitted Diseases 1915
Leroy C. Knodel

- 122.** Bone and Joint Infections 1933
Edward P. Armstrong and Allan D. Friedman
- 123.** Sepsis and Septic Shock 1943
S. Lena Kang-Birken and Joseph T. DiPiro
- 124.** Superficial Fungal Infections 1957
Thomas E. R. Brown and Thomas W. F. Chin
- 125.** Invasive Fungal Infections 1973
Peggy L. Carver
- 126.** Infections in Immunocompromised Patients 2003
Douglas N. Fish
- 127.** Antimicrobial Prophylaxis in Surgery 2027
Salmaan Kanji and John W. Devlin
- 128.** Vaccines, Toxoids, and Other Immunobiologics 2041
Mary S. Hayney
- 129.** Human Immunodeficiency Virus Infection 2065
Peter L. Anderson, Thomas N. Kakuda, and Courtney V. Fletcher

SECTION 17

Oncologic Disorders

Section Editor: Gary C. Yee

- 130.** Cancer Treatment and Chemotherapy 2085
Patrick J. Medina and Chris Fausel
- 131.** Breast Cancer 2121
Laura Boehnke Michaud, Janet L. Espirito, and Francisco J. Esteva
- 132.** Lung Cancer 2157
Jeannine S. McCune and Deborah A. Frieze
- 133.** Colorectal Cancer 2175
Patrick J. Medina, Weijing Sun, and Lisa E. Davis
- 134.** Prostate Cancer 2207
Jill M. Kolesar
- 135.** Lymphomas 2219
Val R. Adams and Gary C. Yee
- 136.** Ovarian Cancer 2245
Judith A. Smith and Judith K. Wolf
- 137.** Acute Leukemias 2259
Helen L. Leather and Betsy Bickert Poon
- 138.** Chronic Leukemias 2281
Amy M. Pick, Marcel Devetten, and Timothy R. McGuire
- 139.** Multiple Myeloma 2295
Timothy R. McGuire

- 140.** Myelodysplastic Syndromes  2309
Julianna A. Burzynski and Trevor McKibbin
- 141.** Skin Cancer. 2311
Rowena N. Schwartz and Lindsay J. Corporon
- 142.** Hematopoietic Stem Cell Transplantation 2331
Janelle B. Perkins and Gary C. Yee

SECTION 18

Nutrition Disorders

Section Editor: Gary R. Matzke

- 143.** Assessment of Nutrition Status and
 Nutrition Requirements 2349
Katherine Hammond Chessman and Vanessa J. Kumpf

- 144.** Prevalence and Significance of Malnutrition ... 2367
Gordon Sacks and Catherine M. Crill
- 145.** Parenteral Nutrition 2379
Todd W. Mattox and Pamela D. Reiter
- 146.** Enteral Nutrition..... 2399
Vanessa J. Kumpf and Katherine Hammond Chessman
- 147.** Nutritional Considerations in Major
 Organ Failure..... 2417
Brian M. Hodges and Mark DeLegge
- 148.** Obesity 2437
John V. St. Peter and Charles J. Billington
- Glossary 2455
- Index 2581

CONTRIBUTORS

Val R. Adams, PharmD, FCCP, BCOP

Associate Professor, University of Kentucky, College of Pharmacy,
Lexington, Kentucky

Chapter 135

Jeffrey R. Aeschlimann, PharmD

University of Connecticut, School of Pharmacy, Storrs, Connecticut

Chapter 108

Rondall E. Allen, PharmD

Clinical Assistant Professor and Assistant Dean for Program
Assessment, Xavier University of Louisiana College of Pharmacy,
New Orleans, Louisiana

Chapter 40

J. V. Anandan, PharmD

Adjunct Associate Professor, Eugene Applebaum College of
Pharmacy and Health Sciences, Wayne State University; Pharmacy
Specialist, Center for Drug Use Analysis and Information,
Department of Pharmacy Services, Henry Ford Hospital, Detroit,
Michigan

Chapter 119

Peter L. Anderson, PharmD

Assistant Professor, School of Pharmacy, University of Colorado,
Denver, Colorado

Chapter 129

Shawn Anderson, PharmD

Postdoctoral Fellow, Colleges of Pharmacy and Medicine,
Departments of Pharmacy Practice and Family Medicine,
University of Florida, Gainesville, Florida

Chapter 79

Tami R. Argo, PharmD, MS, BCPP

Clinical Assistant Professor, Department of Pharmacy Practice,
College of Pharmacy, University of Texas at Austin, Austin, Texas

Chapter 70

Edward P. Armstrong, PharmD

Professor, Department of Pharmacy Practice and Science, College of
Pharmacy, University of Arizona, Tucson, Arizona

Chapter 122

Jacquelyn L. Bainbridge, PharmD

Associate Professor, Department of Clinical Pharmacy and
Department of Neurology, University of Colorado at Denver and
The Health Sciences Center, Denver, Colorado

Chapter 57

Jeffrey F. Barletta, PharmD, FCCM

Clinical Specialist-Critical Care, Department of Pharmacy,
Spectrum Health, Adjunct Assistant Professor, College of
Pharmacy, Ferris State University, Grand Rapids, Michigan

Chapter 14

Kimberly A. Bauer, MD

Clinical Research Fellow, Department of Dermatology, Feinberg
School of Medicine, Northwestern University, Chicago, Illinois

Chapters 100 and 101

Larry A. Bauer, PharmD, FCP, FCCP

Professor, Departments of Pharmacy and Laboratory Medicine,
University of Washington, Seattle, Washington

Chapter 5

Jerry L. Bauman, PharmD, FACC, FCCP

Professor and Dean, College of Pharmacy; Professor, Department of
Medicine, College of Medicine, University of Illinois, Chicago,
Illinois

Chapter 19

Terry J. Baumann, PharmD, BCPS

Clinical Manager, Munson Medical Center, Traverse City,
Michigan; Adjunct Assistant Professor of Pharmacy, Ferris State
University, College of Pharmacy, Big Rapids, Michigan

Chapter 62

Rosemary R. Berardi, PharmD, FCCP, FASHP, FAPhA

Professor of Pharmacy, College of Pharmacy, University of
Michigan; Clinical Pharmacist, Gastrointestinal/Liver Diseases,
Department of Pharmacy, University of Michigan Health System,
Ann Arbor, Michigan

Chapters 35 and 41

Charles J. Billington, MD

Professor, Department of Medicine, University of Minnesota,
Minneapolis VA Medical Center, Minneapolis, Minnesota

Chapter 148

Lisa A. Boothby, PharmD, BCPS

Coordinator, Drug Information Services, Columbus Regional
Healthcare System; Affiliate Clinical Associate Professor, Auburn
University Harrison School of Pharmacy, Columbus, Georgia

Chapters 68 and 69

Bradley A. Boucher, PharmD, FCCP, FCCM

Professor, Department of Clinical Pharmacy, College of Pharmacy,
University of Tennessee, Memphis, Tennessee

Chapter 60

Sharya V. Bourdet, PharmD, BCPS

Critical Care Pharmacist, Veterans Affairs Medical Center, San Francisco, Health Sciences Assistant Clinical Professor, School of Pharmacy, University of California, San Francisco, San Francisco, California

Chapter 29

Denise Boudreau, RPh, PhD

Scientific Investigator, Group Health Center for Health Studies, Seattle, Washington

Chapter 9

Rebecca Boudreaux, PharmD

Clinical Instructor, College of Pharmacy, University of Texas at Austin; Department of Medicine, University of Texas Health Science Center at San Antonio, San Antonio, Texas

Chapter 30

Nancy Brahm, PharmD, MS, BCPP

Clinical Associate Professor, Department of Pharmacy, Clinical and Administrative Sciences, University of Oklahoma College of Pharmacy, Tulsa, Oklahoma

Chapter 76

Donald F. Brophy, PharmD, MSc, FCCP, BCPS

Associate Professor of Pharmacy and Internal Medicine, Virginia Commonwealth University Medical College of Virginia Campus, School of Pharmacy, Richmond, Virginia

Chapter 54

Jason E. Brouillard, PharmD

Adjunct Clinical Instructor, Department of Pharmacotherapy, College of Pharmacy, Washington State University; Critical Care Pharmacist, Department of Pharmacy, Sacred Heart Medical Center, Spokane, Washington

Chapter 11

Robert C. Brown, MD

Adjunct Clinical Associate Professor, University of Oklahoma College of Pharmacy, Department of Pharmacy, Clinical and Administrative Sciences, Oklahoma City, Oklahoma

Chapter 76

Thomas E. R. Brown, PharmD

Associate Professor, Leslie Dan Faculty of Pharmacy, University of Toronto, and Clinical Coordinator, Women's Health Sunnybrook Health Sciences Centre, Toronto, Ontario

Chapter 124

Edward M. Buchanan, MD

Department of Family Medicine, Thomas Jefferson University, Philadelphia, Pennsylvania

Chapter 83

Peter F. Buckley, MD

Professor and Chairman, Department of Psychiatry, Associate Dean of Leadership Development, Medical College of Georgia, Augusta, Georgia

Chapter 70

David S. Burgess, PharmD, FCCP

Clinical Professor of Pharmacy and Medicine, Center for Advancement of Research and Education in Infectious Diseases, University of Texas at Austin College of Pharmacy and Pharmacotherapy Education and Research Center, University of Texas Health Science Center, San Antonio, Texas

Chapter 109

Julianna A. Burzynski, PharmD, BCPS, BCOP

Pharmacy Specialist-Hematology/Oncology, Mayo Clinic, Rochester, Minnesota

Chapter 140

Lucinda M. Buys, PharmD

Associate Professor, Clinical and Administrative Pharmacy Division, University of Iowa, College of Pharmacy and the Siouxland Medical Education Foundation, Sioux City, Iowa

Chapter 95

Karim Anton Calis, PharmD, MPH, FASHP, FCCP

Director, Drug Information Service and Clinical Specialist, Endocrinology and Women's Health, Mark O. Hatfield Clinical Research Center, National Institutes of Health, Bethesda, Maryland; Professor of Pharmacy, School of Pharmacy, Virginia Commonwealth University, Richmond, Virginia; Clinical Professor, Department of Pharmacy Practice and Science, School of Pharmacy, University of Maryland, Baltimore, Maryland; Clinical Professor, Department of Pharmacy Practice, School of Pharmacy, Shenandoah University, Winchester, Virginia

Chapters 80 and 85

Kimberly A. Cappuzzo, PharmD, MS, CGP

Assistant Professor of Pharmacy, School of Pharmacy, Virginia Commonwealth University; Clinical Pharmacist/Geriatric Pharmacotherapy Specialist, Virginia Commonwealth University Medical Center, Richmond, Virginia

Chapter 90

Peggy L. Carver, PharmD, FCCP

Associate Professor of Pharmacy, College of Pharmacy, and Clinical Pharmacist, University of Michigan Health System, Ann Arbor, Michigan

Chapter 125

Larisa H. Cavallari, PharmD, BCPS

Assistant Professor, Department of Pharmacy Practice, University of Illinois College of Pharmacy, Chicago, Illinois

Chapters 6 and 16

Jose E. Cavazos, MD, PhD

Director of Research and Education, South Texas Comprehensive Epilepsy Center, University of Texas Health Science Center, San Antonio, Texas

Chapter 58

C. Y. Jennifer Chan, PharmD

Clinical Assistant Professor of Pharmacy, University of Texas in Austin, College of Pharmacy, Clinical Associate Professor of Pediatrics, University of Texas Health Science Center in San Antonio; Clinical Manager, Pediatric Pharmacy Services, Methodist Children's Hospital, San Antonio, Texas

Chapter 106

Nina H. Cheigh, PharmD

Clinical Associate Professor, University of Illinois College of Pharmacy, Rye, New York

Chapters 99 and 102

Jack J. Chen, PharmD, BCPS, CGP

Loma Linda University, School of Medicine, Department of Neurology and School of Pharmacy, Department of Pharmacotherapy, Outcomes and Research, Loma Linda, California

Chapter 61

Katherine Hammond Chessman, PharmD, FCCP, BCPS, BCNSP

Associate Professor, Department of Pharmacy and Clinical Sciences, South Carolina College of Pharmacy, MUSC Campus; Clinical Pharmacy Specialist, Pediatrics/Pediatric Surgery, Department of Pharmacy Services, Medical University of South Carolina Children's Hospital, Charleston, South Carolina

Chapters 143 and 146

Robert Chilton, DO, FACC, FAHA

Professor, Department of Medicine, University of Texas Health Science Center, San Antonio, Texas

Chapter 13

Thomas W. F. Chin, PharmD, BSc, FCSHP

Clinical Pharmacy Specialist/Leader-Antimicrobials and Infectious Diseases, St. Michael's Hospital; Assistant Professor, Leslie Dan Faculty of Pharmacy, University of Toronto, Toronto, Ontario, Canada

Chapter 124

Elaine Chiquette, PharmD, BCPS

Senior Medical Science Division, Medical Affairs, Amylin Pharmaceuticals, Inc., San Antonio, Texas

Chapter 3

Marie A. Chisholm-Burns, PharmD, MPH, FCCP, FASHP

Professor and Head, Department of Pharmacy Practice and Science, University of Arizona College of Pharmacy, Tucson, Arizona

Chapter 33

Peter A. Chyka, PharmD, FAACT, DABAT

Professor, Department of Clinical Pharmacy and Associate Dean, Knoxville Campus, College of Pharmacy, University of Tennessee, Knoxville, Tennessee

Chapter 10

Elizabeth C. Clark, MD, MPH

University of Medicine and Dentistry of New Jersey, Robert Wood Johnson Medical School, Department of Family Medicine, Somerset, New Jersey

Chapter 96

Stephen Joel Coons, PhD

Professor, Department of Pharmacy Practice and Service, College of Pharmacy, University of Arizona, Tucson, Arizona

Chapter 2

John R. Corboy, MD

Professor, Department of Neurology, University of Colorado School of Medicine; Denver Veteran's Affairs Medical Center, Denver, Colorado

Chapter 57

Lindsay J. Corporon, PharmD, BCDP

Assistant Professor of Pharmacy and Therapeutics, University of Pittsburgh, School of Pharmacy; Clinical Specialist in Oncology, Magee Women's Hospital, Pittsburgh, Pennsylvania

Chapter 141

Lisa T. Costanigro, Pharm D

Infectious Diseases Pharmacy Resident; Deaconess Medical Center, Washington State University College of Pharmacy, Spokane, Washington

Chapter 11

Elizabeth A. Coyle, PharmD, BCPS

Clinical Associate Professor, University of Houston College of Pharmacy, Houston, Texas

Chapter 120

James D. Coyle, PharmD

Assistant Professor of Clinical Pharmacy, College of Pharmacy, Ohio State University, Columbus, Ohio

Chapter 52

Michael Craig, MD

Assistant Professor, Department of Medicine, Section of Hematology/Oncology, West Virginia University, Morgantown, West Virginia

Chapter 103

Catherine M. Crill, PharmD, BCPS, BCNSP

Associate Professor, Department of Clinical Pharmacy; Assistant Professor, Department of Pediatrics, University of Tennessee Health Science Center, Memphis, Tennessee

Chapter 144

M. Lynn Crismon, PharmD, FCCP, BCPP

Dean, James T. Doluisio Chair and Behrens Professor, College of Pharmacy, University of Texas at Austin, Austin, Texas

Chapter 70

Michael A. Crouch, PharmD, BCPS

Associate Professor of Pharmacy and Medicine, Virginia Commonwealth University, Medical College of Virginia Campus, Richmond, Virginia

Chapter 115

William E. Dager, PharmD, FCSHP

Pharmacist Specialist, UC Davis Medical Center, Clinical Professor of Medicine, UC Davis School of Medicine, Sacramento, California; Clinical Professor of Pharmacy, UC San Francisco School of Pharmacy, San Francisco, California

Chapter 45

Joseph F. Dasta, MSc, FCCM, FCCP

Professor Emeritus, Ohio State University, College of Pharmacy, Columbus, Ohio; Adjunct Professor, University of Texas, Austin, Texas

Chapter 25

Lisa E. Davis, PharmD, FCCP, BCPS, BCOP

Associate Professor and Vice Chair of Research, Philadelphia College of Pharmacy, University of the Sciences in Philadelphia, Philadelphia, Pennsylvania

Chapter 133

Susan R. Davis, MD, PhD, FRAPC

Chair of Women's Health, Department of Medicine, Monash University, Clayton, Victoria, Australia

Chapter 85

Larry H. Danziger, PharmD

Professor of Pharmacy, Department of Pharmacy Practice, Interim Vice Chancellor for Research, University of Illinois, Chicago, Illinois

Chapter 114

Simon de Denus, MSc, BPharm

Assistant Professor, Faculty of Pharmacy, University of Montreal,
Montreal Heart Institute, Montreal, Quebec, Canada

Chapter 18

Jeffrey C. Delafuente, MS, FCCP, FASCP

Associate Dean for Professional Education; Professor of Pharmacy
and Director of Geriatric Programs, School of Pharmacy, Virginia
Commonwealth University, Richmond, Virginia

Chapter 90

Mark DeLegge, MD

Professor and Director, Digestive Disease Center, School of
Medicine, Medical University of South Carolina, Charleston, South
Carolina

Chapter 147

Paulina Deming, PharmD

Assistant Professor, College of Pharmacy and Department of
Internal Medicine, University of New Mexico, Albuquerque, New
Mexico

Chapter 42

Marcel Devetten, MD

Associate Professor of Medicine and Director of Hematopoietic Cell
Transplant Program, University of Nebraska Medical Center,
Omaha, Nebraska

Chapter 138

John W. Devlin, PharmD, FCCP, FCCM, BCPS

Associate Professor, Department of Pharmacy Practice, School of
Pharmacy, Northeastern University; Adjunct Associate Professor,
School of Medicine, Tufts University, Boston, Massachusetts

Chapters 55 and 127

Vanessa A. Diaz, MD, MS

Assistant Professor, Department of Family Medicine, Medical
University of South Carolina, Charleston, South Carolina

Chapter 82

Lori M. Dickerson, PharmD, FCCP, BCPS

Associate Professor and Associate Residency Program Director,
Department of Family Medicine, Medical University of South
Carolina, Charleston, South Carolina

Chapter 82

Cecily V. DiPiro, PharmD

Consultant Pharmacist, Mt. Pleasant, South Carolina

Chapter 37

Joseph T. DiPiro, PharmD, FCCP

Executive Dean and Professor, South Carolina College of Pharmacy,
Medical University of South Carolina, Charleston, South Carolina;
University of South Carolina, Columbia, South Carolina

Chapters 36, 91, 118, and 123

Paul L. Doering, MS

Distinguished Service Professor of Pharmacy Practice, College of
Pharmacy, University of Florida, Gainesville, Florida

Chapters 68 and 69

Julie Ann Dopheide, PharmD, BCPP

Associate Professor of Clinical Pharmacy, Psychiatry and the
Behavioral Sciences, University of Southern California Schools of
Pharmacy and Medicine, Los Angeles, California

Chapter 65

John M. Dopp, PharmD

Assistant Professor, Pharmacy Practice Division, School of
Pharmacy, University of Wisconsin-Madison, Madison, Wisconsin

Chapter 75

Thomas C. Dowling, PharmD, PhD

Associate Professor, Director, Renal Clinical Pharmacology Lab,
School of Pharmacy, University of Maryland, Baltimore, Maryland

Chapter 44

Shannon J. Drayton, PharmD

Assistant Professor, Department of Pharmacy and Clinical Sciences,
South Carolina College of Pharmacy, Medical University of South
Carolina Campus, Charleston, South Carolina

Chapter 72

Deepak P. Edward, MD, FACS

Chair and Program Director; Professor/NEOUCOM, Department
of Ophthalmology, Summa Health System, Akron, Ohio

Chapter 97

Mary Elizabeth Elliott, PharmD, PhD

Associate Professor and Vice-Chair, Pharmacy Practice Division,
School of Pharmacy, University of Wisconsin-Madison, Madison,
Wisconsin, Clinical Pharmacist, Osteoporosis Clinic, VA Medical
Center, Madison, Wisconsin

Chapter 95

Michael E. Ernst, PharmD, BCPS

Associate Professor (Clinical), Division of Clinical and Administrative
Pharmacy, College of Pharmacy; Department of Family Medicine,
Carver College of Medicine, University of Iowa, Iowa City, Iowa

Chapter 96

Brian L. Erstad, PharmD

Professor, Department of Pharmacy Practice and Science, College of
Pharmacy, University of Arizona, Tucson, Arizona

Chapter 26

Janet L. Espirito, PharmD, BCOP

Clinical Pharmacy Specialist-Breast Oncology, Division of Pharmacy,
University of Texas M.D. Anderson Cancer Center, Houston, Texas

Chapter 131

Francisco J. Esteva, MD, PhD

Associate Professor of Medicine, Departments of Breast Medical
Oncology and Molecular and Cellular Oncology, University of
Texas, M.D. Anderson Cancer Center, Houston, Texas

Chapter 131

Susan C. Fagan, PharmD, BCPS

Professor, Clinical and Administrative Pharmacy, College of
Pharmacy, University of Georgia and Adjunct Professor of
Neurology, Medical College of Georgia, Augusta, Georgia

Chapters 22 and 56

Chris Fausel, PharmD, BCPS, BCOP

Clinical Pharmacist, Hematology/Oncology/BMT, Indiana University Cancer Center, Indianapolis, Indiana
Chapter 130

Richard G. Fiscella, BS Pharm, MPH

Clinical Professor, Department of Pharmacy Practice, Adjunct Assistant Professor, Department of Ophthalmology, University of Illinois, Chicago, Illinois
Chapter 97

Douglas N. Fish, PharmD

Professor, Department of Clinical Pharmacy, School of Pharmacy; Clinical Associate Professor, Division of Respiratory and Critical Care Medicine, School of Medicine, University of Colorado, Denver, Colorado
Chapters 114 and 126

Courtney V. Fletcher, PharmD

Dean and Professor, College of Pharmacy, University of Nebraska Medical Center, Omaha, Nebraska
Chapter 129

Edward F. Foote, PharmD, FCCP, BCPS

Professor and Chair, Pharmacy Practice Department, Nesbitt College of Pharmacy and Nursing, Wilkes-Barre University, Wilkes-Barre, Pennsylvania
Chapter 48

Sarah Forgie, MD, FRCP(C)

Assistant Professor, Pediatrics, Division of Infectious Diseases, University of Alberta; Associate Director, Infection Control, Stollery Children's Hospital, Edmonton, Alberta, Canada
Chapter 112

Nora Franceschini, MD, MPH

Department of Epidemiology, School of Public Health, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina
Chapter 46

Allan D. Friedman, MD, MPH

Professor and Chair, Division of General Pediatrics, Virginia Commonwealth University, Richmond, Virginia
Chapter 122

Deborah A. Frieze, PharmD, BCOP

Clinical Pharmacist, Hematology/Oncology; Clinical Instructor, Seattle Cancer Care Alliance; University of Washington Medical Center, Seattle, Washington
Chapter 132

Reginald F. Frye, PharmD, PhD

Associate Professor, Departments of Pharmacy Practice and Pharmaceutics, College of Pharmacy, University of Florida, Gainesville, Florida
Chapter 51

Todd W. B. Gehr, MD

Professor and Chairman, Division of Nephrology, Department of Internal Medicine, Virginia Commonwealth University, Richmond, Virginia
Chapter 54

Mark L. Glover, PharmD, BS Pharm

Associate Professor and Director, West Palm Beach Program, Department of Pharmacy Practice, College of Pharmacy, Nova Southeastern University, Palm Beach Gardens, Florida
Chapter 111

Shelly L. Gray, PharmD, MS

Professor, School of Pharmacy, University of Washington, Seattle, Washington
Chapter 8

Jessica S. Gruber, PhD, MPH

Washington State University, College of Pharmacy, Deaconess Medical Center, Spokane, Washington
Chapter 11

David R. P. Guay, Pharm D

Professor, Department of Experimental and Clinical Pharmacology, College of Pharmacy, University of Minnesota; Department of Geriatrics, Health Partners, Inc., Minneapolis, Minnesota
Chapters 8 and 88

John G. Gums, PharmD

Professor of Pharmacy and Medicine, Departments of Pharmacy Practice and Family Medicine, Director of Clinical Research in Family Medicine, University of Florida, Gainesville, Florida
Chapter 79

Stuart T. Haines, PharmD, BCPS

Professor and Vice Chair, University of Maryland School of Pharmacy; Clinical Specialist, University of Maryland Medical System, Baltimore, Maryland
Chapter 21

Emily R. Hajjar, PharmD

Assistant Professor, Jefferson School of Pharmacy, Thomas Jefferson University, Philadelphia, Pennsylvania
Chapter 8

Philip D. Hall, PharmD, FCCP, BCPS, BCOP

Associate Dean and Associate Professor, South Carolina College of Pharmacy, Medical University of South Carolina Campus, Hollings Cancer Center, Charleston, South Carolina
Chapter 89

Steven M. Handler, MP, MS, CMD

Assistant Professor, Department of Medicine, Division of Geriatric Medicine and Department of Biomedical Informatics, University of Pittsburgh, Pittsburgh, Pennsylvania
Chapter 8

Joseph T. Hanlon, PharmD, MS, BCPS

Professor, Division of Geriatrics and Gerontology, Department of Medicine, School of Medicine; Department of Pharmacy and Therapeutics, School of Pharmacy, University of Pittsburgh; Research Health Scientist, Center for Health Equity Research and Promotion, Geriatric Research Education (CHERP) and Clinical Center (GRECC), Pittsburgh, Pennsylvania
Chapter 8

Michelle Harkins, MD

Associate Professor, Department of Internal Medicine, Pulmonary and Critical Care, University of New Mexico Health Sciences Center, Albuquerque, New Mexico
Chapter 31

David W. Hawkins, PharmD

Professor and Dean, California Northstate College of Pharmacy,
Sacramento, California

Chapter 96

Peggy E. Hayes, PharmD

President, Hayes CNS Services, LLC, San Diego, California

Chapter 71

Mary S. Hayney, PharmD, FCCP, BCPS

Associate Professor of Pharmacy (CHS) University of Wisconsin-
Madison, School of Pharmacy, Madison, Wisconsin

Chapter 128

Thomas K. Hazlet, PharmD, DrPH

Pharmaceutical Outcomes Research and Policy Program University
of Washington School of Pharmacy, Seattle, Washington

Chapter 9

Brian A. Hemstreet, PharmD, BCPS

Assistant Professor, University of Colorado at Denver and Health
Sciences Center School of Pharmacy, Department of Clinical
Pharmacy, Denver, Colorado

Chapter 36

Elizabeth D. Hermesen, PharmD, MBA, BCPS

Antimicrobial Specialist and Research Associate, Nebraska Medical
Center; Adjunct Assistant Professor, University of Nebraska
Medical Center, College of Pharmacy and Medicine, Omaha,
Nebraska

Chapters 110 and 113

David C. Hess, MD

Professor and Chair, Department of Neurology, Medical College of
Georgia, Augusta, Georgia

Chapter 22

Angela Massey Hill, PharmD, BCPP

Professor, Division Director of Pharmacy Practice, Florida A&M
University College of Pharmacy, Tallahassee, Florida

Chapter 67

Jonathan Himmelfarb, MD

Director, Division of Nephrology and Transplantation; Associate
Chair for Research, Department of Medicine; Director of Clinical
and Translational Research, Maine Medical Center, Portland,
Maine

Chapter 49

Brian M. Hodges, PharmD, BCPS, BCNSP

Assistant Professor, Department of Clinical Pharmacy, School of
Pharmacy, West Virginia University, Morgantown, West Virginia

Chapter 147

Barbara J. Hoebe, PharmD, MSParm, BCPS

Clinical Pharmacy Flight Commander, 59 MDW, Wilford Hall
Medical Center, Lackland Airforce Base; Clinical Assistant
Professor, Department of General Medicine, University of Texas
Health Science Center, San Antonio, Texas

Chapter 24

Collin A. Hovinga, PharmD

Assistant Professor, Pharmacy and Pediatrics, University of
Tennessee Health Science Center, Memphis, Tennessee

Chapter 59

Thomas R. Howdieshell, MD, FACS, FCCP

Professor of Surgery, Section of Trauma/Surgical Critical Care,
Department of Surgery, University of New Mexico Health Sciences
Center, Albuquerque, New Mexico

Chapter 118

Joanna Q. Hudson, PharmD, BCPS, FASN

Associate Professor, Departments of Clinical Pharmacy and
Medicine (Nephrology), Schools of Pharmacy and Medicine,
University of Tennessee; Clinical Pharmacist, Methodist University
Hospital, Memphis, Tennessee

Chapter 47

Beata A. Ineck, PharmD, BCPS, CDE

Inpatient Clinical Staff Pharmacist, St. Luke's Meridian Medical
Center, Meridian, Idaho

Chapter 104

William L. Isley, MD

Consultant, Mayo Clinic; Associate Professor of Medicine, Mayo
Clinic College of Medicine, Rochester, Minnesota (Deceased)

Chapter 77

Mark W. Jackson, MD

Gastroenterologist, Fort Sanders Regional Medical Center and
Baptist Hospital of East Tennessee, Knoxville, Tennessee

Chapter 33

Thomas E. Johns, PharmD, BCPS

Assistant Director, Clinical Pharmacy Services, Shands at the
University of Florida, Gainesville, Florida

Chapter 107

Heather J. Johnson, PharmD, BCPS, FASN

Assistant Professor, School of Pharmacy, University of Pittsburgh;
Clinical Pharmacist, University of Pittsburgh Medical Center,
Pittsburgh, Pennsylvania

Chapter 92

Melanie S. Joy, PharmD

Associate Professor, Division of Nephrology and Hypertension, UNC
Kidney Center, School of Medicine, Division of Pharmacotherapy
and Experimental Therapeutics, School of Pharmacy, University of
North Carolina at Chapel Hill, Chapel Hill, North Carolina

Chapters 46 and 52

Rose Jung, PharmD, BCPS

Prestige Associate Professor, Department of Pharmacy Practice,
University of Toledo, College of Pharmacy, Toledo, Ohio

Chapter 117

Thomas N. Kakuda, PharmD

Director, Human Pharmacokinetics, Tibotec, Inc., Yardley,
Pennsylvania

Chapter 129

Sophia N. Kalantaridou, MD, PhD

Associate Professor of Obstetrics and Gynecology, Division of
Reproductive Endocrinology, University of Ioannina Medical
School, Ioannina, Greece

Chapter 85

Judith C. Kando, PharmD, BCPP

Senior Scientific Affairs Liaison, Ortho-McNeil Janssen Scientific
Affairs, LLC, Tewksbury, Massachusetts

Chapter 71

S. Lena Kang-Birken, PharmD, FCCP

Associate Professor, Department of Pharmacy Practice, Thomas J. Long School of Pharmacy and Health Sciences, University of the Pacific, Stockton, California

Chapter 123

Salmaan Kanji, PharmD, MSc

Clinical Pharmacy Specialist, Ottawa Health Research Institute, Ottawa, Ontario, Canada

Chapter 127

H. William Kelly, PharmD

Professor Emeritus, Department of Pediatrics, School of Medicine, University of New Mexico Health Sciences Center, Albuquerque, New Mexico

Chapter 28

W. Klugh Kennedy, PharmD, BCPP

Clinical Associate Professor, University of Georgia College of Pharmacy; Associate Professor, Mercer University School of Medicine, Savannah, Georgia

Chapter 69

Yasmin Khaliq, PharmD

Ottawa Hospital, Ottawa, Ontario, Canada

Chapter 112

William R. Kirchain, PharmD

Wilbur and Mildred Robichaux Endowed Professor of Pharmacy, Xavier University, College of Pharmacy, New Orleans, Louisiana

Chapter 40

Cynthia K. Kirkwood, PharmD, BCPP

Associate Professor of Pharmacy, Vice Chair for Education, Department of Pharmacy, School of Pharmacy, Virginia Commonwealth University, Richmond, Virginia

Chapters 73 and 74

Leroy C. Knodel, PharmD

Associate Professor, Department of Surgery, University of Texas Health Science Center, San Antonio, Texas; Clinical Associate Professor, College of Pharmacy, University of Texas, Austin, Texas

Chapter 121

Jill M. Kolesar, PharmD, FCCP, BCPS

Associate Professor, School of Pharmacy, University of Wisconsin, Madison, Wisconsin

Chapter 134

Connie R. Kraus, PharmD, BCPS

Clinical Professor, School of Pharmacy, University of Wisconsin-Madison, Madison, Wisconsin

Chapter 81

Abhijit Kshirsagar, MD, MPH

Assistant Professor of Medicine, Division of Nephrology and Hypertension, UNC Kidney Center, School of Medicine, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina

Chapter 46

Vanessa J. Kumpf, PharmD, BCNSP

Clinical Specialist, Nutrition Support, Vanderbilt University Medical Center, Nashville, Tennessee

Chapters 143 and 146

Thomas Lackner, PharmD

Professor, Department of Experimental and Clinical Pharmacy, College of Pharmacy, University of Minnesota, Minneapolis, Minnesota

Chapter 88

Y. W. Francis Lam, PharmD, FCCP

Associate Professor of Pharmacology and Medicine, Clinical Associate Professor of Pharmacy, Departments of Pharmacology and Medicine, University of Texas Health Science Center, San Antonio, Texas

Chapters 6 and 43

Alan H. Lau, PharmD

Professor, Department of Pharmacy Practice, College of Pharmacy, University of Illinois, Chicago, Illinois

Chapter 50

Helen L. Leather, BPharm

Clinical Pharmacy Specialist BMT/Leukemia, Shands at the University of Florida, Department of Pharmacy, Gainesville, Florida

Chapter 137

Mary Lee, PharmD, BCPS, FCCP

Professor of Pharmacy Practice, Chicago College of Pharmacy; Vice President and Chief Academic Officer, Pharmacy and Health Science Education, Midwestern University, Downers Grove, Illinois

Chapters 86 and 87

Timothy S. Lesar, PharmD

Director of Pharmacy, Patient Care Service Director, Department of Pharmacy, Albany Medical Center, Albany, New York

Chapter 97

Stephanie M. Levine, MD

Professor of Medicine, Division of Pulmonary and Critical Care Medicine, University of Texas Health Science Center, San Antonio, Texas

Chapter 27

Amy Loyd, DO, CPT, MC

Resident, Army Medical Corps, Brooke Army Medical Center, San Antonio, Texas

Chapters 100 and 101

William L. Lyons, MD

Assistant Professor, Section of Geriatrics and Gerontology, University of Nebraska Medical Center, Omaha, Nebraska

Chapter 104

George E. MacKinnon, III, PhD, RPh, FASHP

Vice President of Academic Affairs, American Association of Colleges of Pharmacy, Alexandria, Virginia

Chapter 4

Neil J. MacKinnon, PhD, RPh, FCSHP

Associate Director for Research and Associate Professor, Dalhousie University College of Pharmacy, Halifax, Nova Scotia, Canada

Chapter 4

Robert MacLaren, PharmD, BSc

Associate Professor, Department of Clinical Pharmacy, University of Colorado, Denver, School of Pharmacy, Aurora, Colorado

Chapter 25

Eric J. MacLaughlin, PharmD, BS Pharm

Associate Professor, Texas Tech University Health Sciences Center,
School of Pharmacy, Amarillo, Texas

Chapter 15

Eugene H. Makela, PharmD, BCPP

Associate Professor, Schools of Pharmacy and Medicine, West
Virginia University, Morgantown, West Virginia

Chapter 74

Michael Malkin, MD

Director, Juvenile Court Mental Health Services, Los Angeles
County Department of Mental Health; Assistant Professor, UCLA
Department of Psychiatry, Los Angeles, California

Chapter 65

Harold J. Manley, PharmD, FASN, FCCP, BCPS

Director of Clinical Pharmacy, Village Health Disease Management,
Glenmont, New York

Chapter 48

Patricia A. Marken, PharmD, FCCP, BCPP

Professor and Chair of Pharmacy Practice, School of Pharmacy;
Professor of Psychiatry, School of Medicine, University of Missouri,
Kansas City, Missouri

Chapter 64

Patricia L. Marshik, PharmD

Associate Professor, University of New Mexico Health Sciences
Center, College of Pharmacy, Albuquerque, New Mexico

Chapter 31

Steven Martin, PharmD, BCPS, FCCP, FCCM

Professor and Chairman, Department of Pharmacy Practice,
University of Toledo, College of Pharmacy, Toledo, Ohio

Chapter 117

Barbara J. Mason, PharmD, FASHP

Professor and Vice Chair, Idaho State University College of
Pharmacy; Ambulatory Core Clinical Pharmacist, Boise VA Medical
Center, Boise, Idaho

Chapter 104

Todd W. Mattox, PharmD, BCNSP

Coordinator, Nutrition Support Team, H. Lee Moffitt Cancer
Center and Research Institute, Tampa, Florida

Chapter 145

Gary R. Matzke, PharmD, FCP, FCCP

Professor of Pharmacy and Pharmaceutics and Associate Dean for
Clinical Research and Public Policy, School of Pharmacy, Professor
of Internal Medicine, Nephrology Division, School of Medicine,
Virginia Commonwealth University, Richmond, Virginia

Chapters 51 and 55

J. Russell May, PharmD, FASHP

Clinical Professor, Department of Clinical and Administrative
Pharmacy, University of Georgia College of Pharmacy; Clinical
Pharmacy Specialist, Medical College of Georgia, Augusta, Georgia

Chapter 98

Jeannine S. McCune, PharmD, BCPS, BCOP

Associate Professor, University of Washington, School of Pharmacy;
Affiliate Investigator, Fred Hutchinson Cancer Research Center,
Seattle, Washington

Chapter 132

Timothy R. McGuire, PharmD, FCCP, BCOP

Associate Professor, College of Pharmacy, University of Nebraska
Medical Center, Omaha, Nebraska

Chapters 138 and 139

Jerry R. McKee, PharmD, MS, BCPP

Clinical Assistant Professor, Department of Pharmacotherapy,
University of North Carolina School of Pharmacy, Chapel Hill,
North Carolina; Pharmacy Director-Broughton Hospital,
Morganton, North Carolina

Chapter 76

Trevor McKibbin, PharmD, BCPS, MSc

Assistant Professor, Department of Clinical Pharmacy, College of
Pharmacy, University of Tennessee Health Science Center,
Memphis, Tennessee

Chapter 140

Patrick J. Medina, PharmD, BCOP

Associate Professor, University of Oklahoma College of Pharmacy,
Oklahoma City, Oklahoma

Chapters 130 and 133

Sarah T. Melton, PharmD, BCPP, CGP

Adjunct Associate Professor of Pharmacy Practice, University of
Appalachia College of Pharmacy; Clinical Pharmacist, Lebanon,
Virginia

Chapter 73

Giuseppe Micali, MD

Professor and Chairman, Dermatology Clinic, University of
Catania, Catania, Italy

Chapters 100 and 101

Laura Boehnke Michaud, PharmD, BCOP, FASHP

Manager, Clinical Pharmacy and Clinical Pharmacy Specialist–
Breast Oncology, University of Texas M. D. Anderson Cancer
Center, Houston, Texas

Chapter 131

Gary Milavetz, PharmD, RPh, BS, FCCP

Associate Professor of Pharmacy, Division of Clinical and
Administrative Pharmacy, College of Pharmacy, University of Iowa,
Iowa City, Iowa

Chapter 32

Deborah S. Minor, PharmD

Associate Professor, Department of Medicine, School of Medicine,
University of Mississippi Medical Center, Jackson, Mississippi

Chapter 63

Isaac F. Mitropoulos, PharmD

Research Fellow, Experimental and Clinical Pharmacology, College
of Pharmacy, University of Minnesota, Minneapolis, Minnesota

Chapter 110

Patricia A. Montgomery, PharmD

Clinical Pharmacy Specialist, Mercy General Hospital, Sacramento,
California

Chapter 41

Reginald H. Moore, MD

Clinical Associate Professor, Department of Pediatrics, University
of Texas Health Science Center, San Antonio, Texas

Chapter 106

Stuart Munro, MD

Chair, Department of Psychiatry, School of Medicine, University of Missouri-Kansas City, Kansas City, Missouri

Chapter 64

Maria Letizia Musumeci, MD, PhD

Assistant, Dermatology Clinic, University of Catania, Catania, Italy

Chapter 101

Milap C. Nahata, PharmD, MS, FCCP

Professor of Pharmacy, Pediatrics and Internal Medicine; Division Chair, Pharmacy Practice and Administration, Ohio State University, College of Pharmacy, Associate Director, Department of Pharmacy, Ohio State University Medical Center, Columbus, Ohio

Chapter 7

Jean M. Nappi, PharmD, FCCP, BCPS

Professor of Pharmacy and Clinical Sciences, South Carolina College of Pharmacy-MUSC Campus; Professor of Medicine, Medical University of South Carolina, Charleston, South Carolina

Chapter 20

Merlin V. Nelson, MD, PharmD

Neurologist, Affiliated Community Medical Centers, Willmar, Minnesota

Chapter 61

Fenwick T. Nichols, III, MD

Professor, Department of Neurology, Medical College of Georgia, Augusta, Georgia

Chapter 56

Thomas D. Nolin, PharmD, PhD

Clinical Pharmacologist, Department of Pharmacy Services, Division of Nephrology and Transplantation, Department of Medicine, Maine Medical Center, Portland, Maine

Chapter 49

Edith A. Nutescu, PharmD, FCCP

Clinical Associate Professor, Director, Antithrombosis Center, University of Chicago College of Pharmacy and Medical Center, Chicago, Illinois

Chapter 21

Mary Beth O'Connell, PharmD, BCPS

Department of Pharmacy Practice, Wayne State University, Detroit, Michigan

Chapter 93

Keith M. Olsen, PharmD, FCCP, FCCM

Professor and Chair, Department of Pharmacy Practice, College of Pharmacy, University of Nebraska Medical Center, Omaha, Nebraska

Chapter 33

Rebecca L. Owens, PharmD

Clinical Instructor, College of Pharmacy, University of Texas, Austin, Texas; Department of Medicine, University of Texas Health Science Center at San Antonio, San Antonio, Texas

Chapter 30

Robert L. Page, II, PharmD, CGP, BCPS

Associate Professor of Clinical Pharmacy and Physical Medicine; Clinical Specialist, Division of Cardiology, UHCSC, Schools of Pharmacy and Medicine, Denver, Colorado

Chapter 20

Amy Barton Pai, PharmD, BCPS, FASN

Associate Professor of Pharmacy, College of Pharmacy; School of Medicine, University of New Mexico, Albuquerque, New Mexico

Chapter 53

Paul M. Palevsky, MD

Chief Renal Section, VA Pittsburgh Healthcare System; Professor of Medicine, Renal-Electrolyte Division, School of Medicine, University of Pittsburgh, Pittsburgh, Pennsylvania

Chapter 55

Robert B. Parker, PharmD, FCCP

Professor, University of Tennessee College of Pharmacy, Memphis, Tennessee

Chapter 16

Charles A. Peloquin, PharmD

Director, Infectious Disease Pharmacokinetics Laboratory, National Jewish Medical and Research Center, Denver, Colorado

Chapter 116

Susan L. Pendland, PharmD, MS

Adjunct Associate Professor, Department of Pharmacy Practice, College of Pharmacy, University of Illinois at Chicago, Chicago, Illinois; Clinical Staff Pharmacist, Saint Joseph Berea Hospital, Berea, Kentucky

Chapter 114

Janelle B. Perkins, PharmD

Assistant Professor, Department of Interdisciplinary Oncology, Blood and Marrow Transplant Program, Moffitt Cancer Center, Tampa, Florida

Chapter 142

Jay I. Peters, MD

Professor of Medicine, Pulmonary/Critical Care Division, University of Texas Health Science Center, San Antonio, Texas

Chapter 27

William P. Petros, PharmD, FCCP

Mylan Chair of Pharmacology, Professor of Pharmacy and Medicine, West Virginia University Health Sciences Center; Associate Director of Anti-Cancer Drug Development, Mary Babb Randolph Cancer Center, Morgantown, West Virginia

Chapter 103

Stephanie J. Phelps, PharmD, BCPS

Professor, Department of Clinical Pharmacy, University of Tennessee, Memphis, Tennessee

Chapter 59

Bradley G. Phillips, PharmD, BCPS, FCCP

Milliken-Reeve Professor and Head, Department of Clinical and Administrative Pharmacy, College of Pharmacy, University of Georgia, Athens, Georgia

Chapter 75

Amy M. Pick, PharmD, BCOP

Assistant Professor of Pharmacy Practice, Creighton University School of Pharmacy and Health Professions; Clinical Pharmacist, Nebraska Methodist Hospital, Omaha, Nebraska

Chapter 138

Denise L. Walbrandt Pigarelli, PharmD, BC-ADM

Clinical Associate Professor, University of Wisconsin-Madison,
School of Pharmacy, Madison, Wisconsin

Chapter 81

Betsy Bickert Poon, PharmD

Oncology/Stem Cell Transplant Clinical Pharmacist, Children's
Hospital of Philadelphia, Philadelphia, Pennsylvania

Chapters 105 and 137

L. Michael Posey, BSPHarm

Editorial Director, Periodicals Department, American Pharmacists
Association, Washington, D.C.

Chapter 3

Beth E. Potter, MD

Associate Professor, Department of Family Medicine, School of
Medicine and Public Health, University of Wisconsin-Madison,
Madison, Wisconsin

Michael D. Reed, PharmD, FCCP, FCP

Director, Division of Clinical Pharmacology and Toxicology,
Department of Pediatrics, Children's Hospital Medical Center,
Akron, Ohio

Chapter 111

Pamela D. Reiter, PharmD

Clinical Pharmacy Specialist, Pediatric ICU and Trauma, The
Children's Hospital of Denver; Clinical Associate Professor,
University of Colorado of Denver Health Sciences Center, School of
Pharmacy, Denver, Colorado

Chapter 145

Jo E. Rodgers, PharmD, BCPS (AQ Cardiology)

Clinical Assistant Professor, Department of Pharmacotherapy and
Experimental Therapeutics, School of Pharmacy, University of
North Carolina at Chapel Hill, Chapel Hill, North Carolina

Chapter 16

Susan J. Rogers, PharmD, BCPS

Assistant Clinical Professor, University of Texas at Austin; Clinical
Pharmacy Specialist Neurology, South Texas Healthcare System,
Audie L. Murphy Memorial Veterans Hospital, San Antonio, Texas

Chapter 58

Mark Rohrscheib, MD

Assistant Professor, Department of Internal Medicine, Division of
Nephrology, University of New Mexico Health Sciences Center,
Albuquerque, New Mexico

Chapter 53

John C. Rotschafer, PharmD, FCCP

Professor, Department of Experimental and Clinical Pharmacy,
College of Pharmacy, University of Minnesota, Minneapolis,
Minnesota

Chapter 110

Eric S. Rovner, MD

Associate Professor of Urology, Department of Urology, Medical
University of South Carolina, Charleston, South Carolina

Chapter 88

Maria I. Rudis, PharmD, FCCM

Assistant Professor of Clinical Pharmacy, School of Pharmacy;
Assistant Professor of Clinical Emergency Medicine, Keck School of
Medicine, University of Southern California, Los Angeles,
California

Chapter 25

Mark E. Rupp, MD

Professor, Department of Internal Medicine, University of Nebraska
Medical Center; Medical Director, Department of Healthcare
Epidemiology, Nebraska Medical Center, Omaha, Nebraska

Chapter 113

Michael J. Rybak, PharmD, MPH

Professor of Pharmacy and Medicine, Associate Dean for Research,
Director, Anti-Infective Research Laboratory, Eugene Applebaum
College of Pharmacy and Health Sciences, Wayne State University,
Detroit, Michigan

Chapter 108

Gordon Sacks, PharmD

Clinical Professor and Chair, Pharmacy Practice Division, School of
Pharmacy, University of Wisconsin-Madison, Madison, Wisconsin

Chapter 144

Lisa Sanchez, PharmD

PE Applications, Highlands Ranch, Colorado

Chapter 1

Cynthia A. Sanoski, PharmD, BS

Associate Professor of Clinical Pharmacy, Department of Pharmacy
Practice and Pharmacy Administration, Philadelphia College of
Pharmacy, University of the Sciences, Philadelphia, Pennsylvania

Chapter 19

Joseph J. Saseen, PharmD, FCCP, BCPS

Associate Professor, University of Colorado-Denver, Department of
Clinical Pharmacy, School of Pharmacy; Department of Family
Medicine, School of Medicine, Aurora, Colorado

Chapter 15

Robert R. Schade, MD, FACP, AGAF, FACG, FASGE

Professor of Medicine, Chief, Division of Gastroenterology/
Hepatology, Medical College of Georgia, Division of
Gastroenterology/Hepatology, Augusta, Georgia

Chapter 34

Jeremy A. Schafer, PharmD

Manager of Formulary Development, Prime Therapeutics, Eagan, Minnesota

Chapter 110

Mark E. Schneiderhan, PharmD, BCPP

Clinical Assistant Professor, Department of Pharmacy Practice, Clinical Pharmacist, Department of Psychiatry, University of Illinois, College of Pharmacy, Chicago, Illinois

Chapter 64

Marieke Dekker Schoen, PharmD, BCPS

Clinical Associate Professor, Department of Pharmacy and Department of Medicine, University of Illinois, Chicago, Illinois

Chapter 19

Kristine S. Schonder, PharmD

Assistant Professor, Pharmacy and Therapeutics Department, School of Pharmacy, University of Pittsburgh; Clinical Pharmacist, Thomas E. Starzl Transplantation Institute, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Chapter 92

Arthur A. Schuna, MS

Clinical Coordinator, William S. Middleton VA Medical Center, Clinical Professor, University of Wisconsin-Madison, School of Pharmacy, Madison, Wisconsin

Chapter 94

Pain and Palliative Care Specialists, Lakeland Regional Medical
Center, Lakeland, Florida

Chapter 62

Deborah A. Sturpe, PharmD, BCPS

Assistant Professor, Department of Pharmacy Practice and Science,
University of Maryland, School of Pharmacy, Baltimore, Maryland

Chapter 84

Weijing Sun, MD

Associate Professor of Medicine, University of Pennsylvania,
Abramson Cancer Center, Philadelphia, Pennsylvania

Chapter 133

Russell H. Swerdlow, MD

Professor of Neurology, Molecular and Integrative Physiology,
University of Kansas School of Medicine, Kansas City, Kansas

Chapter 67

David M. Swope, MD

Associate Professor of Neurology, Loma Linda University, Loma
Linda, California

Chapter 61

Carol Taketomo, PharmD

Pharmacy Manager, Children's Hospital of Los Angeles, Adjunct
Assistant Professor of Pharmacy Practice, University of Southern
California School of Pharmacy, Los Angeles, California

Chapter 7

Robert L. Talbert, PharmD, FCCP, BCPS, CLS

SmithKline Professor, College of Pharmacy, University of Texas at
Austin; Professor, Department of Medicine, University of Texas
Health Science Center at San Antonio, San Antonio, Texas

Chapters 13, 17, 23, 24, 30, and 78

Colleen M. Terriff, PharmD

Assistant Professor, Pharmacy Department, College of Pharmacy,
Washington State University; Clinical Pharmacist, Deaconess
Medical Center, Spokane, Washington

Chapter 11

Jane Tran Tesoro, PharmD, BCPP

Clinical Pharmacist, Juvenile Court Mental Health Services, Los
Angeles, California

Chapter 65

Christian J. Teter, PharmD, BCPP

Assistant Professor, School of Pharmacy, Northwestern University,
Boston, Massachusetts; Clinical Research Pharmacist, Alcohol and
Drug Abuse Treatment Program, McLean Hospital, Belmont,
Massachusetts

Chapter 71

Edward G. Timm, PharmD, MS

Senior Clinical Pharmacy Specialist, Critical Care and Adjunct
Assistant Professor, Albany Medical Center Hospital and Albany
College of Pharmacy, Albany, New York

Chapter 39

Shelly D. Timmons, MD, PhD, FACS

Semmes-Murphey Clinic, Assistant Professor and Chief of
Neurotrauma Division, University of Tennessee Health Science
Center, Memphis, Tennessee

Chapter 60

Curtis L. Triplitt, PharmD, CDE

Texas Diabetes Institute; Assistant Professor, Department of
Medicine, Division of Diabetes, University of Texas Health Science
Center, San Antonio, Texas

Chapter 77

Elena M. Umland, PharmD

Associate Dean for Academic Affairs, Jefferson School of Pharmacy,
Thomas Jefferson University, Philadelphia, Pennsylvania

Chapter 83

Angie Veverka, PharmD

Assistant Professor of Pharmacy, Wingate University School of
Pharmacy, Wingate, North Carolina

Chapter 115

Sheryl F. Vondracek, PharmD, FCCP, BCPS

Associate Professor, Department of Clinical Pharmacy, University
of Colorado-Denver; School of Pharmacy, Aurora, Colorado

Chapter 93

William E. Wade, PharmD, FASHP, FCCP

Professor, College of Pharmacy, University of Georgia, Athens,
Georgia

Chapter 38

Nicole A. Weimert, PharmD, BCPS

Clinical Specialist, Solid Organ Transplantation, Department of
Pharmacy Services; Assistant Clinical Professor, South Carolina
College of Pharmacy, Medical University of South Carolina
Campus, Charleston, South Carolina

Chapter 89

Benjamin L. Weinstein, MD

Assistant Professor, Department of Psychiatry, Medical University
of South Carolina, Charleston, South Carolina

Chapter 72

Lara C. Weinstein, MD

Assistant Professor, Department of Family and Community
Medicine, Thomas Jefferson University, Philadelphia, Pennsylvania

Chapter 83

Lynda S. Welage, PharmD, FCCP

Professor of Pharmacy, College of Pharmacy and Associate Dean for
Academic Affairs, University of Michigan; Clinical Pharmacist,
Critical Care, Department of Pharmacy, University of Michigan
Health-System, Ann Arbor, Michigan

Chapter 35

Barbara G. Wells, PharmD, FASHP, FCCP, BCPP

Dean and Professor, Executive Director of the Research Institute of Pharmaceutical Sciences, School of Pharmacy, University of Mississippi, Oxford, Mississippi

Chapters 71 and 74

Lee E. West, BS

Clinical Pharmacist, Northwestern Memorial Hospital, Chicago, Illinois

Chapters 100 and 101

Dennis P. West, PhD, FCCP, CIP

Vincent W. Foglia Family Research Professor of Dermatology; Director, Dermatology Program, Chair for Administrative Review, IRB, Office for the Protection of Research Subjects, Feinberg School of Medicine, Chicago, Illinois

Chapters 100 and 101

James W. Wheless, MD

Professor and Chief of Pediatric Neurology, LeBonheur Chair in Pediatric Neurology, University of Tennessee Health Science Center; Director, Neuroscience Institute and LeBonheur Comprehensive Epilepsy Program, LeBonheur Children's Medical Center, Memphis, Tennessee

Chapter 59

Dale H. Whitby, PharmD, BCPS

Pediatric Editor, Clinical Pharmacology, Gold Standard, Inc., Tampa, Florida

Chapter 107

Dennis M. Williams, PharmD, BCPS

Associate Professor, Division of Pharmacotherapy and Experimental Therapeutics, School of Pharmacy, University of North Carolina, Chapel Hill, North Carolina

Chapter 29

Dianne B. Williams, PharmD, BCPS

Drug Information and Formulary Coordinator, MCG Health, Inc.; Associate Clinical Professor, University of Georgia College of Pharmacy, Augusta, Georgia

Chapter 34

Jeffrey L. Wilt, MD, FACP, FCCP

Program Director, Critical Care Fellowship, Michigan State University, Kalamazoo Center for Medical Studies; Associate Professor, College of Human Medicine, Michigan State University, Kalamazoo, Michigan

Chapter 14

Char Witmer, MD

Assistant Professor, Department of Pediatrics, Division of Hematology, Philadelphia, Pennsylvania

Chapter 105

Daniel M. Witt, PharmD, FCCP, BCPS, CACP

Manager, Clinical Pharmacy Services, Kaiser Permanente Colorado, Aurora, Colorado

Chapter 21

Marion R. Wofford, MD, MPH

Associate Professor, Department of Medicine, School of Medicine, University of Mississippi Medical Center, Jackson, Mississippi

Chapter 63

Judith K. Wolf, MD

Associate Professor, Department of Gynecologic Oncology, University of Texas MD Anderson Cancer Center, Houston, Texas

Chapter 136

FOREWORD

It's a safe assumption that you didn't purchase this seventh edition of *Pharmacotherapy: A Pathophysiologic Approach* for its foreword. It's probable that most of you will never read these musings. The value of this text lies in its succeeding pages, in the collective knowledge and wisdom conveyed by its authors, and in its ability to help you provide better care for your patients.

It's also a safe assumption that many—perhaps most—readers had not yet begun their careers in pharmacy when the first edition of *Pharmacotherapy: A Pathophysiologic Approach* was published in 1988. This seventh edition will mark the text's 20th anniversary. Noting this milestone, it's appropriate to reflect on a few “then and now” comparisons.

Knowing the time required to conceive and create a new publication of the scope and depth of *Pharmacotherapy: A Pathophysiologic Approach*, I imagine that work began on its first edition sometime around 1985. In February of that year, about 150 pharmacy practitioners and educators gathered in Hilton Head, South Carolina for an Invitational Conference on Directions for Clinical Pharmacy Practice. Organized by the American Society of Hospital (now Health-System) Pharmacists (ASHP), the conference objectives included an evaluation of the status of clinical pharmacy practice and education, and identification of practical ways for advancing clinical practice.¹ Today, most readers of *Pharmacotherapy: A Pathophysiologic Approach* would probably concisely describe their professional mission as “ensuring optimal medication therapy outcomes for patients,” or something to that effect. But in 1985, pharmacy's perception of its professional mission could probably best be described by the concept of “drug use control” as articulated by Don Brodie: assuring “optimal safety in the distribution and use of medications.”² Our emphasis had been focused more on the distribution of medicines and was only just beginning to emphasize how those medicines were used. The Hilton Head Conference, as it came to be known, helped to catalyze a change in how organized pharmacy and individual pharmacists viewed their professional mission—their societal purpose. As noted by Max Ray, who was key in organizing the conference as a member of the ASHP staff at the time, the conference represented “. . . a commitment to the establishment of pharmacy as a true clinical profession.” Subsequently, a more specific definition of clinical pharmacy would emerge, the practice philosophy embodied by pharmaceutical care, and today, the set of pharmacist services referred to as medication therapy management.

In 1985, 361 pharmacists graduated from ASHP accredited residency programs. By 2006, that number had increased to nearly 1500 per year. In 1985, 33 schools of pharmacy awarded the Doctor of Pharmacy (PharmD) degree to 812 graduates (most as post-baccalaureate degrees). Responding to evolving trends and future needs within the profession, the Accreditation Council for Pharmacy Education (ACPE) began to implement new accreditation standards and guidelines in 2000. The PharmD degree is now pharmacy's entry-level degree. Accordingly, the number of PharmD graduates has increased more than ten-fold (9040 in 2006). In 1988, Pharmacotherapy and Nutritional Support were formally recognized as specialty

areas of pharmacy practice by the Board of Pharmaceutical Specialties. Psychiatric Pharmacy and Oncology Pharmacy followed in 1992 and 1996, respectively. By 2007, more than 5200 pharmacy specialists had become board certified in one or more of these clinical specialties. Research in a variety of care settings has demonstrated the beneficial impact of pharmacists' services on the clinical, humanistic, and economic outcomes of medication use.^{3,4} Research conducted by pharmacists contributes important new knowledge to rational pharmacotherapy. We've made real progress. But is it good enough? Our focus has shifted from predominantly emphasizing the control of drug distribution to assuring that our patients receive the optimal benefits and outcomes from their use of medicines. Or has it?

In 1985, spending for prescription drugs in the United States was just over \$22 billion. By 2005, that figure had increased to just over \$200 billion (i.e., almost ten-fold in 20 years!), and is predicted to rise to almost \$500 billion in 2016.⁵ A hefty sum indeed, but not the complete picture. Consider that in addition to these costs for the medications themselves, an additional \$177 billion is estimated to be spent annually because of treatment failure or drug-related morbidity and mortality among ambulatory patients alone.⁶ Add to this the human and financial costs associated with medication errors, drug-related problems among nursing home residents, and adverse drug events among hospitalized patients, and the real cost is truly staggering.^{7,8} It is not hyperbole to say that we are in the midst of a public health crisis.

In 2004, the Joint Commission of Pharmacy Practitioners (JCPP) and the eleven national pharmacy organizations that comprise its membership endorsed a future vision of pharmacy practice:

Pharmacists will be the health care professionals responsible for providing patient care that ensures optimal medication therapy outcomes.

The JCPP vision statement goes on to describe pharmacy practice and how pharmacy will benefit patients and society in 2015.⁹ It is my hope that all readers of *Pharmacotherapy: A Pathophysiologic Approach* would adopt this statement not just as a lofty vision for the future of our profession but as their own professional mission—the reason we exist today!

But consider, by “optimal” do we mean “as good as can be expected under the circumstances” the way many dictionaries would define the word? Or do we mean “best possible”? If we're satisfied with the former definition, then let's declare victory and break out the champagne. However, I hope you agree that we could do better for our patients. This public health crisis demands rapid and significant transformation of our medication use system and more effective deployment of resources within that system. One such resource is the nation's pharmacists. As significant as our accomplishments of the past 20 years may appear to be, we cannot rely on a similar, largely evolutionary process as we address this crisis of medication use over the next decade or two. On the whole, today's generation of pharmacists is better educated and trained as clinicians than any other in our history. But as important as that foundation is, it will not suffice alone.

Our pharmacy practices—from the corner drug store in rural America to the most specialized tertiary care center—must adopt a philosophy of practice that emphasizes the pharmacist's patient care responsibilities. The use of support personnel and technology must be optimized so pharmacists can devote the majority of their effort to these patient care responsibilities. Management must adopt different benchmarks for assessing pharmacist productivity. No longer should the key measurement be the number of prescriptions filled. Our metrics must focus instead on patient outcomes that are affected by pharmacists' medication therapy management and other patient care responsibilities (e.g., wellness, disease prevention).

Of course, this practice model must be economically viable. Currently, payment for pharmacy services is largely based on payment for the drug product and the act of dispensing it. Concerted efforts are underway to change the payment policies of both private and government payers and develop the infrastructure needed to enable a different paradigm. However, we cannot wait until all of the payment ducks have been put in a row to broadly implement the philosophy and model of practice alluded to above.

We should not expect private and government health plans to cover pharmacists' medication therapy management and other patient care services if their customers (i.e., our patients) aren't demanding that they do so. In turn, we should not expect our customers (e.g., patients, other health professionals) to demand something they have not personally experienced and come to value. It is our responsibility to create that demand through every encounter with a patient, caregiver, family member, or other health professional.

It must begin with us. With our professional knowledge, skills, and attitudes. With a commitment to care for, and about, patients. With a commitment to drive change in a system that needs a lot of change. Our patients need and deserve nothing less than our true best.

FOREWORD TO THE FIRST EDITION

Evidence of the maturity of a profession is not unlike that characterizing the maturity of an individual; a child's utterances and behavior typically reveal an unrealized potential for attainment, eventually, of those attributes characteristic of an appropriately confident, independently competent, socially responsible, sensitive, and productive member of society.

Within a period of perhaps 15 or 20 years, we have witnessed a profound maturation within the profession of pharmacy. The utterances of the profession, as projected in its literature, have evolved from mostly self-centered and self-serving issues of trade protection to a composite of expressed professional interests that prominently include responsible explorations of scientific/technological questions and ethical issues that promote the best interests of the clientele served by the profession. With the publication of *Pharmacotherapy: A Pathophysiologic Approach*, pharmacy's utterances bespeak a matured practitioner who is able to call upon unique knowledge and skills so as to function as an appropriately confident, independently competent pharmacotherapeutics expert.

In 1987, the Board of Pharmaceutical Specialties (BPS), in denying the petition filed by the American College of Clinical Pharmacy (ACCP) to recognize "clinical pharmacy" as a specialty, conceded nonetheless that the petitioning party had documented in its petition a specialist who does in fact exist within the practice of pharmacy and whose expertise clearly can be extricated from the performance characteristics of those in general practice. A refiled petition from ACCP requests recognition of "pharmacotherapy" as a Specialty Area of Pharmacy Practice. While the BPS had issued no decision when this book went to press, it is difficult to comprehend the basis for a rejection of the second petition.

Within this book one will find the scientific foundation for the essential knowledge required of one who may aspire to specialty practice as a pharmacotherapist. As is the case with any such publication, its usefulness to the practitioner or the future practitioner is limited to providing such a foundation. To be socially and professionally responsible in practice, the pharmacotherapist's foundation must be continually supplemented and complemented by the flow of information appearing in the primary literature. Of course this is not unique to the general or specialty practice of pharmacy; it is essential to the fulfillment of obligations to clients in any occupation operating under the code of professional ethics.

Because of the growing complexity of pharmacotherapeutic agents, their dosing regimens, and techniques for delivery, pharmacy is obligated to produce, recognize, and remunerate specialty practitioners who can fulfill the profession's responsibilities to society for service expertise where the competence required in a particular case exceeds that of the general practitioner. It simply is a component of our covenant with society and is as important as any other facet of that relationship existing between a profession and those it serves.

The recognition by BPS of pharmacotherapy as an area of specialty practice in pharmacy will serve as an important statement by the

profession that we have matured sufficiently to be competent and willing to take unprecedented responsibilities in the collaborative, pharmacotherapeutic management of patient-specific problems. It commits pharmacy to an intention that will not be uniformly or rapidly accepted within the established healthcare community. Nonetheless, this formal action places us on the road to an avowed goal, and acceptance will be gained as the pharmacotherapists proliferate and establish their importance in the provision of optimal, cost-effective drug therapy.

Suspecting that other professions in other times must have faced similar quests for recognition of their unique knowledge and skills I once searched the literature for an example that might parallel pharmacy's modern-day aspirations. Writing in the *Philadelphia Medical Journal*, May 27, 1899, D. H. Galloway, MD, reflected on the need for specialty training and practice in a field of medicine lacking such expertise at that time. In an article entitled "The Anesthetizer as a Specialty," Galloway commented:

The anesthetizer will have to make his own place in medicine: the profession will not make a place for him, and not until he has demonstrated the value of his services will it concede him the position which the importance of his duties entitles him to occupy. He will be obliged to define his own rights, duties and privileges, and he must not expect that his own estimate of the importance of his position will be conceded without opposition. There are many surgeons who are unwilling to share either the credit or the emoluments of their work with anyone, and their opposition will be overcome only when they are shown that the importance of their work will not be lessened, but enhanced, by the increased safety and dispatch with which operations may be done. . . .

It has been my experience that, given the opportunity for one-on-one, collaborative practice with physicians and other health professionals, pharmacy practitioners who have been educated and trained to perform at the level of pharmacotherapeutics specialists almost invariably have convinced the former that "the importance of their work will not be lessened, but enhanced, by the increased safety and dispatch with which" individualized problems of drug therapy could be managed in collaboration with clinical pharmacy practitioners.

It is fortuitous—the coinciding of the release of *Pharmacotherapy: A Pathophysiologic Approach* with ACCP's petitioning of BPS for recognition of the pharmacotherapy specialist. The utterances of a maturing profession as revealed in the contents of this book, and the intraprofessional recognition and acceptance of a higher level of responsibility in the safe, effective, and economical use of drugs and drug products, bode well for the future of the profession and for the improvement of patient care with drugs.

PREFACE

Pharmacists and other healthcare professionals who evaluate, design, and recommend pharmacotherapy for the management of their patients face many new and exciting challenges as the twenty-first century matures. With this seventh edition of *Pharmacotherapy: A Pathophysiologic Approach*, we recognize just how complicated our tasks as editors have become. Balancing the need for accurate, thorough, and unbiased information about the treatment of diseases against the publishing realities of deadlines, page counts, and book length, we strive to adhere to our founding precepts:

- Advance the quality of patient care through evidence-based medication therapy management based on sound pharmacotherapeutic principles.
- Enhance the health of our communities by incorporating contemporary health promotion and disease-prevention strategies in our practice environments.
- Motivate young practitioners to enhance the breadth, depth, and quality of care they provide to their patients.
- Challenge pharmacists and other primary-care providers to learn new concepts and refine their understanding of the pathophysiology tenets that undergird the development of individualized therapeutic regimens.
- Present the pharmacy and health care communities with innovative patient assessment, triage, and pharmacotherapy management skills.

While our emphasis in past editions has been to incorporate diseases that were previously untreatable with pharmacologic agents, this seventh edition is focused on application of evidence-based pharmacotherapy. Most of the disease-oriented chapters have incorporated evidence-based treatment guidelines that include, when available, rating indicators for the key therapeutic approaches. Also, as in recent editions:

- Key concepts are listed at the beginning of each chapter and are identified in the text with numbered icons so that the reader can easily jump to the material of interest.
- The most common signs and symptoms of diseases are presented in highlighted Clinical Presentation boxes in disease-specific chapters.
- Clinical controversies in treatment or patient management are highlighted to assure that the reader is aware of these issues and discuss how practitioners are responding to them.
- Each chapter has about 100 of the most important and current references relevant to each disease, with most published since 2000.
- For easy reference, abbreviations and acronyms and their meanings are presented at the end of each chapter.
- A glossary of the medical terms used throughout the text is presented at the end of the book.
- Finally, the diagnostic flow diagrams, treatment algorithms, dosing guideline recommendations, and monitoring approaches that were present in the sixth edition have been refined.

This edition includes eight new chapters. The new Influenza chapter addresses changing presentation of this group of infections

and focuses on public health and management of the individual. We have incorporated the influence of the emerging pharmacogenetic knowledge on drug metabolism into an integrated authoritative chapter entitled: Drug Therapy Individualization for Patients with Hepatic Disease or Altered Drug-Metabolizing Status. In the respiratory section of this edition, Primary Pulmonary Hypertension replaces Adult Respiratory Distress Syndrome. Other new chapters include Developmental Disabilities and two oncology chapters, Multiple Myeloma and Myelodysplastic Syndromes.

To make room for these new chapters and stay with a single volume of *Pharmacotherapy*, 11 chapters of this edition are being published in our Pharmacotherapy Online Learning Center, accessible at www.pharmacotherapyonline.com or http://higherred.mcgraw-hill.com/sites/0071416137/information_center_view0/. The chapters chosen for Web publication include those of specialized application that may be predominantly used by practitioners rather than serving as core elements of the pharmacotherapy sequences at colleges of pharmacy. In addition, seven introductory chapters provide students and practitioners with an overview of topics typically covered in other courses. Two of the new chapters in this edition are online chapters that focus on the healthcare community's need for accurate, definitive, and concise information regarding emergency preparedness: Identification and Management of Biological Exposures, and Identification and Clinical Management of Chemical and Radiological Exposures. These 11 online chapters are accessible to anyone via the Online Learning Center; users need not have purchased the print text to read this material. Thus, the online chapters are actually more available than are the chapters published in print for this edition.

While preparing for this edition, we sought the advice of users and colleagues to guide modifications. During editing, we reviewed each passage of text—and the references cited—for continued relevance and accuracy. We made deletions, asked authors to summarize concepts more succinctly or use tables to present details more concisely, included new medications as they entered the U.S. market or emerged in other countries, and updated references. This process continued as the book entered production, and even during the review of final proofs, we continued to make changes to ensure that this book is as current and complete as is possible.

As the world increasingly relies on electronic means of communication, we are committed to keeping *Pharmacotherapy* and its companion works, *Pharmacotherapy Casebook: A Patient-Focused Approach* and *Pharmacotherapy Handbook* integral components of clinicians' toolboxes. Two other new works have been created in parallel with the preparation of this edition, *Pharmacotherapy Principles and Practice* and *Pharmacotherapy: A Primary Care Approach*. These texts are intended to meet the needs of additional audiences, including nurse practitioner and physician assistant programs and practicing primary care physicians, nurse practitioners, and physician assistants. The Online Learning Center continues to provide unique features designed to benefit students, practitioners, and faculty around the world. The site includes learning objectives and self-assessment questions for each chapter, and the full text of this

book is now available on the publisher's Access Pharmacy site (www.accesspharmacy.com).

In closing, we acknowledge the many hours that *Pharmacotherapy*'s 200 authors contributed to this labor of love. Without their devotion to the cause of improved pharmacotherapy and dedication in maintaining the accuracy, clarity, and relevance of their chapters, this text would unquestionably not be possible. In addition, we

thank Michael Weitz, Kim Davis, and James Shanahan and their colleagues at McGraw-Hill for their consistent support of the *Pharmacotherapy* family of resources, insights into trends in publishing and higher education, and the critical attention to detail so necessary in pharmacotherapy.

CHAPTER

1

Pharmacoeconomics: Principles, Methods, and Applications

LISA A. SANCHEZ

KEY CONCEPTS

- 1 Pharmacoeconomics identifies, measures, and compares the costs and consequences of drug therapy to healthcare systems and society.
- 2 The perspective of a pharmacoeconomic evaluation is paramount because the study results will be highly dependent on the perspective selected.
- 3 Healthcare costs can be categorized as direct medical, direct nonmedical, indirect nonmedical, intangible, opportunity, and incremental costs.
- 4 Economic, humanistic, and clinical outcomes should be considered and valued using pharmacoeconomic methods, to inform local decision making whenever possible.
- 5 To compare various healthcare choices, economic valuation methods are used, including cost-minimization, cost-benefit, cost-effectiveness, and cost-utility analyses. These methods all provide the means to compare competing treatment options and are similar in the way they measure costs (dollar units). They differ, however, in their measurement of outcomes and expression of results.
- 6 In today's healthcare settings, pharmacoeconomic methods can be applied for effective formulary management, individual patient treatment, medication policy determination, and resource allocation.
- 7 When evaluating published pharmacoeconomic studies, the following factors should be considered: study objective, study perspective, pharmacoeconomic method, study design, choice

of interventions, costs and consequences, discounting, study results, sensitivity analysis, study conclusions, and sponsorship.

- 8 Use of economic models and conducting pharmacoeconomic analyses on a local level both can be useful and relevant sources of pharmacoeconomic data when rigorous methods are employed, as outlined in this chapter.

Today's cost-sensitive healthcare environment has created a competitive and challenging workplace for clinicians. Competition for diminishing resources has necessitated that the appraisal of healthcare goods and services extends beyond evaluations of safety and efficacy and considers the economic impact of these goods and services on the cost of healthcare. A challenge for healthcare professionals is to provide quality patient care while assuring an efficient use of resources.

Defining the *value* of medicine is a common thread that unites today's healthcare practitioners. With serious concerns about rising medication costs and consistent pressure to decrease pharmacy expenditures and budgets, clinicians/prescribers, pharmacists, and other healthcare professionals must answer the question, "What is the value of the pharmaceutical goods and services I provide?" *Pharmacoeconomics*, or the discipline of placing a value on drug therapy,¹ has evolved to answer this question.

Challenged to provide high-quality patient care in the least expensive way, clinicians have developed strategies aimed at containing costs. However, most of these strategies focus solely on determining the least expensive alternative rather than the alternative that represents the best value for the money. The "cheapest" alternative—with respect to drug acquisition cost—is not always the best value for patients, departments, institutions, and healthcare systems.

Quality patient care must not be compromised while attempting to contain costs. The products and services delivered by today's health professionals should demonstrate *pharmacoeconomic value*, that is, a balance of economic, humanistic, and clinical outcomes. Pharmacoeconomics can provide the systematic means for this quantification. This chapter discusses the principles and methods of pharmacoeconomics and how they can be applied to clinical pharmacy practice and thereby how they can assist in the valuation of pharmacotherapy and other modalities of treatment in clinical practice.

STEPHEN JOEL COONS

KEY CONCEPTS

- 1 The evaluation of healthcare is increasingly focused on the assessment of the *outcomes* of medical interventions.
- 2 An essential patient-reported outcome is self-assessed function and well-being, or health-related quality of life (HRQOL).
- 3 In certain chronic conditions, HRQOL may be the most important health outcome to consider in assessing treatment.
- 4 Information about the impact of pharmacotherapy on HRQOL can provide additional data for making decisions regarding medication use.
- 5 HRQOL instruments can be categorized as generic/general or targeted/specific.
- 6 In HRQOL research, the quality of the data collection tool is the major determinant of the overall quality of the results.

Although it has not involved the comprehensive reform that may be necessary,¹ the medical care marketplace in the United States continues to experience change in both the financing and delivery of care.² This change is evidenced by a variety of developments, including an increase in investor-owned organizations, heightened competition, numerous mergers and acquisitions, increasingly sophisticated clinical and administrative information systems, and new financing and organizational structures. In this dynamic and increasingly competitive environment, there is a concern that healthcare quality is being compromised in the push to contain costs. 1 As a consequence, there has been a growing movement to focus the evaluation of healthcare on the assessment of the end results, or *outcomes*, associated with medical care delivery systems as well as specific medical interventions. The primary objective of this effort is to maximize the net health benefit derived from the use of finite healthcare resources.³ However, there is a serious lack of critical information as to what value is received for the tremendous amount of resources expended on medical care.⁴ This lack of critical information as to the outcomes produced is an obstacle to optimal healthcare decision making at all levels.

HEALTH OUTCOMES

Although the implicit objective of medical care is to improve health outcomes, until relatively recently, little attention was paid to the explicit measurement of them. An outcome is one of the three components of the conceptual framework articulated by Donabedian for assessing and ensuring the quality of healthcare: *structure*, *process*, and *outcome*.⁵ For far too long, the approach to evaluating healthcare had emphasized the structure and processes involved in medical care delivery rather than the outcomes. However, healthcare regulators, payers, providers, manufacturers, and patients are placing increasing emphasis on the outcomes that medical care products and services produce.⁶ As stated by Ellwood, outcomes research is “designed to help patients, payers, and providers make rational medical care choices based on better insight into the effect of these choices on the patient’s life.”⁷

TYPES OF OUTCOMES

The types of outcomes that result from medical care interventions can be described in a number of ways. One classic list, called the *five D’s*—death, disease, disability, discomfort, and dissatisfaction—captures a limited range of outcomes for use in assessing the quality of medical care.⁷ The *five D’s* do not reflect any positive health outcomes and, as a result, have little value in contemporary outcomes research.

A more comprehensive conceptual framework, the ECHO model, places outcomes into three categories: *economic*, *clinical*, and *humanistic outcomes*.⁸ As described by Kozma et al.,⁸ *economic outcomes* are the direct, indirect, and intangible costs compared with the consequences of a medical intervention. *Clinical outcomes* are the medical events that occur as a result of the condition and/or its treatment. 2 *Humanistic outcomes*, which now are more commonly called *patient-reported outcomes*,⁹ are the consequences of the disease and/or its treatment as perceived and reported by the patient.

Patient-reported outcomes (PROs) refer to a number of important outcomes, including self-assessed health status, symptom experience, treatment satisfaction, and functioning and perceived well-being. PROs are increasingly being used to complement safety data, survival rates, and traditional indicators of clinical efficacy in therapeutic intervention trials.¹⁰

ELAINE CHIQUETTE AND L. MICHAEL POSEY

KEY CONCEPTS

- 1 The best current evidence integrated into clinical expertise ensures optimal care for patients.
- 2 The four steps in the process of applying evidence-based medicine (EBM) in practice are (a) formulate a clear question from a patient's problem, (b) identify relevant information, (c) critically appraise available evidence, and (d) implement the findings in clinical practice.
- 3 The decision as to whether to implement the results of a specific study, conclusions of a review article, or another piece of evidence in clinical practice depends on the quality (i.e., internal validity) of the evidence, its clinical importance, whether benefits outweigh risks and costs, and its relevance in the clinical setting and patient's circumstances.
- 4 EBM strategies can be applied to help in keeping current.
- 5 EBM is realistic.

In the information age, clinicians are presented with a daunting number of diseases and possible treatments to consider as they care for patients each day. As knowledge increases and as the technology for accessing information becomes widely available, healthcare professionals are expected to stay current in their fields of expertise and to remain competent throughout their careers. In addition, the number of information sources for the typical practitioner has ballooned, and clinicians must sort out information from many sources: college courses and continuing education (including seminars and journals), pharmaceutical representatives, and colleagues, as well as guidelines from committees of healthcare facilities, governmental agencies, and expert committees and organizations.

1 How does the healthcare professional find valid information from such a cacophony? Increasingly, clinicians are turning to the principles of evidence-based medicine (EBM) to identify the best course of action for each patient. EBM strategies help healthcare professionals to ferret out these gold nuggets, enabling them to integrate the best current evidence into their pharmacotherapeutic

decision making. These strategies can help physicians, pharmacists, and other healthcare professionals to distinguish reliably beneficial pharmacotherapies from those that are ineffective or harmful. Also, EBM approaches can be applied to keep up-to-date and to make an overwhelming task seem more manageable.

This chapter describes the principles of EBM, offers guidance for finding EBM sources on the World Wide Web, provides a model for applying EBM in patient care, and explains how EBM strategies can help a practitioner stay current.

WHAT IS EVIDENCE-BASED MEDICINE?

EBM is an approach to medical practice that uses the results of patient care research and other available objective evidence as a component of clinical decision making. Similarly, evidence-based pharmacotherapy, defined by Etminan et al.,¹ is an approach to decision making whereby clinicians appraise the scientific evidence and its strength in support of their therapeutic decisions.

Although few would argue against the necessity for basing clinical decisions on the best possible evidence available, considerable controversy actually surrounds the practice of EBM. Critics note that not all questions relevant to the care of a patient are of a scientific nature and that EBM favors a "cookbook" approach. In fact, EBM integrates knowledge from research with other factors affecting clinical decision making. EBM does not replace clinical judgment. Rather, it informs clinical judgment with the current best evidence. The expertise and experience of the clinician who understands the disease are crucial in determining whether the external evidence applies to the patient and whether it should be integrated in the therapeutic plan. Also, nonmedical factors affect decision making, such as the patient's preferences and readiness and the healthcare delivery system's characteristics.

Other critics state that EBM considers randomized controlled trials (RCTs) as the only evidence to be used in clinical decision making. Actually, EBM seeks the best existing evidence, from basic science to clinical research, with which to inform clinical decision. For example, a decision about the accuracy of a diagnostic test is best informed by evidence from a cross-sectional study, not a RCT. A cohort study, not a RCT, best answers a question about prognosis. However, in selecting a treatment, the RCT is the best study design to provide the most accurate estimate of treatment efficacy and safety.

GEORGE E. MACKINNON III AND NEIL J. MACKINNON

KEY CONCEPTS

- 1 Documentation of pharmacists' interventions, their actions, and the impact on patient outcomes is central to the process of pharmaceutical care.
 - 2 Unless pharmacists in all practice settings document their activities and communicate with other health professionals, they may not be considered an essential and integral part of the healthcare team.
 - 3 Manual systems of documentation for pharmacists have been described in detail, but increasingly electronic systems are used to facilitate integration with other clinicians, payer records, and healthcare systems.
 - 4 Integrated electronic information systems can facilitate provision of seamless care as patients move among ambulatory, acute, and long-term care settings.
 - 5 Medication reconciliation, a process of ensuring documentation of the patient's correct medication profile, has become a central part of patient safety activities in recent years.
 - 6 Systems of pharmacy documentation are becoming increasingly important models in the United States as the Medicare Part D Prescription Drug Plan and accompanying Medication Therapy Management Services are implemented and revised.
 - 7 Electronic medical records and prescribing systems have several advantages over manual systems that will facilitate access by community pharmacists and their participation as fully participating and acknowledged members of the healthcare team.
-

As the opportunities to become more patient-focused increase and market pressures exert increased accountability for pharmacists'

actions, the importance of documenting pharmacists' professional activities related to patient care will become paramount in the years to come. Processes to document the clinical activities and therapeutic interventions of pharmacists have been described extensively in the pharmacy literature, yet universal adoption of documentation throughout pharmacy practice remains inconsistent, incomplete, and misunderstood.

1 Documentation is central to the provision of patient-centered care/pharmaceutical care.¹ Pharmaceutical care is provided through a "system" in which feedback loops are established for monitoring purposes. This has advantages compared with the traditional medication-use process because the system enhances communication among members of the healthcare team and the patient. Pharmaceutical care requires responsibility by the provider to identify drug/medication-related problems (DRPs), provide a therapeutic monitoring plan, and ensure that patients receive the most appropriate medicines and ultimately achieve their desired level of health-related quality of life (HRQOL).

To provide pharmaceutical care, the pharmacist, patient, and other providers enter a covenantal relationship that is considered to be mutually beneficial to all parties. The patient grants the pharmacist the opportunity to provide care, and the pharmacist, in turn, must accept this and the responsibility it entails. Documentation enables the pharmaceutical care model of pharmacy practice to be maximized and communicated to vested parties. Communication among sites of patient care must be accurate and timely to facilitate pharmaceutical care. As discussed by Hepler and Stand,¹ documentation supports care that is coordinated, efficient, and cooperative.

Conversely, failure to document activities and patient outcomes can directly affect patients' quality of care. There are several reasons for failure to document in the medication-use system, and they are related to the process of documentation, the specific data collected on a consistent basis, how documentation is shared (e.g., other pharmacists, healthcare providers, patients, insurers), and methods by which the data are shared.

The contributions of Denise Sprague to the content of this chapter are acknowledged.

Clinical Pharmacokinetics and Pharmacodynamics

LARRY A. BAUER

KEY CONCEPTS

- 1 Clinical pharmacokinetics is the discipline that describes the absorption, distribution, metabolism, and elimination of drugs in patients requiring drug therapy.
- 2 Clearance is the most important pharmacokinetic parameter because it determines the steady-state concentration for a given dosage rate. Physiologically, clearance is determined by blood flow to the organ that metabolizes or eliminates the drug and the efficiency of the organ in extracting the drug from the bloodstream.
- 3 The volume of distribution is a proportionality constant that relates the amount of drug in the body to the serum concentration. The volume of distribution is used to calculate the loading dose of a drug that will immediately achieve a desired steady-state concentration. The value of the volume of distribution is determined by the physiologic volume of blood and tissues and how the drug binds in blood and tissues.
- 4 Half-life is the time required for serum concentrations to decrease by one-half after absorption and distribution are complete. Half-life is important because it determines the time required to reach steady state and the dosage interval. Half-life is a dependent kinetic variable because its value depends on the values of clearance and volume of distribution.
- 5 The fraction of drug absorbed into the systemic circulation after extravascular administration is defined as its bioavailability.
- 6 Most drugs follow linear pharmacokinetics, whereby steady-state serum drug concentrations change proportionally with long-term daily dosing.
- 7 Some drugs do not follow the rules of linear pharmacokinetics. Instead of steady-state drug concentration changing proportionally with dose, serum concentration changes more or less than expected. These drugs follow nonlinear pharmacokinetics.
- 8 Pharmacokinetic models are useful to describe data sets, to predict serum concentrations after several doses or different routes of administration, and to calculate pharmacokinetic constants such as clearance, volume of distribution, and half-life. The simplest case uses a single compartment to represent the entire body.
- 9 Factors to be taken into consideration when deciding on the best drug dose for a patient include age, gender, weight, ethnic background, other concurrent disease states, and other drug therapy.
- 10 Cytochrome P450 is a generic name for the group of enzymes that are responsible for most drug metabolism oxidation reactions. Several P450 isozymes have been identified, including CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4.
- 11 The importance of transport proteins in drug bioavailability and elimination is now better understood. The principal transport protein involved in the movement of drugs across biologic membranes is P-glycoprotein. P-glycoprotein is present in many organs, including the gastrointestinal tract, liver, and kidney.
- 12 When deciding on initial doses for drugs that are renally eliminated, the patient's renal function should be assessed. A common, useful way to do this is to measure the patient's serum creatinine concentration and convert this value into an estimated creatinine clearance ($CL_{cr\ est}$). For drugs that are eliminated primarily by the kidney ($\geq 60\%$ of the administered dose), some agents will need minor dosage adjustments for $CL_{cr\ est}$ between 30 and 60 mL/min, moderate dosage adjustments for $CL_{cr\ est}$ between 15 and 30 mL/min, and major dosage adjustments for $CL_{cr\ est}$ less than 15 mL/min. Supplemental doses of some medications also may be needed for patients receiving hemodialysis if the drug is removed by the artificial kidney or for patients receiving hemoperfusion if the drug is removed by the hemofilter.
- 13 When deciding on initial doses for drugs that are hepatically eliminated, the patient's liver function should be assessed. The Child-Pugh score can be used as an indicator of a patient's ability to metabolize drugs that are eliminated by the liver. In the absence of specific pharmacokinetic dosing guidelines for a medication, a Child-Pugh score equal to 8 or 9 is grounds for a moderate decrease ($\sim 25\%$) in initial daily drug dose for agents that are metabolized primarily hepatically ($\geq 60\%$), and a score of 10 or greater indicates that a significant decrease in initial daily dose ($\sim 50\%$) is required for drugs that are metabolized mostly hepatically.
- 14 For drugs that exhibit linear pharmacokinetics, steady-state drug concentration (C_{ss}) changes proportionally with dose (D). To adjust a patient's drug therapy, a reasonable starting dose is administered for an estimated three to five half-lives. A serum concentration is obtained, assuming that it will reflect C_{ss} . Independent of the route of administration, the new dose (D_{new}) needed to attain the desired C_{ss} ($C_{ss, new}$) is calculated: $D_{new} = D_{old} (C_{ss, new} / C_{ss, old})$, where D_{old} and $C_{ss, old}$ are the old dose and old C_{ss} , respectively.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

- 15 If it is necessary to determine the pharmacokinetic constants for a patient to individualize the patient's dose, a small pharmacokinetic evaluation is conducted in the individual. Additionally, Bayesian computer programs that aid in the individualization of therapy are available for many different drugs.
- 16 Pharmacodynamics is the study of the relationship between the concentration of a drug and the response obtained in a patient. If pharmacologic effect is plotted versus concentration for most drugs, a hyperbola results with an asymptote equal to maximum attainable effect.

Pharmacokinetic concepts have been used successfully by pharmacists to individualize patient drug therapy for about a quarter of a century. Pharmacokinetic consultant services and individual clinicians routinely provide patient-specific drug-dosing recommendations that increase the efficacy and decrease the toxicity of many medications. Laboratories routinely measure patient serum or plasma samples for many drugs, including antibiotics (e.g., aminoglycosides and vancomycin), theophylline, antiepileptics (e.g., phenytoin, carbamazepine, valproic acid, phenobarbital, and ethosuximide), methotrexate, lithium, antiarrhythmics (e.g., lidocaine, procainamide, quinidine, and digoxin), and immunosuppressants (e.g., cyclosporine and tacrolimus). Combined with a knowledge of the disease states and conditions that influence the disposition of a particular drug, kinetic concepts can be used to modify doses to produce serum drug concentrations that result in desirable pharmacologic effects without unwanted side effects. This narrow range of concentrations within which the pharmacologic response is produced and adverse effects prevented in most patients is defined as the *therapeutic range* of the drug. Table 5-1 lists the therapeutic ranges for commonly used medications.

Although most individuals experience favorable effects with serum drug concentrations in the therapeutic range, the effects of a given serum concentration can vary widely among individuals. Clinicians should never assume that a serum concentration within the therapeutic range will be safe and effective for every patient. The response to the drug, such as number of seizures a patient experiences while taking an antiepileptic agent, always should be assessed when serum concentrations are measured.

TABLE 5-1 Selected Therapeutic Ranges

Drug	Therapeutic Range
Digoxin	0.5–2 ng/mL
Lidocaine	1.5–5 mcg/mL
Procainamide/N-acetylprocainamide	10–30 mcg/mL (total)
Quinidine	2–5 mcg/mL
Amikacin ^a	20–30 mcg/mL (peak) <5 mcg/mL (trough)
Gentamicin, tobramycin, netilmicin ^a	5–10 mcg/mL (peak) <2 mcg/mL (trough)
Vancomycin	20–40 mcg/mL (peak) 5–10 mcg/mL (trough)
Chloramphenicol	10–20 mcg/mL
Lithium	0.6–1.4 mEq/L
Carbamazepine	4–12 mcg/mL
Ethosuximide	40–100 mcg/mL
Phenobarbital	15–40 mcg/mL
Phenytoin	10–20 mcg/mL
Primidone	5–12 mcg/mL
Valproic acid	50–100 mcg/mL
Theophylline	10–20 mcg/mL
Cyclosporine	150–400 ng/mL (blood)

^aUsing a multiple-dose-per-day dosage schedule.

TABLE 5-2 Pharmacokinetic Abbreviations

Abbreviation	Definition
CL	Clearance
k_0	Intravenous infusion rate
C_{ss}	Steady-state concentration
D	Dose
τ	Dosage interval
F	Fraction of drug absorbed into the systemic circulation
Q	Blood flow
E	Extraction ratio
f_b	Fraction of drug in the blood that is unbound
CL_{int}	Intrinsic clearance
$C_{ss, u}$	Steady-state concentration of unbound drug
V_D	Volume of distribution
LD	Loading dose
MD	Maintenance dose
$t_{1/2}$	Half-life
k	Elimination rate constant
k_a	Absorption rate constant
α	Distribution rate constant
β	Terminal rate constant
t'	Postinfusion time
T	Duration of infusion
AUC	Area under serum- or blood-concentration-versus-time curve
V_{max}	Maximum rate of drug metabolism
K_m	Serum concentration at which the rate of metabolism equals $V_{max}/2$
C_{max}	Maximum serum or blood concentration
C_{min}	Minimum serum or blood concentration
DR	Dosage rate
P-gp	P-glycoprotein

Throughout this chapter, abbreviations for various pharmacokinetic parameters are used frequently. Table 5-2 lists commonly used abbreviations.

CLINICAL PHARMACOKINETIC CONCEPTS

1 Clinical pharmacokinetics is the discipline that describes the absorption, distribution, metabolism, and elimination of drugs in patients requiring drug therapy. When a drug is administered extravascularly to patients, it must be absorbed across biologic membranes to reach the systemic circulation. If the drug is given orally, the drug molecules must pass through the gastrointestinal tract wall into capillaries. For transdermal patches, the drug must penetrate the skin to enter the vascular system. In general, the pharmacologic effect of the drug is delayed when it is given extravascularly because time is required for the drug to be absorbed into the vascular system.

The vascular system generally provides the “transportation” for the drug molecule to its site of activity. After the drug reaches the systemic circulation, it can leave the vasculature and penetrate the various tissues or remain in the blood. If the drug remains in the blood, it may bind to endogenous proteins such as albumin or α_1 -acid glycoprotein. This binding usually is reversible, and an equilibrium is created between protein-bound drug and unbound drug. Unbound drug in the blood provides the driving force for distribution of the agent to body tissues. If unbound drug leaves the bloodstream and distributes to tissue, it may become tissue-bound, it may remain unbound in the tissue, or if the tissue can metabolize or eliminate the drug, it may be rendered inactive and/or eliminated from the body. If the drug becomes tissue-bound, it may bind to the receptor that causes its pharmacologic or toxic effect or to a nonspecific binding site that causes no effect. Again, tissue binding is usually reversible so that the tissue-bound drug is in equilibrium with unbound drug in the tissue.

Certain organs—such as the liver, gastrointestinal tract wall, and lung—possess enzymes that metabolize drugs. The resulting metabolite may be inactive or have a pharmacologic effect of its own. The blood also contains esterases, which cleave ester bonds in drug molecules and generally render them inactive.

Drug metabolism usually occurs in the liver through one or both of two types of reactions. Phase I reactions generally make the drug molecule more polar and water soluble so that it is prone to elimination by the kidney. Phase I modifications include oxidation, hydrolysis, and reduction. Phase II reactions involve conjugation to form glucuronides, acetates, or sulfates. These reactions generally inactivate the pharmacologic activity of the drug and may make it more prone to elimination by the kidney.

Other organs have the ability to eliminate drugs or metabolites from the body. The kidney can excrete drugs by glomerular filtration or by such active processes as proximal tubular secretion. Drugs also can be eliminated via bile produced by the liver or air expired by the lungs.

LINEAR PHARMACOKINETICS

6 Most drugs follow linear pharmacokinetics: Serum drug concentrations change proportionally with long-term daily dosing. For example, if a drug dose were doubled from 300 to 600 mg/day, the patient's serum drug concentration would double.

When a drug is given by continuous intravenous infusion, serum concentrations increase until an equilibrium is established between the drug dosage rate and the rate of drug elimination. At that point, the rate of drug administration equals the rate of drug elimination, and the serum concentrations remain constant (Fig. 5-1). For example, if a patient were receiving a continuous intravenous infusion of theophylline at 40 mg/h, the theophylline serum concentration would increase until the patient's body was eliminating theophylline at 40 mg/h. When serum drug concentrations reach a constant value, steady state is achieved.

If the drug is given at intermittent dosage intervals, such as 250 mg every 6 hours, steady state is achieved when the serum-concentration-versus-time curves for each dosage interval are superimposable. The amount of drug eliminated during the dosage interval equals the dose.

BIOAVAILABILITY AND BIOEQUIVALENCE

When drugs are administered extravascularly, drug molecules must be released from the dosage form (dissolution) and pass through several biologic barriers before reaching the vascular system **5**

FIGURE 5-1. Normal serum concentration-time curve following a continuous intravenous infusion.

(absorption). The fraction of drug absorbed into the systemic circulation (F) after extravascular administration is defined as its *bioavailability* and can be calculated after single intravenous and extravascular doses as¹

$$F = \frac{D_{iv}(AUC_{0-\infty})}{D(AUC_{iv,0-\infty})}$$

where D and D_{iv} are the extravascular and intravenous doses, respectively, and $AUC_{iv,0-\infty}$ and $AUC_{0-\infty}$ are the intravenous and extravascular areas under the serum- or blood-concentration-versus-time curves, respectively, from time zero to infinity. The AUC represents the body's total exposure to the drug and is a function of the fraction of the drug dose that enters the systemic circulation via the administered route and clearance (Fig. 5-2). When F is less than 1 for a drug administered extravascularly, either the dosage form did not release all the drug contained in it, or some of the drug was eliminated or destroyed (by stomach acid or other means) before it reached the systemic circulation.

When the extravascular dose is administered orally, part of the dose may be metabolized by enzymes or removed by transport proteins contained in the gastrointestinal tract wall or liver before it reaches the systemic circulation.^{2,3} This occurs commonly when drugs have a high liver extraction ratio or are subject to gastrointestinal tract wall metabolism because, after oral administration, the drug must pass through the gastrointestinal tract wall and into the portal circulation of the liver. Transport proteins are also present in the gastrointestinal tract wall that can actively pump drug molecules that already have been absorbed back into the lumen of the gastrointestinal tract. P-glycoprotein (P-gp) is the primary transport protein that interferes with drug absorption by this mechanism. For example, if an orally administered drug is 100% absorbed from the gastrointestinal tract but has a hepatic extraction ratio of 0.75, only 25% of the original dose enters the systemic circulation. This first-pass effect through the liver and/or gastrointestinal tract wall is avoided when the drug is given by other routes of administration. The computation of F does not separate loss of oral drug metabolized by the first-pass effect and drug not absorbed by the gastrointestinal tract. Special techniques are needed to determine the fraction of drug absorbed orally for drugs with high liver extraction ratios or substantial gut wall metabolism.

Two different dosage forms of the same drug are considered to be bioequivalent when the $AUC_{0-\infty}$, maximum serum or blood concen-

FIGURE 5-2. Area under the concentration-versus-time curve (AUC) after the administration of an extravascular dose. The AUC is a function of the fraction of drug dose that enters the systemic circulation and clearance. AUCs measured after intravenous and extravascular doses can be used to determine bioavailability for the extravascular dose.

trations (C_{\max}), and the times that C_{\max} occurs (t_{\max}) are neither clinically nor statistically different. When this occurs, the serum-concentration-versus-time curves for the two dosage forms should be superimposable and identical. Bioequivalence studies have become very important as expensive drugs become available in less costly generic form. Most bioequivalence studies involve 18 to 25 healthy adults who are given the brand-name product and the generic product in a randomized, crossover study design.

CLEARANCE

2 Clearance (CL) is the most important pharmacokinetic parameter because it determines the steady-state concentration for a given dosage rate. When a drug is given at a continuous intravenous infusion rate equal to k_0 , the steady-state concentration (C_{ss}) is determined by the quotient of k_0 and CL ($C_{ss} = k_0/CL$). If the drug is administered as individual doses (D) at a given dosage interval (τ), the average steady-state concentration (C_{ss}) over the dosage interval is given by the equation⁴

$$C_{ss} = \frac{F(D/\tau)}{CL}$$

where F is the fraction of dose absorbed into the systemic vascular system. The average steady-state concentration over the dosage interval is the steady-state concentration that would have occurred had the same dose been given as a continuous intravenous infusion (e.g., 300 mg every 6 hours would produce an average C_{ss} equivalent to the actual C_{ss} produced by a continuous infusion administered at a rate of 50 mg/h).

Physiologically, clearance is determined by (a) blood flow (Q) to the organ that metabolizes (liver) or eliminates (kidney) the drug and (b) the efficiency of the organ in extracting the drug from the bloodstream.⁵ Efficiency is measured using an extraction ratio (E), calculated by subtracting the concentration in the blood leaving the extracting organ (C_{out}) from the concentration in the blood entering the organ (C_{in}) and then dividing the result by C_{in} :

$$E = \frac{C_{in} - C_{out}}{C_{in}}$$

Clearance for that organ is calculated by taking the product of Q and E ($CL = QE$). For example, if liver blood flow equals 1.5 L/min and the drug's extraction ratio is 0.33, hepatic clearance equals 0.5 L/min. Total clearance is computed by summing all the individual organ clearance values. Clearance changes occur in patients when the blood flow to extracting organs changes or when the extraction ratio changes. Vasodilators such as hydralazine or nifedipine increase liver blood flow, whereas congestive heart failure and hypotension can decrease hepatic blood flow. Extraction ratios can increase when enzyme inducers increase the amount of drug-metabolizing enzyme. Extraction ratios may decrease if enzyme inhibitors inhibit drug-metabolizing enzymes or necrosis causes loss of parenchyma.

INTRINSIC CLEARANCE

The extraction ratio also can be thought of in terms of the unbound fraction of drug in the blood (f_b), the intrinsic ability of the extracting organ to clear unbound drug from the blood (CL_{int}), and blood flow to the organ (Q)^{6,7}:

$$E = \frac{f_b(CL_{int})}{Q + f_b(CL_{int})}$$

By substituting this equation for E , the clearance equation becomes

$$CL = \frac{Q[f_b(CL_{int})]}{Q + f_b(CL_{int})}$$

Clearance changes will occur when blood flow to the clearing organ changes (in conditions where blood flow is reduced, e.g., shock, congestive heart failure, or where blood flow is increased, e.g., administration of medications such as vasodilators, resolution of shock or congestive heart failure), binding in the blood changes (e.g., if the concentration of binding proteins is low or highly protein-bound drugs are displaced), or intrinsic clearance of unbound drug changes (e.g., when metabolizing enzymes are induced or inhibited by other drug therapy or functional organ tissue is destroyed by disease processes).

If CL_{int} is large (enzymes have a high capacity to metabolize the drug), the product of f_b and CL_{int} is much larger than Q . When $f_b(CL_{int})$ is much greater than Q , the sum of Q and $f_b(CL_{int})$ in the denominator of the clearance equation almost equals $f_b(CL_{int})$:

$$f_b(CL_{int}) \approx Q + f_b(CL_{int})$$

Substituting this expression in the denominator of the clearance equation and canceling common terms leads to the following expression for drugs with a large CL_{int} : $CL \approx Q$. In this case, clearance of the drug is equal to blood flow to the organ; such drugs are called *high-clearance drugs* and have large extraction ratios. Propranolol, verapamil, morphine, and lidocaine are examples of high-clearance drugs. High-clearance drugs such as these typically exhibit high first-pass effects when administered orally.

If CL_{int} is small (enzymes have a limited capacity to metabolize the drug), Q is much larger than the product of f_b and CL_{int} . When Q is much greater than $f_b(CL_{int})$, the sum of Q and $f_b(CL_{int})$ in the denominator of the clearance equation becomes almost equal to Q : $Q \approx Q + f_b(CL_{int})$. Substituting this expression in the denominator of the clearance equation and canceling common terms leads to the following expression for drugs with a small CL_{int} : $CL \approx f_b(CL_{int})$. In this case, clearance of the drug is equal to the product of the fraction unbound in the blood and the intrinsic ability of the organ to clear unbound drug from the blood; such drugs are known as *low-clearance drugs* and have small extraction ratios. Warfarin, theophylline, diazepam, and phenobarbital are examples of low-clearance drugs.

As mentioned previously, the concentration of unbound drug in the blood is probably more important pharmacologically than the total (bound plus unbound) concentration. The unbound drug in the blood is in equilibrium with the unbound drug in the tissues and reflects the concentration of drug at its site of action. Therefore, the pharmacologic effect of a drug is thought to be a function of the concentration of unbound drug in the blood. The unbound steady-state concentration ($C_{ss,u}$) can be calculated by multiplying C_{ss} and f_b : $C_{ss,u} = C_{ss}f_b$. The effect that changes in Q , f_b , and CL_{int} have on $C_{ss,u}$ and therefore on the pharmacologic response of a drug depends on whether a high- or low-clearance drug is involved. Because $CL = Q$ for high-clearance drugs, a change in f_b or CL_{int} does not change CL or C_{ss} ($C_{ss} = k_0/CL$). However, a change in unbound drug fraction does alter $C_{ss,u}$ ($C_{ss,u} = f_b C_{ss}$), thereby affecting the pharmacologic response. Plasma-protein-binding displacement drug interactions can be very important clinically, but they are also dangerous because the changes in $C_{ss,u}$ are not reflected in changes in C_{ss} for high-clearance drugs. Because laboratories usually measure only total concentrations (concentrations of unbound drug are difficult to determine), the interaction is hard to detect. If CL_{int} changes for high-clearance drugs, CL , C_{ss} , $C_{ss,u}$, and pharmacologic response do not change. Changes in Q cause a change in CL ; changes in C_{ss} , $C_{ss,u}$, and drug response are indirectly proportional to changes in CL .

For low-clearance drugs, total clearance is determined by unbound drug fraction and intrinsic clearance: $CL = f_b(CL_{int})$. A change in Q does not change CL , C_{ss} , $C_{ss,u}$, or pharmacologic response. However, a change in f_b or CL_{int} does alter CL and C_{ss} ($C_{ss} = k_0/CL$). Changes in CL_{int} will cause a proportional change in CL .

Changes in C_{ss} , $C_{ss,u}$, and drug response are indirectly proportional to changes in CL. Altering f_b for low-clearance drugs produces interesting results. A change in f_b alters CL and C_{ss} ($C_{ss} = k_0/CL$). Because CL and C_{ss} change in opposite directions with changes in f_b , $C_{ss,u}$ ($C_{ss,u} = f_b C_{ss}$) and pharmacologic response do not change with alterations in the fraction of unbound drug in the blood. For example, a low-clearance drug is administered to a patient until steady-state is achieved:

$$CL = f_b (CL_{int})$$

$$C_{ss} = \frac{k_0}{CL}$$

Suppose that another drug is administered to the patient that displaces the first drug from plasma-protein-binding sites and doubles f_b (f_b now equals $2f_b$). CL doubles because of the protein-binding displacement [$2CL = 2f_b (CL_{int})$], and C_{ss} decreases by one-half because of the change in clearance [$1/2 (C_{ss}) = k_0/(2CL)$]. $C_{ss,u}$ does not change because even though f_b is doubled, C_{ss} decreased by one-half ($C_{ss,u} = f_b C_{ss}$). The potential for error in this situation is that clinicians may increase the dose of a low-clearance drug after a protein-binding displacement interaction because C_{ss} decreased. Because $C_{ss,u}$ and the pharmacologic effect do not change, the dose should remain unaltered. Plasma protein binding decreases occur commonly in patients taking phenytoin. Low albumin concentrations (as in trauma or pregnant patients), high concentrations of endogenous plasma protein-binding displacers (as with high concentrations of bilirubin), or plasma protein-binding drug interactions (as with concomitant therapy with valproic acid) can result in subtherapeutic total phenytoin concentrations. Despite this fact, unbound phenytoin concentrations usually are within the therapeutic range, and often the patient is responding appropriately to treatment. Thus, in these situations, unbound rather than total phenytoin serum concentrations should be monitored and used to guide future therapeutic decisions.

CLEARANCES FOR DIFFERENT ROUTES OF ELIMINATION AND METABOLIC PATHWAYS

Clearances for individual organs can be computed if the excretion the organ produces can be obtained. For example, renal clearance can be calculated if urine is collected during a pharmacokinetic experiment. The patient empties his or her bladder immediately before the dose is given. Subsequent urine production is collected until the last serum concentration (C_{last}) is obtained. Renal clearance (CL_R) is computed by dividing the amount of drug excreted in the urine by $AUC_{0-t_{last}}$. Biliary and other clearance values are computed in a similar fashion.

Clearances also can be calculated for each metabolite that is formed from the parent drug. This computation is particularly useful in drug-interaction studies to determine which metabolic pathway is stimulated or inhibited. In the following metabolic scheme, the parent drug (D) is metabolized into two different metabolites (M_1 , M_2) that subsequently are eliminated by the kidney (M_{1R} , M_{2R}):

To compute the formation clearance of M_1 and M_2 (CL_{FM1} , CL_{FM2}), urine would be collected for five or more half-lives after a single dose or during a dosage interval at steady state. The amount of

metabolite eliminated in the urine is then determined. The fraction of the dose (in moles, because the molecular weights of the parent drug and metabolites are not equal) eliminated by each metabolic pathway ($f_{M1} = M_{1R}/D$ and $f_{M2} = M_{2R}/D$) can then be computed. Formation clearance for each pathway can be calculated using the following equations: $CL_{FM1} = f_{M1} CL_M$ and $CL_{FM2} = f_{M2} CL_M$, where CL_M is the metabolic clearance for the parent drug.

VOLUME OF DISTRIBUTION

3 The volume of distribution (V_D) is a proportionality constant that relates the amount of drug in the body to the serum concentration (amount in body = CV_D). V_D is used to calculate the loading dose (LD) of a drug that will immediately achieve a desired C_{ss} ($LD = C_{ss} V_D$). However, in practice, the patient's own V_D is not known at the time the loading dose is administered. In this case, an average V_D is assumed and used to calculate a loading dose. Because the patient's V_D is almost always different from the average V_D for the drug, a loading dose does not attain the calculated C_{ss} , but it hopefully achieves a therapeutic concentration. As usual, steady-state conditions are achieved in three to five half-lives for the drug.

The numeric value for the volume of distribution is determined by the physiologic volume of blood and tissues and how the drug binds in blood and tissues⁸:

$$V_D = V_b + (f_b/f_t)V_t$$

where V_b and V_t are the volumes of blood and tissues, respectively, and f_b and f_t are the fractions of unbound drug in blood and tissues, respectively.

HALF-LIFE

4 Half-life ($t_{1/2}$) is the time required for serum concentrations to decrease by one-half after absorption and distribution are complete. It takes the same amount of time for serum concentrations to drop from 200 to 100 mg/L as it does for concentrations to decline from 2 to 1 mg/L (Fig. 5-3).

Half-life is important because it determines the time required to reach steady state and the dosage interval. It takes approximately three to five half-lives to reach steady-state concentrations during continuous dosing. In three half-lives, serum concentrations are at approximately 90% of their ultimate steady-state values. Because most serum drug assays have approximately a 10% error, it is difficult to differentiate concentrations that are within 10% of each

FIGURE 5-3. Calculation of the half-life of a drug following intravenous bolus dosing.

other. For this reason, many clinicians consider concentrations obtained after three half-lives to be C_{ss} .

Half-life is also used to determine the dosage interval for a drug. For instance, it may be desirable to maintain maximum steady-state concentrations at 20 mg/L and minimum steady-state concentrations at 10 mg/L. In this case, it would be necessary to administer the drug every half-life because the minimum desirable concentration is one-half the maximum desirable concentration.

Half-life is a dependent kinetic variable because its value depends on the values of CL and V_D .⁸ The equation that describes the relationship among the three variables is $t_{1/2} = 0.693 V_D / CL$. Changes in $t_{1/2}$ can result from a change in either V_D or CL; a change in $t_{1/2}$ does not necessarily indicate that CL has changed. Half-life can change solely because of changes in V_D . The elimination rate constant (k) is related to the half-life by the following equation: $k = 0.693/t_{1/2}$. Both the half-life and elimination rate constant describe how quickly serum concentrations decrease in the serum or blood.

NONLINEAR PHARMACOKINETICS

Michaelis-Menten Kinetics

7 Some drugs do not follow the rules of linear pharmacokinetics. Instead of C_{ss} and AUC increasing proportionally with dose, serum concentrations change more or less than expected (Fig. 5-4). One explanation for the greater-than-expected increase in C_{ss} and AUC after an increase in dose is that the enzymes responsible for the metabolism or elimination of the drug may start to become saturated. When this occurs, the maximum rate of metabolism (V_{max}) for the drug is approached. This is called *Michaelis-Menten kinetics*. The serum concentration at which the rate of metabolism equals $V_{max}/2$ is K_m . Practically speaking, K_m is the serum concentration at which nonproportional changes in C_{ss} and AUC start to occur when dose is increased. The Michaelis-Menten constants (V_{max} and K_m) determine the dosage rate (DR) needed to maintain a given C_{ss} : $DR = V_{max} C_{ss} / (K_m + C_{ss})$. Most drugs eliminated by the liver are metabolized by enzymes but still appear to follow linear kinetics. The reason for this disparity is that the therapeutic range for most drugs is well below the K_m of the enzyme system that metabolizes the agent. The therapeutic range is higher than K_m for some commonly used drugs. The average K_m for phenytoin is about 4 mg/L. The therapeutic range for phenytoin is usually 10 to 20 mg/L. Most patients experience Michaelis-Menten kinetics while taking phenytoin.

FIGURE 5-4. Relationship of dose and steady-state drug concentration (C_{ss}) or area under the concentration-versus-time curve (AUC) under linear and nonlinear conditions.

Nonlinear Protein Binding

Another type of nonlinear kinetics can occur if C_{ss} and AUC increase less than expected after an increase in dose of a low-clearance drug. This usually indicates that plasma protein-binding sites are starting to become saturated so that f_b increases with increases in dose (see Fig. 5-4). For a low-clearance drug, CL depends on the values of f_b and CL_{int} ($CL = f_b CL_{int}$). When a dosage increase takes place, f_b increases because nearly all plasma-protein-binding sites are occupied and no binding sites are available. If f_b increases, CL increases and C_{ss} increases less than expected with the dosage change ($C_{ss} = k_0 / CL$). However, $C_{ss,u}$ increases proportionally with dose because $C_{ss,u}$ depends on CL_{int} for low-clearance drugs ($C_{ss,u} = k_0 / CL_{int}$). Valproic acid⁹ and disopyramide¹⁰ both follow saturable protein-binding pharmacokinetics.

PHARMACOKINETIC MODELS AND EQUATIONS

8 Pharmacokinetic models are useful to describe data sets, to predict serum concentrations after several doses or different routes of administration, and to calculate pharmacokinetic constants such as CL, V_D , and $t_{1/2}$.¹¹ Compartmental models depict the body as one or more discrete compartments to which drug is distributed and/or from which drug is eliminated. The shape of the serum-concentration-versus-time curve determines the number of compartments in the pharmacokinetic model and the equation used in computations (Fig. 5-5). First-order rate constants, known as *microconstants*, describe the rate of transfer from one compartment to another. Each compartment also has its own V_D . For clinical dosage adjustment purposes using drug concentrations, a one-compartment model is the most commonly used pharmacokinetic model.

One-Compartment Model

The simplest case uses a single compartment to represent the entire body (see Fig. 5-5). Drug enters the compartment by continuous intravenous infusion (k_0), absorption from an extravascular site with an absorption rate constant of k_a , or intravenous bolus (D). After an intravenous bolus, serum concentrations decline in a straight line when plotted on semilogarithmic coordinates (see Fig. 5-3). The slope of the line is $-k/2.303$; $t_{1/2}$ can be computed by determining the time required for concentrations to decrease by one-half ($t_{1/2} = 0.693/k$). The equation that describes the data is $C = (D/V_D)e^{-kt}$. V_D is calculated by dividing the intravenous dose by the y intercept (the concentration at time zero, C_0) of the graph. CL is computed by taking the product of k and V_D . Once V_D and k are known, concentrations at any time after the dose can be computed [$C = (D/V_D)e^{-kt}$].

When an extravascular dose is given, one-compartment-model serum concentrations rise during absorption, reach C_{max} , and then

FIGURE 5-5. Visual representations of one- and two-compartment drug-distribution models.

FIGURE 5-6. Calculation of the half-life of a drug following oral, intramuscular, or other extravascular dosing route.

decrease in a straight line with a slope equal to $-k/2.303$. The equation that describes the data is $C = \{(FDk_a)/[V_D(k_a - k)]\}(e^{-kt} - e^{-k_a t})$, where F is the fraction of the dose absorbed into the systemic circulation. The absorption rate constant (k_a) is obtained using the method of residuals.

The method of residuals is used to obtain the individual rate constants (Fig. 5-6). A is determined by extrapolating the terminal slope to the y axis; k_a can be obtained by calculating the slope or $t_{1/2}$ and using the formulas given for the intravenous bolus case. At each time point in the absorption portion of the curve, the concentration value from the extrapolated line is noted and called the *extrapolated concentration*. For each point, the actual concentration is subtracted from the extrapolated concentration to compute the *residual concentration*. When the residual concentrations are plotted on semilogarithmic coordinates, a line with y intercept equal to A and slope equal to $-k_a/2.303$ is obtained. When these values are calculated, they can be placed into the equation ($C = Ae^{-kt} - Ae^{-k_a t}$, where $A = FDk_a/[V_D(k_a - k)]$) and used to compute the serum concentration at any time after the extravascular dose. The intercepts and rate constants also can be used to compute CL and V_D : $CL = FD/(A/k - A/k_a)$ and $V_D = CL/k$, where F is the fraction of the dose absorbed into the systemic circulation.

During a continuous intravenous infusion, the serum concentrations in a one-compartment model change according to the following function: $C = (k_0/CL)(1 - e^{-kt})$. If the infusion has been running for more than three to five half-lives, the patient will be at steady state, and CL can be calculated ($CL = k_0/C_{ss}$). When the infusion is discontinued, serum concentrations appear to decline in a straight line when plotted on semilogarithmic paper with a slope of $-k/2.303$. V_D is computed by dividing CL by k (Fig. 5-7).

Multicompartment Model

After an intravenous bolus dose, serum concentrations often decline in two or more phases. During the early phases, drug leaves the bloodstream by two mechanisms: (a) distribution into tissues and (b) metabolism and/or elimination. Because the drug is leaving the bloodstream through these two mechanisms, serum concentrations decline rapidly. After tissues and blood are in equilibrium, only metabolism and/or elimination remove drug from the blood. During this terminal phase, serum concentrations decline more slowly. The half-life is measured during the terminal phase by determining the time required for concentrations to decline by one-half.

After an intravenous bolus dose, serum concentrations decrease as if the drug were being injected into a central compartment that not

FIGURE 5-7. Achievement of steady-state serum concentrations after three to five half-lives of a drug. Note the elimination phase after discontinuance of the infusion.

only metabolizes and eliminates drug but also distributes drug to one or more other compartments. Of these multicompartment models, the two-compartment model is encountered most commonly (see Fig. 5-5). After an intravenous bolus injection, serum concentrations decrease in two distinct phases described by the equation:

$$C = \frac{D(\alpha - k_{21})}{V_{D1}(\alpha - \beta)} e^{-\alpha t} + \frac{D(k_{21} - \beta)}{V_{D1}(\alpha - \beta)} e^{-\beta t}$$

or $C = Ae^{-\alpha t} + Be^{-\beta t}$, where k_{21} is the first-order rate constant that reflects the transfer of drug from compartment 2 to compartment 1, V_{D1} is the V_D of compartment 1, $A = D(\alpha - k_{21})/[V_{D1}(\alpha - \beta)]$ and $B = D(k_{21} - \beta)/[V_{D1}(\alpha - \beta)]$. The rate constants α and β found in the exponents of the equations describe the distribution and elimination of the drug, respectively (Fig. 5-8). A and B are the y intercepts of the lines that describe drug distribution and elimination, respectively, on the log concentration-versus-time plot.

The residual line is calculated as before using the method of residuals. The terminal line is extrapolated to the y axis, and extrapolated concentrations are determined for each time point. Because actual concentrations are greater in this case, residual concentrations are calculated by subtracting the extrapolated concentrations from the actual concentrations. When plotted on semilogarithmic paper, the residual line has a y intercept equal to A . The slope of the residual line is used to compute α (slope = $-\alpha/2.303$). With the rate constants (α and β) and the intercepts (A and B), concentrations can be calculated for any time after the intravenous

FIGURE 5-8. Calculation of α and β half-lives following intravenous dosing.

FIGURE 5-9. Calculation of α and β half-lives following a steady-state infusion.

bolus dose ($C = Ae^{-\alpha t} + Be^{-\beta t}$), or pharmacokinetic constants can be computed: $CL = D/[(A/\alpha) + (B/\beta)]$, $V_{D,\beta} = CL/\beta$, $V_{D,ss} = \{D[(A/\alpha^2) + (B/\beta^2)]\}/[(A/\alpha) + (B/\beta)]^2$.

If serum concentrations of a drug given as a continuous intravenous infusion decline in a biphasic manner after the infusion is discontinued, a two-compartment model describes the data set (Fig. 5-9).^{12,13} In this instance, the postinfusion concentrations decrease according to the equation $C = Re^{-\alpha t'} + Se^{-\beta t'}$, where t' is the postinfusion time ($t' = 0$ when infusion is discontinued) and R , S , α , and β are determined from the postinfusion concentrations using the method of residuals with the y axis set at $t' = 0$. R and S are used to compute A and B . A and B are the y intercepts that would have occurred had the total dose given during the infusion ($D = k_0 T$) been administered as an intravenous bolus dose.

$$A = \frac{RD\alpha}{k_0(1 - e^{-\alpha T})}$$

$$B = \frac{SD\beta}{k_0(1 - e^{-\beta T})}$$

where T is the duration of infusion. Once A , B , α , and β are known, the equations for an intravenous bolus are used to compute the pharmacokinetic constants. Often, when a drug is given as an intravenous bolus or continuous intravenous infusion, a two-compartment model is used to describe the data, but when the same agent is given extravascularly, a one-compartment model applies.¹⁴ In this case, distribution occurs during the absorption phase, so a distribution phase is not observed.

Volumes of Distribution in Multicompartment Models

Two different V_D values are needed as proportionality constants for drugs that require multicompartment models to describe the serum-concentration-versus-time curve. The V_D that is used to compute the amount of drug in the body during the terminal (β) portion of the curve is called $V_{D,\beta}$ (amount of drug in body = $V_{D,\beta} C$). During a continuous intravenous infusion at steady state, $V_{D,ss}$ is used to compute the amount of drug in the body (amount of drug in body = $V_{D,ss} C$). $V_{D,ss}$ is also the V_D that can be computed using the physiologic volumes of blood and tissues and the ratio of unbound drug in blood to that in tissues [$V_{D,ss} = V_b + (f_b/f_t)V_t$]. Because the value of $V_{D,\beta}$ changes when CL changes, $V_{D,ss}$ should be used to indicate if

drug distribution changes during pharmacokinetic or drug-interaction experiments.

Multiple Dosing and Steady-State Equations

Any of these compartmental equations can be used to determine serum concentrations after multiple doses. The multiple-dosing factor $(1 - e^{-nK\tau})/(1 - e^{-K\tau})$, where n is the number of doses, K is the appropriate rate constant, and τ is the dosage interval, is simply multiplied by each exponential term in the equation, substituting the rate constant of each exponent for K . Time (t) is set at 0 at the beginning of each dosage interval. For example, a single-dose two-compartment intravenous bolus is calculated as follows: $C = Ae^{-\alpha t} + Be^{-\beta t}$. Thus the equation for a multiple-dose two-compartment intravenous bolus is

$$C = Ae^{-\alpha t} \frac{1 - e^{-n\alpha\tau}}{1 - e^{-\alpha\tau}} + Be^{-\beta t} \frac{1 - e^{-n\beta\tau}}{1 - e^{-\beta\tau}}$$

A single-dose one-compartment intravenous bolus is calculated as $C = (D/V_D)e^{-kt}$. For a multiple-dose one-compartment intravenous bolus, the concentration is $C = (D/V_D)e^{-kt}[(1 - e^{-nK\tau})/(1 - e^{-K\tau})]$.

At steady state, the number of doses becomes large, $e^{-nK\tau}$ approaches zero, and the multiple-dosing factor equals $1/(1 - e^{-K\tau})$. Therefore, the steady-state versions of the equations are simpler than their multiple-dose counterparts:

$$C = \frac{Ae^{-\alpha t}}{1 - e^{-\alpha\tau}} + \frac{Be^{-\beta t}}{1 - e^{-\beta\tau}}$$

and

$$C = \frac{(D/V_D)e^{-kt}}{1 - e^{-K\tau}}$$

for a steady-state two-compartment intravenous bolus and a steady-state one-compartment intravenous bolus, respectively.

USE OF PHARMACOKINETIC CONCEPTS FOR INDIVIDUALIZATION OF DRUG THERAPY

9 Many factors must be taken into consideration when deciding on the best drug dose for a patient. For example, the age of the patient is important because the dose (in milligrams per kilogram) for pediatric patients may be higher and for geriatric patients may be lower than the typically prescribed dose for young adults. Gender also can be a factor because males and females metabolize and eliminate some drugs differently. Patients who are significantly obese or cachectic also may require different drug doses because of clearance and volume of distribution changes. Other drug therapy that could cause drug interactions needs to be considered. Disease states and conditions may alter the drug-dosage regimen for a patient. Three disease states that deserve special mention are congestive heart failure, renal disease, and hepatic disease. Renal and hepatic diseases cause loss of organ function and decreased drug elimination and metabolism. Congestive heart failure causes decreased blood flow to organs that clear the drug from the body.

Many drug compounds are racemic mixtures of stereoisomers. In most cases, one of the isomers is more pharmacologically active than the other isomer, and each isomer may exhibit different pharmacokinetic properties. Warfarin, propranolol, verapamil, and ibuprofen are all racemic mixtures of stereoisomers. Some drug interactions inhibit or increase the elimination of only one stereoisomer. The importance of the drug interaction depends on which isomer is affected. Other drugs, such as dextromethorphan, levofloxacin, and diltiazem, are composed of just one stereoisomer.

10 Genetics also plays a role in drug metabolism. *Cytochrome P450* is a generic term for the group of enzymes that are responsible for

most drug metabolism oxidation reactions. Several cytochrome P450 (CYP) isozymes have been identified that are responsible for the metabolism of many important drugs (Table 5-3). CYP2C19 is responsible for aromatic hydroxylation of (S)-mephenytoin, and CYP2D6 oxidizes debrisoquine.¹⁵ These subsets of the cytochrome P450 enzyme family are also responsible for the metabolism of several other drugs (CYP2D6: many tricyclic antidepressants, codeine, (S)-metoprolol; CYP2C19: most proton pump inhibitors, sertraline, voriconazole). CYP2C9, CYP2C19, and CYP2D6 isozymes appear to be under genetic control. As a consequence, there are “poor metabolizers” who have a defective mutant gene for the isozyme, cannot manufacture a fully functional isozyme, and therefore cannot metabolize the drug substrate very well. “Extensive metabolizers” have the standard gene for the isozyme and metabolize the drugs normally. Poor metabolizers usually are a minority of the general population. They may achieve toxic concentrations of drug when usual doses are prescribed for them or, if the active drug moiety is a metabolite, may fail to have any pharmacologic effect from the drug. The ethnic background of the patient can affect the likelihood that the patient will be a poor metabolizer.¹⁵ For example, the incidence of poor metabolizers for CYP2D6 is approximately 5% to 10% for whites and approximately 0% to 1% for Asians, whereas for CYP2C19, poor metabolizers make up approximately 3% to 6% of the white population and approximately 20% of the Asian popu-

lation. Approximately 7% of the white population are poor metabolizers for CYP2C9 substrates.

Other cytochrome P450 isozymes have been isolated.¹⁵ CYP1A2 is the enzyme that is responsible for the demethylation of caffeine and theophylline; CYP2C9 metabolizes phenytoin, tolbutamide, losartan, and ibuprofen; some antiretroviral protease inhibitors, cyclosporine, nifedipine, lovastatin, simvastatin, and atorvastatin are metabolized by CYP3A4; and ethanol is a substrate for CYP2E1. It is important to recognize that a drug may be metabolized by more than one cytochrome P450 isozyme. Although most tricyclic antidepressants are hydroxylated by CYP2D6, *N*-demethylation probably is mediated by a combination of CYP2C19, CYP1A2, and CYP3A4. Acetaminophen appears to be metabolized by both CYP1A2 and CYP2E1. The 4-hydroxy metabolite of propranolol is produced by CYP2D6, but side-chain oxidation of propranolol is probably a product of CYP2C19. The CYP3A enzyme family comprises approximately 90% of the drug-metabolizing enzyme present in the intestinal wall but only approximately 30% of the drug-metabolizing enzyme found in the liver. The remainder of hepatic drug-metabolizing enzyme is approximately 20% for the CYP2C family, approximately 13% for CYP1A2, approximately 7% for CYP2E1, and approximately 2% for CYP2D6.

Understanding which cytochrome P450 isozyme is responsible for the metabolism of a drug is extraordinarily useful in predicting and understanding drug interactions. Some drug-metabolism inhibitors and inducers are highly selective for certain cytochrome P450 isozymes.¹⁵ Quinidine is an extremely potent inhibitor of the CYP2D6 enzyme system¹⁵; a single 50-mg dose of quinidine can change a rapid metabolizer of debrisoquine into a poor metabolizer. Ciprofloxacin and zileuton inhibit, whereas tobacco or marijuana smoke induce, CYP1A2. Some drugs that are enzyme inhibitors are also substrates for that same enzyme system and appear to cause drug interactions by being a competitive inhibitor. For example, erythromycin is both a substrate for and an inhibitor of CYP3A4. Obviously, if one knows that a new drug is metabolized by a given cytochrome P450 enzyme system, it is logical to assume that the new drug will exhibit drug interactions with the known inducers and inhibitors of that cytochrome P450 isozyme.

❶ The importance of transport proteins in drug bioavailability and elimination is now better understood. A principal transport protein involved in the movement of drugs across biologic membranes is P-gp. P-gp is present in many organs, including the gastrointestinal tract, liver, and kidney. If a drug is a substrate for P-gp, its oral absorption may be decreased when P-gp transports drug molecules that have been absorbed back into the gastrointestinal tract lumen. In the liver, some drugs are transported by P-gp from the blood into the bile, where the drug is eliminated by biliary secretion. Similarly, some drugs eliminated by the kidney are transported from the blood into the urine by P-gp. Digoxin is a substrate of P-gp. Other possible mechanisms for drug interactions are when two drugs that are substrates for P-gp compete for transport by the protein and when a drug is an inhibitor or inducer of P-gp. Drug interactions involving inhibition of P-gp decrease drug transportation in these organs and potentially can increase gastrointestinal absorption of orally administered drug, decrease biliary secretion of the drug, or decrease renal elimination of drug molecules. The drug interaction between amiodarone and digoxin probably involves all three of these mechanisms, and this explains why digoxin concentrations increase so dramatically in patients receiving amiodarone. Many drugs that are metabolized by CYP3A4 are also substrates for P-gp, and some of the drug interactions attributed to inhibition of CYP3A4 may be a result of decreased drug transportation by P-gp. Drug interactions involving induction of P-gp have the opposite effect in these organs and may decrease gastrointestinal absorption of orally administered drug, increase biliary secretion of the drug, or increase renal elimination of drug molecules.

TABLE 5-3 Cytochrome P450 (CYP) Enzyme Family and Selected Substrates

CYP1A2	CYP2E1
Acetaminophen	Enflurane
Caffeine	Ethanol
Ondansetron	Halothane
Tacrine	Isoflurane
Theophylline	CYP3A4
R-Warfarin	Alfentanil
Zileuton	Alprazolam
CYP2C9	Astemizole
Candesartan	Carbamazepine
Diclofenac	Cyclosporine
Ibuprofen	Diltiazem
Losartan	Erythromycin
Naproxen	Felodipine
Phenytoin	Itraconazole
Tolbutamide	Ketoconazole
Valsartan	Lidocaine
S-Warfarin	Lovastatin
CYP2C19	Midazolam
Diazepam	Nifedipine
Lansoprazole	Quinidine
(S)-Mephenytoin	Simvastatin
Nelfinavir	Tacrolimus
Omeprazole	Verapamil

Risperidone	
Thioridazine	
Venlafaxine	

SELECTION OF INITIAL DRUG DOSES

12 When deciding on initial doses for drugs that are eliminated renally, the patient's renal function should be assessed. A common, useful way to do this is to measure the patient's serum creatinine concentration and convert this value into an $CL_{cr\ est}$. Serum creatinine values alone should not be used to assess renal function because they do not include the effects of age, body weight, or gender. The Cockcroft-Gault equation¹⁶ is probably the most widely used method to estimate creatinine clearance (in milliliters per minute) in adults (age 18 years or older) who are within approximately 30% of their ideal body weight and have stable renal function:

$$\begin{aligned}\text{Male: } CL_{cr\ est} &= \frac{(140 - \text{age})BW}{S_{cr} \times 72} \\ \text{Female: } CL_{cr\ est} &= \frac{0.85(140 - \text{age})BW}{S_{cr} \times 72}\end{aligned}$$

where BW is body weight (in kilograms), age is the patient's age (in years), 0.85 is a correction factor to account for lower muscle mass in females, and S_{cr} is serum creatinine (in milligrams per deciliter). For children, the following estimation equations are available according to the age of the child¹⁷: age 0 to 1 years: $CL_{cr\ est}$ (in mL/min/1.73 m²) = $(0.45 \times Lt)/S_{cr}$; age 1 to 20 years: $CL_{cr\ est}$ (in mL/min/1.73 m²) = $(0.55 \times Lt)/S_{cr}$, where Lt is patient length in centimeters. Other methods to determine $CL_{cr\ est}$ for obese adults¹⁸ and patients with rapidly changing renal function¹⁹ are available. Creatinine is a by-product of muscle breakdown in the body, so none of these estimation methods work well in patients with muscle disease, such as multiple sclerosis, or diseases that alter muscle mass, such as cachexia, malnutrition, cancer, or spinal cord injury. Nomograms that adjust initial doses according to a patient's renal function are available for several drugs, including digoxin,²⁰ vancomycin,²¹ and the aminoglycoside antibiotics.²²

For drugs that are eliminated primarily by the kidney ($\geq 60\%$ of the administered dose), some agents will need minor dosage adjustments for $CL_{cr\ est}$ between 30 and 60 mL/min, moderate dosage adjustments for $CL_{cr\ est}$ between 15 and 30 mL/min, and major dosage adjustments for $CL_{cr\ est}$ less than 15 mL/min. Specific recommendations for dosage adjustments of other drugs for patients with renal disease are available.^{23,24} Supplemental doses of some medications also may be needed for patients receiving hemodialysis if the drug is removed by the artificial kidney or for patients receiving hemoperfusion if the drug is removed by the hemofilter.²⁴

13 A similar assessment of liver function should be made for drugs that are metabolized hepatically. Unfortunately, there is no single test that can estimate liver drug-metabolism capacity accurately, and those that are used do not always prove accurate. High aminotransferase (aspartate aminotransferase [AST] and alanine aminotransferase [ALT]) and alkaline phosphatase concentrations usually indicate acute hepatic cellular damage and do not establish poor liver drug metabolism reliably. Abnormal values for three tests that usually indicate that drugs will be metabolized poorly by the liver are high serum bilirubin concentration, low serum albumin concentration, and a prolonged prothrombin time. Bilirubin is metabolized by the liver, and albumin and clotting factors are manufactured by the liver, so aberrant values for all three of these tests are a more reliable indicator of abnormal liver drug metabolism. The Child-Pugh score,²⁵ a widely used clinical classification for liver disease that incorporates clinical signs and symptoms (ascites and hepatic encephalopathy) in addition to these three laboratory tests, can be used as an indicator of a patient's ability to metabolize drugs that are eliminated by the liver. A score in excess of 10 suggests very poor liver function. As a general rule, patients with cirrhosis have the most severe decreases in liver drug metabolism. Patients with acute or

chronic hepatitis often retain relatively normal or slightly decreased hepatic drug-metabolism capacity. In the absence of specific pharmacokinetic dosing guidelines for a medication, a Child-Pugh score equal to 8 to 9 is grounds for a moderate decrease (approximately 25%) in initial daily drug dose for agents that are metabolized primarily ($\geq 60\%$) hepatically, and a score of 10 or greater indicates that a significant decrease in initial daily dose (approximately 50%) is required for drugs that are metabolized mostly by the liver. As in any patient with or without liver dysfunction, initial doses are meant as starting points for dosage titration based on patient response and avoidance of adverse effects.

Because there are no good markers of liver function, clinicians have come to rely on pharmacokinetic parameters derived in various patient populations to compute initial doses of drugs that are eliminated hepatically. Table 5-4 contains average pharmacokinetic parameters for theophylline in several disease states. Initial doses of many liver-metabolized drugs are computed by determining which disease states and/or conditions the patient has that are known to alter the kinetics of the drug and by using these average pharmacokinetic constants to calculate doses. The patient is then monitored for therapeutic and adverse effects, and drug serum concentrations are obtained to ensure that concentrations are appropriate and to adjust doses, if necessary. The following computations illustrate the estimated intravenous loading dose and the intravenous continuous infusion necessary to achieve a theophylline concentration of 10 mg/L for a 55-year-old, 70-kg male with liver cirrhosis (mean kinetic parameters obtained from Table 5-4):

$$V_D = (0.5 \text{ L/kg})(70 \text{ kg}) = 35 \text{ L}$$

$$LD = C_{ss} V_D = (10 \text{ mg/L})(35 \text{ L})$$

$$= 350 \text{ mg theophylline infused over 20 to 30 min}$$

$$CL (\text{in L/h}) = \frac{(0.35 \text{ mL/min/kg})(70 \text{ kg})(60 \text{ min/h})}{1000 \text{ mL/L}}$$

$$= 1.5 \text{ L/h}$$

$$k_0 = C_{ss} CL = (10 \text{ mg/L})(1.5 \text{ L/h})$$

$$= 15 \text{ mg/h of theophylline to begin after loading dose is given}$$

If theophylline is to be given as the aminophylline salt form, each dose would need to be changed to reflect the fact that aminophylline contains only 85% theophylline ($LD = 350 \text{ mg of theophylline}/0.85 = 410 \text{ mg of aminophylline}$ infused over 20 to 30 minutes, $k_0 = 15 \text{ mg/h of theophylline}/0.85 = 18 \text{ mg/h of aminophylline}$ to begin after loading dose is given).

Heart failure is often overlooked as a disease state that can alter drug disposition. Severe heart failure decreases cardiac output and therefore reduces liver blood flow. Theophylline,²⁶ lidocaine,²⁷ and

TABLE 5-4 Theophylline Pharmacokinetic Parameters for Selected Disease States/Conditions

Disease State/Condition	Mean Clearance (mL/min/kg)	Mean Dose (mg/kg/h)
Children age 1-9 y	1.4	0.8
Children age 9-12 y or adult smokers	1.25	0.7
Adolescents age 12-16 y or elderly smokers (>65 y)	0.9	0.5
Adult nonsmokers	0.7	0.4
Elderly nonsmokers (age >65 y)	0.5	0.3
Decompensated congestive heart failure, cor pulmonale, cirrhosis	0.35	0.2

Mean volume of distribution = 0.5 L/kg.

Adapted from reference 49.

drugs with high extraction ratios are compounds whose clearance declines with decreased liver blood flow. Initial dosages of these drugs should be reduced in patients with moderate to severe heart failure (New York Heart Association class III or IV) by 25% to 50% until steady-state concentrations and response can be determined.

USE OF STEADY-STATE DRUG CONCENTRATIONS

Serum drug concentrations are readily available to clinicians to use as guides for the individualization of drug therapy. The therapeutic ranges for several drugs have been identified, and it is likely that new drugs also will be monitored using serum concentrations. Although several individualization methods have been advocated for specific **14** drugs, one simple, reliable method is used commonly. For drugs that exhibit linear pharmacokinetics, C_{ss} changes proportionally with dose. To adjust a patient's drug therapy, a reasonable starting dose is administered for an estimated three to five half-lives. A serum concentration is obtained, assuming that it will reflect C_{ss} . Independent of the route of administration, the new dose (D_{new}) needed to attain the desired C_{ss} ($C_{ss,new}$) is calculated: $D_{new} = D_{old}(C_{ss,new}/C_{ss,old})$, where D_{old} and $C_{ss,old}$ are the old dose and old C_{ss} , respectively. To use this method, $C_{ss,old}$ must reflect steady-state conditions. Often patients are noncompliant with regard to their drug dosage and therefore are not at steady state. This occurs not only in outpatients but also in hospital inpatients. Inpatients can spit out oral doses or alter the infusion rates on intravenous pump rates after the nurse leaves the hospital room. Doses also can be missed if the patient is absent from his or her room at the time medications are to be administered. If $C_{ss,old}$ is much larger or smaller than expected for the D_{old} the patient is taking, one should suspect noncompliance and repeat the serum concentration determination after another three to five half-lives or change the patient's dose cautiously and monitor for signs of toxicity or lack of effect.

MEASUREMENT OF PHARMACOKINETIC PARAMETERS IN PATIENTS

15 If it is necessary to determine the kinetic constants for a patient to individualize his or her dose, a small kinetic evaluation is conducted in the individual. In these cases, the number of serum concentrations obtained from the patient is held to the minimum needed to calculate accurate pharmacokinetic parameters and doses. The reason for using fewer serum drug concentration determinations is to be as cost-effective as possible because these laboratory tests generally cost \$20 to \$50 each.

Although many drugs follow two-compartment-model pharmacokinetics (especially after intravenous administration), a one-compartment model is used to compute kinetic parameters in patients because too many serum concentration determinations would be needed to determine accurately both the distribution and elimination phases found in the two-compartment model. Because of this, serum concentrations usually are not measured in patients during the distribution phase. Another important reason serum concentrations are not measured during the distribution phase for therapeutic drug-monitoring purposes in patients is that drug in the blood and drug in the tissues are not in equilibrium during this time so that serum concentrations do not reflect tissue concentrations. When drug serum concentrations are obtained in patients for the purpose of assessing efficacy or toxicity, it is important that they be measured in the postdistribution phase when drug in the blood is in equilibrium with drug at the site of action.

In the case where the patient has received enough doses to be at steady state, pharmacokinetic parameters can be computed using a predose minimum concentration and a postdose maximum con-

FIGURE 5-10. When a patient has received enough doses to be at steady state, steady-state maximum ($C_{max,ss}$) and minimum ($C_{min,ss}$) concentrations can be used to compute clearance, volume of distribution, and half-life. At steady state, consecutive $C_{min,ss}$ values are equal, so the predose value can be extrapolated to the time before the next dose and be used to calculate half-life (dashed line).

centration. Under steady-state conditions, serum concentrations after each dose are identical, so the predose minimum concentration is the same before each dose (Fig. 5–10). This situation allows the predose concentration to be used to compute both the patient's $t_{1/2}$ and V . If the drug was given extravascularly or has a significant distribution phase, the postdose concentration should be determined after absorption or distribution is finished. To ensure that steady-state conditions have been achieved, the patient needs to receive the drug on schedule for at least three to five estimated half-lives. To make sure that this is the case, inpatients should have their medication administration records checked, and the patient's nurse should be consulted regarding missed or late doses. Outpatients should be interviewed about compliance with the prescribed dosage regimen. When compliance with the dosage regimen has been verified, steady-state conditions reasonably can be assumed.

If the patient is not at steady state, an additional postdose serum concentration determination should be done to compute the patient's pharmacokinetic parameters. Ideally, the third concentration (C_3) should be acquired approximately one estimated half-life after the postdose maximum concentration. Determining serum concentrations too close together will hamper the drug assay's ability to measure differences between them, and getting the third sample too late could result in a concentration too low for the assay to detect. In this situation, the predose minimum and postdose maximum concentrations are used to compute V , and both postdose concentrations are used to calculate $t_{1/2}$ (Fig. 5–11).

FIGURE 5-11. If a patient has not received enough doses to be at steady state, or doses have been given on an irregular schedule, the minimum concentration (C_{min}), maximum concentration (C_{max}), and an additional postdose concentration (C_3) can be used to compute clearance, volume of distribution, and half-life.

After CL , V , and $t_{1/2}$ have been computed for a patient, the dose and dosage interval necessary to achieve desired steady-state serum concentrations can be calculated using one-compartment-model equations. Specific examples of these methods to calculate initial doses and individualized doses using serum concentrations are discussed later in this chapter for the aminoglycoside antibiotics, vancomycin, digoxin, theophylline, phenytoin, and cyclosporine.

COMPUTER PROGRAMS

Computer programs that aid in the individualization of therapy are available for many different drugs. The most sophisticated programs use nonlinear regression to fit CL and V_D to actual serum concentrations obtained in a patient.²⁸ After drug doses and serum concentrations are entered into the computer, nonlinear least-squares regression programs adjust CL and V_D until the sum of the squared error between actual (C_{act}) and computer-estimated concentrations (C_{est}) is at a minimum [$\sum (C_{est} - C_{act})^2$]. Once estimates of CL and V_D are available, doses are calculated easily.

Many programs also take into account what the CL and V_D should be on the basis of disease states and conditions present in the patient.²⁹ Incorporation of expected population-based parameters allows the computer to use a limited number of serum concentrations (one or two) to provide estimates of CL and V_D . This type of computer program is called *Bayesian* because it incorporates portions of Bayes' theorem during the fitting routine.³⁰ Bayesian pharmacokinetic dosing programs are used widely to adjust the dose of a variety of drugs. In the case of renally eliminated drugs (e.g., aminoglycosides, vancomycin, and digoxin), population estimates for kinetic parameters are generated by entering the patient's age, weight, height, gender, and serum creatinine concentration into the computer program. For hepatically eliminated drugs (e.g., theophylline and phenytoin), population estimates for kinetic parameters are computed using the patient's age, weight, and gender, as well as other factors that might change hepatic clearance, such as the presence or absence of disease states (e.g., cirrhosis or congestive heart failure) or other drug therapy that might cause a drug interaction. The Bayesian estimates of the pharmacokinetic parameters are then modified using nonlinear least-squares regression fits of serum concentrations to result in individualized parameters for the patient. The individualized parameters are used to compute doses for the patient that will result in desired steady-state concentrations of the drug.

Aminoglycosides

Although aminoglycoside pharmacokinetics follow multicompartment models,³¹ a one-compartment model appears sufficient to individualize doses in patients.³² Aminoglycosides usually are given as short-term intermittent intravenous infusions and administered as a single daily dose or multiple doses per day. Initial doses for aminoglycosides can be computed using estimated kinetic parameters derived from population pharmacokinetic data. The elimination rate constant is estimated using the patient's creatinine clearance in the following formula: k (in h^{-1}) = $0.00293(CL_{cr}) + 0.014$, where CL_{cr} is the measured or estimated creatinine clearance in milliliters per minute. The volume of distribution is estimated using the average population value for normal-weight (within 30% of ideal weight) individuals equal to 0.26 L/kg [$V = 0.26(Wt)$, where Wt is the patient's weight] or for obese individuals (over 30% of ideal weight)³³ by taking into account the patient's excess adipose tissue: $V = 0.26[IBW + 0.4(TBW - IBW)]$, where TBW is total body weight, IBW is ideal body weight [IBW_{males} (in kilograms) = $50 + 2.3(Ht - 60)$ or $IBW_{females}$ (in kilograms) = $45 + 2.3(Ht - 60)$, and Ht is the patient's height in inches]. Additional volume of distribution population estimates are available for other disease states and conditions such as cystic fibrosis,³⁴ ascites,³⁵ and neonates.³⁶

Appropriate $C_{max,ss}$ and $C_{min,ss}$ values are selected for the patient based on the site and severity of the infection and the sensitivity of the known or suspected pathogen, as well as avoidance of adverse effects. For example, $C_{max,ss}$ values of 8 to 10 mg/L generally are selected for gram-negative pneumonia patients, whereas $C_{min,ss}$ values of less than 2 mg/L usually are chosen to avoid aminoglycoside-induced nephrotoxicity when tobramycin and gentamicin are prescribed using conventional multiple-daily-dosing regimens. Once appropriate steady-state serum concentrations are selected, the dosage interval required to achieve those concentrations is calculated, and τ is rounded to a clinically acceptable value (e.g., 8, 12, 18, 24, 36, or 48 hours): $\tau = [(\ln C_{max,ss} - \ln C_{min,ss})/k] + T$. Finally, a dose is computed for the patient using the one-compartment-model intermittent intravenous infusion equation at steady state, and the dose is rounded off to the nearest 5 to 10 mg:

$$D = TkV_D C_{max,ss} \frac{1 - e^{-k\tau}}{1 - e^{-kT}}$$

The Hull and Sarrubi aminoglycoside dosage nomogram (Table 5-5) is based on this dosage-calculation method and includes precalculated doses and dosage intervals for a variety of creatinine clearance

TABLE 5-5 Aminoglycoside Dosage Chart

1. Compute patient's creatinine clearance (CL_{cr}) using Cockcroft-Gault method: $CL_{cr} = [(140 - \text{age})BW]/(S_{cr} \times 72)$. Multiply by 0.85 for females.
2. Use patient's weight if within 30% of IBW; otherwise use adjusted dosing weight = $IBW + [0.40(TBW - IBW)]$.
3. Select loading dose in mg/kg to provide peak serum concentrations in range listed below for the desired aminoglycoside antibiotic:

Aminoglycoside	Usual Loading Doses	Expected Peak Serum Concentrations
Tobramycin	1.5 to 2.0 mg/kg	4 to 10 mcg/mL
Gentamicin		
Netilmicin		
Amikacin	5.0 to 7.5 mg/kg	15 to 30 mcg/mL
Kanamycin		

4. Select maintenance dose (as percentage of loading dose) to continue peak serum concentrations indicated above according to desired dosage interval and the patient's creatinine clearance. To maintain usual peak to trough ratio, use dosage intervals in unshaded areas below.

Percentage of Loading Dose Required for Dosage Interval Selected

CL_{cr} (mL/min)	Estimated Half-Life (h)	8 h (%)	12 h (%)	24 h (%)
>90	2-3	90	—	—
90	3.1	84	—	—
80	3.4	80	91	—
70	3.9	76	88	—
60	4.5	71	84	—
50	5.3	65	79	—
40	6.5	57	72	92
30	8.4	48	63	86
25	9.9	43	57	81
20	11.9	37	50	75
17	13.6	33	46	70
15	15.1	31	42	67
12	17.9	27	37	61
10 ^a	20.4	24	34	56
7 ^a	25.9	19	28	47
5 ^a	31.5	16	23	41
2 ^a	46.8	11	16	30
0 ^a	69.3	8	11	21

BW, body weight; CL_{cr} , creatinine clearance; IBW, ideal body weight; S_{cr} , serum creatinine; TBW, total body weight.

^aNote: Dosing for patients with $CL_{cr} \leq 10$ mL/min should be assisted by measuring serum concentrations.

Adapted from reference 22.

values.²² The nomogram assumes that $V_D = 0.26 \text{ L/kg}$ and should not be used to compute doses for disease states with altered V_D .

For extended-interval therapy, $C_{\max,ss}$ values of 20 to 30 mg/L and $C_{\min,ss}$ values less than 1 mg/L generally are accepted as appropriate for gram-negative pneumonia patients. A minimum 24-hour dosage interval is chosen for this dosing technique, and the dosing interval is increased in 12- to 24-hour increments for patients with renal dysfunction.

An example of this initial dosage scheme for a typical case is provided to illustrate the use of the various equations. Mr. JJ is a 65-year-old, 80-kg, 6-ft-tall man with the diagnosis of gram-negative pneumonia. His serum creatinine concentration is 2.1 mg/dL and is stable. Compute a conventional gentamicin dosage regimen (infused over 1 hour) that would provide approximate peak and trough concentrations of $C_{\max,ss} = 8 \text{ mg/L}$ and $C_{\min,ss} = 1.5 \text{ mg/L}$, respectively. The patient is within 30% of his ideal body weight [$IBW_{\text{male}} = 50 + 2.3(72 \text{ in} - 60) = 78 \text{ kg}$] and has stable renal function, so the Cockcroft-Gault creatinine clearance estimation equation can be used: $CL_{\text{cr est}} = [(140 - 65 \text{ y})80 \text{ kg}]/[72(2.1 \text{ mg/dL})] = 40 \text{ mL/min}$. The patient's weight and estimated creatinine clearance are used to compute his V and k , respectively: $V = 0.26 \text{ L/kg}(80 \text{ kg}) = 20.8 \text{ L}$; $k = 0.00293(40 \text{ mL/min}) + 0.014 = 0.131 \text{ h}^{-1}$ or $t_{1/2} = 0.693/0.131 \text{ h}^{-1} = 5.3 \text{ h}$. The dosage interval and dose for the desired serum concentrations would then be calculated: $\tau = [(\ln 8 \text{ mg/L} - \ln 1.5 \text{ mg/L})/0.131 \text{ h}^{-1}] + 1 \text{ h} = 13.7 \text{ h}$ rounded to 12 h; $D = (1 \text{ h})(0.131 \text{ h}^{-1})(20.8 \text{ L})(8 \text{ mg/L}) [1 - e^{-(0.131 \text{ h}^{-1})(12 \text{ h})}] / [1 - e^{-(0.131 \text{ h}^{-1})(1 \text{ h})}] = 140 \text{ mg}$. Thus the prescribed dose would be gentamicin 140 mg every 12 hours administered as a 1-hour infusion. If a loading dose were deemed necessary, it would be given as the first dose [$LD = (20.8 \text{ L})(8 \text{ mg/L}) = 166 \text{ mg}$ rounded to 170 mg infused over 1 hour], and the first maintenance dose would be administered 12 hours (e.g., one dosage interval) later. Using the Hull and Sarrubi nomogram for the same patient, the loading dose is 160 mg (gentamicin loading dose for serious gram-negative infection is 2 mg/kg; $2 \text{ mg/kg} \times 80 \text{ kg} = 160 \text{ mg}$), and the maintenance dose is 115 mg every 12 hours (for a 12-hour dosage interval and $CL_{\text{cr est}} = 40 \text{ mL/min}$, maintenance dose is 72% of the loading dose: $0.72 \times 160 \text{ mg} = 115 \text{ mg}$).

CLINICAL CONTROVERSY

Some clinicians use conventional dosing or extended-interval dosing exclusively for patients requiring aminoglycosides, whereas others use a mix of both approaches according to the perceived benefit to the patient. Definitive, authoritative recommendations to guide the choice of one method of aminoglycoside dosing over the other are not available.

If appropriate aminoglycoside serum concentrations are available, kinetic parameters can be calculated at any point in therapy. When the patient is not at steady state, serum aminoglycoside concentrations are obtained before a dose (C_{\min}), after a dose administered as an intravenous infusion of about 1 hour or as a 30-minute infusion followed by a 30-minute waiting period to allow for drug distribution (C_{\max}), and at one additional postdose time (C_3) approximately one estimated half-life after C_{\max} . The $t_{1/2}$ and k values are computed using C_{\max} and C_3 : $k = (\ln C_{\max} - \ln C_3)/\Delta t$ and $t_{1/2} = 0.693/k$, where Δt is the time that expired between the times C_{\max} and C_3 were obtained. If the patient is at steady state, serum aminoglycoside concentrations are obtained before a dose ($C_{\min,ss}$) and after a dose administered as an intravenous infusion of about 1 hour or as a 30-minute infusion followed by a 30-minute waiting period to allow for drug distribution ($C_{\max,ss}$). The $t_{1/2}$ and k values are computed using $C_{\max,ss}$ and $C_{\min,ss}$: $k = (\ln C_{\max,ss} - \ln C_{\min,ss})/(\tau - T)$ and $t_{1/2} = 0.693/k$, where τ is the dosage interval and T is the dose infusion time or dose infusion time plus waiting time.

Assuming a one-compartment model, the following equation is used to compute V_D ³²:

$$V_D = \frac{(D/T)(1 - e^{-kT})}{k(C_{\max} - C_{\min}e^{-kT})}$$

where D is dose and T is duration of infusion. Once these are known, the dose and dosage interval (τ) can be calculated for any desired maximum C_{ss} ($C_{\max,ss}$) and minimum C_{ss} ($C_{\min,ss}$):

$$\tau = \frac{\ln C_{\max,ss} - \ln C_{\min,ss}}{k} + T$$

$$D = TkV_D C_{\max,ss} \frac{1 - e^{-k\tau}}{1 - e^{-kT}}$$

The dose and dosage interval should be rounded to provide clinically accepted values (every 8, 12, 18, 24, 36, and 48 hours for dosage interval, nearest 5 to 10 mg for conventional dosing or every 24, 36, and 48 hours for dosage interval, nearest 10 to 25 mg for extended interval dosing). This method also has been used to individualize intravenous theophylline dosage regimens.³⁷

To provide an example of this technique, the problem given previously will be extended to include steady-state concentrations. Mr. JJ was prescribed gentamicin 140 mg every 12 hours (infused over 1 hour) for the treatment of gram-negative pneumonia. Steady-state trough ($C_{\min,ss}$) and peak ($C_{\max,ss}$) values were obtained before and after the fourth dose was given (more than three to five estimated half-lives), respectively, and equaled $C_{\min,ss} = 2.8 \text{ mg/L}$ and $C_{\max,ss} = 8.5 \text{ mg/L}$. Clinically, the patient was improving with decreased white blood cell counts and body temperatures and a resolving chest radiograph. However, the serum creatinine value had increased to 2.5 mg/dL. Because of this, a new dosage regimen with a similar peak (to maintain high intrapulmonary levels) but lower trough (to decrease the risk of drug-induced nephrotoxicity) concentrations was suggested. The patient's elimination rate constant and half-life can be computed using the following formulas: $k = (\ln 8.5 \text{ mg/L} - \ln 2.8 \text{ mg/L})/(12 \text{ h} - 1 \text{ h}) = 0.101 \text{ h}^{-1}$ and $t_{1/2} = 0.693/0.101 \text{ h}^{-1} = 6.9 \text{ h}$. The patient's volume of distribution can be calculated using the following equation:

$$V = \frac{(140 \text{ mg}/1 \text{ h}) \left[1 - e^{-(0.101 \text{ h}^{-1})(1 \text{ h})} \right]}{(0.101 \text{ h}^{-1}) \left\{ 8.5 \text{ mg/L} - \left[(2.8 \text{ mg/L}) e^{-(0.101 \text{ h}^{-1})(1 \text{ h})} \right] \right\}} = 22.3 \text{ L}$$

Thus the patient's volume of distribution was larger and half-life was longer than originally estimated, and this led to higher serum concentrations than anticipated. To achieve the desired serum concentrations ($C_{\min,ss} = 1.5 \text{ mg/L}$ and $C_{\max,ss} = 8 \text{ mg/L}$), the patient's actual kinetic parameters are used to compute a new dose and dosage interval: $\tau = [(\ln 8 \text{ mg/L} - \ln 1.5 \text{ mg/L})/0.101 \text{ h}^{-1}] + 1 \text{ h} = 17.6 \text{ h}$, rounded to 18 h and

$$D = (1 \text{ h})(0.101 \text{ h}^{-1})(22.3 \text{ L})(8 \text{ mg/L}) \frac{(1 - e^{-(0.101 \text{ h}^{-1})(18 \text{ h})})}{(1 - e^{-(0.101 \text{ h}^{-1})(1 \text{ h})})}$$

$$= 157 \text{ mg, round to 160 mg}$$

Thus the new dose would be gentamicin 160 mg every 18 hours and infused over 1 hour; the first dose of the new dosage regimen would be given 18 hours (e.g., the new dosage interval) after the last dose of the old dosage regimen.

Because aminoglycoside antibiotics exhibit concentration-dependent bacterial killing and the postantibiotic effect is longer with higher

concentrations, investigators studied the possibility of giving a higher dose of aminoglycoside using an extended-dosage interval (24 hours or longer, depending on renal function). Generally, these studies have shown comparable microbiologic and clinical cure rates for many infections and about the same rate of nephrotoxicity (approximately 5% to 10%) as with conventional dosing. Ototoxicity has not been monitored using audiometry in most of these investigations, but loss of hearing in the conversational range, as well as signs and symptoms of vestibular toxicity, usually has been assessed and found to be similar to that with aminoglycoside therapy dosed conventionally. Based on these data, clinicians are using extended-interval dosing in selected patients. For *Pseudomonas aeruginosa* infections where the organism has an expected minimum inhibitory concentration (MIC) \approx 2 mg/L, peak concentrations between 20 and 30 mg/L and trough concentrations of less than 1 mcg/L for gentamicin or tobramycin have been suggested.³⁸

At the present time, there is no consensus on how to approach concentration monitoring using this mode of administration. Some clinicians obtain steady-state peak and trough concentrations and use the kinetic equations given earlier to adjust the dose and dosage interval in order to attain appropriate target levels. Other clinicians measure only trough concentrations, trusting that the large doses administered to patients achieve adequate peak concentrations.

Also, a nomogram that adjusts extended-interval doses based on a single postdose concentration to achieve these steady-state concentration goals has been proposed (Fig. 5–12). The dose is 7 mg/kg of gentamicin or tobramycin. The initial dosage interval is set according to the patient's creatinine clearance (see Fig. 5–12). The Hartford nomogram includes a method to adjust doses based on serum concentrations. This portion of the nomogram contains average serum concentration time lines for gentamicin or tobramycin in patients with creatinine clearances of 60, 40, and 20 mL/min. A serum concentration is measured 6 to 14 hours after the first dose is given, and this concentration/time point is plotted on the graph (see Fig. 5–12). The modified dosage interval is indicated by which zone the serum concentration/time point falls in. Because cystic fibrosis patients have a different volume of distribution (0.35 L/kg) than assumed by this dosing technique and extended-interval dosing has not been tested adequately in patients with endocarditis, the Hartford nomogram should not be used in these situations.

To illustrate how the nomogram is used, the same patient example used previously will be repeated for this dosage approach. Mr. JJ is an 80-kg man with a $CL_{cr\ est}$ of 40 mL/min. Using the Hartford nomogram, the patient would receive gentamicin 560 mg every 36 hours (7 mg/kg \times 80 kg = 560 mg; the initial dosage interval for $CL_{cr\ est}$ = 40 mL/min is 36 hours). Ten hours after the first dose was given, the serum gentamicin concentration is 8.2 mg/L. According to the graph contained in the nomogram, the dosage interval should be changed to 48 hours. The new dose is 560 mg every 48 hours.

CLINICAL CONTROVERSY

“Trough only” measurement of steady-state vancomycin concentrations is a mainstream method to monitor therapy. The exact range for this value is uncertain. Some clinicians recommend 5 to 10 mcg/mL, whereas others suggest 5 to 15 mcg/mL. For some sites of infection with specific organisms (such as hospital-acquired pneumonia caused by multidrug-resistant organisms) guidelines suggest vancomycin trough concentrations as high as 15 to 20 mcg/mL may be necessary. Some clinicians continue to measure both steady-state peak and trough vancomycin concentrations.

Vancomycin

Vancomycin requires multicompartment models to completely describe its serum-concentration-versus-time curves. However, if

1. Administer 7 mg/kg gentamicin with initial dosage interval:

Estimated CL_{cr} (mL/min)	Initial dosage interval
≥ 60 mL/min	q 24 h
40–59 mL/min	q 36 h
20–39 mL/min	q 48 h
<20 mL/min	Monitor serial concentrations and administer next dose when <1 mcg/mL.

2. Obtain timed serum concentration 6 to 14 hours after dose (ideally first dose).

3. Alter dosage interval to that indicated by the nomogram zone (above q 48 h zone, monitor serial concentrations and administer next dose when <1 mcg/mL)

FIGURE 5-12. Hartford nomogram for extended-interval aminoglycosides. (Adapted with permission from reference 38.)

peak serum concentrations are obtained after the distribution phase is completed (usually 30 minutes to 1 hour after a 1-hour intravenous infusion), a one-compartment model can be used for patient dosage calculations. Also, because vancomycin has a relatively long half-life compared with the infusion time, only a small amount of drug is eliminated during infusion, and it is usually unnecessary to use more complex intravenous infusion equations. Thus simple intravenous bolus equations can be used to calculate vancomycin doses for most patients. Although a recent review paper³⁹ questioned the clinical usefulness of measuring vancomycin concentrations on a routine basis, research articles^{40,41} have shown potential benefits in obtaining vancomycin concentrations in selected patient populations. Some clinicians advocate monitoring only steady-state trough concentrations of vancomycin.⁴² The decision to conduct vancomycin concentration monitoring should be made on a patient-by-patient basis.

Initial doses of vancomycin can be computed for adult patients using estimated kinetic parameters derived from population pharmacokinetic data. Clearance is estimated using the patient's creatinine clearance in the following equation⁴¹: CL (in mL/min/kg) = $0.695(CL_{cr}$ in mL/min/kg) + 0.05. The volume of distribution is computed assuming the standard value of 0.7 L/kg: $V_D = 0.7(Wt)$, where Wt is the patient's weight. In the case of obese patients, actual or total body weight is used in the calculation of clearance, but ideal body weight is used to compute volume of distribution.⁴⁴ The elimination rate constant is calculated using clearance and volume of distribution estimates, correcting for possible differences in units for these parameters: $k = CL/V_D$. A nomogram that uses this type of approach for vancomycin therapy is available to determine initial doses rapidly for patients (Table 5–6).⁴⁵

TABLE 5-6 Vancomycin Dosage Chart

1. Compute patient's creatinine clearance (CL_{cr}) using Cockcroft-Gault method: $CL_{cr} = [(140 - \text{age})BW]/(S_{cr} \times 72)$. Multiply by 0.85 for females.
2. Use patient's total body weight to compute doses.
3. Dosage chart designed to achieve peak serum concentrations of 30 $\mu\text{g/mL}$ and trough concentrations of 7.5 $\mu\text{g/mL}$.
4. Compute loading dose of 25 mg/kg.
5. Compute maintenance dose of 19 mg/kg given at the dosage interval listed in the following chart for the patient's CL_{cr} :

CL_{cr} (mL/min)	Dosage Interval (Days)
≥ 120	0.5
100	0.6
80	0.75
60	1.0
40	1.5
30	2.0
20	2.5
10	4.0
5	6.0
0	12.0

Adapted from reference 45.

Steady-state peak and trough concentrations are chosen for the patient based on the site and severity of the infection, as well as the known or suspected pathogen and avoidance of potential side effects. $C_{\max,ss}$ values of between 20 and 40 mg/L and $C_{\min,ss}$ values of between 5 and 15 mg/L typically are used for patients with moderate to severe methicillin-resistant *Staphylococcus aureus*, *Staphylococcus epidermidis*, or penicillin-resistant enterococcal infections. After appropriate steady-state concentrations are chosen, the dosage interval required to attain those concentrations is computed, and τ is rounded to a clinically acceptable value (12, 18, 24, 36, 48, or 72 hours): $\tau = (\ln C_{\max,ss} - \ln C_{\min,ss})/k$. Finally, the maintenance dose is computed for the patient using a one-compartment-model intravenous bolus equation at steady state, and the dose is rounded off to the nearest 100 to 250 mg:

$$D = C_{\max,ss} V_D (1 - e^{-k\tau})$$

If desired, a loading dose can be computed using the following equation:

$$LD = V_D C_{\max,ss}$$

The following case will illustrate the use of this dosage methodology. Ms. HJ is a 65-year-old, 68-kg, 5-ft 4-in tall patient who has developed a surgical wound infection with *S. aureus* the suspected pathogen. Her serum creatinine concentration is 1.8 mg/dL and stable. Compute a vancomycin dosage regimen that would provide approximate peak (obtained 1 hour after a 1-hour infusion) and trough concentrations of 30 and 7 mg/L, respectively. The patient is within 30% of her ideal body weight [$IBW_{\text{female}} = 45 + 2.3(64 \text{ in} - 60) = 54 \text{ kg}$] and has stable renal function, so the Cockcroft-Gault creatinine clearance estimation formula can be used: $CL_{cr \text{ est}} = 0.85[(140 - 65 \text{ y})68 \text{ kg}]/[72(1.8 \text{ mg/dL})] = 33 \text{ mL/min}$. The patient's weight and estimated creatinine clearance are used to calculate her estimated CL , V_D , and k , respectively: $CL = 0.695 (33 \text{ mL/min}/68 \text{ kg}) + 0.05 = 0.387 \text{ mL/min/kg}$; $V_D = 0.7 \text{ L/kg}(68 \text{ kg}) = 48 \text{ L}$; and $k = [(0.387 \text{ mL/min/kg})(68 \text{ kg})(60 \text{ min/h})]/[(48 \text{ L})(1,000 \text{ mL/L})] = 0.033 \text{ h}^{-1}$ or $t_{1/2} = 0.693/0.033 \text{ h}^{-1} = 21 \text{ h}$. The dosage interval, maintenance dose, and loading dose for the desired serum concentrations then can be computed: $\tau = (\ln 30 \text{ mg/L} - \ln 7 \text{ mg/L})/0.033 \text{ h}^{-1} = 44 \text{ h}$, rounded to 48 h; $D = (30 \text{ mg/L}) (48 \text{ L})(1 - e^{-(0.033 \text{ h}^{-1})(48 \text{ h})}) = 1,145 \text{ mg}$, rounded to 1,200 mg; $LD = (48 \text{ L})(30 \text{ mg/L}) = 1,440 \text{ mg}$, rounded to 1,450 mg. Therefore, the prescribed doses would be vancomycin 1,200 mg every 48 hours administered as a 1-hour infusion. If a loading dose was used, it would be given

as the first dose, and the first maintenance dose would be administered 48 hours (one dosage interval) later. Using the Matzke nomogram for the same patient, the loading dose would be 1,700 mg (vancomycin loading dose is 25 mg/kg: $25 \text{ mg/kg} \times 68 \text{ kg} = 1,700 \text{ mg}$), followed by a maintenance dose of 1,300 mg every 48 hours (for $CL_{cr \text{ est}} = 30 \text{ mL/min}$, maintenance dose is 19 mg/kg every 2 days: $19 \text{ mg/kg} \times 68 \text{ kg} = 1,292 \text{ mg}$, rounded to 1,300 mg).

If appropriate vancomycin serum concentrations are available, kinetic parameters can be computed at any point in therapy. When the patient is not at steady state, serum vancomycin concentrations are obtained before a dose (C_{\min}), after a dose administered as an intravenous infusion of 1 hour followed by a 30-minute to 1-hour waiting period to allow for drug distribution (C_{\max}), and at one additional postdose time (C_3) approximately one estimated half-life after C_{\max} . The $t_{1/2}$ and k values are computed using C_{\max} and C_3 : $k = (\ln C_{\max} - \ln C_3)/\Delta t$ and $t_{1/2} = 0.693/k$, where Δt is the time that expired between the times C_{\max} and C_3 were obtained. If the patient is at steady state, serum vancomycin concentrations are obtained before a dose ($C_{\min,ss}$) and after a dose administered as an intravenous infusion of about 1 hour followed by a 30-minute to 1-hour waiting period to allow for drug distribution ($C_{\max,ss}$). The $t_{1/2}$ and k values are computed using $C_{\max,ss}$ and $C_{\min,ss}$: $k = (\ln C_{\max,ss} - \ln C_{\min,ss})/(\tau - T_{\max})$ and $t_{1/2} = 0.693/k$, where τ is the dosage interval and T_{\max} is the dose infusion time plus waiting time.

Assuming a one-compartment model, the following equation is used to compute V_D :

$$V_D = \frac{D}{C_{\max} - C_{\min}}$$

where D is dose. Once these are known, the dose and dosage interval (τ) can be calculated for any desired maximum C_{ss} ($C_{\max,ss}$) and minimum C_{ss} ($C_{\min,ss}$):

$$\tau = \frac{\ln C_{\max,ss} - \ln C_{\min,ss}}{k}$$

$$D = C_{\max,ss} V_D (1 - e^{-k\tau})$$

The dose and dosage interval should be rounded to provide clinically accepted values (every 12, 18, 24, 36, 48, or 72 hours for dosage interval, nearest 100 to 250 mg for dose).

To provide an example for this dosage-calculation method, the preceding problem will be extended to include steady-state concentrations. Ms. HJ was prescribed vancomycin 1,200 mg every 48 hours (infused over 1 hour) for the treatment of a surgical wound infection. Steady-state trough ($C_{\min,ss}$) and peak ($C_{\max,ss}$) values ($C_{\max,ss}$ obtained 1 hour after the end of the infusion) were obtained before and after the third dose was given (more than three to five estimated half-lives), respectively, and equaled $C_{\min,ss} = 2.5 \text{ mg/L}$ and $C_{\max,ss} = 22.4 \text{ mg/L}$. Clinically, the patient had improved somewhat, but her white blood cell count was still elevated, and the patient was still febrile. Because of this, a modified dosage regimen with a $C_{\max,ss} = 30 \text{ mg/L}$ and $C_{\min,ss} = 7 \text{ mg/L}$ was suggested to maintain trough concentrations three to five times above the MIC for the suspected pathogen. The patient's actual elimination rate constant and half-life can be calculated using the following formulas: $k = (\ln 22.4 \text{ mg/L} - \ln 2.5 \text{ mg/L})/(48 \text{ h} - 2 \text{ h}) = 0.048 \text{ h}^{-1}$ and $t_{1/2} = 0.693/0.048 \text{ h}^{-1} = 14.4 \text{ h}$. The patient's volume of distribution can be calculated using the following equation:

$$V_D = \frac{1,200 \text{ mg}}{22.4 \text{ mg/L} - 2.5 \text{ mg/L}} = 60 \text{ L}$$

Thus the patient's volume of distribution was larger and half-life shorter than originally estimated, and this led to lower serum concentrations than anticipated. To achieve the desired serum concentrations ($C_{\max,ss} = 30 \text{ mg/L}$ and $C_{\min,ss} = 7 \text{ mg/L}$), the

patient's actual kinetic parameters are used to calculate a new dose and dosage interval:

$$\begin{aligned}\tau &= \frac{\ln 30 \text{ mg/L} - \ln 7 \text{ mg/L}}{0.048 \text{ h}^{-1}} \\ &= 30 \text{ h, rounded to 36 h} \\ D &= (30 \text{ mg/L})(60 \text{ L}) \left(1 - e^{-(0.048 \text{ h}^{-1})(36 \text{ h})}\right) \\ &= 1,480 \text{ mg, rounded to 1,500 mg}\end{aligned}$$

The new dose would be vancomycin 1,500 mg every 36 hours (infused over 1 hour); the first dose of the new dosage regimen would be given 36 hours (the new dosage interval) after the last dose of the old dosage regimen.

Many clinicians measure only steady-state vancomycin trough concentrations in patients. The justification for this approach is that because vancomycin exhibits time-dependent bacterial killing, the minimum concentration is the most important with regard to therapeutic outcome. Vancomycin pharmacokinetics also support this approach because the volume of distribution is relatively stable and is not changed by many disease states or conditions. Because of this important point, it is difficult to attain peak steady-state concentrations in the toxic range when the steady-state vancomycin trough is in the therapeutic range if typical doses are used (15 mg/kg or $\approx 1,000$ mg for average-weight individuals). Also, toxic peak concentrations (generally greater than 80 to 100 mg/L) are quite a bit higher than therapeutic peak concentrations, which adds a safety margin between effective concentrations and those yielding adverse drug effects.

Coupled with trough-only vancomycin concentration monitoring is a widening of the therapeutic steady-state trough concentration range from 5 to 15 mg/L. The justification for increasing the top of the range from 10 to 15 mg/L comes from limited retrospective⁴¹ and prospective⁴² studies, and until more clinical evidence is available, should be reserved for severely ill patients, infections caused by bacteria with higher MICs, and patients who are not responding to trough concentrations within the usual 5- to 10-mg/L range. Trough concentrations in the range of 15 to 20 mg/L should only be used for specific clinical situations, such as hospital-acquired pneumonia caused by multidrug-resistant organisms.⁵⁶

When trough-only monitoring of vancomycin concentrations is chosen by a clinician, a simple variant of linear pharmacokinetics can be used to adjust the dose (D) and dosage interval (τ): ($D_{\text{new}}/\tau_{\text{new}} = (D_{\text{old}}/\tau_{\text{old}})(C_{\text{ss,new}}/C_{\text{ss,old}})$), where *new* and *old* indicate the new target trough concentration and the old measured trough concentration, respectively. In practice, the dose (typically 1,000 mg) is held constant and only the dosage interval is changed. This equation is an approximation of the actual new steady-state trough concentration that will be attained in the patient because, mathematically, $C_{\text{ss,new}}$ is an exponential function of τ .

An example of this approach is given in the following case. Mr. MK (72 years old, 72-kg weight, 5 ft 9 in tall) was prescribed vancomycin 1,000 mg every 12 hours (infused over 1 hour) for the treatment of an *S. epidermidis* central venous catheter infection. A steady-state trough ($C_{\text{min,ss}}$) value was obtained before the fifth dose was given (more than three to five estimated half-lives), and $C_{\text{min,ss}}$ equaled 19 mg/L. Clinically, the patient was improving, but the trough concentration was judged to be too high. Because of this, a modified dosage regimen with a $C_{\text{min,ss}} = 10$ mg/L was suggested to maintain trough concentrations three to five times above the MIC for the suspected pathogen: ($D_{\text{new}}/\tau_{\text{new}} = (1,000 \text{ mg}/12 \text{ h})(10 \text{ mg/L}/19 \text{ mg/L}) = 44 \text{ mg/h}$). Because the patient is near his ideal weight, the same dose of 1,000 mg can be used (D_{new}), and the new dosage interval (τ_{new}) can be computed: $\tau = 1,000 \text{ mg}/44 \text{ mg/h} = 23 \text{ h}$, rounded to 24 h. The new prescribed dose for the patient would be 1,000 mg every 24 hours.

Digoxin

Digoxin pharmacokinetics are best described by a two-compartment model. However, because digoxin has a long half-life compared with its dosage interval and a very long distribution phase, simple pharmacokinetic equations can be used to individualize dosing when postdistribution serum concentrations are used. Digoxin can be given as an intravenous injection and orally as elixir ($F = 0.8$), tablets ($F = 0.7$), or capsules ($F = 0.9$). When given orally, the appropriate bioavailability fraction must be used to compute the correct dose. Initial doses of digoxin can be computed using population pharmacokinetic data obtained from published studies. Digoxin clearance is estimated using the patient's creatinine clearance in the following formula²⁰: CL (in milliliters per minute) = $1.303(\text{CL}_{\text{cr}}$ in milliliters per minute) + CL_{m} , where CL_{m} is metabolic clearance and equals 40 mL/min for patients with no or mild heart failure or 20 mL/min for patients with moderate to severe heart failure. The volume of distribution decreases with declining renal function and is estimated using the following equation²⁰: V_{D} (in liters) = $226 + [298(\text{CL}_{\text{cr}}$ in milliliters per minute)]/($29.1 + \text{CL}_{\text{cr}}$ in milliliters per minute). The elimination rate constant can be computed by taking the product of CL and V_{D} : $k = \text{CL}/V_{\text{D}}$. For obese individuals, digoxin dosing should be based on ideal body weight.⁴⁶

Appropriate C_{ss} values are chosen for the patient based on the disease state being treated, the goal of therapy, and avoidance of adverse effects. The inotropic effects of digoxin occur at lower concentrations than do the chronotropic effects. Therefore, initial serum concentrations of digoxin for the treatment of heart failure generally are 1 ng/mL or less and for the treatment of atrial fibrillation are 1 to 1.5 ng/mL. Once the appropriate C_{ss} is selected, a dose is computed for the patient: $D/\tau = (C_{\text{ss}}\text{CL})/F$.

An example of this initial dosage scheme is provided in the following case. Mr. PO is a 72-year-old, 83-kg, 5-ft 11-in tall man admitted to the hospital for the treatment of community-acquired pneumonia. While in the hospital, Mr. PO develops atrial fibrillation, and the decision is made to treat him with digoxin to provide ventricular rate control. His serum creatinine concentration is 2.5 mg/dL and stable. Calculate an intravenous loading dose and oral maintenance dose that will achieve a C_{ss} of 1.5 ng/mL. The Cockcroft-Gault equation can be used to estimate the patient's creatinine clearance because his serum creatinine concentration is stable and he is within 30% of his ideal weight [$\text{IBW}_{\text{male}} = 50 + 2.3(71 \text{ in} - 60) = 75 \text{ kg}$]: $\text{CL}_{\text{cr}} = [(140 - 72 \text{ y})83 \text{ kg}]/[72(2.5 \text{ mg/dL})] = 31 \text{ mL/min}$. Using the estimated CL_{cr} , both CL and V_{D} can be computed:

$$\begin{aligned}\text{CL} &= 1.303(31 \text{ mL/min}) + 40 = 80 \text{ mL/min} \\ V_{\text{D}} &= 226 + \frac{298(31 \text{ mL/min})}{29.1 + 31 \text{ mL/min}} = 380 \text{ L}\end{aligned}$$

The maintenance dose will be given as digoxin tablets, so $F = 0.7$ in the dosing equation: $D/\tau = [(1.5 \text{ mcg/L})(80 \text{ mL/min})(60 \text{ min/h})(24 \text{ h/day})]/[0.7(1,000 \text{ mL/L})] = 247 \text{ mcg/day}$, rounded to 250 mcg/day. The loading dose will be given intravenously as a digoxin injection: $\text{LD} = (1.5 \text{ mcg/L})(380 \text{ L}) = 570 \text{ mcg}$, rounded to 500 mcg. The loading dose would be given 50% now (250 mcg), 25% (125 mcg) in 4 to 6 hours after monitoring the patient's heart rate and blood pressure and assessing the patient for digoxin adverse effects, and the final 25% (125 mcg) 4 to 6 hours later after monitoring the same clinical parameters. The first maintenance dose would be given one dosage interval (in this case 24 hours) after the first part of the loading dose was given.

Adjustment of digoxin doses using steady-state concentrations is accomplished using linear pharmacokinetics and dosage ratios: $D_{\text{new}} = D_{\text{old}}(C_{\text{ss,new}}/C_{\text{ss,old}})$. For example, Mr. PO's atrial fibrillation responded to digoxin therapy, and he was discharged after resolution of his pneumonia. A month later he was followed up in the

clinic with moderate nausea, possibly a result of digoxin toxicity. His heart rate was 51 beats per minute. A steady-state digoxin concentration was determined and reported by the clinical laboratory as 2.2 mcg/L. Compute a new dose for the patient to achieve a C_{ss} of 1.5 mcg/L. The digoxin C_{ss} and old dose would be used to calculate a new dose using the linear pharmacokinetic equation: $D_{new} = 250 \text{ mcg/day}[(1.5 \text{ mcg/L})/(2.2 \text{ mcg/L})] = 170 \text{ mcg/day}$. This approximate average daily dose could be achieved by having the patient alternate take two 125-mcg tablets (250 mcg) and one 125-mcg tablet daily, giving an average dose equal to 187.5 mcg/day $[(250 \text{ mcg} + 125 \text{ mcg})/2 = 187.5 \text{ mcg/day}]$.

Theophylline

Theophylline disposition is described most accurately by nonlinear kinetics.^{47,48} However, at the usual doses, theophylline acts as if it obeys linear kinetics in most patients. Initial theophylline doses are computed by taking a detailed medical history of the patient and noting disease states and conditions that are known to change theophylline disposition. Age, smoking of tobacco-containing products, heart failure, and liver disease are among the important factors that alter theophylline kinetic parameters and dosage requirements. Once the patient has been assessed, average theophylline kinetic parameters obtained from the literature for patients similar to the one being currently treated are used to compute either oral or intravenous doses. Dosage guidelines that take into account most common disease states and conditions that change theophylline kinetic parameters are available (see Table 5-4).⁴⁹ Once theophylline is administered, the patient is monitored for the therapeutic effect and potential adverse effects. Theophylline concentrations then are used to individualize the theophylline dose that the patient receives. An example of this approach was given previously for a patient in the section on drug dosing in patients with liver disease.

Continuous intravenous infusions of theophylline (or its salt, aminophylline) can be individualized rapidly by determining the patient's CL before steady state occurs.⁵⁰ Assuming that the patient receives theophylline only by continuous intravenous infusion (previous doses of sustained-release oral theophylline are completely absorbed), two serum theophylline concentration determinations are done 4 hours or more apart. The infusion rate (k_0) cannot be changed between the times the samples are drawn. With one-compartment model equations, the first (C_1) and second (C_2) theophylline concentrations are used to calculate theophylline CL:

$$CL = \frac{2k_0}{C_1 + C_2} + \frac{2V_D(C_1 - C_2)}{(C_1 + C_2)(t_2 - t_1)}$$

V_D is assumed to be 0.5 L/kg, and t_1 and t_2 are the times at which C_1 and C_2 , respectively, are obtained. Once CL is known, k_0 can be computed easily for any desired C_{ss} ($C_{ss} = k_0/CL$). This method probably can be applied to other drugs that are administered as continuous intravenous infusions, such as intravenous antiarrhythmics, when rapid individualization of drug dosage is desirable.

An example of this approach can be obtained by continuing the theophylline patient case from the section on drug dosing in liver disease. In this example, a 55-year-old, 70-kg man with liver cirrhosis was prescribed a loading dose of theophylline 350 mg intravenously over 20 to 30 minutes, followed by a maintenance dose of 15 mg/h of theophylline as a continuous infusion. The infusion began at 9 AM, blood samples were obtained at 10 AM and 4 PM, and the clinical laboratory reported the theophylline serum concentrations as 10.9 and 12.3 mg/L, respectively. The patient's theophylline clearance and revised continuous infusion to maintain a C_{ss} of 15 mg/L can be computed as follows (patient's V_D estimated at 0.5 L/kg):

$$CL = \frac{2(15 \text{ mg/h})}{10.9 \text{ mg/L} + 12.3 \text{ mg/L}} + \frac{2(0.5 \text{ L/kg} \times 70 \text{ kg})(10.9 \text{ mg/L} - 12.3 \text{ mg/L})}{(10.9 \text{ mg/L} + 12.3 \text{ mg/L})(16 - 10 \text{ h})} = 0.59 \text{ L/h}$$

$$k_0 = C_{ss} CL = (15 \text{ mg/L})(0.59 \text{ L/h}) = 9 \text{ mg/h theophylline}$$

If theophylline is to be given as the aminophylline salt form, the doses would need to be changed to reflect the fact that aminophylline contains only 85% theophylline ($k_0 = 9 \text{ mg/h theophylline}/0.85 = 11 \text{ mg/h aminophylline}$).

If continuous intravenous infusions or oral dosage regimens are given long enough for steady state to occur (three to five estimated half-lives based on previous studies conducted in similar patients), linear pharmacokinetics can be used to adjust doses for either route of administration: $D_{new} = D_{old} (C_{ss,new}/C_{ss,old})$. For example, a patient receiving 200 mg of sustained-release oral theophylline every 12 hours with a theophylline steady-state serum concentration of 9.5 mcg/mL can have the dose required to achieve a new steady-state concentration equal to 15 mcg/mL computed by applying linear pharmacokinetics: $D_{new} = 200 \text{ mg}[(15 \text{ mcg/mL})/(9.5 \text{ mcg/mL})] = 316 \text{ mg}$, rounded to 300 mg. Thus the new theophylline dose would be 300 mg every 12 hours.

Phenytoin

Phenytoin doses are very difficult to individualize because the drug follows Michaelis-Menten kinetics, and there is a large amount of interpatient variability in V_{max} and K_m . Initial maintenance doses of phenytoin in adults usually range between 4 and 7 mg/kg per day, yielding starting doses of 300 to 400 mg/day in most individuals. If needed, loading doses of phenytoin or fosphenytoin (a prodrug of phenytoin used intravenously) can be administered in adults at a dose of 15 mg/kg, which is approximately 1,000 mg in many individuals. Loading doses of phenytoin can be given orally but need to be administered in divided doses separated by several hours in order to avoid decreased bioavailability and gastrointestinal intolerance (400 mg, 300 mg, and then 300 mg with each dose separated by 4 to 6 hours). Since phenytoin is metabolized hepatically, decreased doses may be needed in patients with liver disease. Because phenytoin follows dose-dependent pharmacokinetics, the half-life of phenytoin increases for a patient as the maintenance dose increases. Therefore, the time to steady-state phenytoin concentrations increases with dose. On average, at a phenytoin dose of 300 mg/day, it takes approximately 5 to 7 days to achieve steady state; at a dose of 400 mg/day, it takes approximately 10 to 14 days to achieve steady state; and at a dose of 500 mg/day, it takes approximately 21 to 28 days to achieve steady state. It should be noted that the injectable and capsule dosage forms of phenytoin are phenytoin sodium, and the labeled dosage amounts contain 92% of active phenytoin (300-mg phenytoin sodium capsules contain 276 mg $[300 \text{ mg} \times 0.92 = 276 \text{ mg}]$ of active phenytoin). Unbound phenytoin concentrations are useful in patients with hypoalbuminemia (e.g., liver disease, nephrotic syndrome, pregnancy, cystic fibrosis, burns, trauma, and malnourishment, as well as in the elderly), in patients in whom displacement with endogenous compounds is possible (e.g., hyperbilirubinemia, liver disease, or end-stage renal disease), and in patients receiving other drugs that may displace phenytoin from plasma protein-binding sights (e.g., valproic acid, aspirin therapy of more than 2 g/day, warfarin, and nonsteroidal antiinflammatory drugs with high albumin binding).⁵⁷

After steady state has occurred, phenytoin serum concentrations can be obtained as an aid to dosage adjustment. A simple, easy way to approximate new serum concentrations after a dosage adjustment with phenytoin is to temporarily assume linear pharmacokinetics and then add 15% to 33% for a dosage increase or subtract

15% to 33% for a dosage decrease to account for Michaelis-Menten kinetics. To avoid large disproportionate changes in phenytoin concentrations when using this empirical method, dosage adjustments should be limited to 50 to 100 mg/day. This technique is only intended to provide a rough approximation of the resulting phenytoin steady-state concentration after an appropriate dosage adjustment has been made.

For example, Ms. PP is a 35-year-old, 65-kg patient with grand mal seizures who is receiving phenytoin capsules 300 mg orally at bedtime. A steady-state concentration of 9.2 mcg/mL is measured. It is observed that her seizure frequency decreased by only approximately 15% and that she has had no adverse effects as a consequence of phenytoin treatment. Because of this, her phenytoin dose is increased to 400 mg orally at bedtime. The expected phenytoin steady-state concentration would be estimated using linear pharmacokinetics $[C_{\text{new}} = (D_{\text{new}}/D_{\text{old}})C_{\text{old}} = (400 \text{ mg}/300 \text{ mg})/(9.2 \text{ mcg/mL}) = 12.3 \text{ mcg/mL}]$ and then increased by 15% to 33% to account for nonlinear kinetics $[C_{\text{new}} = 1.15(12.3 \text{ mcg/mL}) = 14.1 \text{ mcg/mL}$ or $C_{\text{new}} = 1.33(12.3 \text{ mcg/mL}) = 16.4 \text{ mcg/mL}]$. Thus the patient would be expected to have a steady-state phenytoin concentration of approximately 14 to 16 mcg/mL as a consequence of the dosage increase. An alternative approach would be to use a graphic Bayesian method that allows an estimate of V_{max} and K_m from one steady-state phenytoin concentration and the prediction of new steady-state concentrations when doses are changed.⁵¹

Other methods used to individualize phenytoin doses involve rearrangements of the Michaelis-Menten equation $[DR = V_{\text{max}}C_{\text{ss}}/(K_m + C_{\text{ss}})]$, in which DR is the dosage rate at steady state so that two or more doses and C_{ss} values can be used to obtain graphic solutions for V_{max} and K_m . One rearrangement⁵² is $DR = -K_m(DR/C_{\text{ss}}) + V_{\text{max}}$. When DR is plotted on the y axis and DR/C_{ss} is plotted on the x axis of Cartesian graph paper, a straight line with a y intercept of V_{max} and slope equal to $-K_m$ is found (Fig. 5-13). To use this method, patients are prescribed an initial phenytoin dose, and C_{ss} is obtained. The phenytoin dose is then changed, and a second C_{ss} from the new dose is obtained. Each dose is divided by its respective C_{ss} to derive DR/C_{ss} values. The DR/C_{ss} and C_{ss} values are plotted on the graph to calculate V_{max} (y intercept) and K_m (minus slope). The steady-state Michaelis-Menten equation can be used to compute C_{ss} for a given DR or a DR for any C_{ss} .

Cyclosporine

Because of the large amount of variability in cyclosporine pharmacokinetics, even when concurrent disease states and conditions are identified, many clinicians believe that the use of standardized

initial cyclosporine doses for various situations is warranted. Indeed, most transplant centers use doses that are determined employing a locally derived cyclosporine dosage protocol. The original computations of these doses were based on the pharmacokinetic dosing methods described in preceding sections and subsequently modified based on clinical experience. In general, the expected cyclosporine steady-state concentration used to compute these doses depends on the type of transplanted tissue and the posttransplantation time line. Generally speaking, initial oral doses of 8 to 18 mg/kg per day or intravenous doses of 3 to 6 mg/kg per day (one-third the oral dose to account for approximately 30% oral bioavailability) are used and vary greatly from institution to institution. For obese individuals (more than 30% over ideal body weight), ideal body weight should be used to compute initial doses.

It is likely that doses computed using patient population characteristics will not always produce cyclosporine concentrations that are expected or desirable. Additionally, there is a very high amount of interday variation in cyclosporine concentrations. Because of pharmacokinetic variability, the narrow therapeutic index of cyclosporine, and the severity of cyclosporine adverse side effects, measurement of cyclosporine concentrations is mandatory for patients to ensure that therapeutic, nontoxic levels are present. When cyclosporine concentrations are measured in patients and a dosage change is necessary, clinicians should seek to use the simplest, most straightforward method available to determine a dose that will provide safe and effective treatment. In most cases, a simple dosage ratio can be used to change cyclosporine doses using steady-state concentrations and assuming that the drug follows linear pharmacokinetics:

$$D_{\text{new}} = D_{\text{old}} \frac{C_{\text{ss,new}}}{C_{\text{ss,old}}}$$

For example, LK is a 50-year-old, 75-kg, 5-ft 11-in male renal transplant recipient who is receiving oral cyclosporine 400 mg every 12 hours. The current steady-state blood cyclosporine concentration is 375 ng/mL. To compute a cyclosporine dose that will provide a steady-state concentration of 200 ng/mL, linear pharmacokinetic equations can be used. The new dose to attain the desired concentration should be proportional to the old dose that produced the measured concentration (total daily dose = 400 mg/dose \times 2 doses/day = 800 mg/day):

$$\begin{aligned} D_{\text{new}} &= D_{\text{old}} \frac{C_{\text{ss,new}}}{C_{\text{ss,old}}} = 800 \text{ mg/day} \frac{200 \text{ ng/mL}}{375 \text{ ng/mL}} \\ &= 427 \text{ mg/day, round to 400 mg/day} \end{aligned}$$

The new suggested dose would be 400 mg/day or 200 mg every 12 hours of cyclosporine capsules to be started at the next scheduled dosing time.

FIGURE 5-13. Relationship between dosage rate (DR) and steady-state serum concentrations (C_{ss}).

CLINICAL PHARMACODYNAMICS

16 Pharmacodynamics is the study of the relationship between the concentration of a drug and the response obtained in a patient. Originally, investigators examined the dose-response relationship of drugs in humans but found that the same dose of a drug usually resulted in different concentrations in individuals because of pharmacokinetic differences in clearance and volume of distribution. Examples of quantifiable pharmacodynamic measurements include changes in blood pressure during antihypertensive drug therapy, decreases in heart rate during β -blocker treatment, and alterations in prothrombin time or international normalized ratio during warfarin therapy.

For drugs that exhibit a direct and reversible effect, the following diagram describes what occurs at the level of the drug receptor:

According to this scheme, there is a drug receptor located within the target organ or tissue. When a drug molecule “finds” the receptor, it forms a complex that causes the pharmacologic response to occur. The drug and receptor are in dynamic equilibrium with the drug-receptor complex.

THE E_{MAX} AND SIGMOID E_{MAX} MODELS

The mathematical model that comes from the classic drug receptor theory shown previously is known as the E_{max} model:

$$E = \frac{E_{\text{max}} \times C}{EC_{50} + C}$$

where E is the pharmacologic effect elicited by the drug, E_{max} is the maximum effect the drug can cause, EC_{50} is the concentration causing one-half the maximum drug effect ($E_{\text{max}}/2$), and C is the concentration of drug at the receptor site. EC_{50} can be used as a measure of drug potency (a lower EC_{50} indicating a more potent drug), whereas E_{max} reflects the intrinsic efficacy of the drug (a higher E_{max} indicating greater efficacy). If pharmacologic effect is plotted versus concentration in the E_{max} equation, a hyperbola results with an asymptote equal to E_{max} (Fig. 5-14). At a concentration of zero, no measurable effect is present.

When dealing with human studies in which a drug is administered to a patient and pharmacologic effect is measured, it is very difficult to determine the concentration of drug at the receptor site. Because of this, serum concentrations (total or unbound) usually are used as the concentration parameter in the E_{max} equation. Therefore, the values of E_{max} and EC_{50} are much different than if the drug were added to an isolated tissue contained in a laboratory beaker.

The result is that a much more empirical approach is used to describe the relationship between concentration and effect in clinical pharmacology studies. After a pharmacodynamic experiment has been conducted, concentration–effect plots are generated. The shape of the concentration–effect curve is used to determine which pharmacodynamic model will be used to describe the data. Because of this, the pharmacodynamic models used in a clinical pharmacology study are deterministic in the same way that the shape of the serum-concentration-versus-time curve determines which pharmacokinetic model is used in clinical pharmacokinetic studies.

Sometimes a hyperbolic function does not describe the concentration–effect relationship at lower concentrations adequately.

FIGURE 5-14. The E_{max} model [$E = (E_{\text{max}} \times C)/(EC_{50} + C)$] has the shape of a hyperbola with an asymptote equal to E_{max} . EC_{50} is the concentration where effect = $E_{\text{max}}/2$.

When this is the case, the sigmoid E_{max} equation may be superior to the E_{max} model:

$$E = \frac{E_{\text{max}} \times C^n}{EC_{50}^n + C^n}$$

where n is an exponent that changes the shape of the concentration–effect curve. When $n > 1$, the concentration–effect curve is S- or sigmoid-shaped at lower serum concentrations. When $n < 1$, the concentration–effect curve has a steeper slope at lower concentrations (Fig. 5-15).

With both the E_{max} and sigmoid E_{max} models, the largest changes in drug effect occur at the lower end of the concentration scale. Small changes in low serum concentrations cause large changes in effect. As serum concentrations become larger, further increases in serum concentration result in smaller changes in effect. Using the E_{max} model as an example and setting $E_{\text{max}} = 100$ units and $EC_{50} = 20$ mg/L, doubling the serum concentration from 5 to 10 mg/L increases the effect from 20 to 33 units (a 67% increase), whereas doubling the serum concentration from 40 to 80 mg/L only increases the effect from 67 to 80 units (a 19% increase). This is an important concept for clinicians to remember when doses are being titrated in patients.

LINEAR MODELS

When serum concentrations obtained during a pharmacodynamic experiment are between 20% and 80% of E_{max} , the concentration–effect curve may appear to be linear (Fig. 5-16). This occurs often because lower drug concentrations may not be detectable with the analytic technique used to assay serum samples, and higher drug concentrations may be avoided to prevent toxic side effects. The equation used is that of a simple line: $E = S \times C + I$, where E is the drug effect, C is the drug concentration, S is the slope of the line, and I is the y intercept. In this situation, the value of S can be used as a measure of drug potency (the larger the value of S , the more potent the drug). The linear model can be derived from the E_{max} model. When EC_{50} is much greater than C , $E = (E_{\text{max}}/EC_{50})C = S \times C$, where $S = E_{\text{max}}/EC_{50}$.

The linear model allows a nonzero value for effect when the concentration equals zero. This may be a baseline value for the effect that is present without the drug, the result of measurement error when determining effect, or model misspecification. Also, this model does not allow the prediction of a maximum response.

Some investigators have used a log-linear model in pharmacodynamic experiments: $E = S \times (\log C) + I$, where the symbols have the

FIGURE 5-15. The sigmoid E_{max} model [$E = (E_{\text{max}} \times C^n)/(EC_{50}^n + C^n)$] has an S-shaped curve at lower concentrations. In this example, E_{max} and EC_{50} have the same values as in Fig. 5-14.

FIGURE 5-16. The linear model ($E = S \times C + I$) is often used as a pharmacodynamic model when the measured pharmacologic effect is 20% to 80% of E_{\max} . In this situation, the determination of E_{\max} and EC_{50} is not possible. To illustrate this, effect measurements from Fig. 5-14 between 20% and 80% of E_{\max} are graphed using the linear pharmacodynamic model.

same meaning as in the linear model. The advantages of this model are that the concentration scale is compressed on concentration–effect plots for experiments where wide concentration ranges were used, and the concentration values are transformed so that linear regression can be used to compute model parameters. The disadvantages are that the model cannot predict a maximum effect or an effect when the concentration equals zero. With the increased availability of nonlinear regression programs that can compute the parameters of nonlinear functions such as the E_{\max} model easily, use of the log-linear model has been discouraged.⁵³

BASILINE EFFECTS

At times, the effect measured during a pharmacodynamic study has a value before the drug is administered to the patient. In these cases, the drug changes the patient's baseline value. Examples of these types of measurements are heart rate and blood pressure. In addition, a given drug may increase or decrease the baseline value. Two basic techniques are used to incorporate baseline values into pharmacodynamic data. One way incorporates the baseline value into the pharmacodynamic model; the other way transforms the effect data to take baseline values into account.

Incorporation of the baseline value into the pharmacodynamic model involves the addition of a new term to the previous equations. E_0 is the symbol used to denote the baseline value of the effect that will be measured. The form that these equations takes depends on whether the drug increases or decreases the pharmacodynamic effect. When the drug increases the baseline value, E_0 is added to the equations:

$$E = E_0 + \frac{E_{\max} \times C}{EC_{50} + C}$$

$$E = E_0 + \frac{E_{\max} \times C^n}{EC_{50}^n + C^n}$$

$$E = S \times C + E_0$$

When E_0 is not known with any better certainty than any other effect measurement, it should be estimated as a model parameter similar to the way that one would estimate the values of E_{\max} , EC_{50} , S , or n .^{54,55} If the baseline effect is well known and has only a small amount of measurement error, it can be subtracted from the effect determined in the patient during the experiment and not estimated

as a model parameter. This approach can lead to better estimates of the remaining model parameters.⁵⁵ Using the linear model as an example, the equation used would be $E - E_0 = S \times C$.

If the drug decreases the baseline value, the drug effect is subtracted from E_0 in the pharmacodynamic models:

$$E = E_0 - \frac{E_{\max} \times C}{IC_{50} + C}$$

$$E = E_0 - \frac{E_{\max} \times C^n}{IC_{50}^n + C^n}$$

$$E = E_0 - S \times C$$

where E_{\max} represents the maximum reduction in effect caused by the drug, and IC_{50} is the concentration that produces a 50% inhibition of E_{\max} . These forms of the equations have been called the *inhibitory E_{\max}* and *inhibitory sigmoidal E_{\max}* equations, respectively. In this arrangement of the pharmacodynamic model, E_0 is a model parameter and can be estimated. If the baseline effect is well known and has little measurement error, the effect in the presence of the drug can be subtracted from the baseline effect and not estimated as a model parameter. Using the inhibitory E_{\max} model as an example, the formula would be $E_0 - E = (E_{\max} \times C)/(IC_{50} + C)$.

When using the inhibitory E_{\max} model, a special situation occurs if the baseline effect can be obliterated completely by the drug (e.g., decreased premature ventricular contractions during antiarrhythmic therapy). In this situation, $E_{\max} = E_0$, and the equation simplifies to a rearrangement known as the *fractional E_{\max} equation*:

$$E = E_0 \left(1 - \frac{C}{IC_{50} + C} \right)$$

This form of the model relates drug concentration to the fraction of the maximum effect.

An alternative approach to the pharmacodynamic modeling of drugs that alter baseline effects is to transform the effect data so that they represent a percentage increase or decrease from the baseline value.⁵⁵ For drugs that increase the effect, the following transformation equation would be used: percent effect_{*t*} = [(treatment_{*t*} – baseline)/baseline] × 100. For drugs that decrease the effect, the following formula would be applied to the data: percent inhibition_{*t*} = [(baseline – treatment_{*t*})/baseline] × 100. The subscript indicates the treatment, effect, or inhibition that occurred at time *t* during the experiment. If the study included a placebo control phase, baseline measurements made at the same time as treatment measurements (i.e., heart rate determined 2 hours after placebo and 2 hours after drug treatment) could be used in the appropriate transformation equation.⁵⁵ The appropriate model (excluding E_0) then would be used.

HYSTERESIS

Concentration–effect curves do not always follow the same pattern when serum concentrations increase as they do when serum concentrations decrease. In this situation, the concentration–effect curves form a loop that is known as *hysteresis*. With some drugs the effect is greater when serum concentrations are increasing, whereas with other drugs the effect is greater while serum concentrations are decreasing (Fig. 5-17). When individual concentration–effect pairs are joined in time sequence, this results in clockwise and counter-clockwise hysteresis loops.

Clockwise hysteresis loops usually are caused by the development of tolerance to the drug. In this situation, the longer the patient is exposed to the drug, the smaller is the pharmacologic effect for a given concentration. Therefore, after an extravascular or short-term infusion dose of the drug, the effect is smaller when serum concentrations are decreasing compared with the time when serum concentrations are increasing during the infusion or absorption phase.

FIGURE 5-17. Hysteresis occurs when effect measurements are different at the same concentration. This is commonly seen after short-term intravenous infusions or extravascular doses where concentrations increase and subsequently decrease. Counterclockwise hysteresis loops are found when concentration–effect points are joined as time increases (*shown by arrows*) and effect is larger at the same concentration but at a later time. Clockwise hysteresis loops are similar, but the concentration–effect points are joined in clockwise order and the effect is smaller at a later time.

Accumulation of a drug metabolite that acts as an antagonist also can cause clockwise hysteresis.

Counterclockwise hysteresis loops can be caused by the accumulation of an active metabolite, sensitization to the drug, or delay in time in equilibration between serum concentration and concentration of drug at the site of action. Combined pharmacokinetic–pharmacodynamic models have been devised that allow equilibration lag times to be taken into account.

CONCLUSIONS

The availability of inexpensive, rapidly achievable serum drug concentrations has changed the way clinicians monitor drug therapy in patients. The therapeutic range for many drugs is known, and it is likely that more drugs will be monitored using serum concentrations in the future. Clinicians need to remember that the therapeutic range is merely an average guideline and to take into account interindividual pharmacodynamic variability when treating patients. Individual patients may respond to smaller concentrations or require concentrations that are much greater to obtain a therapeutic effect. Conversely, patients may show toxic effects at concentrations within or below the therapeutic range. Serum concentrations should never replace clinical judgment.

Three kinetic constants determine the dosage requirements of patients. Clearance determines the maintenance dose ($MD = CLC_{ss}$), volume of distribution determines the loading dose ($LD = V_D C_{ss}$), and half-life determines the time to steady state and the dosage interval. Several methods are available to compute these parameters.

Methods available to individualize drug therapy range from clinical pharmacokinetic techniques using simple mathematical relationships that hold for all drugs that obey linear pharmacokinetics to very complex computer programs that are specific to one drug.

KEY CONCEPTS

- 1 Genetic variations contribute to interpatient differences in drug response.
- 2 Genetic variations occur for drug metabolism, drug transporter, and drug target proteins as well as for disease-associated genes.
- 3 Genetic polymorphisms may be linked to drug efficacy and toxicity.
- 4 Pharmacogenetics is the study of the impact of genetic polymorphisms on drug response.
- 5 The goals of pharmacogenetics are to optimize drug efficacy and limit drug toxicity based on an individual's DNA.
- 6 Single nucleotide polymorphisms are the most common variations in the human genome.
- 7 Gene therapy aims to cure disease caused by genetic defects by changing gene expression.
- 8 Inadequate gene delivery and expression and serious adverse effects are obstacles to successful gene therapy.

Individuals vary greatly in their response to drug therapy, and predicting how effective or safe a medication will be for a particular patient often is difficult. For example, when treating a patient with hypertension, several agents or a combination of agents may be attempted before adequate blood pressure control with acceptable tolerability is achieved. A number of nongenetic factors influence drug response, including pharmacokinetics, age, and concomitant drug use. However, considering these factors alone often is insufficient for predicting the likelihood of drug efficacy or safety for a given patient. For instance, identical antihypertensive therapy in two patients with similar demographic characteristics, medical histories, and concomitant drug therapy may produce inadequate blood pressure reduction in one patient and symptomatic hypotension in the other.

1 2 The observed interpatient variability in drug response may result largely from genetically determined differences in drug metabolism, drug distribution, and drug target proteins. The influence of heredity on drug response was demonstrated as early as 1956 with the discovery that an inherited deficiency of glucose-6-phosphate dehydrogenase was responsible for hemolytic reactions to the antimalarial drug primaquine.¹ Variations in genes encoding cytochrome P450

(CYP450) and other drug-metabolizing enzymes now are well-recognized causes of interindividual differences in plasma concentrations of certain drugs. These variations may have serious implications for drugs with a narrow therapeutic index, such as warfarin, phenytoin, and mercaptopurine.²⁻⁴ More recent interest focuses on associations between drug response and variations in genes for drug transporters such as P-glycoprotein and drug targets such as receptors, enzymes, and proteins involved in intracellular signal transduction. Genetic variations of drug-metabolizing enzymes and drug transporter proteins may influence pharmacokinetic drug properties, thus altering drug disposition. Drug target genes may alter pharmacodynamic mechanisms by affecting sensitivity to a drug at its target site. Finally, genes associated with disease severity have been correlated with drug efficacy despite having no direct effect on pharmacokinetic or pharmacodynamic mechanisms.

PHARMACOGENETICS: A DEFINITION

3 4 Pharmacogenetics involves the search for genetic variations that lead to interindividual differences in drug response. The term *pharmacogenetics* often is used interchangeably with the term *pharmacogenomics*. However, *pharmacogenetics* generally refers to monogenetic variants that affect drug response, whereas *pharmacogenomics* refers to the entire spectrum of genes that interact to determine drug efficacy and safety. For example, a pharmacogenetic study would examine the influence of the β_1 -adrenergic receptor gene on blood pressure response to carvedilol. A pharmacogenomic study might examine the interaction between CYP2D6 and β_1 -, β_2 -, and α_1 -adrenergic receptor genes on carvedilol effects. To date, most studies of gene-drug responses are pharmacogenetic in nature. However, given that multiple proteins are involved in determining the ultimate response to most drugs, many investigators are taking a more pharmacogenomic approach to elucidating genetic contributions to drug response. For simplicity, this chapter treats pharmacogenetics and pharmacogenomics as synonymous.

5 The goals of pharmacogenetics are to optimize drug therapy and limit drug toxicity based on an individual's genetic profile. Thus, pharmacogenetics aims to use genetic information to choose a drug, drug dose, and treatment duration that will have the greatest likelihood of achieving therapeutic outcomes with the least potential for harm in a given patient. The results of pharmacogenetic research ultimately will provide opportunities for clinicians to use genetic tests to predict individual responses to drug treatments, specifically to select medications for patients based on DNA profiles and to develop novel strategies for disease treatment and prevention based on an understanding of genetic control of cellular functions.

Although there has been considerable interest in genetic influences of drug response in recent years, pharmacogenetics is not a new area. In 1957, shortly after the discovery of a genetic predisposition toward primaquine-induced toxicity, Arno Motulsky pro-

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

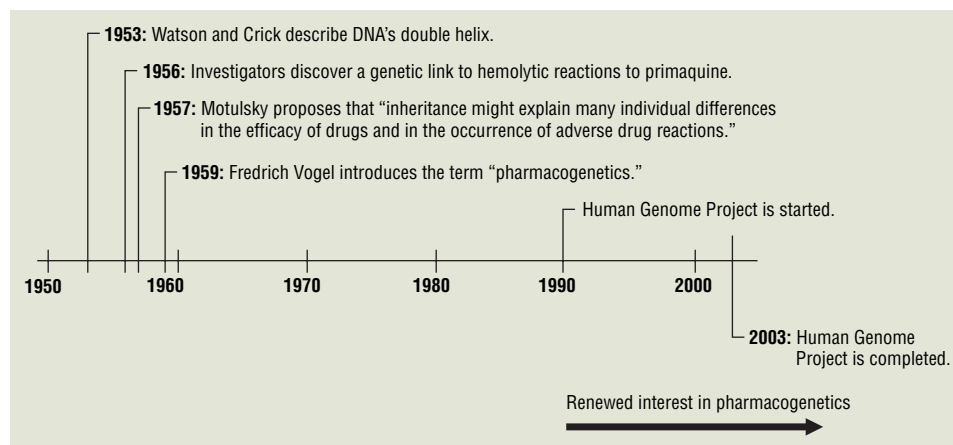

FIGURE 6-1. Time line of genomic discoveries.

posed that inheritance might underlie much of the disparity in drug response among individuals (Fig. 6–1).⁵ Two years later, Fredrich Vogel introduced the term *pharmacogenetics*.⁶ With the advent of the Human Genome Project in 1990 came a resurgence of interest in determining genetic contributions to drug response.

HUMAN GENOME PROJECT

In 1988, Congress commissioned the Department of Energy and the National Institutes of Health to plan and implement the Human Genome Project. The goal of the Human Genome Project was to determine the entire sequence of the human genome by 2005. Mapping of the human genome, which officially began in 1990, has led to a better understanding of genetic contributions to disease susceptibility. To encourage research and ultimately maximize the societal benefits of the Human Genome Project, sequence data from the Human Genome Project have been deposited into a freely accessible database run by the National Center for Biotechnology Information (www.ncbi.nlm.nih.gov). As a consequence of these shared data, research efforts in the 1990s accelerated the discovery of genetic variations affecting treatment response and the development of new treatments and preventive strategies for human disease.

Largely because of advances in biotechnology, the initial working draft of the human genome sequence was completed in 2000, well ahead of schedule.⁷ In April 2003, 50 years after James Watson and Francis Crick described the double-helix structure of DNA and more than 2 years ahead of schedule, researchers announced the completion of the Human Genome Project.⁸ The final version contains 99% of the gene-containing sequence, with 99.9% accuracy.

Following completion of the Human Genome Project, the National Human Genome Research Institute announced its vision for the future of genomic research with the goal of improving human health and well-being.⁹ One of the challenges set forth to meet this goal is to develop genome-based approaches to predict drug response. This challenge involves the accurate, unbiased determination of genetic variants linked to drug response, advanced technology to efficiently determine genotype, and appropriate integration of genetic testing into the therapeutic decision process. The National Human Genome Research Institute also challenges investigators to develop new, gene-based approaches to disease management, which will require a thorough understanding of genetic determinants of disease susceptibility and progression.

GENETIC CONCEPTS

The human genome contains approximately three billion nucleotide bases, which code for approximately 20,000 to 25,000 protein-coding

genes. Two purine nucleotide bases, adenine (A) and guanine (G), and two pyrimidine nucleotide bases, cytosine (C) and thymine (T), are present in DNA. Purines and pyrimidines always pair together as A-T and C-G in the two strands that make up the DNA structure. Most nucleotide base pairs are identical from person to person, with only 0.1% contributing to individual differences.

According to the central dogma, when one strand of DNA is transcribed into RNA and translated to make proteins, three consecutive nucleotides form a *codon*. Each codon specifies an amino acid or amino acid chain termination. For example, the nucleotide sequence, or codon, GGA specifies the amino acid glycine. The genetic code has substantial redundancy, in that two or more codons code for the same amino acid. For example, GGC, GGG, and GGT also code for glycine. Amino acids are the basic constituents of proteins, which mediate all cellular functions. Only 20 different amino acids, in various arrangements, form the basic units of all the proteins in the human body.

A *gene* is a series of codons that specifies a particular protein. Genes contain several regions: *exons* that encode for the final protein, *introns* that consist of intervening noncoding regions, and *regulatory regions* that control gene transcription. In most cases, an individual carries two alleles, one from each parent, at each gene locus. An *allele* is defined as the sequence of nucleic acid bases at a given gene chromosomal locus. Two identical alleles make up a *homozygous* genotype. Two different alleles make up a *heterozygous* genotype. The *phenotype* refers to the outward expression of the genotype.

TYPES OF GENETIC VARIATIONS

Genetic variations occur as either rare defects or polymorphisms. *Polymorphisms* are defined as variations that occur at a frequency of at least 1% in the human population. For example, the genes encoding the CYP450 enzymes CYP2A6, CYP2C9, CYP2C19, CYP2D6, and CYP3A4 are polymorphic, with functional mutations of >1% occurring in different ethnic groups. In contrast, rare mutations occur in <1% of the population and cause inherited diseases such as cystic fibrosis, hemophilia, and Huntington's disease. Common diseases, such as essential hypertension and diabetes mellitus, are polygenic in that multiple genetic polymorphisms likely interact with environmental factors to contribute to the disease susceptibility.

6 Single nucleotide polymorphisms (SNPs; pronounced "snips") are the most common genetic variations in human DNA, occurring approximately once in every 100 to 300 base pairs. To date more than four million SNPs have been mapped in the human genome. SNPs occur when one nucleotide base pair replaces another (Fig. 6–2). Thus, SNPs are single-base differences that exist between individuals. Nucleotide substitution results in two possible alleles. One allele, typically either the most commonly occurring

A. "Wild-type" allele

Nucleotide	... GCA	CCC	AAT	<u>GGA</u>	AGC	CAT	GCG ...
Amino acid	Ala	Pro	Asn	Gly	Ser	His	Ala

FIGURE 6-2. Nucleotide sequence of the β_2 -adrenergic receptor gene from codons 13 through 19. A. Nucleotide sequence of the wild-type allele with adenine (A) at nucleotide position 46 (underlined) located in codon 16 of the β_2 -adrenergic receptor gene. The AGA codon designates the amino acid arginine (Arg), with an average frequency of 39% in the human population. B. Nucleotide sequence of the variant allele with guanine (G) at nucleotide position 46 (underlined), located in codon 16. The GGA codon designates the amino acid glycine (Gly), which occurs at an average frequency of 61%. Although the Arg16 polymorphism occurs less commonly than the Gly16 polymorphism, it is referred to as the wild type because it was identified first.

allele or the allele originally sequenced, is considered the *wild type*; the alternative allele is considered the *variant allele*.

A SNP may change the codon resulting in amino acid substitution, which may or may not alter the amount or function of the encoded protein. For example, in Fig. 6–2, guanine (G) is substituted for adenine (A) at nucleotide 46 in the β_2 -adrenergic receptor gene. This results in the substitution of glycine for arginine at amino acid position (codon) 16 and alterations in receptor downregulation upon prolonged exposure to β_2 -receptor agonists.¹⁰ SNPs such as this that result in amino acid substitution are referred to as *nonsynonymous*. SNPs that do not result in amino acid substitution are called *synonymous*. Referring to a previous example of redundancy in the genetic code, replacement of adenine (A) with cytosine (C) in the codon AGA is an example of a synonymous SNP because the resulting amino acid still is glycine. Synonymous SNPs usually are abbreviated based on the nucleotides involved and the nucleotide base position. For example, A1166C or A1166→C indicates that cytosine is substituted for adenine at nucleotide position 1166 of a given gene region. Nonsynonymous SNPs usually are designated by the amino acids and codon involved. For example, Arg16Gly or Arg16→Gly indicates that glycine is substituted for arginine at codon 16. If a SNP changes the amount or function of a protein that contributes to drug response, it may alter a patient's sensitivity to a drug or predispose the patient to adverse reactions to drug therapy. Other examples of genetic variants include the following:

- *Insertion–deletion polymorphisms*, in which a nucleotide or nucleotide sequence either is added to or deleted from a DNA sequence
- *Tandem repeats*, in which a nucleotide sequence repeats in tandem (e.g., if “AG” is the nucleotide repeat unit, “AGAGAGAGAG” is a five-tandem repeat)
- *Frameshift mutation*, in which there is an insertion/deletion polymorphism and the number of nucleotides added or lost is not a multiple of three, resulting in disruption of the gene's reading frame
- *Defective splicing*, in which an internal polypeptide segment is abnormally removed, and the ends of the remaining polypeptide chain are joined

- *Aberrant splice site*, in which processing of the protein occurs at an alternate site
- *Premature stop codon polymorphisms*, in which there is premature termination of the polypeptide chain by a stop codon (specific sequence of three nucleotides that do not code for an amino acid but rather specify polypeptide chain termination)

SNPs may occur in exon, intron, or regulatory regions of a gene. Those occurring in exon regions may alter the function of a protein, whereas those in regulatory regions may alter the amount of protein that is produced. Variations in the intron region often are silent unless they affect intron splicing. Multiple SNPs may be in *linkage disequilibrium* with each other, meaning that two or more SNPs are inherited together more frequently than expected based on chance alone. For example, if two SNPs, A46T and G72C, are possible in a given gene and if a T at position 46 always occurs with a C at position 72, the two SNPs are said to be in *complete linkage disequilibrium*. A set of SNPs that are inherited together is called a *haplotype*. For more detailed information about genetic concepts, refer to the recommended genetics textbook.¹¹

Most common diseases are polygenic in nature. For example, genes for numerous proteins involved in the renin–angiotensin system, sympathetic nervous system, and renal sodium transport have been associated with the risk for essential hypertension.¹² Environmental factors are well-known risk factors for diseases such as hypertension and often interact with genetic factors to influence disease susceptibility and progression. Given the complex pathophysiology of most common diseases, genes linked to disease susceptibility are not discussed in this chapter. Rather, this chapter focuses on genetic variations linked to responses to pharmacologic agents.

POLYMORPHISMS IN GENES FOR DRUG-METABOLIZING ENZYMES

3 Polymorphisms in the drug-metabolizing enzymes represent the first recognized and the most documented examples of genetic variants with consequences in drug response and toxicity. The major phase I enzymes are the CYP450 superfamily of isoenzymes. *N*-acetyltransferase, uridine diphosphate glucuronosyltransferase (UGT), and glutathione *S*-transferase are examples of phase II metabolizing enzymes that exhibit genetic polymorphisms. Thiopurine *S*-methyltransferase (TPMT) and dihydropyrimidine dehydrogenase (DPD) are examples of nucleotide base-metabolizing enzymes. Table 6–1 lists selected examples of polymorphic metabolizing enzymes, corresponding drug substrates, and consequences of altered enzyme function as a result of gene variation.

CYTOCHROME P450 ENZYMES

Currently, 57 different CYP450 isoenzymes have been documented to be present in humans, with 42 involved in the metabolism of exogenous xenobiotics and endogenous substances such as steroids and prostaglandins.¹² Fifteen of these isoenzymes are known to be involved in the metabolism of drugs, but significant interindividual variabilities in enzyme activity exist as a result of induction, inhibition, and genetic inheritance. Functional genetic polymorphism has been discovered for CYP2A6, CYP2C9, CYP2C19, CYP2D6,¹³ and, more recently, CYP3A4/5.^{14,15} A polymorphism in the regulatory region of the gene encoding for CYP1A2 has been identified,¹⁶ but its functional importance remains to be determined.

CYP2D6

Polymorphisms in the *CYP2D6* gene are the best characterized of the CYP450 variants. At least 48 gene variants and 53 alleles in the

TABLE 6-1 Selected Examples of Genetic Polymorphisms in Drug-Metabolizing Enzymes and Response to Drug Therapy

Genetic Variants/Genes	Drug	Drug Effect Associated with Polymorphism
<i>CYP2D6*4</i> , <i>CYP2D6*5</i>	Perhexiline Codeine Tramadol	Neuropathy ¹⁸ Significant reduction in analgesic effect ^{22,23}
<i>CYP2D6*2</i> (<i>n</i> > 1)	Tricyclic antidepressants (e.g., desipramine, nortriptyline)	Inadequate antidepressant response ^{30,31}
<i>CYP2D6*10</i>	Antipsychotics (e.g., haloperidol)	Elevated plasma concentrations and exaggerated responses ³⁴
<i>CYP2C9*2</i> , <i>CYP2C9*3</i>	Warfarin	Hemorrhage ²
<i>CYP2C9</i> , <i>CYP2C19</i>	Phenytoin	Phenytoin toxicity ³
<i>CYP2C19</i>	Omeprazole	Improved cure rates for <i>Helicobacter pylori</i> ⁴²
Glutathione-S-transferase	Primaquine	Hemolytic reactions ¹
Thiopurine methyltransferase	Mercaptopurine	Bone marrow depression ⁴
<i>N</i> -Acetyltransferase slow acetylator	Isoniazid	More prone to peripheral neuropathy ¹⁰⁵
	Procainamide	More prone to development of systemic lupus erythematosus-like syndrome ^{106,107}
	Hydralazine	Increased hematologic and gastrointestinal adverse reactions ¹⁰⁸
	Sulfonamides	Increased severity of diarrhea and neutropenia in carrier of (TA) ⁷ TAA allele ⁶²
Uridine diphosphate glucuronosyltransferase	Irinotecan	

CYP2D6 gene have been identified.¹⁷ Nevertheless, the *CYP2D6* extensive-metabolizer (EM) and poor-metabolizer (PM) phenotypes (outward expression of genotypes) can be predicted with up to 99% confidence with six genotypic variants. *CYP2D6*1* is considered the wild-type variant and exhibits normal enzyme activity. *CYP2D6*2* has the same activity as *CYP2D6*1* but is capable of duplication or amplification. Both variants are present in EMs. The *CYP2D6*4* (defective splicing) and *CYP2D6*5* (gene deletion) variants are predominantly found in white PMs (5% to 10% of the Caucasian population)¹⁷ and result in an inactive enzyme and an absence of enzyme, respectively. The predominant variants in people of Asian and African heritage are *CYP2D6*10* (Pro34Ser) and *CYP2D6*17* (Arg296Cys), respectively. Both result in a single amino acid substitution and consequent reduction in enzyme activity.

Poor *CYP2D6* metabolizers carry two defective alleles, such as *CYP2D6*3*, *CYP2D6*4* (more common), *CYP2D6*5*, and *CYP2D6*6*, resulting in a total absence of active enzyme and an impaired ability to metabolize *CYP2D6*-dependent substrates. Examples of *CYP2D6* substrates include neuroleptic medications, antidepressants such as tricyclic antidepressants and mianserin, antiarrhythmic drugs such as propafenone, and β -adrenergic antagonists such as metoprolol (see Table 6-1). Depending on the importance of the affected *CYP2D6* pathway to overall drug metabolism and the drug's therapeutic index, clinically significant side effects may occur in PMs as a result of elevated parent drug concentrations. For example, compared with EMs, PMs develop neuropathy after treatment with the antianginal agent perhexiline¹⁸ and have experienced more adverse effects with propafenone¹⁹ and neuroleptic agents such as perphenazine.^{20,21}

The therapeutic implication of *CYP2D6* polymorphism is different if the substrate in question is a prodrug. In this case, PMs would not be able to convert the drug into the therapeutically active metabolite. Two examples of prodrugs dependent on *CYP2D6*-mediated conversion to active forms are codeine and tramadol. Codeine and tramadol are converted by *CYP2D6* to morphine and *O*-desmethyltramadol, respectively; thus, poor *CYP2D6* metabolizers experience little or no analgesic relief after taking these drugs.^{22,23} Another example is *CYP2D6*-catalyzed conversion of tamoxifen to the more potent antiestrogen metabolite 4-hydroxytamoxifen.²⁴

Although PMs are at a disadvantage from the standpoint of drug toxicity for most *CYP2D6* substrates and lack of efficacy for *CYP2D6* prodrugs, data suggest that they may be "protected" from abusing opiates such as codeine, oxycodone, and hydrocodone. This idea is primarily based on the observation that no PMs were found among opiate-dependent subjects, which likely reflects their inability to convert these drugs of abuse into their respective "pharmacologically active" moieties.²⁵ Given the reduced potential for opiate

abuse among *CYP2D6* PMs, investigators have used daily doses of fluoxetine 20 mg, a *CYP2D6* inhibitor, as adjunctive therapy in the management of opiate abuse to "metabolically convert" drug abusers who are EMs to PMs.²⁶

The potential and magnitude of drug interactions involving competitive inhibition of *CYP2D6* are much greater in EMs versus PMs, who have either deficient or absent enzyme activity.^{27,28} For example, Hamelin et al.²⁹ showed that hemodynamic responses to metoprolol (a *CYP2D6* substrate) were pronounced and prolonged during concomitant diphenhydramine administration in EMs but not in PMs. Thus, potent *CYP2D6* inhibitors may reduce the metabolic capacity of EMs significantly so that EMs appear phenotypically as PMs.

Patients who are EMs have a wide range of *CYP2D6* activity, with ultrarapid metabolizers (UMs) on one end of the spectrum and subjects with diminished activity on the other end. Both have clinical implications in terms of dosage adjustment for *CYP2D6* substrates. UMs carry a duplicated or amplified mutant allele, resulting in two or multiple copies of the functional *CYP2D6*1* or *CYP2D6*2* allele, and therefore show very high *CYP2D6* activity. Nontherapeutic plasma concentrations of nortriptyline, a *CYP2D6* substrate, were observed in a UM given normal doses of the drug.³⁰ The *CYP2D6* enzyme converts nortriptyline to 10-hydroxynortriptyline, and one study demonstrated a directly proportional relationship between the number of functional *CYP2D6* genes and the concentration of 10-hydroxynortriptyline after nortriptyline administration.³¹ A patient with three copies of *CYP2D6*2* required nortriptyline doses threefold to fivefold higher than normally recommended to achieve therapeutic plasma concentrations (50 to 150 mcg/mL).^{30,32} In the same report, another patient with duplicated *CYP2D6*2* required twice the usual recommended daily dose (300 mg versus 25 to 150 mg) to achieve adequate therapeutic response.³² On the other hand, UMs administered the usual therapeutic dose of codeine might exhibit symptoms of narcotic overdose associated with high morphine concentration. The UM genotype also has been reported to affect the potential for drug interaction with paroxetine, a *CYP2D6* substrate as well as a potent *CYP2D6* inhibitor.³³

The high prevalence of *CYP2D6*10* (associated with lower enzyme activity) in the Asian population provides a biologic and molecular explanation for the higher drug concentrations and/or lower dosage requirements of neuroleptic medications and mianserin in people of Asian heritage.^{34,35} The widespread presence of the *CYP2D6*17* variant among people of African heritage suggests that native African populations metabolize *CYP2D6* substrates at a slower rate than do other ethnic or racial groups.^{36,37} However, no current genotype- and phenotype-based data document the need for prescribing lower

doses of psychotropics and other CYP2D6 substrates in native African populations.

In addition to the therapeutic implications of genetic polymorphisms, one study showed that the CYP2D6 polymorphism has an economic impact.³⁸ The annual cost of treating UMs and PMs (carriers of two nonfunctional CYP2D6 alleles) was \$4,000 to \$6,000 higher than the cost of treating EMs or intermediate metabolizers (carriers of one nonfunctional allele and one allele associated with diminished activity). The cost of genotyping can be considerably less than that incurred in a patient with a serious adverse drug reaction. Brockmoller et al.³⁹ suggested how CYP2D6 genotyping can be used to achieve higher therapeutic success with the CYP2D6 substrate haloperidol. Along these lines, the Food and Drug Administration (FDA) approved the AmpliChip CYP450 Test (Roche Diagnostics) for analyzing 27 CYP2D6 alleles in addition to the *CYP2C19**1, *2, and *3 alleles (discussed below) to assist clinicians in individualizing therapy with drugs metabolized through the CYP2D6 and CYP2C19 pathways.

CYP2C19

The principal defective alleles for the CYP2C19 genetic polymorphism are *CYP2C19**2 (aberrant splice site) and *CYP2C19**3 (premature stop codon), which result in inactive CYP2C19 enzymes and the PM phenotype. Clinical implication of the CYP2C19 polymorphism has not been examined as extensively as that of the CYP2D6 polymorphism. However, PMs for the CYP2C19 polymorphism showed a more than 12-fold increase in the area under the curve (AUC) of the CYP2C19 substrate omeprazole compared with EMs.⁴⁰ In a separate study, the steady-state AUC of omeprazole and other CYP2C19 substrate proton pump inhibitors was five-fold higher in PMs versus EMs.⁴¹

The presence of a defective CYP2C19 allele has been associated with improved *Helicobacter pylori* cure rates after dual (omeprazole and amoxicillin)⁴² or triple therapy (omeprazole, amoxicillin, and clarithromycin) with omeprazole⁴³ as well as with lansoprazole.⁴⁴ This difference likely reflects the higher achievable intragastric pH in the PM group.⁴⁵ The cure rate achieved with dual therapy was 100% in PMs compared with 60% and 29% in heterozygous and homozygous EMs, respectively.⁴² In two studies, EMs had *H. pylori* eradication rates of 41% with dual therapy and 74% to 83% with triple therapy.^{43,44} In contrast, both dual- and triple-therapy regimens produced 100% cure rates in all 15 PMs included in the same studies. Interestingly, EMs who did not respond to initial triple therapy (lansoprazole, clarithromycin, and amoxicillin) and were retreated with high-dose lansoprazole (30 mg four times daily) and amoxicillin achieved 97% *H. pylori* eradication.⁴⁶

Similar to the CYP2D6 polymorphism, people of Asian heritage also metabolize most CYP2C19 substrates at a slower rate than do white people.⁴⁷ This reflects the higher prevalence of both PMs (13% to 20% versus 2% to 6% in white people) and heterozygotes for the defective *CYP2C19* allele in Asians.⁴⁸ This genotypic difference may explain the practice of prescribing lower diazepam dosages for patients of Chinese heritage.⁴⁹

CYP2C9

Warfarin, phenytoin, and tolbutamide are examples of drugs with a narrow therapeutic index that are metabolized by CYP2C9. Warfarin is a racemic mixture, and the *S*-isomer, which possesses about three times the anticoagulant effects of the *R*-isomer, is metabolized by CYP2C9. *CYP2C9**2 and *CYP2C9**3 are the two most common CYP2C9 variants. Both exhibit single amino acid substitutions at positions critical for enzyme activity.⁵⁰ This could have clinically important consequences in warfarin-treated patients. For example, a 90% reduction in *S*-warfarin clearance was reported in *CYP2C9**3

homozygotes compared with subjects homozygous for the wild-type allele.⁵¹ In another study, an overrepresentation of *CYP2C9* variant alleles was observed in 81% of patients requiring low-dose warfarin therapy (≤ 1.5 mg/day).² The low-dose group was reported to have more difficulty with warfarin induction, requiring longer hospital stays to stabilize the warfarin regimen and experiencing a higher incidence of bleeding complications. In addition, a profound therapeutic response to usual doses of warfarin was observed in a patient homozygous for the *CYP2C9**3 allele, necessitating dose reduction to 0.5 mg/day.⁵²

CYP2A6

A polymorphism has been characterized for CYP2A6, with identification of several variants—*CYP2A6**1 (wild type), *CYP2A6**2 (single amino acid substitution), *CYP2A6**3 (gene conversion)—and three gene-deletion alleles—*CYP2A6**4A, *CYP2A6**4B, and *CYP2A6**4D.⁵³ Deletion of the *CYP2A6* gene is very common in Asian patients,^{53,54} which likely accounts for the dramatic difference in the frequency of PMs in Asian (20%) versus European and white populations ($\leq 1\%$). Nicotine is metabolized by CYP2A6, and the clinical relevance of the CYP2A6 polymorphism lies in management of tobacco abuse.⁵⁵ Investigators reported that nonsmokers were more likely to carry the defective *CYP2A6* allele than were smokers. Smokers who had the defective *CYP2A6* allele smoked fewer cigarettes and were more likely to quit.⁵⁵ The inability to metabolize nicotine, secondary to the presence of a defective *CYP2A6* allele, likely leads to enhanced nicotine tolerance and increased adverse effects from nicotine. Based on these observations, CYP2A6 inhibition may have a role in the management of tobacco dependency.⁵⁶

CYP3A4/5

Within the CYP3A subfamily, at least three isoenzymes, namely, CYP3A4, CYP3A5, and CYP3A7, have been characterized. Despite as much as 40-fold interindividual variability in its expression, functional CYP3A4 is expressed in most adults, with intestinal expression playing a significant role in the first-pass metabolism of numerous drugs. CYP3A4 variants with amino acid substitutions in exons 7 and 12 have been associated with altered catalytic activity for the CYP3A4 substrate nifedipine.¹⁴ The clinical importance of this finding needs further elucidation and confirmation.

CYP3A5 is reported to be polymorphic in 60% of African Americans and 33% of white people. In contrast to individuals with the *CYP3A5**1 allele, subjects with variant alleles such as *CYP3A5**3 (aberrant splice site) in intron 3 have no functional CYP3A5 enzyme.¹⁵ With overlapping substrate specificities, whether there are clinically used drugs that are substrates for CYP3A5 but not CYP3A4 and vice versa is unknown. Although variability exists between dose-adjusted concentration and CYP3A5 genotypes, studies have shown a correlation between pharmacokinetics of tacrolimus and *CYP3A5* genetic constitution.^{57,58}

PHASE II AND NUCLEOTIDE-BASE METABOLIZING ENZYMES

The clinical relevance of genetic polymorphisms in TPMT, DPD, and UGT enzymes has been demonstrated in the treatment of cancer.^{4,59,60} The *TPMT* gene has three mutant alleles: *TPMT**3A (the most common), *TPMT**2, and *TPMT**3C. Patients who are homozygous or heterozygous for the *TPMT* mutant alleles are at higher risk for developing serious anemias during mercaptopurine treatment.⁴ DPD mediates the metabolism of 5-fluorouracil, and patients with a defective allele of the *DPD* gene cannot metabolize 5-fluorouracil and thus may experience enhanced drug-related neurotoxicity.⁵⁹ The camptothecin derivative irinotecan (CPT-11)

is activated by carboxylesterase to SN-38, which is a potent topoisomerase I inhibitor. SN-38 is inactivated by glucuronidation via the polymorphic UGT1A1 enzyme, which may play a role in CPT-11–related toxicity. A polymorphism in the promoter region of the *UGT1A1* gene results in the $(TA)^7TAA$ allele, which possesses lower enzyme activity than the wild-type $(TA)^6TAA$ allele. A patient homozygous for the $(TA)^7TAA$ allele had impaired SN-38 glucuronidation.⁶⁰ Abnormally high SN-38 concentrations have been associated with neutropenia and severe diarrhea.⁶¹ Diarrhea likely results from increased SN-38 excretion into the gut lumen, predisposing patients with the $(TA)^7TAA$ allele to developing diarrhea with usual CPT-11 doses. This observation was confirmed in a prospective clinical trial that demonstrated more severe diarrhea and neutropenia in irinotecan-treated patients who are homozygous or heterozygous carriers of the $(TA)^7TAA$ allele.⁶² The FDA approved the Invader UGT1A1 Molecular Assay (Third Wave Technologies) to genotype for *UGT1A1* alleles and revised the labeling for irinotecan to recommend therapy adjustment for individuals who are homozygous for the $(TA)^7TAA$ allele.

POLYMORPHISMS IN DRUG TRANSPORTER GENES

Certain membrane-spanning proteins facilitate drug transport across the gastrointestinal tract, drug excretion into the bile and urine, and drug distribution across the blood–brain barrier. Genetic variations for drug transport proteins may affect the distribution of drugs that are substrates for these proteins and alter drug concentrations at their therapeutic sites of action. P-glycoprotein is one of the most recognized of the drug transport proteins that exhibit genetic polymorphism. P-glycoprotein is an energy-dependent transmembrane efflux pump encoded by the *ABCB1* gene (also known as the multidrug resistance-1 [MDR1] gene), which is a member of the ATP-binding cassette (ABC) transporter superfamily. P-glycoprotein was first recognized for its ability to actively export anticancer agents from cancer cells and promote multidrug resistance to cancer chemotherapy. P-glycoprotein later was discovered to be widely distributed on normal cell types, including intestinal enterocytes, hepatocytes, renal proximal tubule cells, and endothelial cells lining the blood–brain barrier. At these locations, P-glycoprotein serves a protective role by transporting toxic substances or metabolites out of cells. P-glycoprotein affects the distribution of some nonchemotherapeutic agents, including digoxin, the immunosuppressants cyclosporine and tacrolimus, and antiretroviral protease inhibitors (Fig. 6–3). Increased intestinal expression of P-glycoprotein can limit the absorption of P-glycoprotein substrates, thus reducing their bioavailability and preventing attainment of therapeutic plasma concentrations. Conversely, decreased P-glycoprotein expression may result in supratherapeutic plasma concentrations of relevant drugs and drug toxicity.

CLINICAL CONTROVERSY

Much of the data on individual variations in the *ABCB1* gene and response to P-glycoprotein substrates are inconsistent, even conflicting, and require clarification. The combination of multiple variations in the *ABCB1* gene eventually may prove to be a stronger predictor of drug response than any individual variation.

A number of polymorphisms have been identified in the promoter and exon regions of the *ABCB1* gene. Common SNPs occur in exons 12 (C1236T), 21 (G2677T), and 26 (C3435T). The exon 21 and 26 SNPs have been associated with intestinal *ABCB1* expression, P-glycoprotein activity, and digoxin plasma concentrations in

FIGURE 6-3. Active transport of drugs out of the cell by P-glycoprotein.

healthy volunteers.⁶³ These data imply that the *ABCB1* genotype is useful in predicting digoxin concentrations in patients with atrial arrhythmias or heart failure and in appropriate selection of initial digoxin doses.

The *ABCB1* exon 26 polymorphism also has been associated with plasma concentrations and clinical effects of protease inhibitors in patients infected with the human immunodeficiency virus (HIV).⁶⁴ Specifically, following 6 months of therapy with efavirenz or nelfinavir, a greater rise in CD4 cell counts was observed in individuals with the exon 26 TT genotype compared with CC homozygotes. This finding suggests a role for *ABCB1* genotyping in predicting hematologic responses to protease inhibitors and individualizing antiretroviral drug therapy for HIV-infected patients.

Other examples of polymorphic drug transporter proteins include the dipeptide transporter, organic anion and cation transporters, and L-amino acid transporter. Their effects on drug distribution are the focus of ongoing research.

POLYMORPHISMS IN DRUG TARGET GENES

5 Genetic polymorphisms occur commonly for drug target proteins, including receptors, enzymes, ion channels, and intracellular signaling proteins. Drug target genes may work in concert with genes that affect pharmacokinetic properties to contribute to overall drug response. Table 6–2 provides examples of drug target genes linked to drug response in clinical studies. The following section highlights some of the receptor, enzyme, ion channel, and cell-signaling protein genes that influence the efficacy and safety of various pharmacologic agents.

RECEPTOR GENOTYPES AND DRUG RESPONSE

The β_1 - and β_2 -adrenergic receptor genes have been the focus of much research into genetic determinants of responses to β -adrenergic receptor agonists and antagonists. β_1 -Receptors are located in the heart and kidney, where they are involved in the regulation of heart rate, cardiac contractility, and blood pressure. Two common non-synonymous SNPs in the β_1 -receptor gene are located at codons 49 (Ser→Gly) and 389 (Arg→Gly), and there is evidence of their involvement in blood pressure control.¹⁰ Investigators have examined the influence of the β_1 -receptor gene on blood pressure response to β_1 -receptor blockade with metoprolol. Hypertensive patients who were homozygous for both the Ser49 and Arg389 alleles

TABLE 6-2 Genetic Polymorphisms in Drug Targets and Response to Drug Therapy

Gene	Drug/Drug Class	Drug Effect Associated with Polymorphism
α -Adducin	Hydrochlorothiazide	Blood pressure reduction ⁷⁸
ACE	ACE inhibitors	Blood pressure reduction, regression of left ventricular hypertrophy, renoprotective effects ^{77,78}
Epithelial sodium channel	Amiloride	Blood pressure reduction ⁸³
Angiotensinogen	ACE inhibitors	Blood pressure reduction ⁷⁸
β_1 -Adrenergic receptor	β -Blockers	Blood pressure lowering ⁶⁵
β_2 -Adrenergic receptor	β_2 -Agonists	Bronchodilation ⁶⁸
Cyclooxygenase-1	Aspirin	Antiplatelet effects ¹⁰⁹
Dopamine D ₃ receptor	Levodopa, neuroleptics	Tardive dyskinesia ⁸⁴
3-Hydroxy-3-methylglutaryl-coenzyme A reductase	Statins	Magnitude of cholesterol lowering ¹¹⁰
Inhibitory GTP-binding protein β_3 -subunit	Antidepressants	Antidepressant response ⁸⁰
5-Lipoxygenase	Leukotriene modifier	Change in FEV ₁ ¹¹¹
Combination of H ₂ , 5-HT _{2A} , 5-HT _{2C} , 5-HT transporter	Clozapine	Response in schizophrenia ⁷⁰
Serotonin transporter	Selective serotonin reuptake inhibitors	Antidepressant response ⁸⁰
Stimulatory GTP-binding protein α -subunit	β -Blockers	Blood pressure lowering ⁷⁸
Vitamin K epoxide reductase complex subunit-1	Warfarin	Dose requirements ⁷³

ACE, angiotensin-converting enzyme; H, histamine; FEV₁, forced expiratory volume in the first second of expiration; 5-HT, serotonin.

had greater reductions in diastolic blood pressure with metoprolol monotherapy compared with carriers of the Gly49 and/or Gly389 alleles.⁶⁵ These data suggest that β_1 -receptor genotype may be an important determinant of blood pressure response to β -blockers in the management of hypertension. Given that a significant percentage of hypertensive patients fail to derive adequate blood pressure reduction with β -blocker monotherapy,⁶⁶ the ability to predict the likelihood of response based on genotype would have important clinical implications. Specifically, β -blockers could be started in patients expected to respond well to this drug class based on their β_1 -receptor genotype, whereas other classes of antihypertensive agents could be used in patients expected to respond poorly to β -blockers.

β_2 -Receptors are located on bronchial smooth muscle cells, where they mediate bronchodilation upon exposure to the β_2 -receptor agonists. Inhaled β_2 -agonists are the most effective agents for acute reversal of bronchospasm; however, the magnitude of their effects varies substantially among asthmatic patients.⁶⁷ More than 11 SNPs have been identified in the β_2 -receptor gene, three of which occur frequently and result in amino acid changes. Two common nonsynonymous SNPs are found in the gene's coding block region, at codons 16 and 27, and a third occurs upstream from the coding block in the gene's promoter region.

A number of studies have examined the association between the codon 16 or 27 polymorphisms and bronchodilatory response to β_2 -receptor agonists in asthma; however, the results of these studies have been largely inconsistent.⁶⁸ More recently, investigators found that the combination of SNPs in the gene's coding block and promoter region was a better determinant of β_2 -agonist response than any individual SNP.⁶⁹ These data suggest that an individual SNP in the β_2 -receptor gene is an insufficient predictor of β_2 -agonist effects and that multiple receptor gene variations more accurately correlate with bronchodilatory response to β_2 -agonists.

Clozapine is an example of a drug for which evidence indicates that multiple receptor genes interact to influence the drug's effects. Clozapine is an atypical antipsychotic used for the treatment of schizophrenia. Because of its potential to produce agranulocytosis in 0.5% to 2% of treated patients, clozapine is reserved for schizophrenic patients who are unresponsive to other drug therapies. However, only 30% to 60% of patients with refractory schizophrenia respond to clozapine.⁷⁰ Clozapine's effects are believed to be mediated through dopaminergic, serotonergic, adrenergic, and histaminergic receptors in the central nervous system. Although several studies have demonstrated relationships between single genetic variants for these receptor subtypes and clozapine response,

the data are inconsistent.⁷¹ In a more recent study, a combination of six polymorphisms in the histamine and serotonin 2A and 2C receptor genes and the serotonin transporter gene were 77% predictive of antipsychotic response to clozapine.⁷⁰ These findings imply that, similar to other drug target gene–drug response relationships, a combination of polymorphisms, rather than any single polymorphism, provides more accurate prediction of clozapine response.

ENZYME GENES AND DRUG RESPONSE

Vitamin K epoxide reductase (VKOR) is an example of an enzyme with genetic contributions to drug response. Warfarin exerts its anticoagulant effects by inhibiting VKOR, thus preventing carboxylation of clotting factors II, VII, IX, and X. The vitamin K epoxide reductase complex subunit-1 gene (*VKORC1*) encodes for VKOR. Mutations in the *VKORC1* coding region cause rare cases of warfarin resistance. Carriers of these mutations either require exceptionally high warfarin doses (>100 mg/wk) to achieve effective anticoagulation or fail to respond to any dose of warfarin.⁷²

Aside from rare cases of warfarin resistance, among patients there is substantial variability with regard to the dose of warfarin necessary to produce optimal anticoagulation, defined as an international normalized ratio of 2.0 to 3.0 for most indications. Common SNPs in the *VKORC1* promoter and intron regions have been identified and found to contribute to the interpatient variability in warfarin dose requirements.⁷³ These SNPs are in linkage disequilibrium (i.e., inherited together) and form several haplotypes. *VKORC1* haplotype, together with *CYP2C9* genotype, explains approximately 30% to 40% of the interpatient variability in warfarin dose requirements.⁷⁴ Much of the remainder of the variability is believed to be due to differences in demographic characteristics and dietary habits. Warfarin dosing algorithms that incorporate both genetic and non-genetic (e.g., age, body size) factors have been developed, and their accuracy in prospectively predicting warfarin dose is being tested.^{75,76} In the future, it may be possible to use these algorithms to accurately predict warfarin dose requirements for a given patient, thus reducing the patient's risk for thrombosis and bleeding associated with subtherapeutic or supratherapeutic anticoagulation, respectively.

The angiotensin-converting enzyme (ACE) gene is probably the most widely studied of the enzyme genes. An insertion/deletion (I/D) polymorphism in intron 16 of the *ACE* gene results in the presence or absence of a 287-base-pair fragment. This polymorphism has been linked consistently to plasma concentrations of ACE, the enzyme responsible for conversion of angiotensin I to the

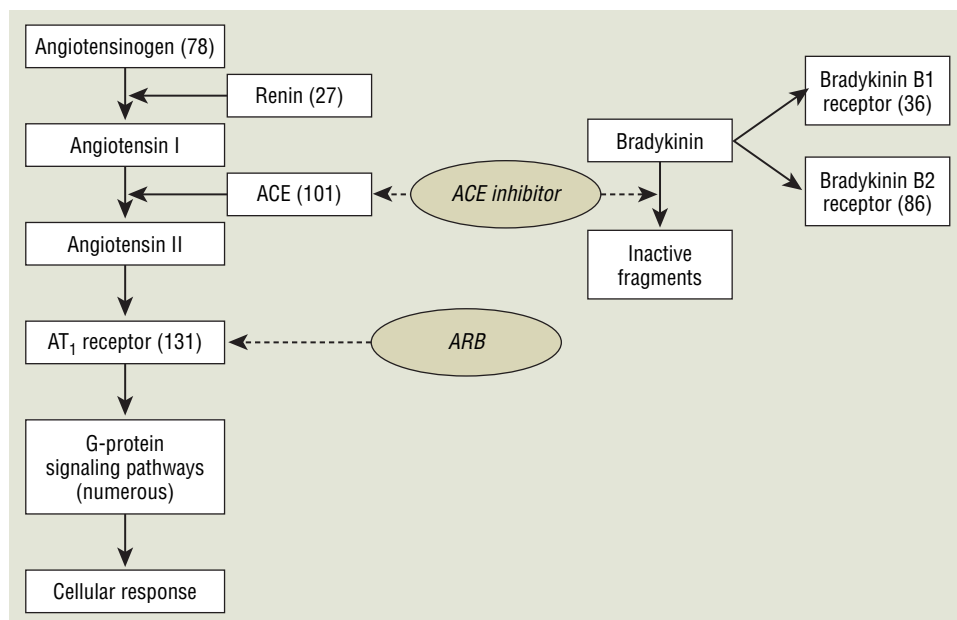

FIGURE 6-4. Single nucleotide polymorphisms (SNPs) identified for renin–angiotensin system genes. The number of polymorphisms identified for each protein is shown in parentheses after the protein name (<http://snp.cshl.org>). (ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker.)

potent vasoconstrictor angiotensin II.⁷⁷ Given its association with ACE concentrations, a number of investigators have examined whether the I/D polymorphism contributes to the interpatient variability in ACE inhibitor response. However, much of the data with the I/D polymorphism and blood pressure response to ACE inhibitors are inconsistent and even conflicting, with some studies demonstrating greater response with the DD genotype but others showing greater response with the II genotype.⁷⁸ In the largest pharmacogenetic study (including nearly 38,000 patients) to date, no association has been found between the ACE I/D genotype and either blood pressure response or cardiovascular or renal outcome with antihypertensive therapy.⁷⁹

The negative findings with regard to the *ACE* gene and ACE inhibitor response are not surprising given that numerous proteins are involved in the complex signaling pathway of the renin–angiotensin system (Fig. 6–4). Multiple genetic polymorphisms have been identified for many of these proteins. Thus, one explanation for the lack of an association between the *ACE* gene and ACE inhibitor response is that a single polymorphism contributes little to the overall response to an ACE inhibitor. Rather, response to ACE inhibition may be best determined by a combination of multiple polymorphisms occurring in multiple genes involved in the renin–angiotensin pathway. Indeed, other renin–angiotensin system genes, including the gene for angiotensinogen and aldosterone synthase, have been correlated with antihypertensive responses to ACE inhibitors and angiotensin receptor blockers,⁷⁸ suggesting that genes for ACE, angiotensinogen, aldosterone synthase, and probably other renin–angiotensin system proteins interact to influence ACE inhibitor response. Thus, before genotype can be used as a predictor of response to renin–angiotensin antagonists, the combination of genetic variants in the renin–angiotensin system that best determines drug response first must be elucidated.

There is evidence of racial differences in response to ACE inhibitors as well as many other pharmacologic agents. Specifically, African Americans in general are believed to have diminished antihypertensive responses to ACE inhibitors compared with white people.⁶⁶ The frequencies of many SNPs in the renin–angiotensin system vary between African American and white populations and may contribute to the observed racial differences in ACE inhibitor response. Indeed, most racial differences in drug response probably can be attributed to racial differences in genotype frequencies, although this is yet to be determined.

GENES FOR INTRACELLULAR SIGNALING PROTEINS, ION CHANNELS, AND DRUG RESPONSE

Cellular responses to many drugs are mediated through GTP-binding proteins, also called *G proteins*. The β_1 -adrenergic receptor is an example of a G-protein–coupled receptor in which a stimulatory G (G_s) protein couples the receptor to intracellular signaling mechanisms to elicit a cellular response (Fig. 6–5). Receptor-coupled G_s proteins contain α -, β -, and γ -subunits that mediate the activation of adenylyl cyclase and the generation of cyclic AMP following receptor stimulation. A SNP in the α -subunit of G_s protein has been linked to the blood pressure response to β -blockers.⁷⁸ Whether the G_s protein α -subunit gene interacts with the β_1 -adrenergic receptor gene or other intracellular signaling-protein genes to determine β -blocker response remains to be determined.

Disturbances in G-protein–mediated signal transduction have been implicated in the response to antidepressant drugs.⁸⁰ A common SNP (C825T) occurs in the gene for the inhibitory G (G_i) protein β_3 -subunit and has been associated with enhanced intracellular signal transduction.⁸¹ The TT genotype has been correlated with greater improvement in depression symptoms among patients treated with either a tricyclic antidepressant or serotonin reuptake

FIGURE 6-5. β_1 -receptor coupled to intracellular signaling mechanisms by a stimulatory G (G_s) protein.

inhibitor,⁸⁰ implying that the G_i protein β_3 -subunit gene may have a role in therapeutic decisions for depression management.

The epithelial sodium channel (ENaC) is an example of an ion channel with genetic contributions to drug response. The ENaC is located in the distal renal tubule and collecting duct of the nephron, where it serves as the final site for sodium reabsorption. The channel is composed of α -, β -, and γ -subunits. Mutations in the β - or γ -subunit cause excessive sodium reabsorption and an inherited form of hypertension called Liddle syndrome. The more common variant Thr594Met occurs exclusively in blacks and is associated with high blood pressure in this population.⁸² Amiloride blocks the ENaC but is a relatively weak diuretic with minimal effects on blood pressure when used as monotherapy in most hypertensive individuals. However, evidence indicates that amiloride monotherapy is as effective as combination therapy with more potent agents in blacks carrying the Thr594Met variant.⁸³ These data suggest that genotyping for the Thr594Met polymorphism may be appropriate for black patients whose blood pressure is resistant to traditional antihypertensive drugs, in whom treatment with amiloride could be instituted if the polymorphism is present.

The examples of drug target genes given thus far relate to drug efficacy. There are also examples of drug target genes linked to drug toxicity. One example is the Ser9Gly polymorphism of the dopamine D_3 receptor gene, which has been associated with neuroleptic-induced tardive dyskinesia.⁸⁴ Tardive dyskinesia is a debilitating adverse effect that occurs in up to 30% of patients treated with typical antipsychotics. Genetic influences of adverse effects that occur less frequently, such as ACE inhibitor-induced angioedema, are more difficult to delineate because of the large sample size needed to establish a definite genetic cause. Investigators for many multicenter clinical drug trials now are asking participants to provide consent for the collection of genetic material so that genetic contributions to rare but serious adverse drug effects can be elucidated in future studies.

DISEASE-ASSOCIATED GENES

Numerous genes have been correlated with disease outcomes, and many of these have been found subsequently to influence response to pharmacologic disease management. These gene–drug response associations often occur despite the lack of a direct effect on pharmacokinetic or pharmacodynamic drug properties. Examples of disease-associated genes are given in the following.

FACTOR V AND PROTHROMBIN GENES AND ORAL CONTRACEPTION

Use of oral contraceptives is associated with an increased risk for developing thromboembolic disorders, including deep-vein thrombosis, pulmonary embolism, and thrombotic stroke. Variations in the genes for the coagulation factors prothrombin and factor V Leiden also have been identified as risk factors for thromboembolic disorders.⁸⁵ In case-control studies, the presence of a factor V Leiden or prothrombin gene variation markedly increased the risk for deep-vein thrombosis and cerebral vein thrombosis among oral contraceptive users.⁸⁵ These data suggest that women who are known to carry a prothrombin or factor V Leiden mutation should use alternative birth control measures.

CONGENITAL LONG QT SYNDROME AND DRUG-INDUCED TORSADES DE POINTES

Drug-induced QT-interval prolongation may precipitate the serious, potentially life-threatening arrhythmia called *torsades de pointes*. It is well recognized that many antiarrhythmic drugs can cause QT-interval prolongation and torsade de pointes. In addition,

numerous noncardiovascular agents can induce torsade de pointes, and many have been withdrawn from the market as a result. Such drugs include the antihistamines terfenadine and astemizole, the fluoroquinolone antibiotic grepafloxacin, and the motility agent cisapride. Given the serious and unpredictable nature of torsade de pointes, there has been great interest in identifying genetic markers that predispose individuals to its occurrence.

Abnormalities in ion flux across the cardiac cell membrane resulting in an excess of intracellular positive ions and delayed ventricular repolarization are characteristic of long QT syndromes. Mutations in genes for the pore-forming channel proteins that affect potassium and sodium transport across the cardiac cell membrane underlie congenital long QT syndromes.⁸⁶ There is evidence that these mutations also may increase the risk for drug-induced torsade de pointes.⁸⁶ The ability to screen for mutations associated with drug-induced torsade de pointes would be of clinical significance, so that individuals with a genetic predisposition for this life-threatening arrhythmia could be spared exposure to potentially causative agents and treated with alternative therapies.

CORONARY DISEASE PROGRESSION GENE AND RESPONSE TO STATIN THERAPY

Several large clinical trials in patients with coronary heart disease, including the Scandinavian Simvastatin Survival Study (4S), have demonstrated significant reductions in coronary events and mortality with β -hydroxy- β -methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors, or statins.⁸⁷ The gene for apolipoprotein E has been correlated with hepatic cholesterol uptake and the risk for coronary heart disease.⁸⁸ Its contribution to coronary heart disease progression and statin response was examined in the 4S population.⁸⁹ Investigators found that the variant $\epsilon 4$ allele was associated with increased risk for all-cause mortality among placebo-treated study participants. However, no such association was observed in the simvastatin group, suggesting that simvastatin abolished the excess mortality risk associated with the $\epsilon 4$ allele.

Several other genes have been associated with responses to statins in coronary heart disease. These include the genes for the cholesterol ester transfer protein, which is involved in the metabolism of high-density lipoprotein cholesterol; β -fibrinogen, which influences plasma fibrinogen concentrations; and stromelysin-1, which is involved in remodeling of the extracellular matrix of atherosclerotic plaques.⁸⁸ In each case, the gene linked to worse disease progression or clinical outcomes also was associated with the greatest response to statin therapy. These data imply that genotype is useful in identifying which coronary heart disease patients are at increased risk for coronary events and death, in whom treatment with a statin would be of particular benefit.

NOVEL SITES FOR DRUG DEVELOPMENT

The discovery of genes that confer disease has led to an improved understanding of the molecular mechanisms involved in disease pathophysiology. Once associations between genes and diseases are discovered, scientists can elucidate the functions of the encoded proteins and more clearly define the consequences of genetic mutations. Insight into the genetic control of cellular functions may reveal new strategies for disease treatment and prevention.

For example, overexpression of the human epidermal growth factor receptor-2 (HER2) secondary to HER2 gene amplification occurs in 20% to 30% of metastatic breast cancers and is associated with decreased survival.⁹⁰ The discovery of HER2 overexpression and its effects on cancer prognosis led to the development of trastuzumab, a recombinant monoclonal antibody that targets and blocks HER2. The addition of trastuzumab to cancer chemotherapy significantly slows

the progression of cancer and improves tumor response rates in women with HER2-positive tumors.⁹⁰ Testing for HER2 overexpression is necessary to determine which patients may benefit from trastuzumab. The FDA has approved several tests that detect HER2 overexpression either directly by measuring the amount of protein or indirectly by measuring gene amplification.

The discovery that the apolipoprotein E gene is strongly linked to Alzheimer's disease⁹¹ and that the α -synuclein gene is associated with Parkinson's disease⁹² raises the possibility of examining these genes as targets for drug therapy for psychiatric and neurologic diseases.

GENE THERAPY

7 Gene therapy has emerged as a possible approach to treating and curing disease by altering gene expression. Initially, the focus of gene therapy was treatment of inherited disorders such as cystic fibrosis, sickle cell anemia, hemophilia, and adenosine deaminase deficiency. Gene therapy trials later were expanded to include patients with acquired diseases such as cancer and heart disease. The goal of gene therapy for inherited diseases is to correct genetic defects permanently and thereby restore normal cellular function. Gene therapy for acquired diseases aims to cure disease by targeting pathogenic processes.

Most gene therapy techniques for inherited diseases attempt to replace defective genes with normally functioning ones. Exogenous genes, called *transgenes*, can be transferred into either somatic (body) or germ-line (egg or sperm) cells of the recipient. In somatic cell gene transfer, genetic changes do not affect future generations. In contrast, germ-line cell transfer, which currently is prohibited by the FDA, results in the passage of genetic alterations to offspring.

The first clinical gene therapy trial for treatment of adenosine deaminase deficiency began in 1990.⁹³ B and T lymphocytes fail to develop in this autosomal recessive disease, resulting in a severe combined immunodeficiency syndrome (SCID) made famous by the "bubble boys" whose lives were confined to tents in an effort to keep them in a germ-free environment. Only two patients were included in this trial, and although both boys continued to demonstrate clinical improvement 10 years later, gene therapy did not cure the disease, as investigators had hoped.

Since then, the FDA has approved more than 700 clinical gene therapy trials (www.clinicaltrials.gov). Most of these trials involve cancer patients; however, a number of studies also target inherited disorders. The results of gene therapy trials to date have been disappointing, with reports of serious toxicities and few therapeutic successes.

OBSTACLES TO SUCCESS

Reasons for limited success with gene therapy include inefficient gene delivery to target cells, inadequate gene expression, and unacceptable adverse effects.⁹³

Sufficient amounts of the transgene must be inserted into a sufficient number of recipient cells to produce a therapeutic response. In addition, the transgene must be inserted into the correct chromosomal position of the correct cell nucleus so as not to disrupt normal gene function and expression. Incorrect chromosomal insertion of the transgene is a problem referred to as *insertional mutagenesis*. Once the therapeutic gene is integrated correctly into host DNA, it must be expressed at adequate levels and at appropriate times to restore normal cell function. Finally, the gene delivery system and delivery technique should lack any potential to cause unwanted effects in the transgene recipient.

RETROVIRAL GENE DELIVERY

8 Because of their efficiency in integrating into human DNA, viruses are the most common vectors used to deliver therapeutic

genes to recipient cell targets. Disease-causing genes are replaced with the desired therapeutic genes; the viral genes that control delivery mechanisms are retained.

The first viral vectors introduced were retroviruses, which are RNA viruses that integrate into the host cell genome and replicate during cell division. Thus, retroviral gene transfer is capable of permanently altering gene expression. Retroviruses can be used to deliver genes through either direct infusion into target organs or ex vivo manipulation of harvested cells followed by reinfusion into the recipient. The disadvantages of retroviral vectors are the limited size of the gene they can carry, relatively low efficiency, and risk of insertional mutagenesis. In fact, the FDA temporarily halted retroviral gene delivery into hematopoietic tissue in early 2003 after leukemia developed as a result of insertional mutagenesis in two of 11 SCID-affected children treated with retroviral gene therapy.⁹⁴ A third child later developed cancer.

Since research with retroviral gene therapy has resumed, some success with this mode of gene delivery has been reported in the area of oncology. In 2003, the FDA granted orphan drug status for a retroviral gene therapy that targets the cyclin G1 gene in the treatment of pancreatic cancer. Retroviruses also have been used in the development of recombinant cancer vaccines designed to stimulate the immune system to recognize and destroy cancer cells. One such vaccine was associated with regression of metastatic lesions in two of 15 patients with advanced melanoma.⁹⁵

ADENOVIRAL GENE DELIVERY

Unlike retroviruses, adenoviruses do not integrate into the host genome and thus do not replicate. As a result, genes delivered by adenoviruses are active only temporarily. Adenoviral-mediated gene therapy is used commonly in cancer patients because permanent gene expression is unnecessary in this patient population.

Tumor cells have been infused with adenoviral vectors carrying the herpes simplex virus-1 thymidine kinase gene and then exposed to ganciclovir as a mode of cancer chemotherapy.⁹⁶ Thymidine kinase converts ganciclovir to its active, cytotoxic form, which is incorporated in the DNA of tumor cells, leading to their death. Adenoviruses can be grown in high titers and do not carry the risk of insertional mutagenesis. The major disadvantage of adenoviruses is their immunogenic potential, which has resulted in one death and prompted federal oversight of gene therapy trials.⁹⁷

OTHER MEANS OF GENE DELIVERY

Adeno-associated viruses are human DNA-containing viruses that do not appear to trigger immune responses upon injection. Similar to retroviruses, adeno-associated viruses are incapable of carrying a large amount of genetic material, and their use entails the risk of insertional mutagenesis. Investigators have reported some success in treating hemophilia B using intramuscular injections of an adeno-associated virus vector that expresses the human coagulation factor IX gene.⁹⁸

Scientists are experimenting with nonviral delivery methods such as the use of direct DNA injection, liposomes, and electroporation. Some success with intramyocardial transfection of plasmid DNA encoding for vascular endothelial growth factor into patients with severe, intractable angina has been reported.⁹⁹ Initially, the procedure improved myocardial perfusion and angina in this patient population, with few major adverse events. One year later, patients continued to report some improvement in anginal symptoms.¹⁰⁰

Scientists have enjoyed few successes with gene therapy for inherited diseases. Improvements in gene delivery techniques and a better understanding of molecular processes controlling gene expression are necessary before gene therapy can correct genetic

defects successfully and thus cure associated diseases without inducing adverse effects. Because of limited success with traditional approaches to gene therapy, scientists are exploring other strategies, such as repairing or regulating (“turning off”) defective genes rather than replacing them.¹⁰¹ Scientists have reported more success with gene therapy for acquired diseases, such as cancer, and a number of phase II and III clinical trials in this area are underway. While gene therapy research is evolving, much progress is needed before effective and safe therapies are available.

ETHICAL CONSIDERATIONS

PHARMACOGENETICS

Traditionally, *genetic testing* refers to screening human genetic material to identify genotypes associated with disease susceptibility or carrier status for inherited diseases, such as Huntington’s disease, Alzheimer’s disease, and breast cancer. This kind of testing can have profound legal, ethical, and social implications. For example, knowledge that a patient is at risk for developing a genetic disorder could result in discrimination by employers or insurance companies. In addition, this information likely would cause emotional distress for the individual at risk and his or her family members.

Within the context of pharmacogenetics, however, testing involves searching for genetic variations linked to drug efficacy or toxicity rather than to disease susceptibility. In many instances, this form of testing will carry little risk for ethical, legal, and social concerns. For example, knowledge that a person has a genotype associated with poor blood pressure response to a β -blocker is of little consequence because a number of alternative therapies are available. However, more serious implications may arise if a person is predicted to respond poorly to a drug based on genotype, and treatment options are limited. Thus, ethical considerations associated with pharmacogenetic testing may need to be addressed before testing is widely accepted by the public.

GENE THERAPY

Many of the ethical concerns with gene therapy center on transgenic manipulation of somatic versus germ-line cells. Somatic gene therapy only affects the recipient, that is, genetic alterations introduced by gene therapy are not passed on to future generations. In contrast, with manipulation of germ-line cells, alterations are passed on to children of the treated patient. Some argue that this is unethical because it violates the rights of future generations. Thus, it appears that most gene therapy in the foreseeable future will focus on somatic gene transfer.

ROLE OF PHARMACISTS

Although pharmacogenetics provides opportunities to improve drug therapy outcomes, it likely will increase the complexity of drug prescribing. In addition to considering factors such as age, concomitant drug therapy, and renal and hepatic function, prescribers will have to interpret the results of genetic analyses when making drug therapy decisions. The FDA has already incorporated genetic information into the package insert for a number of drugs, including irinotecan, azathioprine, mercaptopurine, fluoxetine, and celecoxib.

Further complicating the drug-prescribing process are many medications whose effects are not determined by single polymorphisms in single genes. Rather, pharmacologic effects for most medications likely are determined by the interaction of polymorphisms in multiple genes that encode proteins involved in the various pathways of drug metabolism, distribution, and effects. For example, the immu-

nosuppressants cyclosporine and tacrolimus are believed to be substrates for both P-glycoprotein and the CYP450, CYP3A4, and possibly CYP3A5 enzymes.¹¹² Thus, it is possible that genes for both MDR1 and CYP450 enzymes interact to influence cyclosporine and tacrolimus distribution and plasma concentrations.

Pharmacists are broadly trained in a number of medication-related areas, including pharmacology, pharmacokinetics, and pharmacodynamics. This training places pharmacists in a unique position to deal with the complexities of the drug-decision process in the age of pharmacogenetics. Pharmacists will be in key positions to interpret the results of genetic tests, determine the ultimate effects of multiple genetic variations on drug response, and choose the most appropriate drug for a given patient based on the individual’s DNA. Thus, it will be essential for pharmacists to stay abreast of significant discoveries in genotype–drug response relationships and understand how best to incorporate this genomic information into pharmacotherapeutic decisions.

Recognizing the challenges in healthcare delivery with advancing genetic discoveries, the National Coalition for Health Professional Education in Genetics established core competencies related to genetics for healthcare professionals that are available through the coalition’s website (www.nchpeg.org). The objective of these competencies is to encourage clinicians to incorporate genetics knowledge, skills, and attitudes into their clinical practices. Subsequently, the American Association of Colleges of Pharmacy developed recommendations to guide academic institutions on how to instill these competencies in future pharmacists so that pharmacists will be prepared to provide appropriate pharmacotherapy in the age of genomics.¹⁰²

APPLICATION OF PHARMACOGENETIC DATA TO DISEASE MANAGEMENT

Pharmacogenetics has the potential to greatly improve the pharmacologic management of disease. Clinicians may be able to predict the likelihood that an individual will respond to a particular medication based on the patient’s genotype. Medications may be avoided or prescribed in lower doses with careful monitoring in patients genetically predisposed to the drugs’ adverse effects. This would be of particular benefit for drugs with a narrow therapeutic index. For example, warfarin may be initiated at lower doses, with closer monitoring in patients with a *VKORC1* haplotype associated with increased warfarin sensitivity or a *CYP2C9* allele associated with reduced warfarin metabolism.

With pharmacogenetics, it may be possible to eliminate the trial-and-error approach to drug prescribing for many diseases. Instead, clinicians may be able to use genetic information to match the right drug to the right patient at the right dose while minimizing adverse effects. For example, the current approach to hypertension management involves the trial of various antihypertensives until blood pressure goals are achieved with acceptable drug tolerability. Commonly, the initial agent fails to lower blood pressure to goal or produces intolerable adverse effects (Fig. 6–6). Trials of additional or alternative antihypertensive medications must be undertaken until treatment is deemed successful. In the interim, the patient remains hypertensive and at risk for hypertension-related target-organ damage. With pharmacogenetics, clinicians may choose the antihypertensive drug expected to provide the greatest response with the best tolerability for a particular patient based on his or her DNA.

New drugs may be developed based on knowledge about genetic control of cellular functions. For example, the discovery that chronic myeloid leukemia was caused by chromosome translocation and consequent production of an enzyme capable of producing life-threatening lymphocyte levels led to accelerated FDA approval of Gleevec (also known as STI-571), an inhibitor of the transloca-

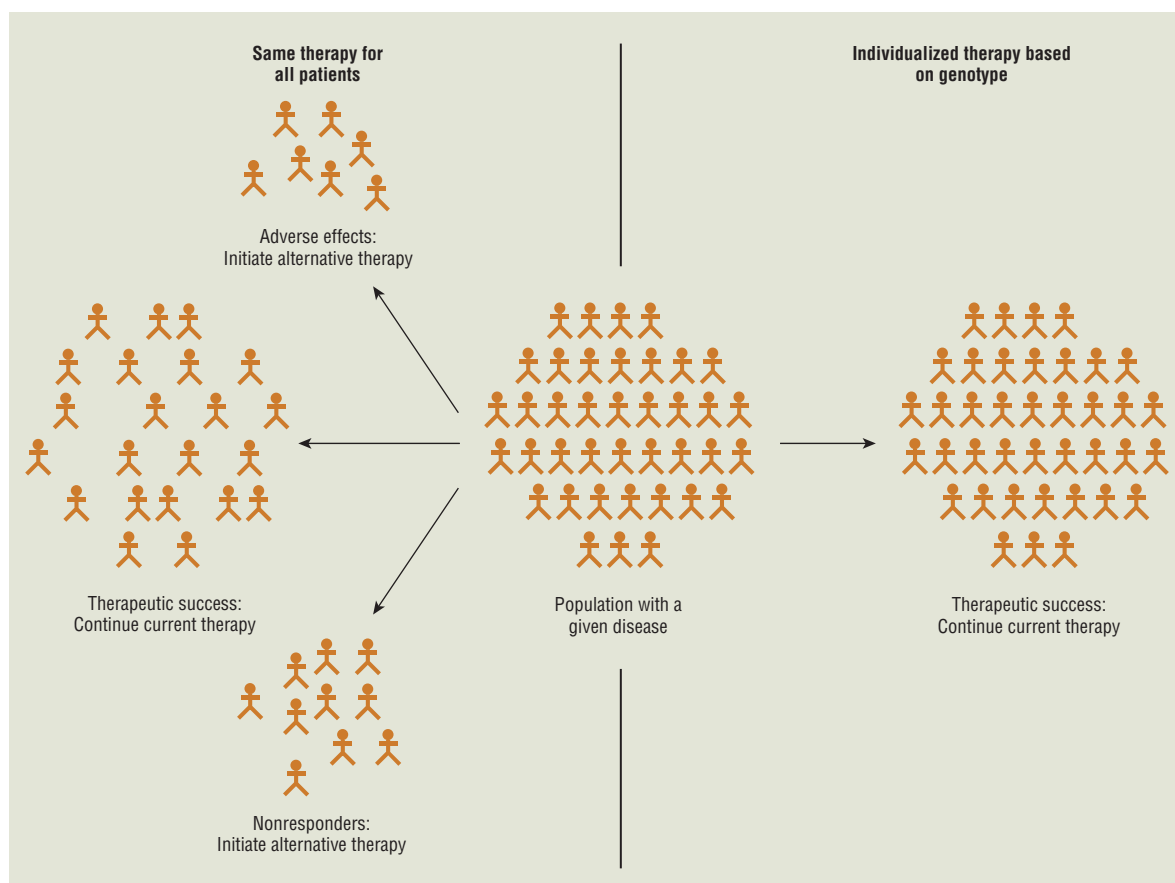

FIGURE 6-6. Current and future approaches to pharmacologic management of disease.

tion-created enzyme, for treatment of chronic myeloid leukemia.¹⁰³ In addition, future drug development may focus on treating specific genetic subgroups instead of broadly treating all individuals with a particular disease. Along these lines, the FDA is encouraging pharmaceutical companies to submit pharmacogenetic data during the drug development process.¹⁰⁴ Ultimately, pharmacogenetics may improve the quality and reduce the overall costs of healthcare by decreasing the number of treatment failures and the number of adverse drug reactions and leading to the discovery of new genetic targets and therapeutic interventions for disease management.

CLINICAL CONTROVERSY

For many drugs, such as warfarin, variations in genes affecting both pharmacokinetic and pharmacodynamic drug properties may interact to determine the ultimate effects of drug therapy. Thus, the challenge for researchers will be to identify the combination of gene variations that best predicts response for these drugs.

ABBREVIATIONS

A: adenine
ACE: angiotensin-converting enzyme
AUC: area under the curve
C: cytosine
CYP450: cytochrome P450
DPD: dihydropyrimidine dehydrogenase
EM: extensive metabolizer

FDA: Food and Drug Administration

G: guanine

HIV: human immunodeficiency virus

I/D: insertion/deletion

MDR1: multidrug resistance-1

PM: poor metabolizer

SCID: severe combined immunodeficiency syndrome

SNPs: single nucleotide polymorphisms

T: thymidine

TPMT: thiopurine S-methyltransferase

UGT: uridine diphosphate glucuronosyltransferase

UM: ultrarapid metabolizer

MILAP C. NAHATA AND CAROL TAKETOMO

KEY CONCEPTS

- 1 Children are not just "little adults," and lack of data on important pharmacokinetic and pharmacodynamic differences has led to several disastrous situations in pediatric care.
- 2 Variations in absorption of medications from the gastrointestinal tract, intramuscular injection sites, and skin are important in pediatric patients, especially in premature and other newborn infants.
- 3 The rate and extent of organ function development and the distribution, metabolism, and elimination of drugs differ not only between pediatric versus adult patients but also among pediatric age groups.
- 4 The effectiveness and safety of drugs may vary among various age groups and from one drug to another in pediatric versus adult patients.
- 5 Concomitant diseases may influence dosage requirements to achieve a targeted effect for a specific disease in children.
- 6 The myth that neonates and young infants do not experience pain has led to inadequate pain management in this pediatric population.
- 7 Special methods of drug administration are needed for infants and young children.
- 8 Many medicines needed for pediatric patients are not available in appropriate dosage forms; thus, the dosage forms of drugs marketed for adults may require modification for use in infants and children, necessitating assurance of potency and safety of drug use.
- 9 The pediatric medication-use process is complex and error-prone because of the multiple steps required in calculating, verifying, preparing, and administering doses.

Remarkable progress has been made in the clinical management of disease in pediatric patients. This chapter highlights important principles of pediatric pharmacotherapy that must be considered when the diseases discussed in other chapters of this book occur in pediatric patients, defined as those younger than 18 years. Newborn infants born before 37 weeks of gestational age are termed *prema-*

ture; those between 1 day and 1 month of age are *neonates*; 1 month to 1 year are *infants*; 1 to 11 years are *children*; and 12 to 16 years are *adolescents*. This chapter covers notable examples of problems in pediatrics, pharmacokinetic differences in pediatric patients, drug efficacy and toxicity in this patient group, and various factors affecting pediatric pharmacotherapy. Specific examples of problems and special considerations in pediatric patients are cited to enhance understanding.

1 Infant mortality has declined from 200 per 1,000 births in the 19th century to 75 per 1,000 births in 1925 to 6.79 per 1,000 births in 2004.¹ This success has resulted largely from improvements in identification, prevention, and treatment of diseases once common during delivery and the period of infancy. Although most marketed drugs are used in pediatric patients, only one fourth of the drugs approved by the Food and Drug Administration (FDA) have indications specific for use in the pediatric population. Data on the pharmacokinetics, pharmacodynamics, efficacy, and safety of drugs in infants and children are scarce. Lack of this type of information led to disasters such as gray baby syndrome from chloramphenicol, phocomelia from thalidomide, and kernicterus from sulfonamide therapy. Gray baby syndrome was first reported in two neonates who died after excessive doses of chloramphenicol (100–300 mg/kg/day); the serum concentrations of chloramphenicol immediately before death were 75 and 100 mcg/mL. Patients with gray baby syndrome usually have abdominal distension, vomiting, diarrhea, a characteristic gray color, respiratory distress, hypotension, and progressive shock.

Thalidomide is well known for its teratogenic effects. Clearly implicated as the cause of multiple congenital fetal abnormalities (particularly limb deformities), thalidomide also can cause polyneuritis, nerve damage, and mental retardation. Isotretinoin (Accutane) is another teratogen. Because it is used to treat severe acne vulgaris, which is common in teenage patients who may be sexually active but not willing to acknowledge that activity to healthcare professionals, isotretinoin has presented a difficult problem in patient education since its marketing in the 1980s.

Kernicterus was reported in neonates receiving sulfonamides, which displaced bilirubin from protein-binding sites in the blood to cause a hyperbilirubinemia. This results in deposition of bilirubin in the brain and induces encephalopathy in infants.

Another area of concern in pediatrics is identifying an optimal dosage. Dosage regimens cannot be based simply on body weight or surface area of a pediatric patient extrapolated from adult data. Bioavailability, pharmacokinetics, pharmacodynamics, efficacy, and adverse-effect information can differ markedly between pediatric and adult patients, as well as among pediatric patients, because of differences in age, organ function, and disease state. Significant progress has been made in the area of pediatric pharmacokinetics during the last 2 decades, but few such studies have correlated pharmacokinetics with the outcomes of efficacy, adverse effects, or quality of life.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

Several additional factors should be considered in optimizing pediatric drug therapy. Many drugs prescribed widely for infants and children are not available in suitable dosage forms. For example, extemporaneous liquid dosage forms of amiodarone, captopril, omeprazole, and spironolactone are prepared for infants and children who cannot swallow tablets or capsules, and injectable dosage forms of aminophylline, methylprednisolone, morphine, and phenobarbital are diluted to accurately measure small doses for infants. Alteration (dilution or reformulation) of dosage forms intended for adult patients raises questions about the bioavailability, stability, and compatibility of these drugs. Because of low fluid volume requirements and limited access to intravenous sites, special methods must be used for delivery of intravenous drugs to infants and children. As simple as it may seem, administration of oral drugs to young patients continues to be a difficult task for nurses and parents. Similarly, ensuring adherence to pharmacotherapy in pediatric patients poses a special challenge.

Finally, the need for additional pharmacologic or therapeutic research brings up the issue of ethical justification for conducting research. Investigators proposing studies and institutional review committees approving human studies must assess the risk-to-benefit ratio of each study to be fair to children who are not in a position to accept or reject the opportunity to participate in the research project.

Enormous progress in pharmacokinetics has been made in pediatric patients. Two factors have contributed to this progress: (a) the availability of sensitive and specific analytic methods to measure drugs and their metabolites in small volumes of biologic fluids and (b) awareness of the importance of clinical pharmacokinetics in optimization of drug therapy. Absorption, distribution, metabolism, and elimination of many drugs are different in premature infants, full-term infants, and older children, and this topic is discussed in detail in the next few sections.

ABSORPTION

GASTROINTESTINAL TRACT

2 Two factors affecting the absorption of drugs from the gastrointestinal tract are pH-dependent passive diffusion and gastric emptying time. Both processes are strikingly different in premature infants compared with older children and adults. In a full-term infant, gastric pH ranges from 6 to 8 at birth but declines to 1 to 3 within 24 hours.² In contrast, gastric pH remains elevated in premature infants because of immature acid secretion.³

In premature infants, higher serum concentrations of acid-labile drugs, such as penicillin,⁴ ampicillin,⁵ and nafcillin,⁶ and lower serum concentrations of a weak acid such as phenobarbital⁷ can be explained by higher gastric pH. Because of a lack of extensive data comparing serum concentration–time profiles after oral versus intravenous drug administration, differences in the bioavailability of drugs in premature infants are poorly understood. Although little is known about the influence of developmental changes with age on drug absorption in pediatric patients, a few studies with drugs (e.g., digoxin and phenobarbital) and nutrients (e.g., arabinose and xylose) have suggested that the processes of both passive and active transport may be fully developed by approximately 4 months of age.⁸ Little is known about the development and expression of the efflux transporter P-glycoprotein and the intestinal drug-metabolizing enzymes and their impact on drug absorption and bioavailability in infants and children.

Studies have shown that gastric emptying is slow in a premature infant.⁹ Thus, drugs with limited absorption in adults may be absorbed efficiently in a premature infant because of prolonged contact time with gastrointestinal mucosa.

INTRAMUSCULAR SITES

Drug absorption from an intramuscular site may be altered in premature infants. Differences in relative muscle mass, poor perfusion to various muscles, peripheral vasomotor instability, and insufficient muscular contractions in premature infants compared with older children and adults can influence drug absorption from the intramuscular site. The net effect of these factors on drug absorption is impossible to predict; phenobarbital has been reported to be absorbed rapidly,¹⁰ whereas diazepam absorption may be delayed.¹¹ Thus, intramuscular dosing is used rarely in neonates except in emergencies or when an intravenous site is inaccessible.

SKIN

Percutaneous absorption may be increased substantially in newborns because of an underdeveloped epidermal barrier (stratum corneum) and increased skin hydration. Furthermore, because the ratio of total body surface area to total body weight is highest in the youngest group, the relative systemic exposure of topically applied drugs, including corticosteroids, may be higher in infants and young children than in adults. The increased exposure can produce toxic effects after topical use of hexachlorophene soaps and powders,¹² salicylic acid ointment, and rubbing alcohol.¹³ Interestingly, a study has shown that a therapeutic serum concentration of theophylline can be achieved for control of apnea in premature infants less than 30 weeks' gestation after topical application of gel containing a standard dose of theophylline.¹⁴ Use of this route of administration may minimize the unpredictability of oral and intramuscular absorption and the complications of intravenous drug administration for certain drugs. A transdermal patch formulation of methylphenidate has been approved for use in children 6 to 12 years of age for treatment of attention-deficit/hyperactivity disorder (ADHD). The patch can be applied once daily and can remain on during normal activities such as bathing, swimming, and exercising.

DISTRIBUTION

3 Drug distribution is determined by the physicochemical properties of the drug itself (pK_a , molecular weight, partition coefficient) and the physiologic factors specific to the patient. Although the physicochemical properties of the drug are constant, the physiologic functions often vary in different patient populations. Some important patient-specific factors include extracellular and total body water, protein binding by the drug in plasma, and presence of pathologic conditions modifying physiologic function. Total body water, as a percentage of total body weight, has been estimated to be 94% in fetuses, 85% in premature infants, 78% in full-term infants, and 60% in adults.¹⁴ Extracellular fluid volume also is markedly different in premature infants compared with older children and adults; the extracellular fluid volume may account for 50% of body weight in premature infants, 35% in 4- to 6-month-old infants, 25% in children 1 year old, and 19% in adults.¹⁵ This conforms to the observed gentamicin distribution volumes of 0.48 L/kg in neonates and 0.20 L/kg in adults.¹⁶ Studies have shown that the distribution volume of tobramycin is largest in the most premature infants and decreases with increases in gestational age and birth weight of the infant.¹⁷

Binding of drugs to plasma proteins is decreased in newborn infants because of decreased plasma protein concentration, lower binding capacity of protein, decreased affinity of proteins for drug binding, and competition for certain binding sites by endogenous compounds such as bilirubin. The plasma protein binding of many drugs, including phenobarbital, salicylates, and phenytoin, is significantly less in the neonate than in the adult.¹⁸ The decrease in plasma protein binding of drugs can increase their apparent volumes of

distribution. Therefore, premature infants require a larger loading dose than do older children and adults to achieve a therapeutic serum concentration of drugs such as phenobarbital¹⁹ and phenytoin.²⁰

The consequences of increased concentrations of free or unbound drug in the serum and tissues must be considered. Pharmacologic and toxic effects are related directly to the concentration of free drug in the body. Increases in free drug concentrations may result directly from decreases in plasma protein binding or indirectly from, for example, drug displacement from binding sites. The increased mortality from the development of kernicterus secondary to displacement of bilirubin by sulfisoxazole in neonates is well documented.²¹ However, because drug bound to plasma proteins cannot be eliminated by the kidney, an increase in free drug concentration also may increase its clearance.²²

The amount of body fat is substantially lower in neonates than in adults, which may affect drug therapy. Certain highly lipid-soluble drugs are distributed less widely in infants than in adults. The apparent volume of distribution of diazepam has ranged from 1.4 to 1.8 L/kg in neonates and from 2.2 to 2.6 L/kg in adults.²³ In recent years, the numbers of mothers breast-feeding their infants has climbed. Thus, certain drugs distributed in breast milk may pose problems for the infants. The American Academy of Pediatrics recommends that bromocriptine, cyclophosphamide, cyclosporine, doxorubicin, ergotamine, lithium, methotrexate, phenindione, and all drugs of abuse (e.g., amphetamine, cocaine, heroin, marijuana, and phencyclidine [PCP]) not be used during breast-feeding. Use of nuclear medicines should be stopped temporarily during breast-feeding.²⁴ Note that these recommendations are based on limited data; other drugs taken over a prolonged period by the mother also may be toxic to the infant. For example, acebutolol, aspirin, atenolol, clemastine, phenobarbital, primidone, sulfasalazine, and 5-aminosalicylic acid have been associated with adverse effects in some nursing infants.^{24,25} Unless the benefits outweigh the risks, the mother should avoid using any drug during pregnancy and while breast-feeding.

METABOLISM

Drug metabolism is substantially slower in infants than in older children and adults. There are important differences in the maturation of various pathways of metabolism within a premature infant. For example, the sulfation pathway is well developed but the glucuronidation pathway is undeveloped in infants.²⁶ Although acetaminophen metabolism by glucuronidation is impaired in infants compared with adults, it is partly compensated for by the sulfation pathway. The cause of the tragic chloramphenicol-induced gray baby syndrome in newborn infants is decreased metabolism of chloramphenicol by glucuronyltransferases to the inactive glucuronide metabolite.²⁷ This metabolic pathway appears to be age related²⁸ and may take several months to 1 year to develop fully, as evidenced by the increase in clearance with age up to 1 year.²⁹

Interestingly, higher serum concentrations of morphine are required to achieve efficacy in premature infants than in adults, in part because infants are not able to metabolize morphine adequately to its 6-glucuronide metabolite (20 times more active than morphine).³⁰ This is balanced to some degree by the fact that the clearance of morphine quadruples between 27 and 40 weeks of postconceptional age.

Metabolism of drugs such as theophylline, phenobarbital, and phenytoin by oxidation also is impaired in newborn infants. However, the rate of metabolism is more rapid with phenobarbital and phenytoin than with theophylline, perhaps because of the involvement of different cytochrome P450 isozymes. Total clearance of phenytoin by CYP2C9 and, to a lesser extent, by CYP2C19 surpasses adult values by 2 weeks of age, whereas theophylline clearance is not fully developed for several months.¹⁸ Two additional observations about theophylline metabolism by CYP1A2 in pediatric patients

should be noted. First, in premature infants receiving theophylline for treatment of apnea, a significant amount of its active metabolite caffeine may be present, unlike the case in older children and adults.¹⁸ Second, theophylline clearance in children 1 to 9 years of age exceeds the values in infants as well as adults. Thus, a child with asthma often requires markedly higher doses on a weight basis of theophylline compared with an adult.³¹ Because of decreased metabolism, doses of drugs such as theophylline, phenobarbital, phenytoin, and diazepam should be decreased in premature infants.

The clearance of unbound *S*-warfarin, a substrate of CYP2C9, was substantially greater in prepubertal children than among pubertal children and adults even after adjustment for total body weight.³² Finally, clearance of caffeine, metabolized by demethylation, declines to adult values when girls reach Tanner stage II (early puberty) and boys reach Tanner stages IV and V (late puberty).³³ The knowledge of pharmacogenetics and pharmacogenomics now is being applied to patient care in some instances. 6-Mercaptopurine (6-MP), a drug commonly used in pediatric leukemias, undergoes catabolism that is facilitated by thiopurine methyltransferase (TPMT). The inherited deficiency (an autosomal recessive trait), which occurs in 6% to 11% of patients, is primarily explained by three polymorphisms in the *TPMT* gene (*2, *3A, and *3C). Children homozygous for one of the variant alleles require 6-MP dose reduction of approximately 90%, and heterozygotic children need a dose reduction of approximately 50% to achieve survival rates observed in patients receiving full doses in the absence of TPMT deficiency. Thus, *TPMT* screening is recommended to identify patients with genotypes associated with TPMT deficiency who may benefit from dose reductions to prevent toxicity.³⁴

ELIMINATION

Drugs and their metabolites are often eliminated by the kidney. The glomerular filtration rate (GFR) may be as low as 0.6 to 0.8 mL/min per 1.73 m² in preterm infants and approximately 2 to 4 mL/min per 1.73 m² in term infants. The processes of glomerular filtration, tubular secretion, and tubular reabsorption determine the efficiency of renal excretion. These processes may not develop fully for several weeks to 1 year after birth.

Studies in infants have shown that tobramycin clearance during the first postnatal week may increase with an increase in gestational age.¹⁷ In infants up to 1 month after birth, postnatal age also was correlated directly with aminoglycoside clearance.²⁹ Thus, premature infants require a lower daily dose of drugs eliminated by the kidney during the first week of life; the dosage requirement then increases with age.

Because of immature renal elimination, chloramphenicol succinate can accumulate in premature infants. Although chloramphenicol succinate is inactive, this accumulation may be the reason for an increased bioavailability of chloramphenicol in premature infants compared with older children.²⁸ These data indicate that dose-related toxicity may result from an underdeveloped glucuronidation pathway as well as increased bioavailability of chloramphenicol in premature infants.

DRUG EFFICACY AND TOXICITY

4 Besides the pharmacokinetic differences previously identified between pediatric and older patients, factors related to drug efficacy and toxicity also should be considered in planning pediatric pharmacotherapy. Unique pathophysiologic changes occur in pediatric patients with some disease states.

Examples of pathophysiologic and pharmacodynamic differences are numerous. Clinical presentation of chronic asthma differs in

children and adults.³⁵ Children present almost exclusively with a reversible extrinsic type of asthma, whereas adults have nonspecific, nonatopic bronchial irritability.³⁵ This explains the value of adjunctive hyposensitization therapy in the management of pediatric patients with extrinsic asthma.^{36,37}

The maintenance dose of digoxin is substantially higher in infants than in adults. This is explained by a lower binding affinity of receptors in the myocardium for digoxin and increased digoxin-binding sites on neonatal erythrocytes compared with adult erythrocytes.³⁸ Insulin requirement is highest during adolescence because of the individual's rapid growth. Growth hormone therapy has allowed children with growth hormone deficiency to attain greater adult height. However, a study has shown that in "normal" short children (without growth hormone deficiency), early and rapid pubertal progression by growth hormone therapy may lead to a shorter final adult height than may have been attained naturally.³⁹ This finding emphasizes the need for identifying specific indications for the effective and safe use of drugs in pediatric patients.

Certain adverse effects of drugs are most common in the newborn period, whereas other toxic effects may continue to be important for many years of childhood. Promethazine now is contraindicated for use in children younger than 2 years because of the risk of severe respiratory depression. Chloramphenicol toxicity is increased in newborns because of immature metabolism and enhanced bioavailability. Similarly, propylene glycol, which is added to many injectable drugs, including phenytoin, phenobarbital, digoxin, diazepam, vitamin D, and hydralazine, to increase their stability, can cause hyperosmolality in infants.⁴⁰ Benzyl alcohol was a popular preservative used in intravascular flush solutions until a syndrome of metabolic acidosis, seizures, neurologic deterioration, gasping respirations, hepatic and renal abnormalities, cardiovascular collapse, and death was described in premature infants. A decline in both mortality and the incidence of major intraventricular hemorrhage was documented after use of solutions containing benzyl alcohol was stopped in low-birth-weight infants.⁴¹

Tetracyclines are contraindicated for use in pregnant women, nursing mothers, and children younger than 8 years because these drugs can cause dental staining and defects in enamelization of deciduous and permanent teeth, as well as a decrease in bone growth.⁴² However, the Centers for Disease Control and Prevention has recommended the use of doxycycline for initial prophylaxis following suspected bioterrorism related exposure to *Bacillus anthracis* (anthrax); the potential benefits outweigh potential risks among infants and children.

CLINICAL CONTROVERSY

Are fluoroquinolones safe in pediatric patients younger than 1 year? Antibiotics of the fluoroquinolone class (e.g., ciprofloxacin) are generally not recommended for pediatric patients or pregnant women because of an association between these drugs and the development of permanent lesions of the cartilage of weight-bearing joints and other signs of arthropathy in immature animals of various species.⁴³ However, there are exceptions. The manufacturer states that ciprofloxacin can be used in pediatric patients **only** for inhalation anthrax (postexposure) or for treatment of complicated urinary tract infections and pyelonephritis caused by susceptible *Escherichia coli*. The American Academy of Pediatrics and Infectious Disease Society of America suggest that their use may be justified for certain other conditions (e.g., endocarditis and multi-drug-resistant gram-negative infections). Reversible arthralgia, sometimes accompanied by synovial effusion, was associated with ciprofloxacin therapy in 1.8% of pediatric patients with cystic fibrosis.⁴⁴ Although these drugs are used to treat certain infections in pediatric populations, additional safety data are needed before these drugs can be prescribed routinely, especially in infants.

CLINICAL CONTROVERSY

Are antidepressants safe and effective in children and adolescents? Because of observations of increased suicidality among adolescents (and adults, for that matter), experts are questioning whether these medications merely bring out an increased suicide risk that the patient has suppressed or has been too depressed to act on, or these medications actually increase the risk per se through some pharmacologic effect. Some selective serotonin reuptake inhibitors (SSRIs)—fluoxetine, sertraline, and fluvoxamine—are approved for use in pediatric patients in the United States. The British regulatory agency banned the use of another SSRI, paroxetine, in 2003 after analysis of the data indicated the occurrence of suicidal thoughts or episodes of self-harm at a rate 1.5 to 3.2 times higher than that with placebo. Subsequently, the FDA added a black-box warning about the use of and need for monitoring SSRI therapy in pediatric patients, and FDA action has continued in this arena.

Some drugs may be less toxic in pediatric patients than in adults. Aminoglycosides appear to be less toxic in infants than in adults. In adults, aminoglycoside toxicity is related to both peripheral compartment accumulation and the individual patient's inherent sensitivity to these tissue concentrations.⁴⁵ Although neonatal peripheral tissue compartments for gentamicin have been reported to closely resemble those of adults with similar renal function,¹⁶ gentamicin rarely is nephrotoxic in infants. This dissimilarity in the incidence of nephrotoxicity implies that newborn infants have less inherent tissue sensitivity for toxicity than do adults.

The differences in efficacy, toxicity, and protein binding of drugs in pediatric versus adult patients raise an important question about the acceptable therapeutic range in children. Therapeutic ranges for drugs are first established in adults and often are applied directly to pediatric patients, but specific studies should be conducted in pediatric patients to define optimal therapeutic ranges of drugs.

FACTORS AFFECTING PEDIATRIC THERAPY

DISEASES

5 Because most drugs are either metabolized by the liver or eliminated by the kidney, hepatic and renal diseases are expected to decrease the dosage requirements in patients. Nevertheless, not all diseases require lower doses of drugs. For instance, patients with cystic fibrosis require larger doses of certain drugs to achieve therapeutic concentrations.⁴⁶

Hepatic Disease

Because the liver is the main organ for drug metabolism, drug clearance usually is decreased in patients with hepatic disease. However, most studies on the influence of hepatic disease on dosage requirements have been performed in adults, and these data may not be extrapolated uniformly to pediatric patients.

Drug metabolism by the liver depends on complex interactions among hepatic blood flow, ability of the liver to extract the drug from the blood, drug binding in the blood, and both type and severity of hepatic disease. Routine hepatic function tests, such as determinations of serum aspartate aminotransferase, serum alanine aminotransferase, alkaline phosphatase, and bilirubin levels, have not correlated consistently with drug pharmacokinetics. Furthermore, because of different pathologic changes in various types of hepatic diseases, patients with acute viral hepatitis may have different abilities to metabolize drugs than patients with alcoholic cirrhosis.⁴⁷

On the basis of hepatic extraction characteristics, drugs can be divided into two categories. The first category consists of drugs with

a high hepatic extraction ratio (>0.7 ; such drugs include morphine, meperidine, lidocaine, and propranolol). Clearance of these drugs is affected by hepatic blood flow. A decreased hepatic blood flow in the presence of disease states such as cirrhosis and congestive heart failure is expected to decrease the clearance of drugs with high extraction ratios. The second category consists of drugs with a low extraction ratio (<0.2) and a low affinity for plasma proteins. Metabolism of these drugs (e.g., theophylline, chloramphenicol, and acetaminophen) is influenced mainly by hepatocellular function and not as much by changes in hepatic blood flow or plasma protein binding. One report suggested that theophylline clearance may decrease by 45% in a child with acute viral hepatitis.⁴⁸ Because of a lack of specific data on dosage adjustment in hepatic disease, drug therapy should be monitored closely in pediatric patients to avoid potential toxicity from excessive doses, particularly for drugs with narrow therapeutic indices.

Renal Disease

Renal failure decreases the dosage requirement of drugs eliminated by the kidney. Once again, because of limited studies, dosage adjustments in pediatric patients are based largely on data obtained in adults. For many important drugs, such as aminoglycoside antibiotics, renal clearance or rate of elimination is directly proportional to the GFR, as measured by endogenous renal creatinine clearance.

In clinical practice, GFR can be estimated from prediction equations such as the Schwartz formula, which takes into account serum creatinine concentration and the patient's height, gender, and age. The advantage of estimating GFR using the Schwartz equation is rapid determination and the avoidance of a cumbersome 24-hour urine collection.^{49,50} The following formula is used to estimate GFR:

$$\text{GFR} = K \times L / S_{\text{Cr}} \quad (7-1)$$

where GFR is expressed in milliliters per minute per 1.73 m^2 , K = age-specific constant of proportionality (see below), L = child's length in centimeters, and S_{Cr} = serum creatinine concentration in milligrams per deciliter.

Age	K
<1 year of age, low-birth-weight infant	0.33
<1 year of age, full-term infant	0.45
2- to 12-year-old child	0.55
13- to 21-year-old female	0.55
13- to 21-year-old male	0.70

Studies comparing the Schwartz-predicted GFR versus measured GFR noted that the Schwartz formula overestimated GFR in patients with decreasing GFR. The formula may not provide an accurate estimation of GFR in patients with rapidly changing serum creatinine concentrations, as seen in the critical care setting, in infants younger than 1 week, and in patients with obesity, malnutrition, or muscle wasting. Factors that interfere with serum creatinine measurement also may cause errors in estimation of GFR.

Serum drug concentrations should be monitored for drugs with narrow therapeutic indices and eliminated largely by the kidney (e.g., aminoglycosides and vancomycin) to optimize therapy in pediatric patients with renal dysfunction. For drugs with wide therapeutic ranges (e.g., penicillins and cephalosporins), dosage adjustment may be necessary only in patients with moderate-to-severe renal failure.

Cystic Fibrosis

Drug therapy in pediatric patients with cystic fibrosis has been reviewed.⁵¹ For unknown reasons, these patients require increased

doses of certain drugs. Studies have reported higher clearance of drugs such as gentamicin, tobramycin, netilmicin, amikacin, dicloxacillin, cloxacillin, azlocillin, piperacillin, and theophylline in patients with cystic fibrosis compared with patients without the disease. The apparent volume of distribution of certain drugs also may be altered in cystic fibrosis.⁵¹ Severity of the illness may influence the change in dosage requirements, but this is not certain. Chapter 32 reviews these changes in detail.

Other Diseases

Although specific dosage guidelines are not available, pediatric patients with gastrointestinal disease (e.g., celiac disease, gastroenteritis, and severe malabsorption) may require dosage adjustments.⁴⁶ Hypoxemia also has been shown to decrease the elimination of amikacin in low-birth-weight infants.⁵² Critically ill adult and pediatric patients with severe head trauma require higher than normal doses of phenytoin in part because of increased intrinsic clearance.⁵³

ISSUES IN PEDIATRIC DRUG THERAPY

PAIN MANAGEMENT

6 For many years, the term *pain* could not be found in the index of any major pediatric medicine or pediatric surgical textbooks.⁵⁴ The prevailing wisdom was that neonates did not experience pain because of their inadequately developed neuroendocrine systems and nerve pathways. During the last years of the 20th century, however, many research and clinical studies have been performed in the areas of pain management and assessment of neonates, infants, children, and adolescents. Today, results of these discoveries have been incorporated into clinical practice, making effective pain therapy a standard of care and pain assessment the fifth vital sign in modern pediatric practice.⁵⁵

The basic mechanisms of pain perception in infants and children are similar to those of adults, except that pain impulse transmission in neonates occurs primarily along slow-conducting, nonmyelinated C fibers rather than along myelinated A δ fibers. In addition, pain signal transmission in the spinal cord is less precise, and descending inhibitory neurotransmitters are lacking. As a result, neonates and young infants may perceive pain more intensely and be more sensitive to pain than are older children or adults.^{56,57} It is now known that previous pain experience leads to long-term consequences such as alterations in response to a subsequent painful event.⁵⁸ Taddio et al.^{59,60} reported that boys circumcised with the topical anesthetic eutectic mixture of local anesthetics (EMLA) had a lower pain response to subsequent immunizations than those who were circumcised without topical anesthesia. An inadequately treated initial painful procedure may decrease the effect of adequate analgesia in subsequent procedures as a result of altered pain response patterns.

Children consistently report that needles and shots are what they fear most. However, with the current immunization schedule that recommends 14 to 33 injections before adolescence, interventions to decrease injection pain need to be performed (Table 7-1).

Pharmacologic pain management for medical conditions and surgical and postoperative events has progressed considerably over the past decade with the use of continuous opioid infusions, epidural anesthesia, peripheral nerve blockade, local anesthetics, nonsteroidal antiinflammatory drugs, different routes for traditional agents (i.e., transmucosal and transdermal), and nonopioid adjuvant drugs (Table 7-2). New pain management techniques, education, research, and increasing awareness of pain management options have helped to improve the quality of life in children.

TABLE 7-1 Techniques for Minimizing Pain Caused by Injection

Pharmacologic methods	
EMLA ⁶¹ (eutectic mixture of lidocaine and prilocaine)	<i>Advantages:</i> Penetrates the skin to provide anesthesia to a depth of 5 mm; effective in decreasing the pain of IM and subcutaneous injections, venipuncture, IV cannulation, lumbar puncture, circumcision, skin-graft harvesting, and laser dermal therapy; safe and effective in newborns >37 weeks' gestation. <i>Disadvantages:</i> Requires 1 hour before onset of adequate anesthesia, has a vasoconstrictive effect that may make starting IV catheters difficult, may induce methemoglobinemia.
Numby Stuff (lidocaine iontophoresis) ⁶²	<i>Advantages:</i> Provides dermal anesthesia to a depth of 10 mm within 10–20 min; effective in decreasing the pain of IM injection, IV cannulation, venipuncture, lumbar puncture, skin biopsy, and bone marrow aspiration. <i>Disadvantage:</i> Tingling, itching, or burning sensation from the electric current used to transport drug to the tissues.
Vapocoolant sprays (ethyl chloride or dichlorodifluoromethane) ⁶³	<i>Advantages:</i> Vapocoolant is sprayed directly onto the skin or applied to a cotton ball that is held on the area to be anesthetized; provides local anesthesia within 15 seconds; effective in reducing injection pain in children 4–6 years of age. <i>Disadvantages:</i> Brief duration of action, so procedure should be completed in 1 or 2 min; may not be effective in reducing injection pain in infants aged 2–6 months.
Local anesthetic (lidocaine) ⁶⁴	<i>Advantage:</i> Reduces the pain of subsequent needle insertion. <i>Disadvantage:</i> Local anesthetic injection itself is associated with pain and burning sensation.
Pacifier with sucrose ^{65,66}	<i>For preterm neonates:</i> 0.1–0.4 mL of a 12%–24% sucrose solution (place on pacifier or the tongue 2 min before procedure). <i>For term neonates:</i> 1–2 mL of a 12%–24% sucrose solution (place on pacifier or the tongue 2 min before procedure). <i>Advantage:</i> Noninvasive method to reduce pain associated with needle insertion in infants. <i>Disadvantage:</i> Sucrose solution's effect in reducing pain gradually decreases over time.
Other techniques	
Site selection ⁶⁷	<i>For children older than 18 months:</i> Use of the deltoid muscle for IM injections is associated with less pain than injections administered in the thigh. <i>For children older than 3 years:</i> Use of the ventrogluteal area for injection is associated with less pain than the anterior thigh or dorsogluteal area.
Z-tract technique	Z-tract intramuscular injection technique is less painful (pull skin taut at the injection site, give injection, then release the skin); use a higher-gauge needle when the injectable solution is not viscous.
Behavioral	Use of distraction methods (e.g., blowing bubbles, providing music by headphones, relaxation, imagery, self-hypnosis, or having parents present for the procedure) can be helpful.

DRUG ADMINISTRATION

7 Drugs often are given by the intravenous route to seriously ill patients. Syringe pumps are widely used for administration of intravenous drugs. Important steps in successfully administering intravenous drugs include selecting the drug, calculating the dose, preparing the infusion, programming the infusion pump, and delivering the infusion. Use of “smart” pumps is preferred because they can recognize syringes and have drug libraries and dose limits as safety features. The pumps should be accurate; precise; easy to use; accept syringes and administration sets from various manufac-

TABLE 7-2 Opioid Administration for Acute and Severe Pain

Intermittent IV or PO bolus administration (not as needed)	Weak opioids (e.g., codeine, hydrocodone, oxycodone) often are combined with acetaminophen or a nonsteroidal antiinflammatory agent (NSAID) for moderate pain. With dose escalation of combination oral products, be aware that the dose does not exceed recommended daily amounts for acetaminophen or ibuprofen. IV administration of codeine has been associated with allergic reactions related to histamine release. Parenteral administration of codeine is not recommended. Intermittent opioid administration is associated with wide fluctuation between peak and trough levels, so the patient may alternate between peak blood levels associated with untoward effects and trough levels associated with inadequate pain relief when being treated for severe pain.
Intravenous continuous infusion ^{68,69}	Oxycodone and morphine are available in a sustained-release formulation for use with chronic pain (not acute pain). Tablet must be swallowed whole and cannot be administered to patients through gastric tubes. Loading dose is administered to achieve rapidly a therapeutic blood level and pain relief (i.e., morphine loading dose of 0.05–0.15 mg/kg in children; 0.1 mg/kg infused over 90 min in neonates). Loading dose is followed by a maintenance continuous infusion. Doses that are considered safe in children can cause respiratory depression and seizures in neonates because of decreased clearance, immature blood–brain barrier at birth that is more permeable to morphine, and an increased unbound fraction of morphine that increases CNS effects of the drug.
Patient-controlled analgesia (PCA) ⁷⁰	Gives patient some control over his/her pain therapy. PCA allows the patient to self-administer small opioid doses. The PCA-Plus (Abbott, Chicago, IL) pump allows the patient to receive a continuous infusion together with a set number of self-administered doses per hour. PCA helps to eliminate wide peak and trough fluctuations so that levels remain in a therapeutic range. Children as young as 6 or 7 years of age can master the use of PCA.
Epidural and intrathecal analgesia ⁷¹	Effective in the management of severe postoperative, chronic, or cancer pain. Spinal opioids can be administered by a single bolus injection into the epidural or subarachnoid space or by continuous infusion via an indwelling catheter. Dosage requirement by these routes is significantly less than with IV administration (epidural opioid doses: 10-fold lower than IV doses; intrathecal opioid doses: 100-fold lower than IV doses). Morphine, hydromorphone, fentanyl, and sufentanil are effective when administered intrathecally. Bupivacaine is the most commonly used local anesthetic in continuous epidural infusions. Fentanyl, morphine, or hydromorphone usually is combined with bupivacaine for epidural infusions.
Transmucosal administration	Fentanyl lozenge is absorbed transmucosally. It is useful for providing analgesia during painful procedures. Advantages include rapid onset of action (within 15 min), short duration of action (60–90 min), and painless administration because no injection is needed. A common side effect is vomiting and mild-to-moderate oxygen desaturation. Doses of 10–15 mcg/kg provide blood levels equivalent to 3–5 mcg/kg IV.

turers; offer extensive delivery mode combinations including milliliters per hour, body weight, mass, volume over time, custom dilution and intermittent, loading dose, bolus dose, standby, volume limit; wide-ranging flow rates and rate to keep vein open; and adequate internal battery capacity.

No single infusion system is ideal for delivery of all drugs in all institutions for all patients. Each facility must be cognizant of problems of drug delivery and develop specific guidelines for

intravenous infusions. At our institution, specific guidelines are provided for administration of each drug. These guidelines take into account various infusion rates and provide consistency of delivery with each dose. As long as the time for actual delivery is known, times to obtain blood samples for measurement of drug concentration can be adjusted accordingly to generate meaningful data.

ALTERATION OF DOSAGE FORMS

8 Many drugs used in pediatric patients are not available in suitable dosage forms. This necessitates dilution of high concentrations of drugs intended for adult patients. Examples of these drugs include atropine, carbamazepine, diazepam, digoxin, epinephrine, hydralazine, insulin, morphine, phenobarbital, and phenytoin. Volumes ranging from 0.01 to 0.1 mL must be measured to dispense these drugs for use in infants. This obviously can be associated with large errors in measurements, and such errors have caused intoxication with digoxin⁷² and morphine⁷³ in infants. One solution to this problem is to dilute these concentrated products, but such alterations can influence the stability or compatibility of these drugs. Because of limited data, pharmacists justifiably may be reluctant to alter dosage forms of certain drugs.

Selection of the appropriate vehicle to dilute the adult dosage forms for use in pediatric patients can be difficult. Phenobarbital sodium contains propylene glycol in the original product to improve drug stability. Because propylene glycol can cause hyperosmolality in infants,⁴⁰ further addition of this vehicle may not be wise. Because of limited access to intravenous sites in pediatric patients, drugs must be administered through the same site; however, data on drug compatibilities often are missing. Newborn infants often require aminoglycosides for presumed or proven sepsis and calcium gluconate for correction of hypocalcemia. Tobramycin and calcium gluconate have been found to be compatible, at least during a 1-hour administration at the same site.⁷³

Administration of oral drugs continues to challenge parents and nurses. Alteration of these drugs by crushing or mixing, refusal of patients to accept the medication, and loss of drug during administration are some factors that can affect pediatric therapy. A common practice is to mix medications in applesauce, syrup, ice cream, or other vehicles just before administration to make the drugs palatable.

A number of extemporaneous formulations for oral, intravenous, and rectal administration are included in a compilation of products for use in pediatric patients.⁷⁴ However, a specific reference on the stability of many drug formulations is lacking and emphasizes the need for continued research in this area.

Drug administration into the middle ear, nose, or eye of a child requires special attention. Certain drugs (e.g., sodium valproate and morphine) can be administered rectally to infants who have limited access for intravenous drug administration or if oral drug administration cannot be accomplished.

Transdermal drug delivery can be used in pediatric patients (a) to avoid problems of drug absorption from the oral route and complications from the intravenous route and (b) to maximize duration of effect and minimize adverse effects of drugs. As discussed earlier in this chapter, methylphenidate (Daytrana) now is available as a transdermal patch for children with ADHD. Unfortunately, the commercially available transdermal dosage forms (e.g., clonidine and scopolamine) are not intended for pediatric patients; these would deliver doses much higher than needed for infants and children.

MEDICATION ADHERENCE

The issue of medication adherence is more complex in pediatric patients than in adults. Caregivers of young patients must appreci-

ate the importance of understanding and following the prescribing information.

In one study, medication adherence was considered to be a problem in nearly 60% of adolescents (age 12 to 15 years) with asthma. Approximately 40% of patients had severe denial regarding their asthma and its severity. Nearly 80% of patients had preventable asthma exacerbations.⁷⁵

Among the factors that can negatively affect adherence are poor communication between the physician and patient or parent; insufficient prescribing information; lack of understanding about the severity of illness by the patient or parent; lack of interest (e.g., among adolescents); fear of side effects; failure of the patient or parent to remember to administer the drugs; inconvenient dosage forms or dosing schedules involving administration of three or more doses daily; and unpalatability of drug products.⁷⁶ Studies in pediatric volunteers have compared the palatability of antibiotics,⁷⁷ and the data may have important implications for adherence in children.

DOSE REQUIREMENTS

Medication doses often are based on the body weight of neonates, infants, and children, for example, milligrams per kilogram of body weight per day to be given in one or more portions daily. However, certain drugs, including antineoplastic agents, may be given based on body surface area, for example, milligrams per square meter in one or more doses daily. In either case, the total amount of weight- or surface area-based individual or daily dose in a pediatric patient, especially an adolescent, should not exceed the amount of drug indicated in an adult patient.

An additional challenge in managing pediatric drug therapy is understanding the effects of obesity on a population that relies on weight-based dosing. According to the Centers for Disease Control and Prevention, the prevalence of overweight and obese children in the United States nearly doubled from 15% during 1976 to 1980 to more than 30% during 1999 to 2002.⁷⁸ Using ideal body weight versus total body weight to calculate a weight-based dose or to determine body surface area can result in a large variance in obese patients. Additional pharmacokinetic studies are needed to study the effects of obesity on drug distribution, protein binding, and clearance and to identify whether dosing should be adjusted according to total body weight or ideal body weight to achieve consistent drug exposure for individual drugs.^{79,80} Generally, the highest drug dose recommended for a child is the maximum dose approved for adults. However, determining the highest dose of certain drugs for use in children without a known maximum dose for adults (e.g., intravenous immunoglobulin, infliximab, rituximab, and liposomal amphotericin B [AmBisome]) can be difficult.

DRUG INTERACTIONS

Drug interaction studies in pediatric age groups generally are lacking. The data often are extrapolated from studies in adult populations. Special attention should be given to adolescents, who may concurrently use alcohol, recreational/illicit drugs, or other prescription or nonprescription medications without the knowledge of the primary healthcare provider, who must attempt to determine their use to avoid drug interactions.

COMPLEMENTARY AND ALTERNATIVE THERAPY

In a study of patients between 3 weeks and 18 years (mean 5.3 years) of age, 45% of caregivers were giving a product to the children; 27% had given three or more products in the past year. The most

commonly used products were aloe plant/juice (44% of those reporting use of herbal therapies), echinacea (33%), and sweet oil (25%). The most dangerous combination was ephedra (which was withdrawn from the U.S. market in 2004) with albuterol given to adolescents with asthma. Most caregivers did not recognize potential adverse effects or drug interactions associated with herbs. Friends or relatives were the main source of information for 80% of caregivers.⁸¹

Little is known about the efficacy of herbal products in infants, children, and adolescents. Healthcare professionals must ask caregivers specifically about the use of complementary and alternative treatments to minimize the adverse effects and costs associated with ineffective therapies.

MEDICATION SAFETY

9 The Institute of Medicine reported that between 44,000 and 98,000 Americans each year die as a result of medical errors in hospitals.⁸² According to this report, the vast majority of medical errors that cause harm to patients are preventable. Healthcare professionals have a responsibility for creating a safe medication environment and reducing risk to a vulnerable pediatric population.

Pediatric medication errors commonly occur at the medication-ordering step because of the multiple calculations required for weight-based dosing and the adjustments needed for providing therapy to the developing pediatric patient.^{83–85} The United States Pharmacopeia (USP) Center for the Advancement of Patient Safety states that risk to patients when performing repeated calculations involving multiple steps can be minimized using computer-based algorithms.⁸⁶ Since the medication-preparation step is also a high-hazard point owing to the need for dilution or manipulation of commercially available products only available in adult doses, the USP recommends that compounded pediatric medications be prepared and labeled in the pharmacy and verified by a pharmacist. Among drug administration–related errors, wrong dose, wrong technique, and wrong drug are the three most common errors and may be related to an inability to access pediatric drug information. In 2001, the Agency for Healthcare Research and Quality (AHRQ) published an evidence-based assessment of patient safety practices that prevent or reduce medication errors.⁸⁷ Risk-reduction strategies include placing a clinical pharmacist on pediatric wards in hospitals, simplifying the medication-use system, ordering standardized concentrations and doses, implementing computerized physician order-entry systems with dose range checking, dispensing pharmacy-prepared/ready-to-administer doses, standardizing infusion equipment, using smart infusion pumps, using bar-coded medications and bar-coding systems that check the medication at the point of care, and implementing computerized adverse event detection systems.^{85,87–89} Identifying and understanding the high-hazard areas or points of failure in the medication-use process will help in designing strategies that prevent problems before they arise.

CONCLUSIONS

Although tremendous progress has been made in the area of pediatric pharmacotherapy, many questions remain unanswered. The pharmacokinetics of many important drugs have been elucidated, but their pharmacodynamics have not been explored fully. Similarly, the effect of disease states and patient characteristics, such as genetic status, have not been studied for most drugs. The effect of these factors on the development of cytochrome P450 isozymes (e.g., CYP3A4, CYP2D6, CYP1A2, CYP2C9, and CYP2C19), other enzymes, and P-glycoprotein needs to be studied (see Chaps. 5 and 6). Similarly, comparative efficacy and safety data for many therapies are unavailable. Studies on the influence of drug therapy on

clinical and economic outcomes and on quality of life in pediatric patients are needed.

The development of new drugs has contributed to improved patient care. The new FDA regulations (Best Pharmaceuticals for Children Act of 2002) can require the industry to conduct studies and seek labeling of important drugs for use in pediatric patients. As an incentive, a 6-month patent extension and waiver of supplemental new drug application fee are offered to the industry. This should encourage the industry to develop and market more drugs for the pediatric population. However, greater emphasis also should be placed on disease prevention. Millions of children die because of preventable diseases, particularly in developing countries of the world. Administration of vaccines and control of diarrhea alone could save millions of these lives annually. However, the developed countries face different problems. The infant mortality rate in the United States is nearly twice as high among blacks as whites. Improved prenatal care, educational programs, and avoidance of alcohol, smoking, and drugs of abuse during pregnancy may decrease mortality as well as morbidity from illnesses, including acquired immunodeficiency syndrome.

Finally, efforts should be made to offer evidence-based pharmacotherapy. This often is difficult in pediatric populations when the drugs must be used outside the guidelines and indications approved by the FDA. Institutions should develop guidelines for the use of drugs in specific diseases and for the use of high-cost drugs such as colony-stimulating factors, monoclonal antibodies, dornase-alfa, epoetin-alfa, immunoglobulins, surfactants, and growth hormones.

Although much needs to be learned about the optimization of therapy, it is encouraging to witness the continued growth of knowledge in this area that has improved the quality of life and survival from pharmacotherapy in pediatric patients.

KEY CONCEPTS

- 1 The population of persons aged 65 years and older is increasing.
- 2 Age-related changes in physiology can affect the pharmacokinetics and pharmacodynamics of numerous drugs.
- 3 Improving and maintaining functional status is a cornerstone of care for older adults.
- 4 Drug-related problems in older adults are common and cause considerable morbidity.
- 5 Pharmacists can play a major role in optimizing drug therapy and preventing drug-related problems in older adults.

Pharmacotherapy for older adults can cure or palliate disease as well as enhance health-related quality of life (HRQOL). HRQOL considerations for older adults include focusing on improvements in physical functioning (e.g., activities of daily living), psychological functioning (e.g., cognition, depression), social functioning (e.g., social activities, support systems), and overall health (e.g., general health perception).¹ Despite the benefits of pharmacotherapy, HRQOL can be compromised by drug-related problems. The prevention of drug-related adverse consequences in older adults requires that health professionals become knowledgeable about a number of age-specific issues. To address these knowledge needs, this chapter discusses the epidemiology of aging; physiologic changes associated with aging, with emphasis on those changes that can affect the pharmacokinetics and pharmacodynamics of drugs; clinical conditions commonly seen in older adult patients; epidemiology of drug-related problems in older adults; and an approach to reducing drug-related problems through the provision of comprehensive geriatric assessment.

EPIDEMIOLOGY OF AGING

- 1 The older American population is highly diverse and heterogeneous with respect to health status. The demographics and health characteristics of persons aged 65 to 74 years are different from those of persons 85 years of age and older, as are those of persons who are institutionalized compared with those living in the community. It is teasing apart the various threads of wellness and illness,

independence and dependence, and function and dysfunction that make the available demographic and health status data relevant for clinical practice. Understanding this diversity and growth of the older population will allow society to plan for the training, research, and resources needed for future clinical practice and adequate healthcare.

In 2000, persons aged 65 and older accounted for 12.4% (35 million) of the total U.S. population.² Among those older than 65 years, women outnumbered men and accounted for 58.8% of this segment of the population. The gender gap widens with increasing age, with women accounting for 71.1% of the cohort aged 85 years and older and 80% of centenarians.²

In 2011, the first baby boomers will turn 65 years old; this will mark a rapid increase in the older population in the years between 2010 and 2030. By 2030, the older population is projected to double in size relative to the year 2000, with one in five (20%) Americans older than 65 years. This 20% projection for persons aged 65 years and older will remain relatively stable through 2050. However, the proportion of the oldest old (>85 years) will continue to grow. In 2000, the oldest old represented 12.1% of the older population but are projected to double by 2050. The increase in the number of older persons is due not just to the higher post–World War II birth rate but also to the declining mortality rate and the overall better health among older adults.² The decline in early death and the better health of older adults arise for a variety of reasons: (a) public health measures affecting all age groups (e.g., immunizations, prenatal care), (b) advances in medical technology, (c) promotion of a healthy lifestyle, and (d) improvements in living conditions.³ More relevant to providers of care to older Americans is life expectancy at age 65 years. In 2000, white women 65 years of age can expect an average additional 19.2 years of life; black women, 17.4 years; white men, 16.3 years; and black men, 14.5 years.² For a person who survived to age 85 years in 2000, another 5.6 years of life can be expected for men and 6.7 years for women. Given this increase in life expectancy, the increase in the number of centenarians from 37,000 in 1990 to 50,000 in 2000 is not surprising.²

Along with changes in the life expectancy of future older adults, the older population will become more diverse in racial/ethnic composition. In 2000, an estimated 84% of persons aged 65 years and older were non-Hispanic white, 8% were black, 5% were Hispanic, and 2.3% were Asian. By 2050, the percent of non-Hispanic white older adults is projected to decline to 61%, whereas Hispanics will account for 18% and Asians 8% of the older population.²

Most older persons are self-sufficient and live in the community. However, as they age in the community, the likelihood of living alone increases, more so for women than for men. Only 4.5% of older persons reside in a long-term care facility, a decrease since 1990 (5.1%). This decline may be due to the improved health of older adults or the use of alternative long-term care services (e.g., assisted-living facilities, in-home healthcare). Nursing homes resi-

Learning objectives, review questions,
and other resources can be found at
www.pharmacotherapyonline.com.

dents are predominately 85 years and older (45%), followed by persons 75 to 84 years (33.5%), 65 to 74 years (12.2%), and younger than 65 years (9.5%).² Oldest old women (>85 years) compose 42% of nursing home residents.

Physical activity has many positive health benefits in adults, including disease reduction (e.g., cardiovascular disease), weight maintenance, and reduction in physical disability. Only 22% of older adults engage in regular leisure-time physical activity, and this percentage decreases with increasing age.⁴ It is no surprise that obesity is a growing problem in both men (33%) and women (36%) aged 65 to 74 years. The prevalence of obesity decreases to approximately one in four for those older than 75 years.⁴

An important goal in the care of older adults is allowing them to maintain independence and avoid the need for institutionalization for as long as possible. Functional loss or disability often is a final common pathway of many clinical problems in older persons, especially among those older than 75 years. In 2000, 28.6% of older adults reported a physical disability (e.g., difficulty walking, climbing stairs, reaching, lifting, carrying), and 9.5% reported disability with self-care or *basic* activities of daily living (ADLs; e.g., dressing, bathing, transferring, feeding, toileting).⁵ Disability increases with increasing age and is higher in institutionalized older persons, among whom approximately 80% have some problems with mobility and 65% have difficulty with bowel control.⁶ Segments of the population that are especially vulnerable to disability include women, minorities, and those in lower socioeconomic classes. Disability rates have declined significantly during the last 2 decades.² The decline in late-life disability was greatest for limitations in *instrumental* ADLs (e.g., housekeeping chores, shopping, going outside, medication management) and physical disability. Conflicting evidence exists for basic ADL disability, the most severe type of disability that often leads to institutionalization. Multiple factors likely are responsible for the decline in disability prevalence, including improved medical treatment, change in health behaviors (e.g., reduced smoking), and widespread use of assistive devices.²

Chronic diseases or impairments, such as heart disease, stroke, and diabetes, are major causes of disability in older adults. An estimated 80% of older adults have at least one chronic health condition, and more than half have at least two concomitant conditions. Many chronic conditions can be prevented or improved with behavioral

modification, such as diet and physical activity. The prevalence of select common conditions in 2003 to 2004 included hypertension (52%), arthritis (50%), heart disease (32%), any cancer (21%), diabetes (17%), stroke (9%), and asthma (9%). Sensory impairments are common in older adults and pose challenges for maintaining functional independence and interactions with healthcare providers. In 2004, 40% of older adults reported some trouble hearing, and 17% reported difficulties with vision. Furthermore, 13% of older adults have moderate or severe memory impairment, which is a major risk factor for nursing home admission. The prevalence of memory impairment increases dramatically (to 32%) for the oldest old.⁴

Chronic diseases are the primary cause of death in older adults. The leading causes of death among older adults have changed little over the last 20 years. Fig. 8–1 illustrates the leading causes of death from 2004.⁴ Some important trends have emerged over the past 2 decades. First, the death rates for heart disease and stroke have decreased. This trend is secondary to the gains made in the prevention and treatment of these diseases. Second, death secondary to Alzheimer's disease has increased rapidly in recent years. The increased rate is due in part to improvements in the diagnosis and awareness of Alzheimer's disease in the medical community.⁴

Older adults are devoted consumers of medical and prescription drug resources. With older persons accounting for 36% of all hospital stays and 49% of all days of care in hospitals, elders consume almost one third of total U.S. healthcare expenditures.⁷ By 2030, healthcare spending by the U.S. population is projected to increase by 25% simply because of aging demographics.⁷ Although older persons compose 12.4% of the U.S. population, they account for 34% of all prescription drug expenditures.⁸ Overall in 2002, prescription drug spending was estimated to be between \$91 and \$117 billion.⁹ National estimates in 2002 indicated that individuals older than 65 years filled nearly 32 prescriptions per year and that their average annual expenditure for prescription drugs was \$1,740.⁴ In 2003, approximately one fourth (27%) of older adults had no prescription drug coverage, with the poor disproportionately affected (34%).¹⁰ The Medicare Prescription Drug, Improvement and Modernization Act (MMA) began offering coverage to the 43 million Medicare beneficiaries as of January 1, 2006, and this has improved prescription drug coverage for older adults. However, as

FIGURE 8-1. Leading causes of death in 2004, by age group. (Data from Centers for Disease Control and Prevention, National Center for Injury Prevention and Control. 2007, <http://webappa.cdc.gov/sasweb/ncipc/leadcaus10.htm>.)

of June 2006, five million beneficiaries still did not have coverage under MMA or other sources of credible coverage.⁹

HUMAN AGING AND CHANGES IN DRUG PHARMACOKINETICS AND PHARMACODYNAMICS

② There is a progressive functional decline in many organ systems with advancing age. Table 8–1 reviews some common physiologic changes associated with aging, with an emphasis on those changes that can affect pharmacotherapy. For more detailed information, readers are referred to excellent reviews.^{11,12}

Age-associated physiologic changes may cause reductions in functional reserve capacity (i.e., ability to respond to physiologic challenges or stresses) and the ability to preserve homeostasis, thus making elders susceptible to decompensation in stressful situations.^{11–13} To deal with physiologic challenges or stresses, older individuals may require up to 95% of their remaining reserve capac-

ity.^{11,12} The cardiovascular, musculoskeletal, and central nervous systems appear to be most affected.¹² Examples of homeostatic mechanisms that may become impaired include postural or gait stability, orthostatic blood pressure responses, thermoregulation, cognitive reserve, and bowel and bladder function. An event resulting in functional impairment may involve an insult for which the body cannot compensate, and relatively small stresses may result in major morbidity and mortality.^{11–13}

A number of age-related physiologic changes occur that could affect drug pharmacokinetics and pharmacodynamics (see Table 8–1). Unfortunately, data on the pharmacokinetics and pharmacodynamics of individual drugs commonly used in older adults are limited. This information gap may improve with implementation of Food and Drug Administration guidelines calling for pharmacokinetic studies by pharmaceutical companies for new molecular entities likely to be used in older adults.¹⁴

ALTERED PHARMACOKINETICS

Table 8–2 and the following discussion summarize what is known about the effect of aging on each of the four major facets of pharmacokinetics.^{13,15} Of interest, when multivariate population pharmacokinetic analyses are conducted, age by itself seldom is a significant predictor of individual pharmacokinetic parameters (e.g., clearance). Aging-associated changes in drug absorption, distribution, metabolism, and elimination are more important predictors of altered pharmacokinetics than is aging, per se.

Absorption

Most drugs are taken orally; thus, a number of age-related changes in gastrointestinal physiology could affect the absorption of medications. Fortunately, most drugs are absorbed via passive diffusion, and age-related physiologic changes appear to have little influence on drug bioavailability.¹⁶ A few drugs require active transport for absorption, so their bioavailability may be reduced (e.g., calcium in the setting of hypochlorhydria). However, there is evidence for a decreased first-pass effect on hepatic and/or gut wall metabolism that results in increased bioavailability and higher plasma concentrations of drugs such as propranolol and morphine.¹⁶ Increased drug bioavailability also may be seen with the concurrent ingestion of grapefruit juice. Constituents of this product inhibit cytochrome P450 (CYP450) isoenzyme CYP3A4, thus decreasing first-pass metabolism and resulting in exaggerated pharmacologic effects.¹⁷

TABLE 8-1 Physiologic Changes with Aging

Organ System	Manifestation
Body composition	↓ Total body water ↓ Lean body mass ↑ Body fat ↔ or ↓ Serum albumin ↑ α_1 -Acid glycoprotein (↔ or ↑ by several disease states)
Cardiovascular	↓ Myocardial sensitivity to β -adrenergic stimulation ↓ Baroreceptor activity ↓ Cardiac output ↑ Total peripheral resistance
Central nervous system	↓ Weight and volume of the brain Alterations in several aspects of cognition
Endocrine	Thyroid gland atrophies with age Increased incidence of diabetes mellitus, thyroid disease Menopause
Gastrointestinal	↑ Gastric pH ↓ Gastrointestinal blood flow Delayed gastric emptying Slowed intestinal transit
Genitourinary	Atrophy of the vagina due to decreased estrogen Prostatic hypertrophy due to androgenic hormonal changes Age-related changes may predispose to incontinence
Immune	↓ Cell-mediated immunity
Liver	↓ Hepatic size ↓ Hepatic blood flow
Oral	Altered dentition ↓ Ability to taste sweetness, sourness, bitterness
Pulmonary	↓ Respiratory muscle strength ↓ Chest wall compliance ↓ Total alveolar surface ↓ Vital capacity ↓ Maximal breathing capacity
Renal	↓ Glomerular filtration rate ↓ Renal blood flow ↑ Filtration fraction ↓ Tubular secretory function ↓ Renal mass
Sensory	↓ Accommodation of the lens of the eye, causing farsightedness Presbycusis (loss of auditory acuity) ↓ Conduction velocity
Skeletal	Loss of skeletal bone mass (osteopenia)
Skin/hair	Skin dryness, wrinkling, changes in pigmentation, epithelial thinning, loss of dermal thickness ↓ Number of hair follicles ↓ Number of melanocytes in hair bulbs

From Kane et al.¹¹ and Masoro.¹²

TABLE 8-2 Age-Related Changes in Drug Pharmacokinetics

Pharmacokinetic Phase	Pharmacokinetic Parameters
Gastrointestinal absorption	Unchanged passive diffusion and no change in bioavailability for most drugs ↓ Active transport and ↓ bioavailability for some drugs ↓ First-pass extraction and ↑ bioavailability for some drugs
Distribution	↓ Volume of distribution and ↑ plasma concentration of water-soluble drugs ↑ Volume of distribution and ↑ terminal disposition half-life ($t_{1/2}$) for fat-soluble drugs ↑ or ↓ Free fraction of highly plasma protein-bound drugs
Hepatic metabolism	↓ Clearance and ↑ $t_{1/2}$ for some oxidatively metabolized drugs ↓ Clearance and ↑ $t_{1/2}$ for drugs with high hepatic extraction ratios
Renal excretion	↓ Clearance and ↑ $t_{1/2}$ for renally eliminated drugs and active metabolites

From Cusack¹³ and Chapron.¹⁵

Distribution

The distribution of medications in the body depends on factors such as blood flow, plasma protein binding, and body composition, each of which may be altered with age. For example, the volume of distribution of water-soluble drugs is decreased, whereas lipophilic drugs exhibit an increased volume of distribution.^{13,15} Changes in the volume of distribution can have a direct impact on the amount of medication that must be given as a loading dose.

P-glycoprotein, a member of the multidrug resistance (MDR)-associated protein family of efflux transporters, influences the transport of drugs across the blood–brain barrier. Studies using verapamil labeled with carbon-11 (a positron emitter) and positron emission tomography have demonstrated decreased P-glycoprotein activity in the blood–brain barrier with aging. As a result of this, the brain of aged individuals may be exposed to higher than normal levels of drugs and toxins.¹⁸

The two major plasma proteins to which medications can bind are albumin and α_1 -acid glycoprotein, and concentrations of these proteins may change with concurrent pathologies seen with increasing age.¹⁹ For acidic drugs such as naproxen, phenytoin, tolbutamide, and warfarin, decreased serum albumin may lead to an increase in free fraction. An increase in α_1 -acid glycoprotein induced by burns, cancer, inflammatory disease, or trauma may lead to a decreased free fraction of basic drugs such as lidocaine, propranolol, quinidine, and imipramine. In the absence of compromise in excretory pathways, these potential changes are unlikely to have any deleterious clinical effect. However, they may be important to consider when interpreting serum concentrations of these drugs because usually only total drug concentrations (sum of free and protein-bound drug) are reported.

Metabolism

The liver is the major organ responsible for drug metabolism, including phase I (oxidative) and phase II (conjugative) reactions.²⁰ The most remarkable characteristic of hepatic function in older adults is the increase in interindividual variability compared with other age groups, a feature that may obscure true age-related changes.²⁰ Data suggest that age-related declines in phase I metabolism more likely are the result of reduced hepatic volume than reduced hepatic enzymatic activity.²¹ Decreased phase I metabolism (e.g., hydroxylation, dealkylation) producing decreased drug clearance and increased terminal disposition half-life ($t_{1/2}$) has been reported in elders for medications such as diazepam, piroxicam, theophylline, and quinidine. Phase II metabolism (e.g., glucuronidation, acetylation) of medications such as lorazepam and oxazepam appears to be relatively unaffected by advancing age. Hepatic enzyme induction (e.g., by rifampin, phenytoin) or inhibition (e.g., by fluoroquinolone and macrolide antimicrobials, cimetidine) does not appear to be affected by the aging process.^{20,22}

Age-related decreases in hepatic blood flow can decrease significantly the metabolism of drugs with high hepatic extraction ratios, such as imipramine, lidocaine, morphine, and propranolol.²⁰ The effect of aging on polymorphic drug metabolism has not been well studied. Advancing age has been reported both to have no significant effect and to reduce significantly the activity of the CYP450 isoenzyme CYP3A4.^{23,24} Other available data suggest that advancing age has no significant effect on drug acetylation or on CYP450 isoenzyme CYP2D6 or CYP2C9 isoenzyme-mediated metabolism.^{25–28} A single-point blood sampling method for evaluating CYP450 isoenzyme CYP3A4 activity in older adults has been described.²⁹ A number of potential confounding factors, including race, sex, frailty, smoking, diet, and drug–drug interactions, may significantly affect hepatic metabolism in older adults.²⁰

Elimination

Renal excretion is the primary route of elimination for many drugs. Although age-related reductions in glomerular filtration are well

documented, as many as one third of “normal” older adult subjects may have no reduction as measured by creatinine clearance.^{13,15} Moreover, emerging information suggests that renal tubular secretion may not decline in proportion to other renal processes.³⁰ The estimation of creatinine clearance, although not entirely accurate in individual patients, can serve as a useful screening approximation. Cockcroft and Gault³¹ created one of the most commonly used equations for adults with stable renal function whose actual weight is within 30% of ideal body weight:

$$\text{Creatinine clearance} = \frac{(140 - \text{Age}) (\text{Actual body weight})}{72 (\text{Serum creatinine concentration})}$$

where age is given in years, actual body weight in kilograms, and serum creatinine concentration in milligrams per deciliter. For women, multiply this result by 0.85. The Modified Diet in Renal Disease³² equation has become more widely used for estimation of glomerular filtration rate. However, dosing guidelines for medications that primarily are renally cleared still are based on estimated creatinine clearance determined using the Cockcroft and Gault equation. In the future, use of another protein, cystatin C, a low-molecular-mass protein that is produced by all nucleated cells, is freely filtered at the glomerulus, and is not secreted by the renal tubules, may prove to be superior to use of creatinine. This could be the case especially with coexisting conditions such as cachexia, sedentary lifestyle, malnutrition, and hepatic disease, because creatinine clearance is a poor predictor of glomerular filtration in the presence of these conditions.³³

Medications whose excretion is primarily renal and for which there is evidence of age-related reduction in renal and total body clearance include (but are not limited to) amantadine, aminoglycosides, atenolol, captopril, cimetidine, digoxin, lithium, and vancomycin. Some hepatically metabolized medications can yield active, primarily renally excreted metabolites, such as *N*-acetylprocainamide, normeperidine, and morphine-6-glucuronide, which can accumulate with advancing age because of reduced renal function.

CLINICAL CONTROVERSY

When using the Cockcroft and Gault equation to estimate creatinine clearance in older adults, some clinicians round the value up to 1 if the patient's serum creatinine concentration is less than 1. Rounding the serum creatinine concentration may provide an underestimation of creatinine clearance and result in improper dose adjustment of renally eliminated medications. It is important to realize that the equation is merely an estimate, and attempts should be made to determine creatinine clearance accurately when use of certain medications (e.g., metformin) is being contemplated.

ALTERED PHARMACODYNAMICS

There is some evidence of altered drug response or “sensitivity” in older adults. Four possible mechanisms have been suggested: (a) changes in receptor numbers, (b) changes in receptor affinity, (c) postreceptor alterations, and (d) age-related impairment of homeostatic mechanisms.^{13,34} For example, muscarinic, parathyroid hormone, β -adrenergic, α_1 -adrenergic, and μ -opioid receptors exhibit reduced density with increasing age.^{13,34} Evidence from epidemiologic and experimental studies suggests that, independent of pharmacokinetic alterations, older adults are more sensitive to the central nervous system effects of benzodiazepines.^{13,34} Older adults exhibit a greater analgesic responsiveness to opioids compared with their younger counterparts, even when pharmacokinetic parameters are similar in the two groups.^{13,34} In addition, older adults demonstrate an enhanced responsiveness to anticoagulants such as warfarin and heparin as well as to thrombolytic therapy but not to the direct thrombin inhibitor ximelagatran.^{13,34,35} In contrast, older adults exhibit decreased responsiveness to certain drugs

(e.g., β -agonists/antagonists).^{13,34} Reflex tachycardia, seen commonly with vasodilator therapy, often is blunted in older adults, perhaps because of dampened baroreceptor function. For some drugs (e.g., calcium channel blockers), both enhanced responsiveness (as demonstrated by greater reduction in blood pressure) and decreased responsiveness (as demonstrated by reduced atrioventricular nodal blockade) can occur simultaneously in older adults.^{13,34}

CLINICAL GERIATRICS

3 Maintenance of independence and prevention of disability are primary goals in the clinical care of persons 65 years of age and older. To achieve these goals, it is necessary that all healthcare professionals understand the concept of functional status. Functional status is a proxy measure of a patient's ability to live independently and can be determined in part by inquiring about an older person's ability to perform specific tasks. As mentioned previously, the two types of functional measurements are basic ADLs and the more complex instrumental ADLs.^{36,37} However, to fully assess functional status, the patient's psychological state, financial resources, physical function, and social circumstances also must be considered.¹

One of the challenges of maintaining and improving functional status in geriatric individuals is recognizing and managing conditions frequently seen in older adults. Problems found more commonly in older persons sometimes are referred to as the "I's of geriatrics" (Table 8–3).¹¹ These problems are often due to underlying disease processes that may or may not be diagnosed. Examples of diseases and syndromes that can present as common problems in older adults include Parkinson's disease, falls, hip fractures, benign prostatic hypertrophy, dementia, glaucoma, postherpetic neuralgia, and tuberculosis.

Another factor contributing to the challenge of clinical geriatrics is that approximately 50% of older patients present with atypical symptoms or complaints, so use of the classic medical model for diagnosis is difficult. For example, cardiac ischemia in an older person may present as syncope or weakness rather than the typical presentation of chest pain. Confusion may be the presenting symptom of an acute abdominal process rather than the expected severe pain, rigid abdominal muscles, and leukocytosis. Serious adverse consequences may result if a diagnosis is delayed or missed because of these atypical presentations. Such unusual presentations may be due to age-related physiologic changes, the presence of multiple comorbid illnesses or compromised function, and the presence of psychological stressors.³⁸ Table 8–4 lists other examples of medical illnesses that often present atypically in older adults.^{38–40} For very frail older adults, delirium, falls, and nonspecific functional decline (e.g., failure to thrive) frequently are presenting problems.^{38–40}

Multiple coexisting chronic illnesses are another common threat to independence that distinguishes older adults from younger patients. Older patients usually have multiple comorbidities, such as osteoarthritis, heart disease, and diabetes. Although multiple comorbidities can have a substantial impact on a patient's functional status, the mere existence of multiple diseases alone does not determine functional impairment.

TABLE 8-3 The I's of Geriatrics: Common Problems in Older Adults

Immobility	Instability
Isolation	Intellectual impairment
Incontinence	Impotence
Infection	Immunodeficiency
Inanition (malnutrition)	Insomnia
Impaction	Iatrogenesis
Impaired senses	

From Kane et al.¹¹

TABLE 8-4 Atypical Disease Presentation in Older Adults

Disease	Presentation
Acute myocardial infarction	Only ~50% present with chest pain. In general, older adults present with weakness, confusion, syncope, and abdominal pain; however, electrocardiographic findings are similar to those in younger patients.
Congestive heart failure	Instead of dyspnea, the older patient may present with hypoxic symptoms, lethargy, restlessness, and confusion.
Gastrointestinal bleed	Although the mortality rate is ~10%, presenting symptoms are nonspecific, ranging from altered mental status to syncope with hemodynamic collapse. Abdominal pain often is absent.
Upper respiratory infection	Older patients typically present with lethargy, confusion, anorexia, and decompensation of a preexisting medical condition. Fever, chills, and a productive cough may or may not be present.
Urinary tract infection	Dysuria, fever, and flank pain may be absent. More commonly, older adults present with incontinence, confusion, abdominal pain, nausea/vomiting, and azotemia.

From Fried et al.,³⁸ Jarrett et al.,³⁹ and Merck Manual of Geriatrics, 3rd ed, Whitehouse Station, NJ.⁴⁰

DRUG-RELATED PROBLEMS IN OLDER ADULTS

4 Although medications used by older adults can lead to improvement in HRQOL, negative outcomes due to drug-related problems are considerable.^{41–43} Three important and potentially preventable negative outcomes due to drug-related problems that can occur in older adults are adverse drug withdrawal events (ADWEs), which are clinically significant sets of symptoms or signs caused by the removal of a drug; therapeutic failure (inadequate or inappropriate drug therapy and not related to the natural progression of disease); and adverse drug reactions (ADRs), defined as reactions that are noxious and unintended and occur at dosages normally used in humans for prophylaxis, diagnosis, or therapy.^{41–43}

Data on the prevalence of ADWEs and therapeutic failures in older adults are limited. Graves et al.⁴⁴ reported ADWEs in 38 of 124 male outpatients who had discontinued taking 238 medications. Kaiser et al.⁴⁵ reported that 11% of hospital admissions in a group of older frail men were related to therapeutic failure. ADRs occur commonly in older adults, with reported rates ranging from 2.5% to 50.6% depending on the study population and methodology used.⁴¹ In a large study of more than 30,000 Medicare outpatients, Gurwitz et al.⁴⁶ reported that 5% experienced an ADR in a 1-year period, with more serious reactions more likely to be preventable. In contrast, Hanlon et al.⁴⁷ reported that 33% of frail male outpatients had one or more ADRs in a 1-year period. A review suggests that ADRs are the most common type of medication-related problem in elderly nursing home patients.⁴²

ADRs and other drug-related problems (e.g., ADWEs, therapeutic failure) are major threats to the HRQOL of outpatient elders and account for billions of healthcare dollars per year.⁴⁸ In the nursing home setting alone, a cost-of-illness study estimated that drug-related problems (including ADRs and therapeutic failure) cost \$4 billion per year.⁴⁹

RISK FACTORS

Overuse

Polypharmacy can be defined as either the concomitant use of multiple drugs or the administration of more medications than are indicated clinically.⁵⁰ Polypharmacy is common and increasing among older adults. Community-based surveys reveal that older adults take an average of two to nine prescription and nonprescription medications each day.^{50–52} A study of community-dwelling older adults in Finland reported an increase in polypharmacy, with the largest growth among

patients older than 85 years.⁵³ Increased use of dietary supplements, such as herbal products, vitamins, and minerals, may add to the increase in polypharmacy. In a nationwide survey, Kaufman et al.⁵⁴ found that 59% of women and 46% of men older than 65 years used a vitamin or mineral supplement and that 14% of these women and 11% of these men used an herbal product. Outside of the community, a nursing facility survey found that institutionalized older persons took an average of 6.69 routine medications and 27.1% took nine or more medications on a regular basis.⁵⁵ Drug-use studies that defined polypharmacy as use of one or more unnecessary medications showed that polypharmacy occurs in 55% to 59% of older outpatients.^{56,57} A study of frail veterans at hospital discharge reported that 44% of patients were taking one or more unnecessary medications, with 25% of patients starting the medication(s) during hospitalization.⁵⁸ Multiple medication use has been strongly associated with ADRs.⁴¹ Polypharmacy also is problematic for older adults because it may increase the risk of geriatric syndromes (e.g., falls, cognitive impairment), diminished functional status, and healthcare costs.^{50,59,60}

Inappropriate Prescribing

Inappropriate prescribing can be defined as prescribing medications outside the bounds of accepted medical standards.⁶¹ This phenomenon occurs commonly in older outpatients, as exemplified by one study in which 92% of patients were taking at least one medication with one or more inappropriate ratings based on clinical review applying explicit criteria.⁶² Studies using explicit drug-use review criteria have found that between 15% and 21% of community-dwelling older adults take one or more medications that have a dose, duration, duplication, or drug-interaction problem.^{63,64}

Alternatively, inappropriate prescribing can be defined as prescribing drugs whose use should be avoided because their risk outweighs their potential benefit.⁶⁵ A European study found that 20% of older home-care patients used at least one inappropriate medicine as defined by explicit criteria.⁶⁶ A study of inappropriate drug use in U.S. long-term care facilities found that 25% of residents took one or more inappropriate medications as defined by explicit criteria.⁶⁷

CLINICAL CONTROVERSY

At present, the best way to measure inappropriate prescribing is not clear. The association between explicit criteria developed by Beers et al. (known commonly as the Beers' criteria)⁶⁵ for inappropriate prescribing or other measures of inappropriate prescribing and health outcomes has been mixed.⁶⁸ We recommend further studies of the predictive validity of evidence-based standards for measuring inappropriate prescribing of medications in older adults.

Underuse

An important and increasingly recognized problem in elders is *underuse*, defined as the omission of drug therapy that is indicated for treatment or prevention of a disease or condition.⁶¹ A study of community-dwelling elders found that 50% of 372 vulnerable adults were not prescribed an indicated medication. The most common problems were the lack of a gastroprotective agent for high-risk nonsteroidal antiinflammatory drug users, no angiotensin-converting enzyme inhibitor for patients with diabetes and proteinuria, and no calcium and/or vitamin D for those with osteoporosis.⁶⁹ A study of older adults in assisted-living facilities revealed that 62% of residents with a diagnosis of heart failure did not take an angiotensin-converting enzyme inhibitor, and 61% of those with osteoporosis did not take calcium supplements.⁷⁰

Underuse may have an important relationship with negative health outcomes in older adults, including functional disability, death, and

health services use.⁶¹ Underuse of medication in general because of limiting access of Medicaid patients to medications more than doubled the risk of admission to a nursing home.⁷¹ Tamblyn et al.⁷² studied the effects of a deductible and a 25% coinsurance fee for medications taken by elders in Canada. This reform led to a decrease in the number of essential medications (e.g., furosemide, anticoagulants, angiotensin-converting enzyme inhibitors) used by older patients and increased costs owing to adverse events and emergency department visits.

Medication Nonadherence

The World Health Organization (WHO) defines *medication adherence* as “the extent to which a person’s behavior—taking medication...corresponds with agreed recommendations from a healthcare provider.”⁷³ Given that definition, nonadherence could be defined as not filling the prescription, stopping use of the medication before the entire supply is consumed, or taking more or less of the medication than stated by the label. The prevalence rate of medication nonadherence in older adults ranges from 40% to 80% (mean approximately 50%).^{74,75} Older and younger patients have similar adherence when the number of drugs taken is similar.⁷⁶ In fact, some evidence indicates that adherence may be better in older adults for some conditions.^{74,77,78} According to the AARP (formerly the American Association for Retired Persons) and a study in the Medicare population, cost is a common reason why older adults do not fill their prescriptions.^{79,80} Older patients also may not adhere to their regimens because of possible adverse effects, an inability to read product labels, or a lack of full understanding of information about the prescribed medication.^{79,81}

Limited retrospective data suggest that nonadherence is associated with increased health services use and ADRs. In a 2001 study, nonadherence was the possible cause of more than 10% of older adult hospital admissions.⁸² A study by Col et al.⁸³ evaluated 315 consecutive older patients admitted to a hospital and determined that 11.4% of admissions resulted from nonadherence. Gurwitz et al.⁴⁶ found that 21% of preventable ADRs in elderly outpatients were due to errors in patient adherence. On the positive side, a study found that increased medication adherence was associated with fewer hospitalizations and decreased cost in patients with certain chronic medical conditions (e.g., diabetes, hypertension).⁸⁴

PROVISION OF COMPREHENSIVE GERIATRIC ASSESSMENT

⑤ Given that drug-related problems are common, costly, and clinically important, how can they be prevented/managed? A solution may lie in comprehensive geriatric assessment. The term *comprehensive geriatric assessment* has been applied to geriatric evaluation and management (GEM), in which GEM clinicians (which often include pharmacists) manage the patient. Comprehensive geriatric assessment has become a cornerstone in the care of older adults. A comprehensive review has summarized its effectiveness in improving suboptimal prescribing and reducing ADRs.⁶¹

Pharmacists can independently play a significant role in optimizing pharmacotherapy for older adults. The results from 13 randomized controlled studies show that clinical pharmacy interventions can reduce drug-related problems and improve health outcomes in older adults.⁸⁵ Subsequent published studies also have demonstrated the value of pharmacists in improving drug therapy for elders.^{61,86,87}

The following subsections provide an approach to how pharmacists in any practice setting (especially those providing medication therapy management services under the new Medicare Part D program) can optimize medication use through the provision of comprehensive geriatric assessment.

HISTORY TAKING

Several difficulties may occur while taking medication histories from older adults. They include (a) communication problems (impaired hearing and vision), (b) underreporting (e.g., health beliefs, cognitive impairment), (c) reporting of vague or nonspecific symptoms (altered presentation), (d) coexistence of multiple diseases and/or use of multiple medications, (e) reliance on a caregiver for the history, and (f) lack of medical records to confirm findings. Despite these potential difficulties, health professionals should find value in collecting this vital medication history information.

The importance of inquiring about use of nonprescription medications and dietary supplements in older adults cannot be overstressed. A national survey reported that half of community-dwelling older adults take one or more vitamins or minerals and another 12% take one or more herbal/botanical agents.⁵⁴

Asking older adults and their caregivers about methods they use to keep track of medicines is important. This will allow design of solutions to any problems detected and prevent repeating of ineffective, previously used methods.

Patients and caregivers should be asked about risk factors for prescribing problems (e.g., utilizing multiple physicians and pharmacies) and adherence problems (e.g., impaired hearing, vision, and/or cognition; inability to open safety caps, pay for medicines, or swallow medications).⁸⁸ The drug history should end with an inquiry about any past allergies to medications and whether patients currently or in the recent past experienced any adverse effects, unwanted reactions, or other problems with their medications.⁸⁹

ASSESSING AND MONITORING DRUG THERAPY

The first step in the assessment is to determine whether drug-related problems are causing any of the patient's symptoms/problems. In particular, consider whether any current medications are causing any geriatric syndrome (e.g., falls, urinary incontinence, cognitive impairment). Table 8-5 lists medications for which there is evidence that use increases the risk of cognitive impairment.⁹⁰ The next step is to match the medical problem list with the drug list. If a drug does not have a match with the problem list, the drug may not be needed. Conversely, if the patient has a chronic condition and is not taking a medication, consider whether the patient would benefit from an essential evidence-based drug to treat the condition. Next, examine laboratory test results and vital signs that can be used to monitor the efficacy and toxicity of each medication. Table 8-6 lists laboratory monitoring recommendations for medications used in long-term care facilities.⁹¹ Finally, assess

TABLE 8-5 Drugs/Drug Classes Associated with Altered Cognition and/or Cognitive Disorders

Antiarrhythmic agents (e.g., disopyramide)
Antiemetic/antivertigo agents (e.g., meclizine)
Antihistamines (e.g., diphenhydramine, hydroxyzine)
Antiparkinsonian agents (e.g., benztropine, trihexyphenidyl)
Antipsychotic agents (e.g., thioridazine)
Antispasmodic agents (e.g., belladonna, flavoxate)
Benzodiazepines
Central nervous system drugs, especially when several agents are used concomitantly (as in polypharmacy)
Digoxin
Histamine H ₂ receptor antagonists
Nonsteroidal antiinflammatory drugs
Opioid agonists (especially meperidine, pentazocine)
Skeletal muscle relaxants (e.g., cyclobenzaprine)
Tricyclic antidepressants (e.g., amitriptyline)

Data from Kotlyar M, Gray SL, Lindblad CJ, Hanlon JT. *Psychiatric Manifestations of Medications in the Elderly*. In Malletta G, Agronin M (editors). *Principles and Practice of Geriatric Psychiatry*, 1st ed. Philadelphia, PA: Lippincott Williams and Wilkins 2005;605-615.

TABLE 8-6 Centers for Medicare and Medicaid Services Guidelines for Monitoring Medication Use

Drug	Monitoring
Acetaminophen (>4 g/day)	Hepatic function tests
Aminoglycosides	Serum creatinine, drug levels
Hypoglycemic agents	Blood sugar levels
Antiepileptic agents (older)	Drug levels
Angiotensin-converting enzyme inhibitors	Potassium levels
Antipsychotic agents	Extrapyramidal adverse effects
Appetite stimulants	Weight, appetite
Digoxin	Serum creatinine, drug levels
Diuretic	Potassium levels
Erythropoiesis stimulants	Blood pressure, iron and ferritin levels, complete blood count
Fibrates	Hepatic function test, complete blood count
Iron	Iron and ferritin levels, complete blood count
Lithium	Drug levels
Niacin	Blood sugar levels, hepatic function tests
Statins	Hepatic function tests
Theophylline	Drug levels
Thyroid replacement	Thyroid function tests
Warfarin	Prothrombin time/international normalized ratio

From reference 91.

the appropriateness of the remaining medications. A variety of approaches can be used.⁶¹ One standardized measure with demonstrated reliability and validity is the Medication Appropriateness Index (MAI).^{68,92} The MAI consists of 10 questions that should be asked about each medication (Table 8-7). Some other factors to consider during drug regimen review include medication storage problems and drug interactions with food and/or laboratory test results.

CLINICAL CONTROVERSY

An increasing number of clinical trials are enrolling older adult patients. For example, we now have evidence supporting the cardiac benefits of pravastatin in older adults.⁹³ Clinicians must weigh the risks and benefits of adding drug therapy to a patient's drug regimen because increasing the number of drugs may decrease adherence and lead to an increased risk for ADRs. Furthermore, a clinician must decide whether adding drug therapy in patients who may not live long enough to benefit from the medication is ethical.

DOCUMENTING PROBLEMS AND FORMULATING A THERAPEUTIC PLAN

The clinician must document the problems that have been detected, develop a therapeutic plan to resolve them, and establish reasonable

TABLE 8-7 Medication Appropriateness Index

Questions to Ask About Each Individual Medication

1. Is there an indication for the medication?
2. Is the medication effective for the condition?
3. Is the dosage correct?
4. Are the directions correct?
5. Are the directions practical?
6. Are there clinically significant drug-drug interactions?
7. Are there clinically significant drug-disease/condition interactions?
8. Is there unnecessary duplication with other medication(s)?
9. Is the duration of therapy acceptable?
10. Is this medication the least expensive alternative compared with others of equal utility?

Reprinted and adapted from *J Clin Epidemiol*, Vol. 45, Hanlon JT, Schmadre KE, Samsa GP, et al. A method for assessing drug therapy appropriateness, Pages 1045-1051, Copyright 1992, with permission from Elsevier.

therapeutic end points. Remember that what may be a reasonable end point for a 40-year-old patient may not be as reasonable for an 80-year-old patient when comorbidities, functional status, and life expectancy are taken into consideration.

CONSULTING THE PHYSICIAN REGARDING PROBLEMS AND CONCERNS

In most cases, the pharmacist or other healthcare professional should contact a patient's physician regarding problems and concerns that have been detected and documented. In discussing the patient in this context, the importance of optimizing the prescribing for the older adult patient before implementing strategies to enhance his or her adherence cannot be overstressed. Otherwise, adherence intervention, if effective, may result in patient harm. Similarly, in institutional settings, strategies to reduce medication errors may not improve patient outcomes if prescribing is not improved beforehand.

COUNSELING AND ADHERENCE AIDS

Before dispensing medication, consider some general factors that may enhance adherence by older adults, such as modifying medication schedules to fit patients' lifestyles, prescribing generic agents to reduce costs, and using easy-to-open bottles, easy-to-swallow dosage forms, and larger type on direction and auxiliary labels.⁹⁴ The WHO suggests clinicians consider five dimensions when assessing medication adherence: social/economic factors (e.g., cultural beliefs), provider–patient/healthcare system factors (e.g., provider–patient relationship), condition-related factors (e.g., chronic conditions), therapy-related factors (e.g., regimen complexity), and patient-related factors (e.g., visual or hearing impairment).⁷³ Finally, when dispensing medications (particularly new medications or previously used medications that have changed in appearance or directions for use), provide both written and oral drug information to the patient and caregiver.

To improve the likelihood of adherence, the healthcare professional should recruit active patient and caregiver involvement, stress the importance of adherence, and consider the use of adherence-enhancing aids (e.g., special packaging, a medication record, a drug calendar, medication boxes, magnification for insulin syringes, dose-measuring devices, and spacers for metered-dose inhalers).^{95,96} In institutional settings, discussion of special considerations (e.g., medications that can be crushed and given via feeding tube) with healthcare professionals responsible for medication administration is prudent.

DOCUMENTING INTERVENTIONS AND MONITORING PATIENT PROGRESS

All interventions must be documented, and the steps just outlined must be repeated over time with older adult patients. During followup contacts, minimum inquiry should include asking patients whether they have any questions or concerns regarding medicines and determining whether the therapeutic end points previously established have been achieved. To assess potential ADRs, ask patients whether they currently or recently have experienced any side effects, unwanted reactions, or other problems with their medications.

TARGETING HIGH-RISK OLDER ADULTS

In busy practices, the approach outlined may not be feasible for every patient. Therefore, practitioners may consider targeting these activities to patients at high risk for developing drug-related problems. Geriatric experts have identified risk factors for preventable ADRs in older adult nursing home patients.⁹⁷ These include the following medication-related factors: (a) polypharmacy (i.e., use of seven or more medications or more than three cardiac medications), and (b) taking specific

high-risk drugs (e.g., anticoagulant, antidepressant, anti-infective, anti-psychotic, anticonvulsant, opioid analgesic, sedative/hypnotic, skeletal muscle relaxant). Another study of geriatric experts identified 21 risk factors for ADRs in ambulatory older adults.⁹⁸ Other unique risk factors include (a) medication-related issues (i.e., with anticholinergics, benzodiazepines, chlorpropamide, corticosteroids, nonsteroidal antiinflammatory drugs), (b) certain patient characteristics (e.g., multiple comorbidities, multiple prescribers, age 85 years and older, dementia, regular use of alcohol, decreased renal function), (c) use of drugs with narrow therapeutic ranges (e.g., lithium, theophylline), (d) history of an ADR, and (e) recent hospitalization.

CONCLUSIONS

The number of people older than 65 years is growing in the United States and around the world, and individuals older than 85 years are the fastest growing segment of the U.S. population. A number of physiologic changes associated with age, especially hepatic metabolism and renal excretion, affect the pharmacokinetics and pharmacodynamics of drugs. Improving and maintaining the patient's functional status and managing the patient's comorbidities are hallmarks of clinical geriatrics. Certain medical conditions are restricted to older adults, and drug-related problems represent a major concern for this group. Innovative approaches, such as the provision of comprehensive geriatric assessment by pharmacists and other healthcare professionals, are needed to decrease the occurrence of these drug-related problems.

Pharmacoepidemiology

ANDY STERGACHIS, THOMAS K. HAZLET, AND DENISE BOUDREAU

KEY CONCEPTS

- 1 Risks and benefits are commonly identified only after a drug is used widely by the general population.
- 2 Observational study designs are essential for the study of risks and benefits associated with marketed drugs.
- 3 Not all associations represent a cause-and-effect relationship.
- 4 Regulatory agencies are under pressure to identify and respond to postapproval drug safety issues.

1 The practice of pharmacotherapy presents numerous challenges to clinicians as they apply knowledge of the benefits and risks of pharmaceuticals to individual and population-based patient care. A great deal of our understanding about the efficacy and short-term safety of drugs arises from well-controlled studies conducted during the drug development and approval process. However, many additional risks and, increasingly, additional benefits are only identified after the drug is used widely by the general population. Our gaps in knowledge of risks and benefits at the time a drug is marketed is a result of numerous characteristics of preapproval studies, including limited sample size, relatively short study followup, restricted characteristics of persons studied, and differences in research settings from real-life conditions

once a drug is marketed. Benefits and risks learned following a drug's approval may range from relatively minor to clinically important effects that seriously alter an individual drug's risk-to-benefit profile. The association between certain appetite-suppressant drugs and primary pulmonary hypertension and valvular heart disease, and between some cyclooxygenase-2 inhibitors and cardiovascular events, are two examples where serious adverse effects were discovered only after these drugs had come into widespread use.¹⁻⁴ These examples highlight the inherent limitations of the drug development process, the limitations of the regulatory framework for contemporary medical products (drugs, biologics, and medical devices), and the need to study populations receiving medications obtained through usual clinical practice. The liver toxicity seen with troglitazone and more recently, rosiglitazone, is another example of the valuable contribution of close monitoring to drug safety. The first thiazolidinedione introduced for treatment of type 2 diabetes mellitus in 1997, troglitazone was withdrawn from the market based on reports of serious hepatocellular injury. In mid-2007, heart attacks and related deaths were observed in pooled clinical trials data for some patients receiving rosiglitazone, another thiazolidinedione subsequently approved for diabetes.⁵ Medical products must also be monitored closely following their introduction into the marketplace, and this information has value when applied to clinical practice. This chapter describes the role of pharmacoepidemiology in drug development and therapeutics and characterizes the primary methods and contemporary issues in this field.

PETER A. CHYKA

KEY CONCEPTS

- 1 Poisoning can result from exposure to excessive doses of any chemical, with medicines being responsible for most childhood and adult poisonings.
- 2 The total number and rate of poisonings have been increasing, but preventive measures, such as child-resistant containers, have reduced mortality in young children.
- 3 Immediate first aid may reduce the development of serious poisoning, and consultation with a poison control center may indicate the need for further therapy.
- 4 The use of ipecac syrup, gastric lavage, and cathartics has fallen out of favor as routine therapies, whereas activated charcoal and whole-bowel irrigation still are useful for gastric decontamination of appropriate patients.
- 5 Antidotes can prevent or reduce the toxicity of certain poisons, but symptomatic and supportive care is essential for all patients.
- 6 Acute acetaminophen poisoning produces severe liver injury and occasionally kidney failure. A determination of serum acetaminophen concentration may indicate whether there is risk of hepatotoxicity and the need for acetylcysteine therapy.
- 7 Anticholinesterase insecticides may produce life-threatening respiratory distress and paralysis by all routes of exposure and can be treated with symptomatic care, atropine, and pralidoxime.
- 8 An overdose of calcium channel antagonists will produce severe hypotension and bradycardia and can be treated with supportive care, calcium, glucagon, and insulin with supplemental dextrose.
- 9 Poisoning with iron-containing drugs produces vomiting, gross gastrointestinal bleeding, shock, metabolic acidosis, and coma and can be treated with supportive care and deferoxamine.
- 10 Overdoses of tricyclic antidepressants can cause arrhythmias, such as prolonged QRS intervals and ventricular dysrhythmias, coma, respiratory depression, and seizures and are treated with symptomatic care and intravenous sodium bicarbonate.

Poisoning is an adverse effect from a chemical that has been taken in excessive amounts. The body is able to tolerate and, in some

Learning objectives, review questions, and other resources can be found at
www.pharmacotherapyonline.com.

cases, detoxify a certain dose of a chemical; however, once a critical threshold is exceeded, toxicity results. Poisoning can produce minor local effects that can be treated readily in the outpatient setting or systemic life-threatening effects that require intensive medical intervention. This spectrum of toxicity is typical for many chemicals with which humans come in contact. Virtually any chemical can become a poison when taken in sufficient quantity, but the potency of some compounds leads to serious toxicity with small quantities (Table 10–1).¹ Poisoning by chemicals includes exposure to drugs, industrial chemicals, household products, plants, venomous animals, and agrochemicals. This chapter describes some examples of this spectrum of toxicity, outlines means to recognize poisoning risk, and presents principles of treatment.

EPIDEMIOLOGY

Each year poisonings account for approximately 30,000 deaths and at least 1.4 million emergency department visits in the United States.^{2,3} Adults, 20 to 59 years of age are at greatest risk for a poisoning death, and males have a twofold higher incidence of death than do females. One fifth of all adult poisoning deaths are due to suicide. Poisoning deaths in adults are most commonly caused by motor vehicle exhaust (carbon monoxide), opioids, antidepressants, benzodiazepines, sedatives, alcohol, and cocaine.^{3,4} Approximately 0.2% of poisoning deaths involve children younger than 5 years. The number and rates of poisoning deaths from all circumstances have been increasing steadily, with a 50% increase from 1999 to 2004.³ Age-adjusted annual rates for unintentional poisoning deaths increased from 4.4 per 100,000 population in 1999 to 7.1 in 2004 (63% increase).⁵ This increase in mortality is attributed to poisonings from drugs (primarily prescription opioids; secondarily cocaine and prescription psychotherapeutic drugs, e.g., sedatives), which increased by 68% compared to an increase of 1% from other substances.⁵

1 Several databases in the United States provide different levels of insight into and documentation of the poisoning problem (Table 10–2). Poisonings documented by U.S. poison centers are compiled in the annual report of the American Association of Poison Control Centers' National Poison Data System (AAPCC-NPDS).⁶ Although it represents the largest database on poisoning, it

TABLE 10-2 Comparison of Various Poisoning Databases

Database (Abbreviation)	Characteristics
Death certificates from state health departments compiled by the National Center for Health Statistics (NCHS) www.cdc.gov/nchpc/wisqars	Compiles all death certificates whether the cause of death was by disease or external forces. Data typically verified by laboratory and clinical observations.
National Electronic Injury Surveillance System of U.S. Consumer Product Safety Commission (NEISS) www.cdc.gov/nchpc/wisqars	Surveys electronically all injuries, including poisonings, treated daily at a sample of approximately 100 emergency departments. Used to identify product-related injuries.
Drug Abuse Warning Network (DAWN) of the Federal Substance Abuse and Mental Health Services Administration www.dawninfo.samhsa.gov (SAMHSA)	Identifies substance abuse-related episodes and deaths as reported to approximately 420 hospitals and 120 medical examiners.
The American Association of Poison Control Centers'-National Poison Data System (AAPCC-NPDS) www.aapcc.org	Represents largest database of poisonings with high representation of children based on voluntary reporting to poison control centers.

is not complete because it relies on individuals voluntarily contacting a poison control center. The AAPCC-NPDS dataset captures approximately 5% of the annual number of deaths from poisoning tabulated in death certificates.⁴ Despite this shortcoming, AAPCC-NPDS provides valuable insight into the characteristics and frequency of poisonings. In the 2005 AAPCC-NPDS summary, 2,424,180 poisoning exposures were reported by 61 participating poison centers that served a population of 296 million people.⁶ Children younger than 6 years accounted for 51% of cases. The home was the site of exposure in 93% of the cases, and a single substance was involved in 91% of cases. An acute exposure accounted for 92% of cases, 84% of which were unintentional or accidental exposures. Only 13% were intentional. Fatalities accounted for 1,261 (0.05%) cases, of which 2% were children younger than 6 years. The distribution of substances most frequently involved in pediatric and adult exposures differed; however, medicines were the most frequently involved (51%) substances (Table 10-3). Seventy-four percent of the poison exposures were treated at the scene, typically a home. In summary, children account for most of the reported poisonings with morbidity, but adults account for a greater proportion of mortality from poisoning.

ECONOMIC IMPACT OF POISONING

Poisoning accounted for a total lifetime cost of \$12.6 billion annually in 2003 dollars.⁷ Estimates of the lifetime cost of injury include related health care costs and lost lifetime earnings of the victim; however, they do not include the costs of suffering, reduced productivity of caregivers, or legal costs. The definition of poisoning

TABLE 10-3 Poison Exposure by Age Group and Fatal Outcome, Ranked in Decreasing Order

for this economic estimate excluded poisoning from alcohol and illicit drugs.

POISON PREVENTION STRATEGIES

2 The number of poisoning deaths in children has declined dramatically over the past three decades, due, in part, to the implementation of several poison prevention approaches.^{7,8} These include the Poison Prevention Packaging Act (PPPA) of 1970, the evolution of regional poison control centers, the application of prompt first aid measures, improvements in overall critical care, development of less toxic product formulations, better clarity in the packaging and labeling of products, and public education on the risks and prevention of poisoning.⁹ Although all these factors play a role in minimizing poisoning dangers, particularly in children, the PPPA has perhaps had the most significant influence.⁸ The intent of the PPPA was to develop packaging that is difficult for children younger than 5 years to open or to obtain harmful amounts within a reasonable period of time. However, the packaging was not to be difficult for normal adults to use properly. Safety packaging is required for a number of products and product categories (Table 10-4). Child-resistant containers are not totally childproof and may be opened by children, which can result in poisoning. Despite the success of child-resistant containers, many adults disable the hardware or simply use no safety cap, thus placing children at risk.¹⁰ Fatigue of the packaging materials can occur, which underscores the need for new prescription ware for refills, as required in the PPPA.¹¹

Poison prevention requires constant vigilance because of new generations of families in which parents and grandparents must be educated on poisoning risks and prevention strategies. New products and changes in product formulations present different poisoning dangers and must be studied to provide optimal management. Strategies to prevent poisonings should consider the various psychosocial circumstances of poisoning (Table 10-5), prioritize risk groups and behaviors, and customize an intervention for specific situations.^{12,13}

TABLE 10-5 Psychosocial Characteristics of Poisoning Patients

Children	Young Adults	Elderly
Act purposefully or are poisoned by caretaker or sibling	Intentional abuse or suicidal intent is possible	Suicidal intent or unintentional misuse
Act with developmentally appropriate curiosity	Disregard or cannot read directions	Confuse product identity and directions for use
Attracted by product appearance	Do not recognize poisoning risk	Do not recognize poisoning risk
Ingest substances that adults find unpleasant	Reluctant to seek assistance until ill	Comorbid conditions complicate toxicity
React to stressful and disrupted household	Exaggerate or misrepresent situation	Unable or unwilling to describe situation
Imitate adult behaviors (e.g., taking medicine)	Peer pressure to experiment with drugs	Multiple drugs may lead to adverse reactions

TABLE 10-6 Considerations in Evaluating the Results of Some Common Immunoassays Used for Urine Drug Screening

Drug	Detection after Stopping Use	Comments
Amphetamines	2–5 days	Many sympathomimetic amines, such as pseudoephedrine, ephedra, phenylephrine, fenfluramine, and phentermine, may cause positive results.
Benzodiazepines	Up to 2 weeks with prolonged or heavy use Up to 6 weeks with chronic use of some drugs	Other drugs, such as selegiline, chlorpromazine, trazodone, bupropion, and amantadine, may cause false-positive results depending on the assay. Ability to detect benzodiazepines varies by drug.
Cannabinoid metabolite (marijuana)	7–10 days Up to 1–2 months with prolonged or heavy use	Extent and duration of use will affect detection time. Drugs such as ibuprofen and naproxen may cause false-positive results depending on the assay.
Cocaine metabolite (benzoylecgonine)	12–72 hours Up to 1–3 weeks with prolonged or heavy use	Cocaine is metabolized rapidly, and specific metabolites are typically the substance detected. False-positive results from “caine” anesthetics and other drugs are unlikely.
Opioids	2–3 days Up to 6 days with sustained-release formulations Up to 1 week with prolonged or heavy use	Because the assay was made to detect morphine, detection of other opioids, such as codeine, oxycodone, hydrocodone, and other semisynthetic opioids, may be limited. Some synthetic opioids, such as fentanyl and meperidine, may not be detected. Drugs such as rifampin and some fluoroquinolones may cause false-positive results depending on the assay.
Phencyclidine	2–10 days 1 month or more with prolonged or heavy use	Drugs such as ketamine, dextromethorphan, diphenhydramine, and sertraline may cause false-positive results depending upon the assay.

RECOGNITION AND ASSESSMENT

The clinician's initial responsibility is to determine whether a poisoning has occurred or a potential for development of a poisoning exists. Some patients provide a clear account of an exposure that occurred with a known quantity of a specific agent. Other patients appear with an unexplained illness characterized by nonspecific signs and symptoms and no immediate history of ingestion. Exposure to folk remedies, dietary supplements, and environmental toxins also should be considered. Patients with suicide gestures can deliberately give an unclear history, and poisoning should be suspected routinely. Poisoning and drug overdoses should be suspected in any patient with a sudden, unexplained illness or with a puzzling combination of signs and symptoms, particularly in high-risk age groups. Nearly any symptom can be seen with poisoning, but some signs and symptoms are suggestive of a particular toxin exposure.¹⁴ Compounds that produce characteristic clinical pictures (toxidromes), such as organophosphate poisoning with pinpoint pupils, rales, bradycardia, central nervous system depression, sweating, excessive salivation, and diarrhea, are most readily recognizable.¹⁵ The recognition of chemicals responsible for acute mass emergencies resulting from industrial disasters, hazardous materials accidents, or acts of terrorism may be aided by evaluating characteristic signs and symptoms.¹⁶ Assessment of the patient may be aided by consultation with a poison control center. The center can provide information on product composition, typical symptoms, range of toxicity, laboratory analysis, treatment options, and bibliographic references. Furthermore, the center will have specially trained physicians, pharmacists, nurses, and toxicologists on staff or available for consultation to assist with difficult cases. Consultation with a poison control center also may identify changes in recommended therapy. A nationwide toll-free poison center access number (1-800-222-1222) routes callers to the local poison control center.

When the circumstances of a poison exposure indicate that it is minimally toxic, many poisonings can be managed successfully at the scene of the poisoning.^{6,17} Poison control centers typically monitor the victim by telephone during the first 2 to 6 hours of the exposure to assess the patient's status and outcome of first aid.

Once a poisoning is suspected and confirmation of the diagnosis is needed for medical or legal purposes, appropriate biologic material should be sent to the laboratory for analysis. Gastric contents may

contain the greatest concentration of drug, but they are difficult to analyze. Blood or urine can be tested by qualitative screening in order to detect a drug's presence.^{18,19} The results of a qualitative drug screen can be misleading because of interfering or low-level substances (Table 10-6); it rarely guides emergency therapy and thus has questionable value for nonspecific, general screening purposes.^{18,19} Consultation with the laboratory technician and review of the assay package insert will help to determine the sensitivity and specificity of the assay. Quantitative determination of serum concentrations may be important for the assessment of some poisonings, such as those containing acetaminophen, ethanol, methanol, iron, theophylline, and digoxin.²⁰

PHARMACOKINETICS OF OVERDOSE

The pharmacokinetic characteristics of drugs taken in overdose may differ from those observed following therapeutic doses (Table 10-7).^{21,22} These differences are the result of dose-dependent changes in absorption, distribution, metabolism, or elimination;

TABLE 10-7 Examples of the Influence of Drug Overdosage on Pharmacokinetic and Pharmacodynamic Characteristics

Effect of Overdosage ^a	Examples
Slowed absorption due to formation of poorly soluble concretions in the gastrointestinal tract	Aspirin, lithium, phenytoin, sustained-release theophylline
Slowed absorption due to slowed gastrointestinal motility	Benzotropine, nortriptyline
Slowed absorption due to toxin-induced hypoperfusion	Procainamide
Decreased serum protein binding	Lidocaine, salicylates, valproic acid
Increased volume of distribution associated with toxin-induced acidemia	Salicylates
Slowed elimination due to saturation of biotransformation pathways	Ethanol, phenytoin, salicylates, theophylline
Slowed elimination due to toxin-induced hypothermia (<35°C)	Ethanol, propranolol
Prolonged toxicity due to formation of longer-acting metabolites	Carbamazepine, dapsone, glutethimide, meperidine

^aCompared to characteristics following therapeutic doses or resolution of toxicity.

pharmacologic effects of the drug; or pathophysiologic consequences of the overdose. Dose-dependent changes may decrease the rate and extent of absorption, whereas the bioavailability of the agent may be increased due to saturation of first-pass metabolism. The distribution of a compound may be altered due to saturation of protein-binding sites. Metabolism and elimination of a compound may be retarded due to saturation of biotransformation pathways leading to nonlinear elimination kinetics. Delayed gastric emptying by anticholinergic drugs or as the result of general central nervous system depression caused by many drugs may alter the rate and extent of absorption. Patients with a drug overdose may inherently exhibit prolonged gastric emptying and gastric hypomotility.²³ The formation of concretions or bezoars of solid dosage forms may delay the onset, prolong the duration, or complicate the therapy for an acute overdose.²⁴ A combination of pharmacokinetic and pharmacodynamic factors may lead to delayed onset of toxicity of several toxins, such as thyroid hormones, oral anticoagulants, acetaminophen, and drugs in sustained-release dosage forms.²⁵ Drug-induced hypoperfusion may affect drug distribution and result in reduced hepatic or renal clearance. Changes in blood pH may alter the distribution of weak acids and bases. Drug-induced renal or hepatic injury also can decrease clearance significantly. Implications of these changes for poisoning management include delayed achievement of peak concentrations with a corresponding longer period of opportunity to remove the drug from the gastrointestinal tract. The expected duration of effects may be much greater than that observed with therapeutic doses because of continued absorption and impaired clearance. The application of pharmacokinetic variables, such as percentage protein binding and volume of distribution, from therapeutic doses may not be appropriate in poisoning cases.²¹ Data on toxicokinetics often are difficult to interpret and compare because the doses and times of ingestion are uncertain, the duration of sampling is inadequate, active metabolites may not be measured, protein binding typically is not assessed, and the severity of toxicity may vary dramatically.

TREATMENT

Clinical Toxicology

GENERAL APPROACHES TO TREATMENT OF THE POISONED PATIENT

■ PREHOSPITAL CARE

First Aid

③ The presence of adequate airway, breathing, and circulation should be assessed, and cardiopulmonary resuscitation should be started if needed. The most important step in preventing a minor exposure from progressing to a serious intoxication is early decontamination of the poison. Basic poisoning first aid and decontamination measures (Table 10-8) should be instituted immediately at the scene of the poisoning. If there is any question about the potential severity of the poison exposure, a poison control center should be consulted immediately (1-800-222-1222). While awaiting transport, placing the patient on the left side may afford easier clearance of the airway if emesis occurs and may slow absorption of drug from the gastrointestinal tract.²⁶

Ipecac Syrup

④ Ipecac syrup, a nonprescription drug, has been used in the United States for the past 50 years as a means to induce vomiting for treatment of ingested poisons. Despite its widespread use, concerns about its effectiveness and safety have been raised recently. An expert

TABLE 10-8 First Aid for Poison Exposures

Inhaled poison

Immediately get the person to fresh air. Avoid breathing fumes. Open doors and windows. If victim is not breathing, start artificial respiration.

Poison on the skin

Remove contaminated clothing and flood skin with water for 10 minutes. Wash gently with soap and water and rinse. Avoid further contamination of victim or first aid providers.

Poison in the eye

Flood the eye with lukewarm or cool water poured from a glass 2 or 3 inches from the eye. Repeat for 10–15 continuous minutes. Keep eye open, but do not force the eyelid open.

Swallowed poison

Unless the patient is unconscious, having convulsions, or cannot swallow, give 2–4 ounces of water immediately and then seek further help.

panel of North American and European toxicologists concluded that its routine use in the emergency department should be abandoned.²⁷ In 2003 the American Academy of Pediatrics issued a policy statement indicating that ipecac syrup was no longer to be used routinely to treat poisonings at home and that parents should discard any ipecac.²⁸ The key reason for the policy change was that research failed to show benefits in children who were treated with ipecac syrup. It likely will take several years for these recommendations to be adopted fully by parents and healthcare professionals, and rare exceptions may arise. In the 2005 AAPCC-NPDS report, 0.1% of 2.4 million cases received ipecac syrup, with or without poison center direction.⁶

There are several contraindications to the use of ipecac syrup or any form of induced emesis, such as gagging.²⁷ If the patient is without a gag reflex; is lethargic, comatose, or convulsing; or is expected to become unresponsive within the next 30 minutes, emesis should not be induced. If a fruitful emesis has occurred spontaneously shortly after ingestion, further emesis may not be necessary. Ingestions of caustics, corrosives, ammonia, and bleach are definite contraindications to induced emesis. Ingestion of aliphatic hydrocarbons (e.g., gasoline, kerosene, and charcoal lighter fluid) typically does not require emesis. When the agent is definitely known to be nontoxic, induction of emesis is purposeless and potentially dangerous. The rapid onset of coma or seizures or the potential to exaggerate the toxic effects of the poison may preclude the induction of emesis. Some examples include poisonings with diphenoxylate, propoxyphene, clonidine, tricyclic antidepressants, hypoglycemic agents, nicotine, strychnine, β -blocking agents, and calcium channel blockers. Debilitated, pregnant, and elderly patients may be further compromised by induction of emesis.

■ HOSPITAL TREATMENT

General Care

Supportive and symptomatic care is the mainstay of treatment of a poisoned patient. In the search for specific antidotes and methods to increase excretion of the drug, attention to vital signs and organ functions should not be neglected. Establishment of adequate oxygenation and maintenance of adequate circulation are the highest priorities. Other components of the acute supportive care plan include the management of seizures, arrhythmias, hypotension, acid–base balance, fluid status, electrolyte balance, and hypoglycemia. Placement of intravenous and urinary catheters is typical to ensure delivery of fluids and drugs when necessary and to monitor urine production, respectively.

Gastric Lavage

Gastric lavage involves the placement of an orogastric tube and washing out of the gastric contents through repetitive instillation

and withdrawal of fluid. Gastric lavage may be considered only if a potentially toxic agent has been ingested within the past hour for most patients. If the patient is comatose or lacks a gag reflex, gastric lavage should be performed only after intubation with a cuffed or well-fitting endotracheal tube. The largest orogastric tube that can be passed (external diameter at least 12 mm in adults and 8 mm in children) should be used to ensure adequate evacuation, especially of undissolved tablets. Lavage should be performed with warm (37°C to 38°C) normal saline or tap water until the gastric return is clear; this usually requires 2 to 4 L or more of fluid. Relative contraindications for gastric lavage include ingestion of a corrosive or hydrocarbon agent. Complications of gastric lavage include aspiration pneumonitis, laryngospasm, mechanical injury to the esophagus and stomach, hypothermia, and fluid and electrolyte imbalance.²⁹ Use of gastric lavage has declined in recent years as evidenced by the finding that only 2.2% of 553,292 cases treated at a healthcare facility received gastric lavage.⁶

Single-Dose Activated Charcoal

Reduction of toxin absorption can be achieved by administration of activated charcoal. It is a highly purified, adsorbent form of carbon that prevents gastrointestinal absorption of a drug by chemically binding (adsorbing) the drug to the charcoal surface. There are no toxin-related contraindications to its use, but it is generally ineffective for iron, lead, lithium, simple alcohols, and corrosives. It is not indicated for aliphatic hydrocarbons because of the increased risk for emesis and pulmonary aspiration. Activated charcoal is most effective when given within the first few hours after ingestion, ideally within the first hour.³⁰ The recommended dose of activated charcoal for a child (1 to 12 years old) is 25 to 50 g; for an adolescent or adult the recommended dose is 25 to 100 g. Children younger than 1 year can receive 1 g/kg.⁹ Activated charcoal is mixed with water to make a slurry, shaken vigorously, and administered orally or via a nasogastric tube. Activated charcoal is contraindicated when the gastrointestinal tract is not intact. Activated charcoal is relatively nontoxic, but two identified risks are (a) emesis following administration and (b) pulmonary aspiration of charcoal and gastric contents leading to pneumonitis in patients with an unprotected airway or absent gag reflex.³⁰ Some activated charcoal products contain sorbitol, a cathartic that may be associated with an increased incidence of emesis following use.³¹ Single-dose activated charcoal use has remained relatively steady during the past decade, with 4.9% of 2.4 million cases having received it according to the 2005 AAPCC-NPDS report.⁶

Cathartics

Cathartics, such as magnesium citrate and sorbitol, were thought to decrease the rate of absorption by increasing gastrointestinal elimination of the poison and the poison-activated charcoal complex, but their value is unproven. Poisoned patients do not routinely require a cathartic, and it is rarely, if ever, given without concurrent activated charcoal administration.³² If used, a cathartic should be administered only once and only if bowel sounds are present. Infants, the elderly, and patients with renal failure should be given saline cathartics cautiously, if at all.^{9,32}

Whole-Bowel Irrigation

Polyethylene glycol electrolyte solutions, such as GoLYTELY and Colyte, are used routinely as whole-bowel irrigants prior to colonoscopy and bowel surgery.³³ These solutions also can be used to decontaminate the gastrointestinal tract of ingested toxins.^{9,14,34} Large volumes of these osmotically balanced solutions are administered continuously through a nasogastric or duodenal tube for 4 to 12 hours or more. They quickly cause gastrointestinal evacuation and are continued until the rectal discharge is relatively clear. This procedure may be indicated for certain patients in whom the ingestion occurred several hours prior to hospitalization and the drug still is suspected to be in the gastrointestinal tract, such as drug smugglers who swallow condoms filled with cocaine.³⁵ In addition, patients who have ingested delayed-release or enteric-coated drug formulations or have ingested substances such as iron that are not well adsorbed by activated charcoal may benefit from whole-bowel irrigation.³⁴ It should not be used in patients with a bowel perforation or obstruction, gastrointestinal hemorrhage, ileus, or intractable emesis. Emesis, abdominal cramps, and intestinal bloating have been reported with whole-bowel irrigation.³⁴ During 2005, whole-bowel irrigation was used in 0.5% of 553,292 cases managed at a healthcare facility.⁶

CLINICAL CONTROVERSY

Some clinicians believe that whole-bowel irrigation should be used more routinely as a rapid means to evacuate the gastrointestinal tract. Others recognize that it does have a quick onset but point out that little proof indicates whole-bowel irrigation makes a difference in patient outcome.

Perspectives on Gastric Decontamination

Although there are a variety of options for gastric decontamination, two clinical toxicology groups (the American Academy of Clinical Toxicology and the European Association of Poison Centers and Clinical Toxicologists) have concluded that no means of gastric decontamination should be used routinely for a poisoned patient without careful consideration.^{27,29,30,32,34} They indicate that therapy is most effective within the first hour and that effectiveness beyond this time cannot be supported or refuted with the available data. A clinical policy statement by the American College of Emergency Physicians concludes that although no definitive recommendation can be made on the use of ipecac syrup, gastric lavage, cathartics, or whole-bowel irrigation, activated charcoal is advocated for most patients when appropriate.³⁶ The clinical policy also states that ipecac syrup is rarely of value in the emergency department and that the use of whole-bowel irrigation following ingestion of substances not well adsorbed by activated charcoal is not supported by evidence. The efficacy of activated charcoal has been demonstrated for many compounds,³⁰ but a randomized, controlled clinical trial of poisoned patients indicated that charcoal therapy did not reduce length of hospital stay or positively influence patient outcomes.³⁷ Although gastric lavage can reduce drug absorption if performed within 1 hour of ingestion, its use is not recommended routinely.^{29,36,38} In recent years, the use of ipecac syrup has declined markedly in part because of its apparent lower efficacy compared with activated charcoal in minimizing drug absorption.^{6,27,30} The American Academy of Pediatrics has recommended that ipecac syrup no longer be used for treatment of poisonings at home and has called for its removal from the home.²⁸ Recently, activated charcoal has been promoted for treatment of poisonings at home, but issues of safety, patient compliance, and effectiveness have not been proven in the home setting.^{28,39} Poison control centers may be

CLINICAL CONTROVERSY

Activated charcoal has been promoted for use at home as a replacement for ipecac syrup, but some have contended that little evidence indicates activated charcoal can be used safely and properly in this setting.

a source of guidance on the contemporary application of gastric decontamination techniques for a specific patient.

Enhanced Elimination Numerous methods have been used to increase the rate of excretion of poisons from the body. Of these, only diuresis, multiple-dose activated charcoal, and hemodialysis have demonstrated usefulness. These approaches should be considered only if the risks of the procedure are significantly outweighed by the expected benefits or if the recovery of the patient is seriously in doubt and the method has been shown to be helpful.

Diuresis Diuresis can be used for poisons excreted predominantly by the renal route; however, most drugs and poisons are metabolized, and only a good urine flow (e.g., 2 to 3 mL/kg/h) needs to be maintained for most patients. Fluid and electrolyte balance should be monitored closely. Ionized diuresis by altering urinary pH may increase excretion of certain chemicals that are weak acids or bases by trapping ionized drug in the renal tubule and minimizing reabsorption.¹⁴ Alkalinization of the urine to achieve a urine pH of 7.5 or greater for poisoning by weak acids such as salicylates or phenobarbital can be achieved by intravenous administration of sodium bicarbonate 1 to 2 mEq/kg over a 1- to 2-hour period. Complications of urinary alkalinization include alkalosis, fluid and electrolyte disturbances, and inability to achieve target urinary pH values.⁴⁰ Acid diuresis may enhance the excretion of weak bases, such as amphetamines, but it is rarely, if ever, used because it risks worsening rhabdomyolysis commonly associated with amphetamine overdose.¹⁴ Generally, diuresis or ionized diuresis is rarely indicated for poisoned patients because it is inefficient relative to other methods of enhancing elimination, it is associated with a risk of unacceptable adverse effects, and renal elimination of most drugs is not enhanced dramatically.

Multiple-Dose Activated Charcoal Multiple doses of activated charcoal can augment the body's clearance of certain drugs by enhanced passage from the bloodstream into the gastrointestinal tract and subsequent adsorption. This process, termed *charcoal intestinal dialysis* or *charcoal-enhanced intestinal exsorption*, describes the attraction of drug molecules across the capillary bed of the intestine by activated charcoal in the intestinal lumen and subsequent adsorption of the drug to the charcoal.⁴¹ Furthermore, it may interrupt the enterohepatic recirculation of certain drugs.^{14,41} Once the drug is adsorbed to the charcoal, it is eliminated with the charcoal in the stool. Systemic clearance of several drugs has been shown to be enhanced up to severalfold.^{41,42} An international toxicology group's position statement on multiple-dose activated charcoal concluded that it should be considered only if a patient has ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline.⁴² Although a prospective, randomized study of the effects of multiple-dose activated charcoal on phenobarbital-overdosed patients demonstrated increased drug elimination, no demonstrable effect on patient outcome was observed.⁴³

This approach provides a rapid onset of action that is limited by blood flow and a maximal "ceiling effect" related to the dose of charcoal present in the intestine. The response to multiple-dose activated charcoal is greatest for drugs with the following characteristics: good affinity for adsorption by activated charcoal, low intrinsic clearance, sufficient residence time in the body (long serum half-life), long distributive phase, and nonrestrictive protein binding. A small volume of distribution is desirable, but it has a marginal influence as an isolated characteristic,⁴⁴ particularly if multiple-dose activated charcoal is instituted during the toxin's distributive phase. A typical dosage schedule is 15 to 25 g of activated charcoal every 2 to 6 hours until serious symptoms abate or the serum concentration of the toxin is below the toxic range. This procedure has been used in premature and full-term infants in doses of 1 g/kg every 1 to 4

hours. Serious complications, such as pulmonary aspiration, occur in <1% of patients.⁴⁵ The risks of aspiration pneumonitis in obtunded or uncooperative patients and of intestinal obstruction in patients prone to ileus following a period of bowel ischemia (e.g., after cardiopulmonary arrest in the elderly) may be higher.⁴⁶ Contraindications are the same as those for single-dose charcoal.

Hemodialysis Hemodialysis may be necessary for certain severe cases of poisoning. Dialysis should be considered when the duration of symptoms is expected to be prolonged, normal pathways of excretion are compromised, clinical deterioration is present, the drug is dialyzable, and appropriate personnel and equipment are available. Drugs that are hemodialyzable usually have a low molecular weight, are not highly or tightly protein bound, and are not highly distributed to tissues. The principles of hemodialysis for acutely ill individuals are described in Chap. 48. Hemodialysis and charcoal hemoperfusion are efficient methods of dialysis, but both pose serious risks related to anticoagulation, blood transfusions, loss of blood elements, fluid and electrolyte disturbances, and infection.⁴⁷ Hemodialysis may be lifesaving for methanol and ethylene glycol poisoning and effective for other poisons, such as lithium, salicylates, ethanol, and theophylline.^{14,36} Charcoal hemoperfusion was popular in the 1970s and 1980s as a means to remove toxins, but this approach has fallen out of favor because of poor clinical results, inappropriate use for drugs with large volumes of distribution, and limited availability of charcoal hemoperfusion columns.⁴⁸ Continuous hemofiltration transports drugs across a semipermeable membrane by convection in response to hydrostatic pressure gradients.^{14,47} Limited experience is reported with the use of hemofiltration for poisonings, but it may be attractive for the hemodynamically unstable patient who cannot tolerate hemodialysis.

Antidotes

5 The search for and use of an antidote should never replace good supportive care.³⁶ Specific systemic antidotes are available for many common poisonings (Table 10-9).^{49,50} Inadequate availability of antidotes at acute care hospitals has been noted throughout the United States and can complicate the care of a poisoned patient. An evidenced-based consensus of experts has recommended minimum stocking requirements for 16 antidotes for acute care hospitals.⁵¹ These recommendations may provide guidance to pharmacy and therapeutics committees in establishing a hospital's antidote needs. Drugs used conventionally for nonpoisoning situations may act as antidotes to reverse acute toxicity, such as glucagon for β -adrenergic blocker or calcium channel antagonist overdose and octreotide for sulfonyleurea-induced hypoglycemia.⁵² As our understanding of drug toxicity increases, antidotes may have applications beyond contemporary indications, such as for acetylcysteine, which has shown promise for treating approximately 25 different poisonings and adverse drug reactions.⁵³ The use of toxin-specific antibodies (e.g., fragment antigen binding [Fab] antibody fragments for digoxin⁵⁴ or crotalid snake venom⁵⁵) has offered a new approach to treatment of poisoning victims.

Assessing the Effectiveness of Therapies

Our knowledge of poisoning treatment is derived from case reports, clinical studies, human volunteer studies, animal investigations, and in vitro tests. Each of these approaches has limited applicability to the care of humans who have been poisoned. Case reports often are difficult to assess because they are uncontrolled, the histories are uncertain, and multiple therapies frequently are used. However, they can be useful to describe unique or new toxicities or characterize adverse effects associated with a therapy. Although clinical studies may describe tens to hundreds of patients, they can exhibit

TABLE 10-9 Systemic Antidotes Available in the United States

Toxic Agent	Antidote
Acetaminophen	Acetylcysteine
Anticholinesterase insecticides	Atropine
Anticoagulants	Phytonadione
Benzodiazepines	Flumazenil
Botulism	Botulism antitoxin
Carbon monoxide	Oxygen
Cyanide	Cyanide antidote kit (amyl nitrite, sodium nitrate, and sodium thiosulfate)
Cyanide	Hydroxocobalamin
Digoxin	Digoxin immune Fab
Ethylene glycol, methanol	Ethanol
Ethylene glycol, methanol	Fomepizole
Heavy metals (arsenic, inorganic mercury, lead, gold)	Dimercaprol
Heavy metals (copper, lead)	Penicillamine
Iron	Deferoxamine
Isoniazid	Pyridoxine
Lead	Calcium EDTA
Lead	Succimer
Methemoglobinemia	Methylene blue
Opioids	Nalmefene
Opioids	Naloxone
Organophosphate insecticides	Pralidoxime
Radioactive americium, curium, plutonium	Diethylenetriamine pentaacetate
Radioactive iodine	Potassium iodide
Snake, coral	<i>Micurus fulvius</i> antivenin
Snakes (rattlesnakes, cottonmouth, copperhead)	<i>Crotalidae</i> polyvalent antivenin <i>Crotalidae</i> polyvalent immune Fab
Spider, black widow	<i>Lactrodectus mactans</i> antivenin
Thallium	Prussian blue

serious shortcomings, such as weak randomization procedures, no laboratory confirmation or correlation with history, insufficient number of severe cases, no control group, and no quantitative measure of outcome. Extrapolation of data from human volunteer studies to patients who overdose is difficult because of potential or unknown variations in pharmacokinetics (e.g., differing dissolution, gastric emptying, and absorption rates) seen with toxic as opposed to therapeutic doses,^{21,22} differences in time to institute therapy in the emergency setting, and differences in absorption in fasted human volunteers compared with the full stomach of some patients who overdose. However, these studies provide the most controlled and objective measures of the efficacy of a treatment. Experiences from animal studies cannot be applied directly to humans because of interspecies differences in toxicity and metabolism. In vitro tests serve to screen the efficacy of some approaches, such as activated charcoal adsorption, but they do not mimic physiologic conditions sufficiently to allow direct clinical application of the findings. Despite their limitations, these data compose the basis for the therapy of poisoned patients and are tempered with the consideration of nonpoisoning-related factors such as a particular patient's underlying medical condition, age, and need for concurrent supportive measures.

CLINICAL SPECTRUM OF POISONING

Poisoning and drug overdose with acetaminophen, anticholinesterase insecticides, calcium channel blockers, iron, and tricyclic antidepressants are the focus of the remainder of this chapter because they represent commonly encountered poisonings for which pharmacotherapy is indicated. These agents also were chosen because they represent common examples with different mechanisms of toxicity,

and they illustrate the application of general treatment approaches as well as some agent-specific interventions.

ACETAMINOPHEN

Clinical Presentation

6 Acute acetaminophen poisoning characteristically results in hepatotoxicity^{56,57} and is the leading cause of acute liver failure in the United States.⁵⁸ Clinical presentation (see below) is dependent on the time since ingestion, presence of risk factors, and the ingestion of other drugs. During the first 12 to 24 hours after ingestion, nausea, vomiting, anorexia, and diaphoresis may be observed; however, many patients are asymptomatic. During the next 1 to 3 days, which is a latent phase of lessened symptoms, patients often have an asymptomatic rise in liver enzymes and bilirubin. Signs and symptoms of hepatic injury become manifest 3 to 5 days after ingestion and include right upper quadrant abdominal tenderness, jaundice, hypoglycemia, and encephalopathy. Prolongation of the prothrombin time worsens as hepatic necrosis progresses and may lead to disseminated intravascular coagulopathy. Patients with hepatic damage may develop hepatic coma and hepatorenal syndrome, and death can occur.^{56,57,59} Even in patients with severe hepatotoxicity, usually no residual functional or histologic abnormalities of the liver are noted within 1 to 6 months of the incident.⁵⁷

CLINICAL PRESENTATION OF ACUTE ACETAMINOPHEN POISONING

General

- No or mild nonspecific symptoms within 6 hours of ingestion

Symptoms

- Nausea, vomiting, and abdominal discomfort within 1 to 12 hours after ingestion
- Right upper abdominal quadrant tenderness typically within 1 to 2 days

Signs

- Typically no signs present within first day
- Jaundice, scleral icterus, bleeding within 3 to 10 days
- Oliguria occasionally within 2 to 7 days
- With severe poisoning, hepatic encephalopathy (delirium, depressed reflexes, coma) within 5 to 10 days

Laboratory Tests

- Toxic serum acetaminophen concentration no earlier than 4 hours after ingestion by comparison with nomogram
- Elevated aspartate aminotransferase (AST), alanine aminotransferase (ALT), serum bilirubin, and international normalization ratio (INR); hypoglycemia within 1 to 3 days
- Elevated serum creatinine and blood urea nitrogen (BUN) within 2 to 7 days

Mechanism of Toxicity

Acetaminophen is metabolized in the liver primarily to glucuronide or sulfate conjugates, which are excreted into the urine with small amounts (<5%) of unchanged drug. Approximately 5% of a therapeutic dose is metabolized by the cytochrome P450 mixed-function oxygenase system, primarily CYP2E1, to a reactive metabolite, *N*-acetyl-*p*-benzoquinoneimine (NAPQI). This metabolite normally is conjugated with glutathione, a sulfhydryl-containing compound, in the hepatocyte and excreted in the urine as a mercapturate conjugate (Fig. 10–1).⁵⁹

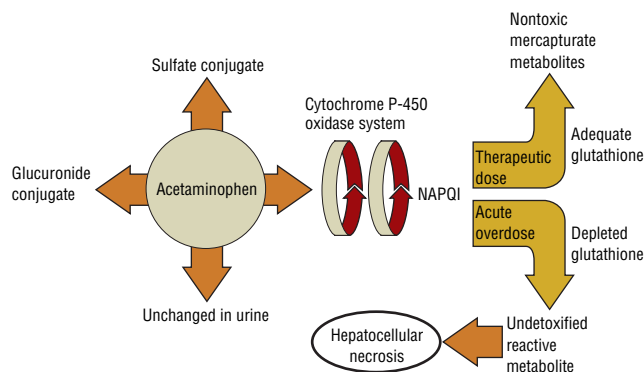

FIGURE 10-1. Pathway of acetaminophen metabolism and basis for hepatotoxicity. (NAPQI, *N*-acetyl-*p*-benzoquinoneimine, a reactive acetaminophen metabolite.)

In an acute overdose situation, sulfate stores are depleted, shifting more drug through the cytochrome system, thereby depleting the available glutathione used to detoxify the reactive metabolite. The reactive metabolite NAPQI then reacts with other hepatocellular sulfhydryl compounds such as those in the cytosol, cell wall, and endoplasmic reticulum. This results in centrilobular hepatic necrosis.⁵⁹ Several other mechanisms, such as cytokine release and oxidative stress, also may be initiated by the initial cellular injury.⁵⁹

In many cases of severe hepatotoxicity, renal injury also is present and may range from oliguria to acute renal failure. The etiology of the renal injury may be a direct effect of the toxic metabolite of acetaminophen, NAPQI, generated by renal cytochrome oxidase, or a consequence of hepatic injury resulting in hepatorenal syndrome.⁶⁰

Causative Agents

Acetaminophen, also known as paracetamol, is available widely without prescription as an analgesic and antipyretic. It is available in various oral dosage forms, including extended-release preparations. Acetaminophen may be combined with other drugs, such as antihistamines or opioid analgesics, and marketed in cough and cold preparations, menstrual remedies, and allergy products.

Incidence

Acetaminophen is one of the drugs most commonly ingested by small children and is used commonly in suicide attempts by adolescents and adults. The 2005 AAPCC-NPDS report documented 67,393 nonfatal exposures and 138 deaths from acetaminophen, with 49% of the exposures in children younger than 6 years.⁶

Age-based differences in the metabolism of acetaminophen appear to be responsible for major differences in the incidence of serious toxicity. Despite the common ingestion of acetaminophen by young children, few develop hepatotoxicity from acute overdose.⁶ In children younger than 9 to 12 years, acetaminophen undergoes more sulfation and less glucuronidation. The reduced fraction available for metabolism by the cytochrome system may explain the rare development of serious toxicity in young children who take large overdoses. Earlier treatment intervention and spontaneous emesis also may reduce the risk of toxicity in children.

Risk Assessment

There is a risk of developing hepatotoxicity when patients 6 years or older acutely ingest at least 10 g or 200 mg/kg, whichever is less, of acetaminophen or when children younger than 6 years acutely ingest 200 mg/kg or more.⁶¹ Patients have survived much larger doses, particularly with early treatment. Initial symptoms, if present, do not predict how serious the toxicity eventually may become.

Chronic exposure to drugs that induce the cytochrome oxidase system—specifically isoenzyme CYP2E1, which is responsible for most of the formation of NAPQI—may increase the risk of acetaminophen hepatotoxicity. Poorer outcomes have been noted in patients who chronically ingest alcohol and those receiving anticonvulsants, both known to induce CYP2E1.^{57,62} Patients with chronic alcoholism have a 3.5 greater odds of mortality with acute acetaminophen poisoning.⁶³ Concurrent acute ingestion of alcohol and acetaminophen may decrease the risk of acetaminophen-induced hepatotoxicity by ethanol acting as a competitive substrate for CYP2E1, thus reducing NAPQI formation.⁶⁴ Ethanol coingestion is not advocated as a preventive measure, and it is difficult to account for its specific impact on care.

Repeated ingestion of supratherapeutic doses of acetaminophen (defined for patients <6 years: ≥ 200 mg/kg over 8 to 24 hours, ≥ 150 mg/kg/day for 2 days, ≥ 100 mg/kg/day for 3 days or longer; for patients ≥ 6 years: ≥ 10 g or 200 mg/kg (whichever is less) over a single 24-hour period, ≥ 6 g or 150 mg/kg (whichever is less) per 24-hour period for ≥ 48 hours) has been associated with hepatotoxicity.^{57,61} Patients who are fasting or have ingested alcohol in the preceding 5 days appear to be at greater risk.⁶⁵ Young children who receive repetitive supratherapeutic doses of acetaminophen have a higher risk of developing hepatotoxicity, particularly when they have been acutely fasting as the result of a febrile illness or gastroenteritis.^{61,66} Patients with suspected risk factors, such as alcoholism, isoniazid therapy, or prolonged fasting, should be referred for medical evaluation if there is evidence that the ingestion exceeded 4 g/day or 100 mg/kg/day, whichever is less.⁶¹

The risk of developing hepatotoxicity may be predicted from a nomogram (Fig. 10-2) based on the acetaminophen serum concentration and time after ingestion.⁵⁶ The treatment line of the nomogram (150 mcg/mL at 4 hours), which allows a margin of error in laboratory analysis and time of ingestion, should be used to make treatment decisions. The other lines on the nomogram indicate differing levels of risk for hepatotoxicity based on a multicenter study of 11,195 patients.⁵⁶

If the plasma concentration plotted on the nomogram falls above the nomogram treatment line, indicating that hepatic damage is possible, a full course of treatment with acetylcysteine is indicated. When the results of the acetaminophen determination will be available later than 8 hours after the ingestion, acetylcysteine therapy should be initiated based on the history and later discontinued if the results indicate nontoxic concentrations. The nomogram has not been evaluated and thus is not useful for assessing chronic exposure to acetaminophen. Some have advocated that patients with chronic alcoholism should be treated with acetylcysteine regardless of the risk estimation.⁶³

Management of Toxicity

Therapy of an acute acetaminophen overdose depends on the amount ingested, time after ingestion, and serum concentration of acetaminophen. When excessive amounts are ingested, the history is unclear, or an intentional ingestion is suspected, the patient should be evaluated at an emergency department and acetaminophen serum concentrations obtained.⁶¹ No prehospital care generally is indicated, and ipecac syrup typically is not recommended.⁶¹ If the patient presents to the emergency department within 4 hours of the ingestion or ingestion of other drugs is suspected, one dose of activated charcoal can be administered.

Acetylcysteine (also known as *N*-acetylcysteine), a sulfhydryl-containing compound, replenishes the hepatic stores of glutathione by serving as a glutathione surrogate that combines directly with reactive metabolites or by serving as a source of sulfate, thus preventing hepatic damage.⁶⁷ It should be started within 10 hours of the ingestion to be most effective.⁵⁶ Initiation of therapy 24 to 36 hours after the ingestion may be of value in some patients, particu-

FIGURE 10-2. Nomogram for assessing hepatotoxic risk following acute ingestion of acetaminophen. (Adapted from reference 56.)

larly those with measurable serum acetaminophen concentrations.^{67,68} Patients with fulminant hepatic failure may benefit through other mechanisms by the administration or initiation of acetylcysteine several days after ingestion.⁶⁷

CLINICAL CONTROVERSY

The routine administration of acetylcysteine more than 24 hours after acetaminophen overdose has been proposed. Case reports and animal studies indicate that it is relatively safe and that its use may minimize hepatotoxicity. Although accepted criteria for its use are lacking, it may be considered for patients with fulminant hepatotoxicity, when acetaminophen is still measurable in the serum, or when the ingestion was not recognized within 24 hours and liver toxicity is apparent.

Therapy should be initiated with acetylcysteine within 10 hours of ingestion when indicated. The oral liquid was the only approved form of acetylcysteine in the United States until 2004, when the Food and Drug Administration (FDA) approved an intravenous formulation.⁶⁹ The dosage regimen for the intravenous form is based on one used in Europe for two decades, and outcomes similar to the 72-hour oral regimen have been reported.^{53,70} A systematic review of the literature indicated that acetylcysteine is superior to supportive care, but there is no clear evidence of which regimen is better.⁷¹ Although there are several notable differences (Table 10–10),^{53,56,69,70} a clear preference for the oral or intravenous form of acetylcysteine likely will not evolve until further experience with IV formulation accumulates. When acetaminophen plasma concentrations are below the nomogram treatment line, there is little risk of toxicity, protective therapy with acetylcysteine is not necessary, and medical therapy likely is unnecessary.⁵⁶ The acetaminophen blood sample should be drawn no sooner than 4 hours after the ingestion to ensure that peak acetaminophen concentrations have been reached. If a concentration is obtained less than 4 hours after ingestion, it is uninterpretable, and a second determination should be done at least 4 hours after ingestion. Serial determinations of a serum concentration, 4 to 6 hours apart, typically are unnecessary unless there is some evidence of slowed gastrointestinal motility as the result of the ingestion of certain drugs (e.g., opioids, antihistamines, or anticholinergics) or unless an extended-release product is involved. Therapy with acetylcysteine is continued if any concentration is above the treatment line of the nomogram, and provisional therapy is discontinued when both concentrations are below the treatment line.

TABLE 10-10 Comparison of Intravenous and Oral Regimens for Acetylcysteine in the Treatment of Acute Acetaminophen Poisoning

Characteristic	Intravenous	Oral
Regimen	150 mg/kg in 200 mL D ₅ W infused over 1 hour, then 50 mg/kg in 500 mL D ₅ W over 4 hours, followed by 100 mg/kg in 1,000 mL D ₅ W over 16 hours ^a	140 mg/kg, followed 4 hours later by 70 mg/kg every 4 hours for 17 doses diluted to 5% with juice or soft drinks
Total dose (mg/kg)	300	1,330
Duration (h)	21	72
Adverse effects	Anaphylactoid reactions (rash, hypotension, wheezing, dyspnea); acute flushing and erythema in first hour of the infusion that typically resolves spontaneously	Nausea, vomiting
Ancillary therapy, if needed	Antihistamines and epinephrine for severe anaphylactic reactions	Antiemetics, e.g., metoclopramide, ondansetron, or droperidol
Trade name	Acetadote	Mucomyst
Available strength	20%	10%, 20%

^aFor patients <40 kg and those requiring fluid restriction, the total volume for dilution should be reduced as directed in the package insert.

D₅W, 5% dextrose in water for injection.

Although young children have an inherently lower risk of acetaminophen-induced hepatotoxicity, these patients should be managed in the same manner as adults. When acetaminophen plasma concentrations predict that toxicity is probable, young children should receive acetylcysteine in the dosing regimen described previously.⁶⁶ If fulminant hepatic failure develops, the approaches described in Chap. 39 should be considered. In unresponsive patients, liver transplantation is a lifesaving option.⁵⁷

Monitoring and Prevention

Baseline liver function tests (AST, ALT, bilirubin, prothrombin time), serum creatinine determination, and urinalysis should be obtained on admission and repeated at 24-hour intervals until at least 96 hours have elapsed for patients at risk. Most patients with liver injury develop elevated transaminase concentrations within 24 hours of ingestion. AST or ALT concentrations >1,000 international units per liter commonly are associated with other signs of liver dysfunction and have been used as the threshold concentration in outcome studies to define severe liver toxicity.⁵⁶ The extent of transaminase elevation is not correlated directly with the severity of hepatic injury, with nonfatal cases demonstrating peak concentrations as high as 30,000 international units per liter between 48 and 72 hours after ingestion.⁵⁷

Prevention of acetaminophen poisoning is based on recognition of the maximum daily therapeutic doses, observance of general poison prevention practices, and early intervention in cases of suspected overdose. The frequent involvement of acetaminophen in poisonings and overdoses, whether or not declared by the patient, has led to the routine determination of acetaminophen concentrations in patients admitted to emergency departments for any overdose.¹⁸

ANTICHOLINESTERASE INSECTICIDES

Clinical Presentation

7 The clinical manifestations of anticholinesterase insecticide poisoning include any or all of the following: pinpoint pupils, excessive

TABLE 10-11 Effects of Acetylcholinesterase Inhibition at Muscarinic, Nicotinic, and CNS Receptors

Muscarinic receptors	Nicotinic-sympathetic neurons
Diarrhea	Increased blood pressure
Urination	Sweating and piloerection
Miosis ^a	Mydriasis ^a
Bronchorrhea	Hyperglycemia
Bradycardia ^a	Tachycardia ^a
Emesis	Priapism
Lacrimation	Nicotinic-neuromuscular neurons
Salivation	Muscular weakness
CNS receptors (mixed type)	Cramps
Coma	Fasciculations
Seizures	Muscular paralysis

^aGenerally muscarinic effects predominate, but nicotinic effects can be observed.

lacrimation, excessive salivation, bronchorrhea, bronchospasm and expiratory wheezes, hyperperistalsis producing abdominal cramps and diarrhea, bradycardia, excessive sweating, fasciculations and weakness of skeletal muscles, paralysis of skeletal muscles (particularly those involved with respiration), convulsions, and coma.⁷² Symptoms of anticholinesterase poisoning and their response to antidotal therapy depend on the action of excessive acetylcholinesterase at different receptor types (Table 10-11).

The time of onset and severity of symptoms depend on the route of exposure, potency of the agent, and total dose received (see presentation box below). Toxic signs and symptoms develop most rapidly after inhalation or intravenous injection and slowest after skin contact. Anticholinesterase insecticides are absorbed through the skin, lungs, conjunctivae, and gastrointestinal tract. Severe symptoms can occur from absorption by any route. Most patients are symptomatic within 6 hours, and death may occur within 24 hours without treatment. Death typically is caused by respiratory failure resulting from the combination of pulmonary and cardiovascular effects (Fig. 10-3).⁷² Poisoning may be complicated by aspiration pneumonia, urinary tract infections, and sepsis.⁷³

CLINICAL PRESENTATION OF ANTICHOLINESTERASE INSECTICIDE POISONING

General

- Mild symptoms may resolve spontaneously; life-threatening toxicity may develop with 1 to 6 hours of exposure

Symptoms

- Diarrhea, diaphoresis, excessive urination, miosis, blurred vision, pulmonary congestion, dyspnea, vomiting, lacrimation, salivation, and shortness of breath within 1 hour
- Headache, confusion, coma, and seizures possible within 1 to 6 hours

Signs

- Increased bronchial secretions, tachypnea, rales, and cyanosis within 1 to 6 hours
- Muscle weakness, fasciculations, and respiratory paralysis within 1 to 6 hours
- Bradycardia, atrial fibrillation, atrioventricular block, and hypotension within 1 to 6 hours

Laboratory Tests

- Markedly depressed serum pseudocholinesterase activity below normal range
- Altered arterial blood gases (acidosis), serum electrolytes, BUN, and serum creatinine in response to respiratory distress and shock within 1 to 6 hours

Other Diagnostic Tests

- Chest radiographs for progression of pulmonary edema or hydrocarbon pneumonitis in symptomatic patients
- Electrocardiogram (ECG) with continuous monitoring and pulse oximetry for complications from toxicity and hypoxia

Organophosphate poisoning has been associated with several residual effects, such as intermediate syndrome, extrapyramidal symptoms, neuropsychiatric effects, and delayed chronic neuropathy. Intermediate syndrome becomes manifest in some patients approximately 1 to 3 days after exposure. It is characterized by muscle weakness of proximal limbs, cranial nerve innervated muscles, and muscles of respiration. The inability of the patient to raise his or her head is often an initial sign. It often follows resolution of cholinergic symptoms but typically is unresponsive to further therapy with atropine or pralidoxime. It generally resolves within weeks of onset without further treatment. Extrapyramidal symptoms, which may develop 1 to 7 days after exposure, usually resolve spontaneously within a few days of onset. Neuropsychiatric effects, such as confusion, lethargy, memory impairment, headache, and depression, typically begin weeks to months after exposure and may last for years. The etiology is unclear. Delayed chronic neuropathy often presents as cramping muscle pain in the legs (upper extremities are sometimes involved), followed by rapidly progressive weakness and paralysis. Paresthesia and pain may be present. The onset often is delayed by 1 to 5 weeks after recovery from the acute poisoning exposure. It is unresponsive to further atropine or pralidoxime therapy. Improvement may be delayed for months to years, and in some cases the patient develops permanent disability. It is not associated with all organophosphates.^{72,74}

Mechanism of Toxicity

Anticholinesterase insecticides phosphorylate the active site of cholinesterase in all parts of the body.^{72,75} Inhibition of this enzyme leads to accumulation of acetylcholine at affected receptors and results in widespread toxicity. Acetylcholine is the neurohormone responsible for physiologic transmission of nerve impulses from preganglionic and postganglionic neurons of the cholinergic (parasympathetic) nervous system, preganglionic adrenergic (sympathetic) neurons, neuromuscular junction in skeletal muscles, and multiple nerve endings in the central nervous system (Fig. 10-4).

Causative Agents

Anticholinesterase insecticides include organophosphate and carbamate insecticides. These insecticides are currently in widespread use throughout the world for eradication of insects in dwellings and crops. Carbamates typically are less potent and inactivate cholinesterase in a more reversible fashion through carbamylation compared with organophosphates.⁷² The prototype anticholinesterase agent is the organophosphate, which is the focus of this discussion. A large number of organophosphates are used as pesticides (e.g., dichlorophos disulfoton, malathion, mevinphos, phosmet), and several were specifically developed for use as potent chemical warfare agents (see Chap. 12).^{72,73,76,77} The chemical warfare agents act like organophosphate insecticides, but they are highly potent, are quickly absorbed, and can be deadly to humans within minutes (see Chap. 12).^{77,78} An anticholinesterase insecticide typically is stored in a garage, chemical storage area, or living area. Anticholinesterase agents also can be found in occupational (e.g., pest exterminators) or agricultural (e.g., crop dusters or farm workers) settings. These agents also have been used as a means for suicide or homicide.

Incidence

Anticholinesterase insecticides are among the most poisonous substances commonly used for pest control and are a frequent source of

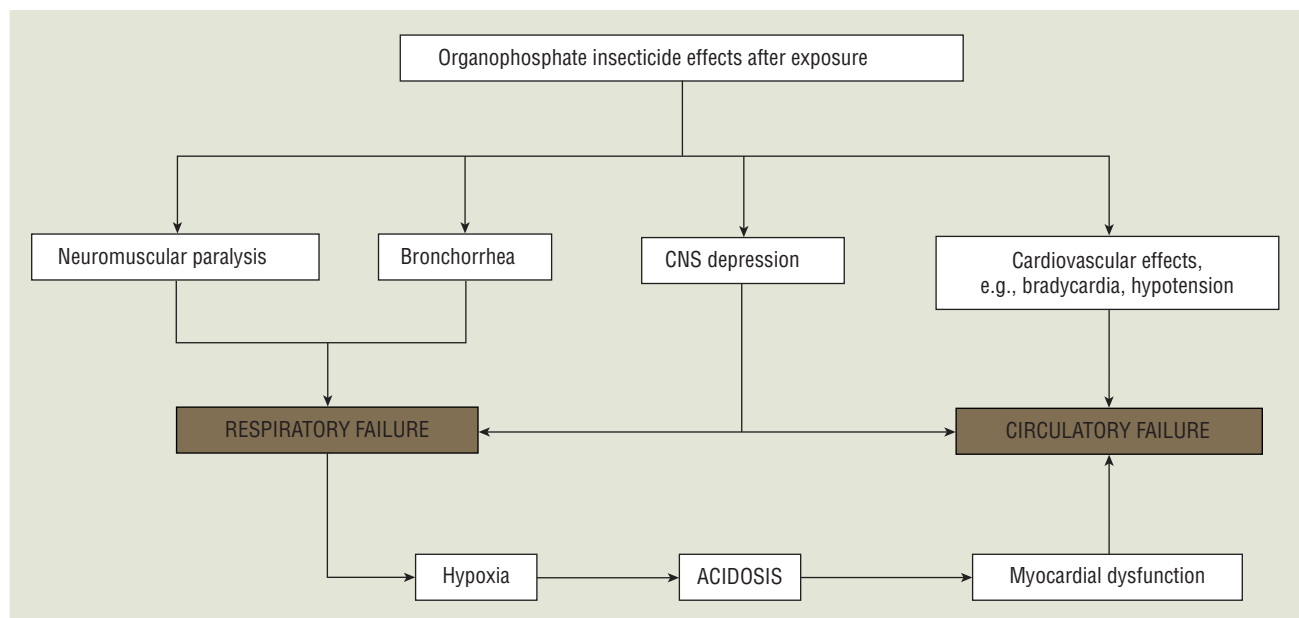

FIGURE 10-3. Pathogenesis of life-threatening effects of organophosphate poisoning. (CNS, central nervous system.)

serious poisoning in children and adults in rural and urban settings. The 2005 AAPCC-NPDS report documented 9,942 nonfatal exposures and 12 deaths from anticholinesterase insecticides alone or in combination with other pesticides, with 29% of exposures in children younger than 6 years.⁶

Risk Assessment

The triad of miosis, bronchial secretions, and muscle fasciculations should suggest the possibility of anticholinesterase insecticide poisoning and warrants a therapeutic trial of the antidote atropine. In cases of low-level exposure, failure to develop signs within 6 hours indicates a low likelihood of subsequent toxicity.⁷² Ruling out other chemical exposures may be guided initially by symptoms at presentation.¹⁶

Although the lethal dose for parathion is approximately 4 mg/kg, as little as 10 to 20 mg can be lethal to an adult and 2 mg (0.1 mg/kg) to a child. Small children may be more susceptible to toxicity because less pesticide is required per body weight to produce toxicity.^{72,76} Estimation of an exact dose is impossible in most cases

of acute poisoning; thus, tabulated “toxic” doses generally are not helpful in assessing risk of toxicity. Generally, ingestion of a small mouthful (~5 mL) of the concentrated forms of an organophosphate intended to be diluted for commercial or agricultural use will produce serious, life-threatening toxicity, whereas a mouthful of an already diluted household product, such as an aerosol insecticide for household use, typically does not produce serious toxic effects.⁷⁶

Measurement of acetylcholinesterase activity at the neuronal synapse is not feasible clinically. Cholinesterase activity can be measured in the blood as the pseudocholinesterase (butylcholinesterase) activity of the plasma and acetylcholinesterase activity in the erythrocyte. Both cholinesterases will be depressed with anticholinesterase insecticide poisoning.^{72,79} Severity can be estimated roughly by the extent of depressed activity in relation to the low end of normal values. Because there are several methods to measure and report cholinesterase activity, each particular laboratory’s normal range must be considered. Clinical toxicity usually is seen only after a 50% reduction in enzyme activity, and severe toxicity typically is observed at levels 20% or less of the normal range.^{75,76,79} The intrinsic activity of acetylcholinesterase may be depressed in some individuals, but the absence of any manifestations in most people does not permit recognition of the relative deficiency in the general population. Therapy should not be delayed pending laboratory confirmation when insecticide poisoning is clinically suspected.

Management of Toxicity

People handling the patient should wear gloves and aprons to protect themselves against contaminated clothing, skin, or gastric fluid of the patient.^{72,76} Because many insecticides are dissolved in a hydrocarbon vehicle, there is an additional risk of pulmonary aspiration of the hydrocarbon leading to pneumonitis. The risks and benefits of gastric decontamination (e.g., gastric lavage, activated charcoal) should be considered carefully and should involve consultation with a poison control center or clinical toxicologist. Symptomatic cases of anticholinesterase insecticide exposure typically are referred to an emergency department for evaluation and treatment.

If the poison has been ingested within the hour, gastric lavage should be considered and followed by the administration of activated charcoal. For the patient with skin contamination, contaminated clothing should be removed and the patient washed with copious amounts of soap and water before he or she is admitted to

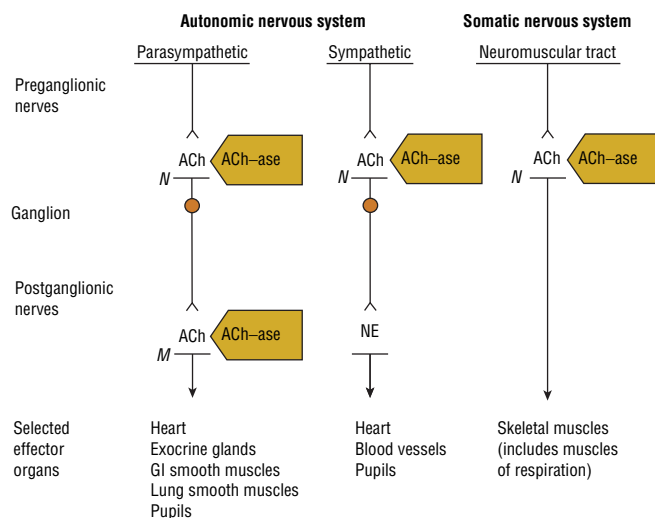

FIGURE 10-4. Organization of neurotransmitters of the peripheral nervous system and site of acetylcholinesterase action. (ACh, acetylcholine; ACh-ase, acetylcholinesterase; M, muscarinic receptor; N, nicotinic receptor; NE, norepinephrine.)

the emergency department or other patient care area. An alcohol wash may be useful for removing residual insecticide because of its lipophilic nature. A surgical scrub kit for the hands, feet, and nails may be useful for exposure to those areas. Supportive therapy should include maintenance of an airway (including bronchotracheal suctioning), provision of adequate ventilation, and establishment of an intravenous line. Based on a history of an exposure and presence of typical symptoms, the anticholinesterase syndrome should be recognized without difficulty.

Pharmacologic management of organophosphate intoxication relies on the administration of atropine and pralidoxime.^{72,75,76} Atropine has no effect on inhibited cholinesterase, but it competitively blocks the actions of acetylcholine on cholinergic and some central nervous system receptors. It thereby alleviates bronchospasm and reduces bronchial secretions. Although atropine has little effect on the flaccid muscle paralysis or the central respiratory failure of severe poisoning, it is indicated in all symptomatic patients and can be used as a diagnostic aid. It should be given intravenously and in larger than conventional doses of 0.05 to 0.1 mg/kg in children younger than 12 years and 2 to 5 mg in adolescents and young adults.⁷⁶ It should be repeated at 5- to 10-minute intervals until bronchial secretions and pulmonary rales resolve. Therapy may require large doses over a period of several days until all absorbed organophosphate is metabolized, and acetylcholinesterase activity is restored.

Restoration of enzyme activity is necessary for severe poisoning, characterized by a reduction of cholinesterase activity to <20% of normal, profound weakness, and respiratory distress. Pralidoxime (Protopam), also called 2-PAM or 2-pyridine aldoxime methiodide, breaks the covalent bond between the cholinesterase and organophosphate and regenerates enzyme activity. Organophosphate-cholinesterase binding is reversible initially, but it gradually becomes irreversible. Therefore, therapy with pralidoxime should be initiated as soon as possible, preferably within 36 to 72 hours of exposure.⁷⁶ The drug should be given at a dose of 25 to 50 mg/kg up to 1 g intravenously over 5 to 20 minutes. If muscle weakness persists or recurs, the dose can be repeated after 1 hour and again if needed. A continuous infusion of pralidoxime has been shown to be effective in adults when administered at 2 to 4 mg/kg/h preceded by a loading dose of 4 to 5 mg/kg⁸⁰ and in children at 10 to 20 mg/kg/h with a loading dose of 15 to 50 mg/kg.⁸¹ Both atropine and pralidoxime should be given together because they have complementary actions (Table 10-12). Systematic reviews of the literature indicate that the effectiveness of pralidoxime and similar oxime compounds in the treatment of organophosphate poisoning is inconclusive because of problems with study design.^{82,83} Carbamate insecticide poisonings typically do not require the administration of pralidoxime.

CLINICAL CONTROVERSY

Some references indicate that pralidoxime should be avoided in the treatment of carbamate (another type of anticholinesterase insecticide) poisoning because of reports of worsened toxicity in animals. Pralidoxime may be considered when exposure to carbamates is not known but an anticholinesterase is suspected based on symptoms or when respiratory paralysis due to nicotinic effects is not managed sufficiently by mechanical ventilation.

One of the pitfalls of therapy is the delay in administering sufficient doses of atropine or pralidoxime.^{72,76} The adverse effects of atropine and pralidoxime, predictable extensions of their anticholinergic actions, are minimally important compared with the life-threatening effects of severe anticholinesterase poisoning and can be minimized easily by decreasing the dose.

TABLE 10-12 Comparative Characteristics of Atropine and Pralidoxime for Anticholinesterase Poisoning

Characteristic	Atropine	Pralidoxime
Interaction	Synergy with pralidoxime	Reduces atropine dose requirement
Indication	Any anticholinesterase agent	Typically needed for organophosphates
Primary sites of action	Muscarinic, CNS	Nicotinic > muscarinic > CNS
Adverse effects	Coma, hallucinations, tachycardia	Dizziness, diplopia, tachycardia, headache
Daily dose ^a	2–1,600 mg	1–12 g
Total dose ^a	2–11,422 mg	1–92 g

^aRange of reported cases; higher doses may be required in rare cases.

MONITORING AND PREVENTION

Poisoned patients may require monitoring of vital signs, measurement of ventilatory adequacy such as blood gases and pulse oximetry, leukocyte count with differential to assess development of pneumonia, and chest radiographs to assess the degree of pulmonary edema or development of hydrocarbon pneumonitis. Workers involved in the formulation and application of pesticides should be monitored by periodic measurement of cholinesterase activity in their bloodstream. Untreated, anticholinesterase-depressed acetylcholinesterase activity returns to normal values in approximately 120 days. Long-term followup for severe cases of poisoning may be necessary to detect the presence of delayed or persistent neuropsychiatric effects.

Many anticholinesterase insecticide poisonings are unintentional as a result of misuse, improper storage, failure to follow instructions for mixing or application, or inability to read directions for use. Training and vigilant adherence to directions may minimize some poisonings. Storing pesticides in original or labeled containers can minimize the risk of unintentional ingestion. Keeping pesticides out of children's reach may decrease the risk of childhood poisoning.⁸⁴

CALCIUM CHANNEL BLOCKERS

Clinical Presentation

8 Overdosage with calcium channel blockers typically results in bradycardia and hypotension (Fig. 10-5). Many patients become lethargic and may develop agitation and coma. If the degree of hypotension becomes severe or is prolonged, the secondary effects of seizures, coma, and metabolic acidosis usually develop. Pulmonary edema, nausea and vomiting, and hyperglycemia are frequent complications of calcium channel blocker overdoses. Paralytic ileus, mesenteric ischemia, and colonic infarction have been observed in patients with severe hypotension. Many symptoms become manifest within 1 to 2 hours of ingestion (see presentation box below). If a sustained-release formulation is involved, the onset of overt toxicity may be delayed by 6 to 18 hours from the time of ingestion. Severe poisoning can result in refractory shock and cardiac arrest. Death can occur within 3 to 4 hours of ingestion.^{85–88}

CLINICAL PRESENTATION OF CALCIUM CHANNEL BLOCKER POISONING

General

- Life-threatening cardiac toxicity (bradycardia, depressed contractility, dysrhythmias) within 1 to 3 hours of ingestion, delayed by 12 to 18 hours if a sustained-release product is involved

mg for immediate release and chewed sustained release, >360 mg for sustained release, >540 mg for extended release; children younger than 6 years: >1 mg/kg).⁹¹ Patients on chronic therapy with these agents who acutely ingest an overdose may have a greater risk of serious toxicity. Elderly patients and those with underlying cardiac disease may not tolerate mild hypotension or bradycardia. Concurrent ingestion of β -adrenergic blocking drugs, digitalis, class I antiarrhythmics, and other vasodilators may worsen the cardiovascular effects of calcium channel blockers.^{86,88,91}

Management of Toxicity

There is no accepted specific prehospital care for calcium channel blocker poisoning except to summon an ambulance for symptomatic patients. Ipecac syrup should be avoided because of the risks of seizures and coma.⁹¹ The therapeutic options for management of calcium channel blocker poisoning include supportive care, gastric decontamination, and adjunctive therapy for the cardiovascular and metabolic effects. Supportive care consists of airway protection, ventilatory support, intravenous hydration to maintain adequate urine flow, and maintenance of electrolyte and acid–base balance. Maintaining vital organ perfusion is critical for successful therapy in order to allow time for calcium channel blocker toxicity to resolve.^{87,88}

Gastric lavage and a single dose of activated charcoal should be administered if instituted within 1 to 2 hours of ingestion. Besides exhibiting a slower onset of symptoms, sustained-release formulations can form concretions in the intestine.^{87,88} Whole-bowel irrigation with polyethylene glycol electrolyte solution may accelerate rectal elimination of the sustained-release tablets and should be considered routinely for ingestion of sustained-release calcium channel blocker formulations.^{34,92}

Adjunctive therapy is focused on treating hypotension, bradycardia, and resulting shock. Hypotension is treated primarily by correction of coexisting dysrhythmias (e.g., bradycardia, heart block) and implementation of conventional measures to treat decreased blood pressure. Infusion of normal saline and placement of the patient in the Trendelenburg position are initial therapies. Further fluid therapy should be guided by central venous pressure monitoring. Dopamine and epinephrine in conventional doses for cardiogenic shock should be considered next. If hypotension persists, dysrhythmias are present, or other signs of serious toxicity are present, calcium should be administered intravenously.^{85,88}

A calcium chloride bolus test dose (10 to 20 mg/kg up to 1 to 3 g) is the preferred therapy for patients with serious toxicity. In adults, calcium chloride 10% can be diluted in 100 mL normal saline and infused over 5 minutes through a central venous line. If a positive cardiovascular response is achieved with this test dose, a continuous infusion of calcium chloride (20 to 50 mg/kg/h) should be started. Calcium gluconate is less desirable to use because it contains less elemental calcium per milligram of final dosage form. Intravenous calcium salts can produce vomiting and tissue necrosis on extravasation.^{52,88} Atropine also may be considered for treatment of bradycardia, but it is seldom sufficient as a sole therapy.⁸⁷

If the bradycardia and hypotension are refractory to the foregoing therapy, a bolus infusion of glucagon (0.05 to 0.20 mg/kg, initial adult dose is 3 to 5 mg over 1 to 2 minutes) should be considered. Benefit typically is observed within 5 minutes of administration and can be sustained with a continuous intravenous infusion (0.05 to 0.1 mg/kg/h) titrated to clinical response.⁹³ Glucagon possesses chronotropic and inotropic effects in part by stimulating adenyl cyclase and increasing cyclic adenosine monophosphate, which may promote intracellular entry of calcium through calcium channels. It thereby may improve hypotension and bradycardia.⁵² Vomiting is not uncommon with these large doses of glucagon, and the airway should be protected to prevent pulmonary aspiration. Hyperglycemia may occur or be exacerbated in those patients receiving glucagon therapy. Hyperglycemia

from calcium channel blocker toxicity or glucagon therapy typically does not require treatment with insulin. Intravenous sodium bicarbonate, however, may be necessary to establish acid–base balance and correct the metabolic acidosis that is common with serious calcium channel blocker overdoses.

For severe cases of calcium channel blocker toxicity refractory to conventional therapy, an infusion of high-dose insulin with supplemental dextrose and potassium to produce a state of hyperinsulinemia and euglycemia should be considered.^{52,85,87–89} Case reports suggest that an intravenous bolus of regular insulin (0.5 to 1 units/kg) with 50 mL dextrose 50% (0.25 mg/kg for children) followed by a continuous infusion of regular insulin (0.5 to 1 units/kg/h) may improve myocardial contractility. The effect of insulin is presently unclear, but it may improve myocardial metabolism that is adversely affected by calcium channel blocker overdoses, such as decreased cellular uptake of glucose and free fatty acids and a shift from fatty acid oxidation to carbohydrate metabolism.^{85,87,89} This insulin regimen is titrated to improvement in systolic blood pressure over 100 mm Hg and heart rate over 50 beats/min. Serum glucose concentrations should be monitored closely to maintain euglycemia. Patients with serum potassium concentrations <2.5 mEq/L may need supplemental potassium (see Chap. 54). The insulin infusion rate can be reduced gradually as signs of toxicity resolve. Therapies with glucagon and insulin are based on animal studies and case reports; clinical trials demonstrating effectiveness have not been performed to date.^{52,85,87–89}

Several lifesaving options may be warranted for patients with cardiogenic shock that is refractory to conventional therapy. Electrical cardiac pacing may restore an acceptable heart rate in patients with severe bradycardia.⁸⁸ Intraaortic balloon counterpulsation or cardiopulmonary bypass may improve shock in patients unresponsive to other therapies.^{52,88,94,95}

Measures to enhance elimination from the bloodstream by hemodialysis or multiple-dose activated charcoal have not been shown to be effective and are not indicated for calcium channel blocker poisoning.^{42,86,88,96}

CLINICAL CONTROVERSY

Some clinicians believe that hyperinsulinemia/euglycemia or glucagon therapy for calcium channel blocker poisoning should be used early in the course of therapy. Others reserve it for life-threatening symptoms not responsive to other therapy. More safety and effectiveness data are needed to define the place of these two agents in therapy.

Monitoring and Prevention

Regular monitoring of vital signs and ECG is essential in suspected calcium channel blocker poisoning. Determinations of serum electrolytes, serum glucose, arterial blood gases, urine output, and renal function are indicated to assess and monitor symptomatic patients. If serious toxicity is likely to develop, overt symptoms will manifest within 6 hours of ingestion.⁹¹ For ingestions of sustained-release products in toxic doses, observation for 24 hours in a critical care unit may be prudent because the onset of symptoms may be slow and delayed up to 12 to 18 hours after ingestion.^{85,91,92,96,97} Serum concentrations of these agents in overdose patients do not correlate well with the ingested dose, degree of toxicity, or outcome.

Poisonings resulting from these agents are likely to increase as their therapeutic indications and use increase. These poisonings may be the result of an intentional suicide or unintentional ingestion by young children. Prevention of calcium channel blocker poisonings in children rests with the education of patients receiving these agents, particularly of grandparents and those who have children visit their homes infrequently, of their dangers on overdos-

age. Safe storage and use of child-resistant closures may reduce the opportunities for unintentional poisonings by children.⁸⁶

IRON

Clinical Presentation

9 In the first few hours after ingestion of toxic amounts of iron, symptoms of gastrointestinal irritation (e.g., nausea, vomiting, and diarrhea) are common (see presentation box below). In certain severe cases, acidosis and shock can become manifest within 6 hours of ingestion. Some have observed a quiescent phase between 6 and 48 hours after ingestion when symptoms improve or abate, but this phenomenon is poorly characterized.⁹⁸ Continued gastrointestinal symptoms, poor perfusion, and oliguria should suggest the development of severe toxicity, with other effects still to become manifest. Generally, within 24 to 36 hours of the ingestion, central nervous system involvement with coma and seizures; hepatic injury characterized by jaundice, increased prothrombin time, increased bilirubin, and hypoglycemia; cardiovascular shock; and acidosis also develop.^{98,99} Adult respiratory distress syndrome (ARDS) may develop in patients with severe cardiovascular shock and further compromise recovery.¹⁰⁰ Coagulopathy with decreased thrombin formation is one of the early direct effects of excessive iron concentrations, and later disturbances of coagulation (after 24 to 48 hours of ingestion) are a consequence of hepatotoxicity.¹⁰¹ Mucosal injury, an iron-rich circulation, or deferoxamine therapy may promote septicemia with *Yersinia enterocolitica* during iron overdose; other bacteria or viruses also may cause septicemia.⁹⁸ Two to four weeks after the exposure, a few rare patients experience persistent vomiting from gastric outlet obstruction as the result of pyloric and duodenal stenosis from the earlier gastric mucosal necrosis. Autopsy findings in children indicate prominent iron deposition in intestinal mucosa and periportal necrosis of the liver that correlate with the primary symptoms of serious iron poisoning.¹⁰²

CLINICAL PRESENTATION OF ACUTE IRON POISONING

General

- Gastrointestinal symptoms shortly after ingestion with possible rapid progression to shock and coma

Symptoms

- Vomiting, abdominal pain, and diarrhea within 1 to 6 hours
- Lethargy, coma, seizures, bloody vomiting, bloody diarrhea, and shock within 6 to 24 hours

Signs

- Hypotension and tachycardia within 6 to 24 hours
- Liver dysfunction and failure possible in 2 to 5 days

Laboratory Tests

- Toxic serum iron concentrations >500 mcg/dL
- Altered arterial blood gases and serum electrolytes associated with a high anion gap metabolic acidosis within 3 to 24 hours
- Elevated BUN, serum creatinine, AST, ALT, and INR within 1 to 2 days

Other Diagnostic Tests

- Guaiac test of stools for the presence of blood
- Abdominal radiograph to detect solid iron tablets in gastrointestinal tract

Mechanism of Toxicity

The toxicity of acute iron poisoning includes local effects on the gastrointestinal mucosa and systemic effects induced by excessive

iron in the body.^{98,100} Iron is irritating to the gastric and duodenal mucosa, which may result in hemorrhage and occasional perforations. Once absorbed, iron is taken up by tissues, particularly the liver, and acts as a mitochondrial poison. It occasionally causes hepatic injury. Iron may inhibit aerobic glycolysis and perturb the electron transport system. Further, iron may shunt electrons away from the electron transport system, thereby reducing the efficiency of oxidative phosphorylation. These biochemical factors, along with the cardiovascular effects of iron, lead to metabolic acidosis. The pathogenesis of shock is not well understood but may include the development of hypovolemia and lactic acidosis, release of endogenous vasodilators, and the direct vasodepressant effects of iron and ferritin on the circulation (Fig. 10–6).

Causative Agents

Iron poisoning results from the ingestion and absorption of excessive amounts of iron from iron tablets, multiple vitamins with iron, and prenatal vitamins. Different iron salts and formulations contain varying amounts of elemental iron (see Chap. 104). Generally, children's chewable vitamins are less likely to produce systemic iron poisoning in part because of their lower iron content.¹⁰³

Incidence

Acute iron poisoning can produce death in children and adults.^{102,103} The 2005 AAPCC-NPDS report documented 3,635 nonfatal and 4 fatal cases, respectively, of iron poisoning, with 54% of the exposures in children younger than 6 years. Multiple vitamins with iron were involved in 24,599 cases, with 84% of ingestions occurring in those younger than 6 years. No deaths were associated with these products.⁶

Risk Assessment

A patient who exhibits lethargy, paleness, persistent or bloody emesis, or diarrhea should be immediately referred to an emergency department.¹⁰³ Ingestion of 10 to 20 mg/kg elemental iron usually elicits mild gastrointestinal symptoms. Ingestion of 20 to 40 mg/kg is not likely to produce systemic toxicity, and typically these patients can be conservatively managed at home. Ingestions of 40 mg/kg or more of elemental iron are often associated with serious toxicity and require immediate medical attention.¹⁰³ Psychiatric as well as medical intervention is indicated for adults and adolescents who intentionally ingest iron as a suicide gesture.^{98,100,103}

An abdominal radiograph may help to confirm the ingestion of iron tablets and indicate the need for aggressive gastrointestinal evacuation with whole-bowel irrigation. An abdominal radiograph is most useful within 2 hours of ingestion. The visualization of radiopaque iron tablets is confounded by the presence of other hard-coated tablets and some extended-release tablets that also are radiopaque. Furthermore, the radiopacity of iron tablets diminishes as the tablets disintegrate, and chewable and liquid formulations typically are not radiopaque.¹⁰⁴

Iron poisoning causes vomiting and diarrhea, but these symptoms are poor indicators of later serious toxicity. The presence of a combination of findings such as coma, radiopacities, leukocytosis, and increased anion gap, however, is associated with dangerously high serum concentrations >500 mcg/dL. The presence of single signs and symptoms, such as vomiting, leukocytosis, or hyperglycemia, is not a reliable indicator of the severity of iron poisoning in adults or children.^{105,106}

Once iron is absorbed, it is eliminated only as the result of blood loss or sloughing of the intestinal and epidermal cells. Thus, iron kinetics essentially represent a closed system with multiple compartments. The serum iron concentration represents a small fraction of the total-body content of iron and is at its greatest concentration in

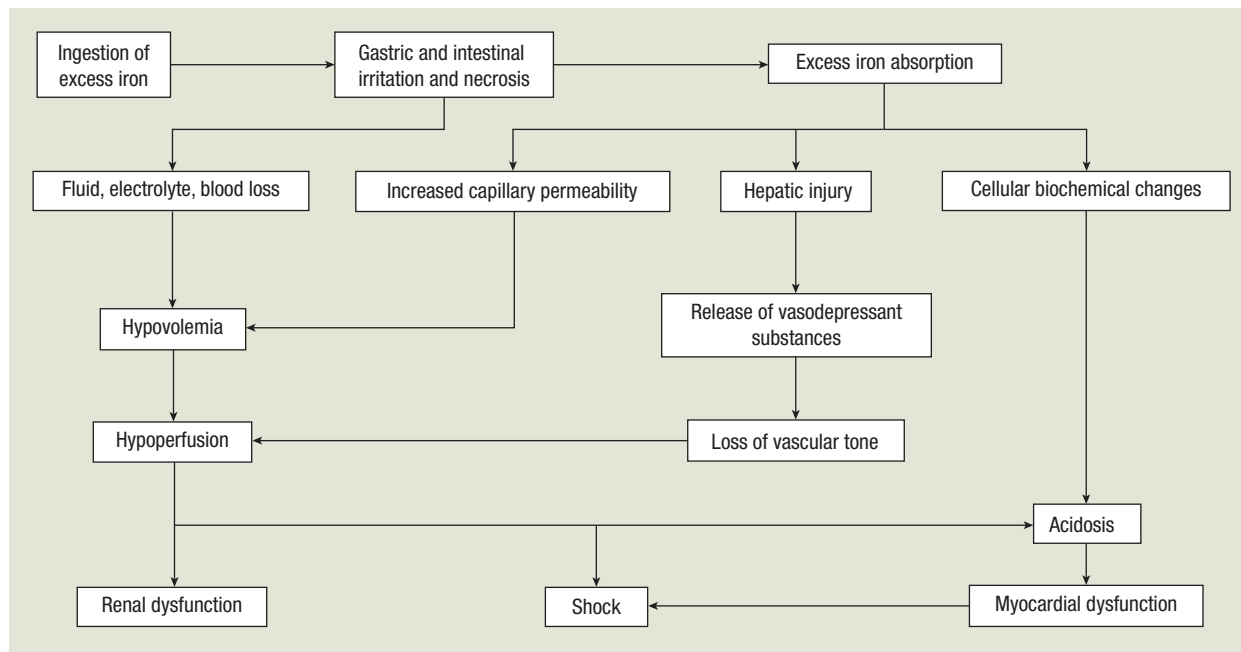

FIGURE 10-6. Pathophysiology of acute iron poisoning.

the postabsorptive and distributive phases, typically 2 to 10 hours after ingestion.¹⁰⁷ Serum iron concentrations >500 mcg/dL have been associated with severe toxicity, whereas concentrations <350 mcg/dL typically are not associated with severe toxicity; however, exceptions have been reported for both thresholds.¹⁰⁷ Serious toxicity is best determined by assessing the development of gross gastrointestinal bleeding, metabolic acidosis, shock, and coma regardless of the serum iron concentration.¹⁰⁰ The serum iron concentration serves as a guide for further assessment and treatment options. The ratio of the serum iron concentration to the total iron-binding capacity previously has been advocated to assess acute iron poisoning, but it is no longer used. This procedure is unreliable, insensitive, and has little relationship to toxicity.¹⁰⁶

Management of Toxicity

Many patients vomit spontaneously, and ipecac syrup should be avoided.¹⁰³ At the emergency department, gastric lavage with normal saline can be considered. Lavage with normal saline may remove iron tablet fragments and dissolved iron, but because the lumen of the tube is often smaller than some whole tablets, effective removal is unlikely.⁹⁸ Activated charcoal administration is not warranted routinely because it adsorbs iron poorly. If abdominal radiographs reveal a large number of iron tablets, whole-bowel irrigation with polyethylene glycol electrolyte solution typically is necessary.³⁴ Although removal by gastrostomy has been used in a few cases,¹⁰⁰ early and aggressive decontamination and evacuation of the gastrointestinal tract usually will be adequate to minimize iron absorption and thereby reduce the risk of systemic toxicity.

Patients with systemic symptoms (e.g., shock, coma, or gross gastrointestinal bleeding or metabolic acidosis) should receive deferoxamine as soon as possible. If the serum iron concentration is >500 mcg/dL, deferoxamine is also indicated because serious systemic toxicity is likely.^{98,100} Its use is less clear in patients with serum iron concentrations in the range from 350 to 500 mcg/dL because many of these patients do not develop systemic symptoms.¹⁰⁷

Deferoxamine is a highly selective chelator of iron that theoretically binds ferric (Fe^{3+}) iron in a 1:1 molar ratio (100 mg deferoxamine to 8.5 mg ferric iron) that is more stable than the binding of iron to transferrin. Deferoxamine removes excess iron from the circulation and some iron from transferrin by chelating ferric

complexes in equilibrium with transferrin. The resulting iron–deferoxamine complex, ferrioxamine, is then excreted in the urine. Its action on intracellular iron is unclear, but it may have a protective intracellular effect or may chelate extramitochondrial iron.¹⁰⁰ The parenteral administration of deferoxamine produces an orange–red-colored urine within 3 to 6 hours because of the presence of ferrioxamine in the urine.⁹⁸ For mild-to-moderate cases of iron poisoning, where its use is unclear, the presence of discolored urine indicates the persistent presence of chelatable iron and the need to continue deferoxamine. The reliance on discolored urine as a therapeutic end point has been challenged because it is not sensitive and is difficult to detect.¹⁰⁸

An initial intravenous infusion of 15 mg/kg/h generally is indicated, although some have used up to 30 mg/kg/h for life-threatening cases. In these situations, the dose must be titrated carefully to minimize deferoxamine-induced hypotension.^{98,100,109} The rapid intravenous infusion of deferoxamine (>15 mg/kg/h) has been associated with tachycardia, hypotension, shock, generalized erythema, and urticaria.^{98,110} Anaphylaxis has been reported rarely. The use of deferoxamine for more than 24 hours at doses used for treatment of acute poisoning has been associated with exacerbation or development of ARDS.^{110–112} Although the manufacturer states that the total dose in 24 hours should not exceed 6 g, the basis for this recommendation is unclear, and daily doses as high as 37.1 g have been administered without incident.^{109,111} Good hydration and urine output may moderate some of the secondary physiologic effects of iron toxicity and ensure urinary elimination of ferrioxamine. In the patient who develops renal failure, hemodialysis or hemofiltration does not remove excess iron but will remove ferrioxamine.⁹⁸

CLINICAL CONTROVERSY

There is little evidence on how much deferoxamine should be given for iron poisoning or for how long it should be administered. The dosage regimen should balance the benefits of increased iron removal in patients with exceedingly high serum iron concentrations versus the risk of developing ARDS when therapy lasts for more than 1 to 3 days.

The desired end point for deferoxamine therapy is not clear. Some have suggested that deferoxamine therapy should cease when the serum iron concentration falls below 150 mcg/dL.¹⁰⁰ The decline of serum iron concentrations, however, may not account for the potential cellular action of deferoxamine irrespective of its effect on iron elimination. The cessation of orange-red urine production that is indicative of ferrioxamine excretion is not reliable because many individuals cannot distinguish its presence in the urine.¹⁰⁸ Considering these shortcomings, deferoxamine therapy should be continued for 12 hours after the patient is asymptomatic and the urine returns to normal color or until the serum iron concentration falls below 350 mcg/dL and approaches 150 mcg/dL.

Other Therapies

Lavage solutions of phosphate or deferoxamine have been proposed previously as a means to render iron insoluble, but they were found ineffective and dangerous.⁹⁵ Oral iron chelating agents, such as deferiprone and deferasirox, are available for the management of chronic iron overload states such as sickle cell anemia, but their role in the treatment of acute iron poisoning remains to be determined.^{113,114}

Monitoring and Prevention

Once a poisoning has occurred, acid-base balance (anion gap and arterial blood gases), fluid and electrolyte balance, and perfusion should be monitored. Other indicators of organ toxicity, such as ALT, AST, bilirubin, prothrombin time, serum glucose and creatinine concentrations, as well as markers of physiologic stress or infection such as leukocytosis, also should be monitored.

Iron poisoning often is not recognized as a potentially serious problem by parents or victims until symptoms develop; thus, valuable time to institute treatment is lost. Parents should be made aware of the potential risks and asked to observe basic poison prevention measures. Some hard-coated iron tablets resemble candy-coated chocolates and are confused easily by children. Based on these considerations and the frequency of this poisoning, iron tablets are packaged in child-resistant containers.

TRICYCLIC ANTIDEPRESSANTS

Clinical Presentation

10 Patients may deteriorate rapidly and progress from no symptoms to life-threatening cardiotoxicity or seizures within 1 hour.^{115,116} Major symptoms of tricyclic antidepressant overdose typically are manifest within 6 hours of ingestion.¹¹⁵ The principal effects of tricyclic antidepressant poisoning involve the cardiovascular system and the central nervous system and can result in arrhythmias, hypotension, coma, and seizures (see presentation box below).

CLINICAL PRESENTATION OF TRICYCLIC ANTIDEPRESSANT POISONING

General

- Sedating and cardiovascular effects observed within 1 hour of ingestion, quickly leading to life-threatening symptoms; death is possible within 1 to 2 hours

Symptoms

- Lethargy, coma, and seizures occur within 1 to 6 hours
- Dry mouth, mydriasis, urinary retention, and hypoactive bowel sounds, develop within 1 to 6 hours

Signs

- Tachycardia within 1 to 3 hours

- Mild hypertension early will change to severe hypotension and shock within 1 to 6 hours
- Unresponsiveness and depressed reflexes within 1 to 3 hours
- Depressed respiratory rate and depth depending on the degree of coma
- Common arrhythmias, such as prolonged QRS and QT intervals to ventricular dysrhythmias, within 1 to 6 hours

Laboratory Tests

- Altered arterial blood gases associated with metabolic acidosis from hypoxia and seizures
- Altered serum electrolytes, BUN, and serum creatinine in response to seizures and shock within 3 to 12 hours

Other Diagnostic Tests

- ECG with continuous monitoring and pulse oximetry to monitor for toxicity and shock
- Monitor for complications of pulmonary aspiration, such as hypoxia and pneumonia, by physical findings and chest radiograph

Prolongation of the QRS complex on ECG indicating nonspecific intraventricular conduction delay or bundle-branch block is the most distinctive feature of tricyclic antidepressant overdose.¹¹⁶ Sinus tachycardia with rates typically <160 beats/min is common and does not cause serious hemodynamic changes in most patients. Ventricular tachycardia is a common ventricular arrhythmia, but it may be difficult to distinguish from sinus tachycardia in the presence of QRS complex prolongation and the apparent absence of P waves. It often occurs in patients with marked QRS complex prolongation or hypotension and may be precipitated by seizures.^{116,117} High rates of mortality are associated with ventricular tachycardia; ventricular fibrillation is the terminal rhythm. Torsade de pointes is observed infrequently with tricyclic antidepressant poisoning. With massive tricyclic antidepressant overdose, slow ventricular rhythms may be observed. Hypotension is a significant factor in most cases of tricyclic antidepressant poisoning. Refractory hypotension leading to death is due to vasodilation and impaired cardiac contractility.¹¹⁶ Other factors, such as extreme heart rates, intravascular volume depletion, hypoxia, hyperthermia, seizures, and acidosis, may contribute to refractory hypotension.

Coma usually is present in patients with tricyclic antidepressant poisoning and may or may not be associated with QRS complex prolongation. In severe cases, coma is sufficient to depress respirations. Delirium, manifest as agitation or disorientation, may occur early in the course of severe poisoning or with poisoning of moderate severity. Seizures often occur within 2 hours of ingestion and usually are generalized, single, and brief. Seizures may result in acidosis, hyperthermia, or rhabdomyolysis, and 10% to 20% of patients may abruptly develop cardiovascular deterioration.¹¹⁶ Myoclonus also may be observed with tricyclic antidepressant overdose.

Hyperthermia often results from seizure and myoclonic activity in the presence of decreased sweating and is associated with a high incidence of neurologic sequelae and mortality. Anticholinergic symptoms, such as urinary retention, ileus, and dry mucous membranes, often are observed with tricyclic antidepressant overdose.^{115,116} Pupil size is variable. Tricyclic antidepressant overdose can be staged based on the patient's symptoms and recovery time. In stage 1, patients are responsive to pain, have sinus tachycardia, and recover within 24 hours. In stage 2, seizures, coma, and cardiac conduction problems are evident; respiratory support typically is needed. Patients recover within 24 to 48 hours of ingestion. Stage 3 is characterized by the features of stage 2 with the addition of respiratory arrest, hypotension, ventricular dysrhythmias, and asys-

tole, which may occur within 1 to 24 hours of ingestion. Typically symptoms appear within 2 hours, and more serious effects usually are not seen until 6 hours postingestion; rarely rapid clinical deterioration is observed within 1 to 2 hours.¹¹⁸

Amoxapine, bupropion, and maprotiline are atypical antidepressants associated with a higher incidence of seizures on overdose; amoxapine produces minimal cardiotoxicity,^{116,119} but venlafaxine has been associated with greater mortality.¹²⁰ The selective serotonin reuptake inhibitors (SSRIs) generally produce a common toxicity profile on overdose despite their structural and pharmacologic distinctions.¹²¹ The SSRIs inhibit presynaptic neuronal uptake of serotonin, resulting in increased synaptic serotonin levels. When ingested in excess, SSRIs rarely cause death and typically produce nausea, vomiting, diarrhea, tremor, and decreased level of consciousness.¹²¹ Tachycardia and seizures are infrequent.^{116,119,122}

Serotonin syndrome is a condition in which associated drugs (e.g., meperidine, nonselective monoamine oxidase inhibitors, dextromethorphan, linezolid, tricyclic antidepressants, SSRIs) acutely increase serotonin levels and develops within minutes to hours (typically within 6 hours) after starting a medication, increasing the dose of a medication, or overdosing. It is characterized by a collection of neurobehavioral (e.g., confusion, agitation, coma, seizures), autonomic (e.g., hyperthermia, diaphoresis, tachycardia, hypertension), and neuromuscular (e.g., myoclonus, rigidity, tremor, ataxia, shivering, nystagmus) signs and symptoms.¹²³ Most cases are mild and resolve spontaneously within 24 to 72 hours. Cardiac arrest, coma, and multiorgan system failure have been reported as consequences of serotonin syndrome.¹²³ Recognition of the syndrome is based on a high index of suspicion and identification of risk factors.

Mechanism of Toxicity

Many of the toxic effects of tricyclic antidepressants are associated with an exaggeration of their pharmacologic action. The tricyclic antidepressants, such as type Ia antiarrhythmic drugs, inhibit the fast sodium channel so that phase 0 depolarization of the myocardium is slowed.¹¹⁶ This action leads to QRS complex prolongation, atrioventricular block, ventricular tachycardia, and decreased myocardial contractility. Tricyclic antidepressants also block vascular α -adrenergic receptors, resulting in vasodilation, which contributes to hypotension. Sinus tachycardia is related to the inhibition of norepinephrine reuptake and anticholinergic effects. Other anticholinergic effects include urinary retention, ileus, dry mucous membranes, and impaired sweating. Inhibition of norepinephrine reuptake also may account for the early, transient, and self-limiting elevation of blood pressure observed in some patients. The central nervous system toxicity of tricyclic antidepressants is not well understood.

Causative Agents

Tricyclic antidepressants and SSRIs are used to treat a variety of behavioral conditions (see Chaps. 71–73). The tricyclic antidepressants include drugs such as amitriptyline, desipramine, doxepin, imipramine, and nortriptyline. Atypical agents include amoxapine, bupropion, maprotiline, nefazodone, trazodone, and venlafaxine. The SSRIs include fluoxetine, paroxetine, and sertraline. The tricyclic antidepressants are generally highly protein bound, exhibit a large volume of distribution, and possess elimination half-lives of 8 to 24 hours or more. Virtually none of the drug is eliminated unchanged in the urine. Metabolism of the parent drug produces active metabolites in most cases (e.g., amitriptyline to nortriptyline) that may contribute to toxicity after the first 12 to 24 hours.¹¹⁶ Genetic polymorphism at CYP2D6 may lead to slower recovery in patients who are slow hydroxylators.¹²⁴

Incidence

Tricyclic antidepressant poisoning is a common cause of death from drug overdose.^{116,117} The 2005 AAPCC-NPDS report documented 11,198 patients with exposures to tricyclic antidepressants; 63% of these cases were considered to be intentional overdoses. A total of 1,256 people experienced a major effect, and 101 people died.⁶ The SSRIs accounted for 48,161 nonfatal exposures and 118 deaths.

Risk Assessment

Referral to an emergency department is warranted for ingestions >5 mg/kg of amitriptyline, clomipramine, doxepin, and imipramine; >2.5 mg/kg of desipramine, nortriptyline, and trimipramine; and >1 mg/kg of protriptyline.¹¹⁸ Patients who exhibit weakness, drowsiness, dizziness, tremulousness, and palpitations after an ingestion of a tricyclic antidepressant and patients suspected of a suicide gesture or those who are suspected victims of malicious poisoning should be promptly referred to an emergency department.¹¹⁸ A QRS complex >160 milliseconds or progressive prolongation of the QRS complex is an indicator of toxicity such as seizures or ventricular arrhythmias and often precedes the onset of serious symptoms.^{115,117,125} The QRS complex duration should not be used as the sole indicator of risk for tricyclic antidepressant poisoning.¹²⁵ Although urine drug analyses routinely screen for tricyclic antidepressants, the qualitative result can only suggest or confirm a potential risk for the development of toxicity.

Patients with coexisting cardiovascular and pulmonary conditions (e.g., ARDS, pulmonary infection, pulmonary aspiration) may be more susceptible to the toxic effects or complications of tricyclic antidepressant poisoning.¹¹⁸ Tricyclic antidepressants interact with other central nervous system depressant drugs, which together may lead to increased central nervous system and respiratory depression.

Consult a poison control center for current recommendations for doses of SSRIs that would warrant referral to an emergency department.¹²⁶ The risk of serotonin syndrome may be increased shortly after dosage increases of SSRIs or when drug interactions increase serotonin activity.¹²³ Concomitant or proximal use of SSRIs, tricyclic antidepressants, or nonselective monoamine oxidase inhibitors may cause serotonin syndrome. Furthermore, the addition of certain drugs, such as tryptophan, dextromethorphan, cocaine, or sympathomimetics, to SSRI therapy may increase the risk of developing serotonin syndrome.¹²³

Management of Toxicity

Once the ingestion of an overdose of tricyclic antidepressant is suspected or for any intentional ingestions, medical evaluation and treatment should be sought promptly. If the patient is symptomatic, it may be prudent to call for an ambulance because of the rapid progression of some cases. At the emergency department, the patient should be monitored carefully, have vital signs assessed regularly, and have an intravenous line started. Supportive and symptomatic care includes oxygen, intravenous fluids, and other treatments as indicated. Prompt administration of activated charcoal may decrease the absorption of any remaining tricyclic antidepressant. It also may be useful beyond the first hour of ingestion because of decreased gastrointestinal motility from the anticholinergic action of tricyclic antidepressants. Gastric lavage may be considered if the time of the ingestion is unknown or if ingestion occurred within the past 1 to 2 hours. Some practitioners avoid gastric lavage altogether.¹¹⁶ Ipecac syrup should be avoided in patients who ingest tricyclic antidepressants because the rapid onset of toxicity limits its usefulness. Multiple-dose activated charcoal has been shown to increase the elimination of some tricyclic antidepressants in human volunteers⁴² and has been used in poisoned patients.^{115,116} It may be most useful during the first 12 hours of

ingestion while the drug is distributing to tissue compartments. Because the tricyclic antidepressants possess a large volume of distribution, little of the drug is present in the bloodstream; thus hemodialysis is not useful for the extracorporeal removal of tricyclic antidepressants.

Intravenous sodium bicarbonate is part of the first-line treatment of QRS complex prolongation, ventricular arrhythmias, and hypotension caused by tricyclic antidepressant overdose.^{52,116,127} Typically 1 to 2 mEq/kg sodium bicarbonate (1 mEq/mL) is administered as a bolus infusion (usually a 50-mEq ampule in an adult) and repeated as necessary to achieve an arterial blood pH of 7.50 to 7.55 or abatement of toxicity.^{115,116} A therapeutic effect usually is observed within minutes. Excessive use of sodium bicarbonate may produce dangerous alkalemia, which by itself is associated with ventricular arrhythmias.¹¹⁶ The mechanism of action of sodium bicarbonate is unclear. Although some practitioners have proposed that sodium bicarbonate increases protein binding of tricyclic antidepressants, this theory has been discounted. Sodium may play an important role by stabilizing tricyclic antidepressant-induced changes to the sodium gradient of the myocardium.^{116,128} Regardless of its action, it is effective and generally safe. Hyperventilation to produce a mild state of respiratory alkalosis has been used to treat some dysrhythmias, but it is used less widely than sodium bicarbonate.^{115,116}

CLINICAL CONTROVERSY

Because intravenous sodium bicarbonate is used as therapy for certain arrhythmias and hypotension caused by tricyclic antidepressant poisoning, some practitioners have advocated its prophylactic use. Little evidence indicates which patients would benefit from prophylactic use. The risks of potentially producing alkalosis in a patient who is not seriously toxic should be considered.

Treatment of the complications of tricyclic antidepressant poisoning is outlined in Table 10–13 and includes pharmacologic and nonpharmacologic approaches.^{115,116} Several agents generally should be avoided in the treatment of tricyclic antidepressant poisoning. Other drugs that inhibit the fast sodium channel, such as procainamide and quinidine, are contraindicated. Phenytoin has limited usefulness in treating tricyclic antidepressant seizures and has questionable efficacy in managing cardiotoxicity.¹¹⁵ Physostigmine was used in the past as a treatment of tricyclic antidepressant cardiotoxicity and seizures because it antagonizes anticholinergic actions. However, physostigmine has been associated with bradycardia and asystole^{116,129} and has been avoided in the contemporary treatment of tricyclic antidepressant cardiovascular or central nervous system toxicity. Flumazenil is used to antagonize the effects of benzodiazepines, but its use in the presence of a tricyclic antidepressant has been associated with the development of seizures and should be avoided.¹³⁰

Treatment of an overdose of the atypical antidepressants and SSRIs is directed primarily toward decontamination of the gastrointestinal tract with activated charcoal, symptomatic treatment, and general supportive care. Management of the serotonin syndrome involves discontinuation of the serotonergic agent and supportive therapy. Benzodiazepines, propranolol, and cyproheptadine, a serotonin antagonist, have been used successfully.¹²³

Monitoring and Prevention

Measurement of vital signs, electrolytes, and BUN and a urinalysis are indicated for initial assessment. Patients should be monitored continuously by ECG, and a 12-lead ECG should be obtained if QRS complex prolongation is noted. If patients start to show signs of

TABLE 10-13 Treatment Options for Acute Tricyclic Antidepressant Toxicity

Toxicity	Treatment
Cardiovascular	
QRS prolongation, if progressive or >0.16 s	Intravenous sodium bicarbonate to a blood pH of 7.5 even in the absence of acidosis; generally avoid other antiarrhythmic drugs
Hypotension	Intravascular fluids; intravenous sodium bicarbonate; consider norepinephrine or dopamine
Ventricular tachycardia	Intravenous sodium bicarbonate; lidocaine, overdrive pacing
Ventricular bradycardia	Epinephrine drip; cardiac pacemaker
Atrioventricular block type II, second or third degree	Cardiac pacemaker
Cardiac arrest	Advanced cardiac life support, prolonged resuscitation may be needed
Neurologic	
Seizures, agitation	Benzodiazepines; neuromuscular blockade may be needed if hyperthermia or acidosis is present
Coma	Endotracheal intubation; mechanical ventilation if needed
Homeostatic	
Hyperthermia	Treat seizures and agitation; consider cooling blanket, ice water lavage, and cool water mist of body
Acidosis	Intravenous sodium bicarbonate

cardiotoxicity, arterial blood gases should be determined. Patients who show no signs of toxicity during 6 hours of observation and have received activated charcoal promptly require no further medical monitoring. Psychiatric evaluation is indicated for adolescents and adults. When signs of tricyclic antidepressant toxicity are present in a patient, cardiac monitoring generally is recommended for at least 24 hours after the patient is without findings.¹¹⁶

Prevention of tricyclic antidepressant poisoning poses unique challenges. Many of the dosage forms are small in size, and adults and children can consume large numbers easily. In the course of treating depression, several antidepressant agents may be tried to achieve results. By not discarding unused medicines, a storehouse of potentially deadly drugs may be available for children to discover or for the despondent patient to use to attempt suicide. Although patients take tricyclic antidepressants for therapeutic relief of depression, they are also a group likely to contemplate suicide with tricyclic antidepressants. Strategies that would limit the amount of tricyclic antidepressant prescribed at one time also potentially would impair adherence to a dosage regimen and thereby compromise the therapeutic potential of these agents.^{116,127} Patients with a history of suicidal gestures may be candidates for the atypical antidepressants or SSRIs, which possess less cardiotoxicity. General poison prevention measures may limit childhood poisonings, and monitoring depressed patients for suicidal ideation may identify patients at risk.¹³¹

ABBREVIATIONS

AAPCC-NPDS: American Association of Poison Control Centers' National Poison Data System

ALT: alanine aminotransferase

ARDS: adult respiratory distress syndrome

AST: aspartate aminotransferase

BUN: blood urea nitrogen

ECG: electrocardiogram

INR: international normalized ratio

NAPQI: *N*-acetyl-*p*-benzoquinoneimine

Emergency Preparedness: Identification and Management of Biological Exposures

COLLEEN M. TERRIFF, JASON E. BROUILLARD, LISA T. COSTANIGRO, AND
JESSICA S. GRUBER

KEY CONCEPTS

- 1 Bioterrorism agents are organisms or toxins that can cause disease and death in humans, animals, or plants and elicit terror.
- 2 Category A bioterrorism agents include anthrax (*Bacillus anthracis*), tularemia (*Francisella tularensis*), smallpox (*variola major*), plague (*Yersinia pestis*), botulinum toxin (*Clostridium botulinum*), and viral hemorrhagic fevers.
- 3 Many bioterrorism agents cause symptoms similar to other more common infectious diseases, like seasonal influenza, and may be difficult to differentiate without confirmatory laboratory testing.
- 4 Anthrax is a highly virulent, lethal infection; human-to-human transmission, however, has not been documented.
- 5 Individuals with signs and symptoms of botulism should be administered a test dose prior to receiving equine antitoxin therapy.
- 6 Prompt initiation of appropriate empiric therapy, after cultures are obtained, is vital to decreasing the mortality rate associated with plague.
- 7 Emergency preparedness for those at risk and response efforts for those exposed to smallpox involves mass vaccination campaigns.
- 8 Viral hemorrhagic fever, caused by one of a variety of viruses, can manifest as a febrile illness with a large range of sequela, including bleeding complications.

The fall of 2001 forever changed how many people throughout the world felt about flying, airport security, and even opening their mail. Terrorism, especially bioterrorism, became a common term used by the media, military analysts, both governments and public health officials, and the public at large. Anxiety caused by the 2001 intentional anthrax release through the United States mail system, and the ensuing exposures and deaths, was further escalated by numerous false alarms surrounding the delivery of parcels containing unidentified white powder.¹ Recent devastating natural disasters, such as tsunamis and hurricanes, have reawakened our appreciation of the power and destruction

associated with natural disasters. Isolated reports during the past decade have heightened concern about a global outbreak of severe acute respiratory syndrome (SARS) or avian influenza and as a result many levels of the community, including schools, businesses, health systems, first responders, and governments, have begun to address the need for planning for public health emergencies. Stockpiling of antibiotics for bioterrorism attacks and antivirals for pandemic influenza is becoming a crucial public health issue. Healthcare providers need to play an active role in awareness and preparedness for biological threats released by terrorists or nature, and the decision-making process regarding postexposure prophylaxis (PEP), mass vaccination, and treatment of biologic exposures to help protect the public.

1 Bioterrorism agents—organisms or toxins that can cause disease and death in humans, animals or plants for the purpose of eliciting terror—have been used against civilians and military personnel for centuries. Thousands of years ago crude, but effective methods were used for bioterrorism. Filth, human cadavers, and animal carcasses were flung over city walls, poisons were dropped in drinking wells, and contaminated clothing and blankets were offered as gifts to cause disease and, ultimately, death to enemies. More recently, sophisticated methods have been utilized, such as aerosolized technology for spraying plague and an umbrella-looking device used to shoot ricin toxin pellets for a targeted assassination.^{2,3} Over the past 80 years a variety of methods to weaponize biologic agents—enhance the shelf-life or dissemination properties (i.e., aerosolize) and/or fill munitions—have been researched.³ Approximately 12 countries throughout the world are believed to have active biological weapons programs, ranging from conducting research on the virulence of selected agents to actually weaponizing them.⁴

This chapter describes the natural history, symptomatology, diagnostic procedures, pharmacologic and nonpharmacologic treatment of biological agents of highest concern that could be used in a bioterrorism attack, such as anthrax, botulinum toxin, plague, smallpox, tularemia, viral hemorrhagic fevers and select Category B and C agents. The potential consequences of infectious disease outbreaks surrounding natural disasters, which rival bioterrorist events in their devastating potential, are also discussed. An evidence-based approach evaluating the various treatment options, including those for special populations, is presented, when the relevant data is available. Finally, information about the roles of healthcare providers in emergency preparedness and response is shared.

Emergency Preparedness: Identification and Management of Chemical and Radiological Exposures

GREENE SHEPHERD AND RICHARD B. SCHWARTZ

KEY CONCEPTS

- 1 In mass casualty events with chemical or radiologic exposure, the majority of victims can be managed with decontamination, observation and supportive care. Antidotal therapies should be reserved for more critically injured victims.
- 2 Nerve agent poisoning is similar to organophosphate insecticide poisoning with atropine and pralidoxime being the primary antidotes.
- 3 Cyanide gas exposure can be rapidly fatal but most victims that are conscious upon arrival to the hospital will not require antidote therapy.
- 4 Respiratory problems caused by pulmonary agents with low water solubility may take several hours to develop thus requiring extended observation.
- 5 Vesicant chemical weapons are less lethal than other chemical weapons but cause significant morbidity leaving many survivors that need extensive care.
- 6 Therapeutic agents are available that can block the uptake or enhance the elimination of radioactive contamination.
- 7 Clinicians, especially pharmacists need to be prepared to take an active role in the design and operationalization of disaster plans for their workplace and community. Pharmacists may participate on established disaster response teams that may be deployed to assist in the care of individuals outside of their local area.

Life-threatening hazardous material exposures may happen anywhere and at any time. The exposure may be due to an unintentional release or at the other extreme be the result of an intentional and catastrophic act of terrorism.¹⁻⁶ A hazardous material is defined as any substance that poses a substantial risk to the health or safety of individuals, or the environment when improperly handled, stored, transported, or disposed.¹ The specific risks are dependent on the quantity and concentration of the substance exposure and the physical, chemical, or infectious characteristics of the material. Many of these substances have the potential to be used as weapons. Small quantities of hazardous materials are used in many commercial products, such as pesti-

cides. Larger and more concentrated quantities are found at industrial sites and in their waste byproducts. Injuries from hazardous materials are relatively common as evidenced by the tens of thousands of hazardous material incidents recorded by the U.S. Environmental Protection Agency during the last decade. The majority of these incidents occur during transport rather than at the site of manufacture or use and represent a complex and significant danger for emergency healthcare workers.¹ At the other extreme, a hazardous material exposure may be the result of an intentional and catastrophic act of terrorism. Historically, acts of chemical or radiologic terrorism have been rare but have had very high visibility and marked psychological impact. Terrorism represents a profound threat to many countries around the world. Terrorists, whether representing foreign governments, organized religious sects, or individuals, have the capacity to endanger our communities with hazardous materials. Even a single patient contaminated with a hazardous material has the potential to overwhelm an unprepared healthcare facility.

1 A common thread in all disasters is that community healthcare systems are severely strained by limited communication, lack of personnel with disaster training or experience, lack of plans for facility surge capacity and limited availability of medical supplies. If chemical or radiologic contamination occurs the system is strained even further because of a lack of decontamination training and equipment at hospitals. Preplanning and early detection systems need to be in place to facilitate early recognition of the event and the substances involved if the community has any likelihood of being able to mount an effective response to a chemical or radiologic disaster. In all disasters, the normal flow of care is disrupted and the influx of victims becomes the major focus of the healthcare community. Preplanning for acute care needs for large numbers of patients, may include devising a method for expanding bed and surgical capacity as well as preparing specialized antidotes. Even if only minor injuries result from the event a significant portion of the affected population will need access to critical every day medications, such as insulin and personal needs, such as food and shelter.

This chapter discusses the major groups of hazardous materials that have been used as weapons. Chemical and radiologic events that have occurred in recent years are reviewed to provide an understanding of the scope, size, and complexity of such events. The clinical presentation, mechanisms of toxicity, and relevant diagnostic approaches are discussed for each type of agent. The community and individual preventative measures that can be taken to minimize the risks associated with the major types of chemical and radiologic threats are reviewed and the nonpharmacologic and pharmacologic treatment options are critically evaluated. Because controlled clinical trial data is lacking in this area the majority of treatment recommendations in this chapter are based on animal studies, anecdotal experience, and expert opinion. Finally, the ways in which clinicians can actively participate in disaster planning and response at the local, state and national level are presented.

SECTION 2

CARDIOVASCULAR DISORDERS

CHAPTER

13

Cardiovascular Testing

ROBERT CHILTON AND ROBERT L. TALBERT

KEY CONCEPTS

- 1 A careful patient history and physical examination are extremely important in diagnosing cardiovascular disease and should be done prior to any test.
- 2 Heart sounds and heart murmurs are important in identifying heart valve abnormalities and other structural cardiac defects.
- 3 Elevated jugular venous pressure is an important sign of heart failure and may be used to assess severity and response to therapy.
- 4 Electrocardiography is useful for determining rhythm disturbances (tachy- or bradyarrhythmias) and changes in ventricular and atrial size.
- 5 Exercise stress testing provides important information concerning the likelihood and severity of coronary artery disease; changes in the electrocardiogram, blood pressure, and heart rate are used to assess the response to exercise.
- 6 Cardiac catheterization and angiography are used to assess coronary anatomy and ventricular performance.
- 7 Echocardiography is used to assess valve structure and function as well as ventricular wall motion; transesophageal echocardiography is more sensitive for detecting thrombus and vegetations than transthoracic echocardiography.
- 8 Radionuclides such as technetium-99m and thallium-201 are used to assess wall motion and myocardial viability in patients with coronary artery disease and heart failure.
- 9 Pharmacologic stress testing is used when patients cannot perform physical exercise to assess the likelihood of coronary artery disease.

Every 36 seconds 1 person dies from cardiovascular disease and each day about 2,500 people die in the United States. Cardiovascular disease exceeds the next four leading causes of death combined (cancer, lung disease, accidents, and diabetes).¹ Another important factor in cardiovascular disease is that greater than 60% of unexpected cardiac deaths occur *without* prior history of heart disease and 70% of patients having a myocardial infarction have coronary artery blockages of about 40% to 60% (Fig. 13–1).

Cardiovascular disease affects 71,300,000 Americans, with one-third being older than age 65 years based on the National Health and Nutrition Examination Survey.² The current increase in patients older than age 65 years with cardiovascular disease will undoubtedly generate a large financial burden on the economy and families. Adding to the increasing burden of cardiovascular disease is information from Centers for Disease Control and Prevention revealing a marked increase in the number of patients with obesity; additionally, the projected 2050 growth rate in both obesity and diabetes is staggering. In 1997, the percentage of patient with obesity was approximately 19.5% of the U.S. population, and in 2004 it was found to have increased by 25% (24.3%). Along with this increase in obesity there was a 30% increase in diabetes from 5.3% to 6.9% over this same period of time.³ The rise of obesity and diabetes will undoubtedly lead to increases in heart disease prevalence.

Another area of concern in cardiovascular disease is illustrated by the Framingham Heart Study, which has followed patients for more than 40 years and found that the average annual rate of first major cardiovascular events increase significantly with age. Patients ages 35 to 44 years were found to have 7 major cardiovascular events per 1,000 men and to increase to 68 per 1,000 men by age 85 years, a 9-fold increase.⁴

In summary, one of the most important pieces of information that patients need to know is that lifestyle changes, that is, healthy-smart eating with reasonable caloric intake and frequent exercise, are major keys to a productive healthy life. The importance of lifestyle in saving lives is well illustrated from a recent study by Chiuvé et al., which studied 42,847 men in the Health Professionals Follow-up Study (cohort) who were 40 to 75 years of age and free of disease in 1986.⁵ The healthy lifestyle was defined as no smoking, body mass index <25 kg/m², moderate to vigorous activity >30 min/day, moderate alcohol consumption (5 to 30 g/day), and a healthy diet score. Tracking nonfatal myocardial infarctions and fatal coronary heart disease using a multivariate-adjusted Cox proportional hazards model, men complying with these five lifestyle factors had a

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

FIGURE 13-1. Intravascular ultrasound (IVUS) of a coronary artery. *A.* High-grade obstruction which on angiogram was thought to be only approximately 50% stenotic. *B.* Another coronary artery segment with 50% stenosis but more prone to rupture.

lower risk of coronary heart disease (relative risk: 0.13; 95% confidence interval [CI]: 0.09 to 0.19) compared with men who were at low risk with no lifestyle factors. Using population-attributable risk calculations (proportion of cases within the population that could have been avoided had all the men adhered to the low-risk lifestyle) adherence to five lifestyle changes could prevent 62% of men from having a coronary event. If patients were taking medication for hypertension or hypercholesterolemia they still would have a 57% reduction ([95% confidence interval (CI) 0.07 to 0.43]).

THE HISTORY

A comprehensive history is the cornerstone of a cardiovascular workup. The value of the history depends on the clinician's ability to elicit relevant information. Family history is very important because of the genetic links involved in many cardiovascular diseases from early myocardial infarction, strokes, diabetes, valvular heart disease, hypertension and familial hypercholesterolemia. The elements of a comprehensive history include the chief complaint, present problems, past medical history, review of systems, and social history.

The chief complaint needs to be narrowed down and focused if possible. Usually the chief complaint/main concern is a short brief statement as to the reason why the patient seeks medical care (get to the point). The duration of the chief complaint is important, along with any prior history of the same problem, the severity of the problem, and whether there are any limitations on the patient's daily activities. Other areas that need to be addressed are character, any types of motion or other things that increase or decrease the discomfort, any association with additional signs or symptoms, and whether the discomfort is increasing in frequency or duration. All these and many other matters need to be considered as the clinician does the intake interview with a new patient.

CARDIOVASCULAR HISTORY

1 Ischemic heart disease is the most common cardiovascular disease seen in clinical practice. A focus on chest pain history is very impor-

tant. The clinical syndrome of angina is frequently described by patients as a discomfort from chest ache, pain, or pressure, to dull pain in the jaw, back, shoulder, or either arm. Many research studies have found that family/work stress or exertion brings on increased symptoms of angina and rest or nitroglycerin frequently relieves it.⁶ Another important consideration when one considers angina is that in addition to epicardial large-vessel coronary artery disease (CAD), angina can develop in patients with valvular heart disease, obstructive cardiomyopathies, and hypertension. Symptoms of angina can occur in patients with noncardiac conditions such as gastrointestinal (esophageal), chest wall, or pulmonary disease (see Chap. 17). Angina does not necessarily relate to the severity or extent of CAD obstruction. Angina that is increasing in severity, longer in duration or occurring at rest is consistent with unstable angina and should be evaluated immediately.⁷

Initial evaluation of chest pain requires a good history and physical examination.^{8,9} The quality of chest pain, its location and duration, and factors that provoke or relieve the chest pain are important elements. Rarely do patients with ischemic heart disease describe their pain as sharp or stabbing. Commonly, patients state they do not have chest pain but a heaviness or pressure in the chest. Ischemic chest pain typically lasts only a few minutes and is generally brought on by exertion or emotional stress, and is commonly relieved by rest or nitroglycerin. Based on the history, classify the patient's symptoms. Three characteristics to consider are (a) whether the substernal chest discomfort has a classic quality and duration that is (b) provoked by exertion or emotional stress and (c) relieved by rest or nitroglycerin. If all three of these conditions are met, then the patient has classical angina; if only two of these conditions exist, the pain is considered to be atypical or probably angina; and if none are met, it is considered to be noncardiac chest pain. It is equally important that the patient inform the healthcare professional that the discomfort the patient is experiencing, which could be atypical, is the patient's "angina equivalent." Important information when taking a history of patients with angina is being aware of the grading of angina pectoris by the Canadian Cardiovascular Society (see Chap. 17).

It is important in an ischemic chest to differentiate angina from acute coronary syndrome. Acute coronary syndrome is more frequent, dramatic, and severe (see Chap. 18).

FIGURE 13-2. Correlation of the electrocardiogram (ECG) with an aortic pressure tracing and heart sounds. Normal heart sounds are S_1 and S_2 ; S_3 and S_4 are abnormal, as is an opening snap (OS), which is heard with mitral stenosis. S_1 may be split in some conditions (M_1 , mitral; T_1 , tricuspid.)

PHYSICAL EXAMINATION

The cardiovascular physical examination is divided into four categories:

1. Global examination of the patient for signs of cardiovascular disease (CVD) and a review of all body systems.
2. Observation and assessment of physical findings (e.g., jugular venous pressure).
3. Measurement of parameters of CVD function (pulse, blood pressure).
4. Auscultation, percussion, and palpation of the chest and related cardiac structures.

The initial part of the physical examination consists of inspection of the precordium for normal patterns of rise and fall and any abnormal markings or shape. The chest is then palpated for normal pulses, thrills (humming vibrations like the throat of a purring cat), and heaves (lifting of the chest wall). Thrills may indicate murmurs, and heaves may indicate enlargement of one of the heart chambers or an abnormal vessel such as an aneurysm. The apical pulse (also known as the *point of maximum impulse*) is helpful to estimate heart size and rotation. This is usually located in the fifth intercostal space in the midsternal line and radiates in an arc of 1 to 2 cm. Heightened intensity and/or displacement laterally suggests left or right ventricle enlargement, and reduced intensity may be a sign of fluid overload or pericardial effusion. Factors such as obesity, large breasts, muscularity, and pulmonary disease can interfere with determination of the apical pulse. The carotid pulse is examined for its intensity and, concurrently with the apical pulse, for concordance within the cardiac cycle. Decreased carotid pulsations may be a result of reduced stroke volume or atherosclerotic narrowing of the carotid artery.

Important physical correlations need to be carefully noted, as shown in Figs. 13–2 and 13–3. These critical associations are basic facts needed to understanding the physical examination of the human heart.

HEART SOUNDS

2 Auscultation with a stethoscope is used to characterize heart sounds. Auscultation is conducted in a systematic manner to ensure that all sites where normal and abnormal sounds are heard are reviewed. Respiratory pattern, various maneuvers such as handgrip and the Valsalva maneuver, sitting versus standing, and pharmacologic agents (e.g., amyl nitrate) also may be used in the evaluation of heart sounds to accentuate or diminish the intensity of these sounds. Auscultation is an acquired art and requires considerable practice to become competent.

The normal heart sounds include S_1 (first heart sound—closure of the mitral and tricuspid valves) and S_2 (second heart sound—aortic and pulmonic valves). Normally the second heart sound becomes split during inspiration because of delayed closure of the pulmonic valve (prolongation of right ventricle systole secondary to an increase in venous return) or because of an inspiratory decrease in impedance of the pulmonary bed.

Other sounds, such as S_3 (third heart sound) and S_4 (fourth heart sound) and murmurs, are not considered normal but provide important diagnostic information. Initially, the patient is examined lying partially on the left side to accentuate left-sided S_3 and S_4 and mitral murmurs, with the bell on the point of maximum impulse. To identify S_1 and S_2 , the patient can be examined lying or sitting. The other areas that are auscultated are the apex or base of the heart (mitral sounds), the lower left sternal border (tricuspid sounds), the second left interspace (pulmonic sounds), and the second right interspace (aortic sounds). At each of these locations, S_1 and S_2 should be heard (Fig. 13–4).

Heart sounds are characterized by location, pitch, intensity, duration, and timing within the cardiac cycle. High-pitched sounds such as S_1 and S_2 , murmurs of aortic and mitral regurgitation, and pericardial friction rubs are best heard with the diaphragm. The bell is preferred for low-pitched sounds such as S_3 and S_4 . S_1 is heard as a click at the end of diastole and usually is synchronous with the apical pulse. The intensity of S_1 can be increased if systole begins

FIGURE 13-3. Correlation of the electrocardiogram (ECG) with a carotid pulse pressure tracing and heart sounds. A split S_2 is heard in some conditions (A_2 , aortic; P_2 , pulmonic).

prior to the mitral valve closing, which may occur in high-output states (e.g., exercise, tachycardia, anemia, or hyperthyroidism) and mitral valve stenosis. S_1 intensity is decreased in first-degree heart block, mitral regurgitation, states of reduced myocardial contractility (such as heart failure or coronary artery disease), obesity (difficult to hear), and systemic or pulmonary hypertension. S_2 is heard at the end of systole and is best heard at the tricuspid and mitral areas. Most of the sound arises from aortic valve closure. Heart sounds may be “spilt” if the two valves do not close synchronously. Physiologic splitting of S_1 or S_2 is accentuated by inspiration and may disappear with expiration. Splitting of S_2 creates a pulmonic (P_2) and aortic (A_2) sound. S_2 frequently is heard as a split sound and is most predominant at the height of inspiration. Although S_1 also may be split, this is often difficult to hear.

Pathologic splitting of S_2 during expiration is described as *wide splitting*, *fixed splitting*, and *paradoxical splitting* and may be indicative of both stenosis and regurgitation. With right-sided heart failure, right bundle-branch block, pulmonic stenosis, or atrial septal defects, S_2 may be split owing to delayed closure of the pulmonic valve. Fixed splitting of S_2 is associated with large atrial septal defects and right

ventricular failure. Increased intensity of P_2 is seen in pulmonary hypertension and dilated pulmonary arteries and with atrial septal defects. Decreased or absent P_2 occurs with aging and in pulmonic stenosis. Extra heart sounds in systole include early systolic ejection sounds and clicks and midsystolic clicks. Early ejection sounds such as aortic or pulmonic ejection sounds often are associated with valvular disease. Midsystolic to late systolic clicks usually are a result of mitral valve prolapse. Mitral valve prolapse is best heard at or medial to the apex, but also may be heard at the left lower sternal border.

The S_3 heart sound, or ventricular gallop, is an abnormal low-pitched sound usually heard at the apex of the heart. It is thought to be caused by rapid filling and stretching of the left ventricle when the left ventricle is somewhat noncompliant. This heart sound is characteristic of volume overloading, such as in congestive heart failure (especially left-sided heart failure), tricuspid or mitral valve insufficiency, and atrial and/or ventricular septal defects. A physiologic S_3 is heard commonly in children and may persist into young adulthood. Localization of S_3 is helpful for determining heart rotation within the chest cavity.

The S_4 diastolic sound is a dull, low-pitched postsystolic atrial gallop (rapid blood flow) usually caused by reduced ventricular compliance. It is best heard at the apex in the left lateral position. Like S_3 , it occurs with reduced ventricular compliance and is present in conditions such as aortic stenosis, hypertension, hypertrophic cardiomyopathies, and coronary artery disease. It is less specific for congestive heart failure than S_3 .

The frequency range of S_3 and S_4 is below 100 Hz and requires the bell of the stethoscope to be used most of the time. This should be lightly touched to the skin to obtain the best results.

FIGURE 13-4. Schematic illustrations of topographic areas on the precordium for cardiac auscultation. Auscultatory areas do not correspond to anatomic locations of the valves but to the sites at which particular valves are heard best. (Redrawn from Kinney MR, Packa DR, eds. *Andreoli's Comprehensive Cardiac Care*, 8th ed. St. Louis: Mosby, 1996, with permission.)

HEART MURMURS

Murmurs are auditory vibrations heard on auscultation, and they occur because of turbulent blood flow within the heart chambers or through the valves.¹⁰ They are classified by timing and duration within the cardiac cycle (systolic, diastolic, and continuous), location, intensity, shape (configuration or pattern), pitch (frequency), quality, and radiation (Table 13-1). It is important to first note where it is heard best and where it radiates for example from apex to left axilla. Using S_1 and S_2 as a marker for timing, ask yourself this

TABLE 13-1 Characteristics of Heart Sounds

Type of Murmur	Examples	Location	Pitch	Radiation	Quality
Midsystolic	Aortic stenosis	2nd RICS	Medium	Neck, left sternal border	Harsh
	Pulmonic stenosis	2nd and 3rd LICS	Medium	Left shoulder and neck	Harsh
	Hypertrophic cardiomyopathy	3rd and 4th LICS	Medium	Left sternal border to apex	Harsh
Pansystolic	Mitral regurgitation	Apex	Medium to high	Left axilla	Blowing
	Tricuspid regurgitation	Lower left sternal border	Medium	Right sternum, xiphoid	Blowing
	Ventricular septal defect	3rd, 4th, and 5th LICS	High		Often harsh
Diastolic	Aortic regurgitation	2nd to 4th LICS	High	Apex	Blowing
	Mitral stenosis	Apex	Low	Little or none	

LICS, left intercostal space; RICS, right intercostal space.

question: Does the murmur occur in systole or diastole? Next carefully listen to see if the murmur completely fills that phase of the systolic cycle (i.e., holosystolic), or if it has discrete start and end points. Murmurs that occur after second heart sound are considered diastolic murmurs and most commonly relate to mitral stenosis or aortic insufficiency; however there are many other possibilities. Regurgitant murmurs for example, mitral valve insufficiency, usually fill the entire phase, while ejection murmurs, like aortic stenosis, usually have discrete beginning and end points within systole (between S_1 and S_2). Next the shape and quality of the murmur should be described along with descriptive terms about the murmur, that is, blowing, harsh, rumbling, machinery, musical, and others.

Some murmurs are considered innocent or physiologic and result from rapid, turbulent flow of blood into the left ventricle during atrial systole and through the aorta during ventricular systole. Fever, anxiety, anemia, hyperthyroidism, and pregnancy exacerbate physiologic murmurs, and these murmurs need to be distinguished from those suggestive of valvular abnormalities. Another important consideration is the grading of heart murmurs. The intensity or loudness of a murmur is graded using a scale of I to VI. Below are the different grades.

- I — Lowest intensity; difficult to hear even by expert listeners
- II — Low intensity, but usually audible by all listeners
- III — Medium intensity; easy to hear even by inexperienced listeners but without a palpable thrill

- IV — Medium intensity with a palpable thrill
- V — Loud intensity with a palpable thrill; audible even with the stethoscope placed on the chest with the edge of the diaphragm
- VI — Loudest intensity with a palpable thrill; audible even with the stethoscope raised above the chest

Multiple factors determine the grade, which includes the amount of blood ejected across a valve, severity of the lesion, and chest anatomy.

Systolic murmurs begin with or after S_1 and end at or before S_2 , depending on the origin of the murmur. They are classified based on time of onset and termination within systole: midsystolic, holosystolic (pansystolic), early, or late. Some examples of pathologic midsystolic murmurs are pulmonic stenosis, aortic stenosis, and hypertrophic cardiomyopathy. Midsystolic murmurs may include obstruction to ventricular outflow (a common example is aortic stenosis; Fig. 13-5), dilation of the aortic root or pulmonary trunk, an increased flow in the great arteries, anatomic changes in the semilunar valves, and some forms of regurgitation. Holosystolic murmurs occur when blood flows from a chamber of higher pressure to one of lower pressure, such as with mitral or tricuspid regurgitation and ventricular septal defects. Early systolic murmurs can be decrescendo and may be associated with ventricular septal defects, mitral regurgitation, or tricuspid regurgitation. A late systolic murmur preceded by one or more midsystolic to late systolic clicks is the hallmark of mitral valve

FIGURE 13-5. Aortic valve anatomy. A near-normal aortic valve is shown on the left and critical stenosis is shown on the right. The relationship of the aortic valve to coronary artery anatomy is shown below.

prolapse, which classically moves during changes in ventricular volume. Atherosclerotic obstruction of the carotid, subclavicular, or iliofemoral artery can give rise to a crescendo-decrescendo extracardiac systolic arterial murmur.

Early diastolic murmurs that are heard more commonly are mitral stenosis and aortic regurgitation. Aortic regurgitation begins with A_2 and generally is decrescendo, reflecting the progressive decline in volume and rate of regurgitant flow during diastole. Aortic regurgitation is best heard by having the patient lean forward while holding his or her breath and listening with the diaphragm along the mid left sternal border. Pulmonary hypertension (Graham Steell murmur: an early diastolic murmur caused by pulmonary insufficiency secondary to pulmonary hypertension) also may cause an early diastolic murmur. Midsystolic murmurs occur across the atrioventricular valves (mitral or tricuspid) during rapid filling and are consistent with mitral stenosis or mitral stenosis along with a ventricular septal defect or tricuspid regurgitation with an atrial septal defect. The Austin Flint murmur is a consequence of blood jets from the aortic regurgitation hitting the anterior leaflet of the mitral valve, leading to a midsystolic, low-pitched rumbling best heard at the cardiac apex that results in early mitral valve closure because of simultaneous rapid left ventricular filling (volume overload) from aortic regurgitation. Continuous murmurs begin in systole and continue without interruption into all or part of diastole. Such murmurs are mainly a result of aortopulmonary connections (e.g., patent ductus arteriosus), arteriovenous connections (e.g., arteriovenous fistula, coronary artery fistula), and disturbances of flow patterns in arteries or veins.

Anatomic correlation of murmurs may require cardiac catheterization or echocardiography with Doppler, where direct visualization of the blood flow abnormality and calculation of flow and chamber pressures can be obtained. In special cases the use of positron emission tomography (PET) and magnetic resonance imaging (MRI) are also possible options to evaluate flow patterns and gradients of murmurs across heart valves.

JUGULAR VENOUS PRESSURE

3 The jugular venous pressure (JVP) is used as an indirect measure of right atrial pressure.¹⁰ The JVP is measured in centimeters from the sternal angle and is best visualized with the patient's head rotated to the left. The JVP is described for its quality and character, effects of respiration, and patient position-induced changes. When reporting a JVP, both the extent of elevation and the patient position must be reported. The JVP can be reported as centimeters above the manubrium, or this value plus 5 to 7 cm to indicate the rise of the JVP above the right ventricle. For persons in whom the central venous pressure is normal, JVP is observed in the right internal jugular vein with the patient supine at 30° or less. In the presence of an elevated central venous pressure, the JVP is measured at 60 to 90°. In patients with poor myocardial function, the accuracy of the JVP as a measure of central venous pressure is reduced, and central venous pressure is best measured directly by means of a Swan-Ganz catheter.

The normal JVP is a v wave 1 to 2 cm above the sternal ridge. Elevation in JVP more than halfway to the jaw angle are elevated. Both the degree of elevation of the JVP and its wave flow in conjunction with the heartbeat are noted. The first wave, or a wave, represents atrial contraction and occurs just prior to S_1 , giving rise to increased pressure. It is seen as an undulating pulsation in the internal jugular vein. The second and much larger wave, the v wave, represents the increased venous pressure that occurs during venous filling. To interpret the JVP accurately, the carotid pulse is palpated concurrently. The a wave occurs just before the pulse and the v wave just after. Jugular venous pressure is often elevated in heart failure, and the degree of elevation can be used to assess the severity of heart failure, and diminution of JVP can be used to assess therapy.

PERIPHERAL CIRCULATION AND ARTERIAL PULSES

In recent years the recognition of peripheral arterial disease (PAD) has become very important because of the marked number of patients with asymptomatic disease. PAD affects about 8 million Americans and is associated with significant morbidity and mortality.^{11,12} PAD affects 12% to 20% of Americans age 65 years and older. Despite its prevalence and cardiovascular risk implications, only 25% of PAD patients are undergoing treatment.¹³ Approximately 40% do not complain of leg pain and only approximately 10% of persons with PAD have the classic symptoms of intermittent claudication (see Chap. 24).

It includes a variety of arterial syndromes (noncoronary artery) that are caused by pathobiologic changes of the arteries that supply the brain, visceral organs, and the limbs. Terminology is also important in discussing this area of arterial disease. Peripheral arterial disease includes an assorted group of disorders that lead to progressive stenosis or occlusion, or aneurysmal dilation, of the aorta and its noncoronary branch arteries, including the carotid, upper extremity, visceral, and lower extremity arterial branches. PAD is the preferred clinical term that should be used to denote stenotic, occlusive, and aneurysmal diseases of the aorta and its branch arteries, exclusive of the coronary arteries. Peripheral vascular disease includes pathophysiologic syndromes that affect the arterial, venous, and lymphatic circulations.

Current American College of Cardiologists/American Heart Association (ACC/AHA) guidelines¹¹ for the management of peripheral artery disease recommend a vascular history and physical examination (class I) for patients who are at risk for lower extremity PAD, age less than 50 years with diabetes and one other atherosclerosis risk factor (smoking, dyslipidemia, hypertension, or hyperhomocysteinemia), age 50 to 69 years and a history of smoking or diabetes, age 70 years and older, ischemic leg symptoms with exertion (intermittent claudication) or ischemic rest pain, abnormal lower extremity pulse examination, or known atherosclerotic coronary, carotid, or renal artery disease. They also recommend that patients older than 50 years of age should be asked if they have a family history of a first-degree relative with an abdominal aortic aneurysm.

One of the most important tests that can be easily done in patients suspected of PAD is to do an ankle-brachial index. An ankle-brachial index of <0.90 is 90% sensitive and 95% specific for PAD. Severe PAD causing rest pain or ulceration generally occurs with ankle-brachial indices of <0.40. This is easily calculated by measuring the systolic blood pressure in the ankle and dividing it by the systolic blood pressure in the arm (brachial). Normally the lower extremity blood pressure is higher than the arm. To appreciate the significance of PAD, one only needs to recognize that over a 5-year period in patients with PAD the mortality is 30%.¹⁴

Arterial pulses are evaluated and characterized bilaterally by observation, palpation, and auscultation for presence, character, pattern, and rhythm. Various arterial pulse patterns are described: pulsus alternans (variation in amplitude beat to beat), bisferiens pulse (increased arterial pulse with a double systolic peak), bigeminal pulse (reduced amplitude associated with premature ventricular beats), and paradoxical pulse (decrease in amplitude with inspiration). Although each may be associated with certain disorders (e.g., bigeminal pulse in premature ventricular contractions), none is sensitive or specific enough to be diagnostic. The status of the patient's overall peripheral circulation is recorded, especially the presence and degree of edema or skin changes suggestive of venous or arterial insufficiency. Color, condition, and integrity of the skin are also recorded, including signs of thrombophlebitis, tenderness, or swelling. Capillary refill (normal less than 2 seconds) is assessed by depressing the nail bed until it blanches and then releasing pressure and watching for the return of color, indicating blood flow.

HEART RATE

Heart rate is described by both rate and rhythm. The arterial pulse usually is taken at the radius, but carotid or other arterial pulses may be used. In healthy individuals, the heart rate is usually assessed by counting the pulse for 15 seconds and multiplying by 4. In patients with irregular rhythms, the pulse should be taken over an extended period, approximately 1 to 2 minutes, to try to determine the patient's average pulse and rhythm.

Arterial pulses are an accurate measure of the ventricular rate in healthy persons with good ventricular function. In patients with a rapid ventricular rate—because of supraventricular tachyarrhythmias such as atrial flutter or fibrillation or rapid ventricular rates (e.g., ventricular tachycardia or premature ventricular beats)—extremity pulses (e.g., radial pulse) may be considerably slower than the true ventricular rate. A more accurate ventricular rate is determined by listening to the ventricles with the stethoscope (usually at the apex) or counting from an electrocardiogram (ECG). In patients with atrial fibrillation and a fast ventricular rate, a pulse deficit (measure of the difference in true ventricular rate and peripheral pulse rate) may exist. This may be as much as 10 to 20 beats per minute. Consequently, the location of the pulse (radial or apical) should be recorded. The pulse deficit will be reduced as the ventricular rate is controlled with drug therapy or normal sinus rhythm is restored.

PRACTICE GUIDELINES FOR DIAGNOSTIC AND PROGNOSTIC TESTING IN CARDIOVASCULAR DISEASE TESTING

The American Heart Association (AHA) and American College of Cardiology (ACC) task force on practice guidelines publishes guidelines as to the recommended uses for many diagnostic testing methods. Such guidelines were first developed in the 1980s and are updated as more information is available. These are evidence-based recommendations that rank the indications and uses of tests into three primary classes. Class I indications are those where there is evidence or agreement that the specific procedure is useful and effective. Class II indications are those situations where there is divergence of opinion as to the usefulness of the method. Class III indications are those where there is evidence or agreement that a diagnostic test is not useful. Each class (usually class II) may be broken down into two or three subcategories. Class IIa indications are those where there is evidence or opinion in favor of the test, whereas class IIb indications are those where there is less evidence favoring the test. With each class of recommendation for a specific clinical scenario, the guidelines indicate the level of evidence for the recommendation. Level A evidence is given if the recommendation is based on the availability of multiple randomized clinical trials. Level B evidence is given if only a single randomized trial or multiple nonrandomized trials exist. Level C evidence is given if the recommendation is afforded based on expert opinion only.

Each guideline provides a preamble to indicate how it was constructed and the peer review process. These documents provide the clinician with an extensive database on the testing methodologies and are endorsed by both organizations as acceptable standards of practice.

TESTING MODALITIES

CHEST RADIOGRAPHY

The chest radiograph provides supplemental information to the physical examination and is usually the first diagnostic test in a cardiac workup. It does not provide details of internal cardiac structures but gives global information about position and size of the

heart and chambers and surrounding anatomy. The standard chest radiographs for evaluation of lungs and heart are standing posteroanterior and lateral views taken at maximal inspiration. Portable chest radiographs usually are less satisfactory because of penetration difficulties, patient rotation, and poor inspiratory effort.

Initial assessment of the chest radiograph evaluates the quality of the film for patient rotation, inspiratory effort, and penetration. Rotation is assessed by evaluating symmetry of the clavicles and central placement of the carina. Inspiratory effort is considered adequate if the diaphragms are pulled below the ninth rib. Lack of inspiratory effort and obesity lead to a poor-quality chest radiograph, which makes it more difficult to assess the presence of pleural effusions and fluid in the costophrenic angles. Where possible, comparison with previous or baseline films is done to determine the quality of film and comparison of structures.

The posteroanterior view chest radiograph outlines the superior vena cava, right atrium on the right and left sides, aortic knob, main pulmonary artery, left atrial appendage (especially if enlarged), and left ventricle. In the lateral view, the chest radiograph visualizes the right ventricle, inferior vena cava, and left ventricle. These structures are visualized as shadows of differing density rather than discrete structures.

The chest radiograph is approached from two perspectives: (a) observation and (b) clinical correlation. Observation notes gross anatomic features such as size and placement of the cardiac silhouette, definition of the cardiac border, chamber enlargement, pulmonary vasculature, air–fluid levels, and diaphragm. Cardiac enlargement is determined by the cardiothoracic ratio, which is the maximal transverse diameter of the heart divided by the maximal transverse diameter of the thorax of a posteroanterior view. Normal averages 0.45, but it may be up to 0.55 in subjects with large stroke volumes (e.g., highly trained athletes). Heart conditions, such as heart failure and hypertension, may enlarge the heart and so the cardiothoracic ratio. Individual chamber enlargement can be seen on the chest radiograph. Right ventricle enlargement is best seen on the lateral film, where the heart appears to occupy the retrosternal space. Left atrial enlargement is suspected if there is elevation of the left bronchus or an increase in the atrial appendage bulge. Left ventricular enlargement is the most common feature identified on chest radiograph and is seen as an elongation and downward displacement of the apex of the heart. Sometimes a characteristic “boot” or “water bottle” outline is seen with left ventricular enlargement, as in heart failure.

The pulmonary vessels are examined for plumpness and definition of vessel walls. Decreased pulmonary flow (e.g., tetralogy of Fallot) causes central and peripheral vessels to be decreased in size. Increased pulmonary flow is associated with high-output states such as hyperthyroidism and atrial septal defects. This may lead to enlargement and tortuosity of the central and peripheral vessels. Pulmonary arterial hypertension (increased pulmonary resistance) is identified by enlargement of the central vessels and diminished peripheral vessels. Pulmonary venous hypertension usually is caused by mitral stenosis or left ventricular failure. This is characterized by larger-than-normal vessels in the upper lung zones owing to recruitment of upper vessels from blood diverted from the lower constricted vessels (cephalization of flow).

Heart failure causes Kerley B lines (edema of interlobular septa), which appear as thin, horizontal reticular lines in the costophrenic angles. At higher pressures, alveolar edema and pleural effusions appear in the pleural space or as blunting of the costophrenic angles. Pericardial effusions also may appear as a large heart, but because it usually occurs rapidly, there is no evidence of pulmonary venous congestion.

ELECTROCARDIOGRAM

4 Measurement of electrical activity in the heart, now known as the ECG, was introduced about 75 years ago by Willem Einthoven. The

TABLE 13-2 Drugs That May Affect the Electrocardiogram	
Digoxin	Pentamidine
Antiarrhythmics—classes I–IV	Lithium
Tricyclic antidepressants	Catecholamines (e.g., dopamine, albuterol)
H ₁ antagonists	Diuretics (electrolyte abnormalities)
Methylxanthines	
Doxorubicin	

ECG is simple to perform and is the most frequently used, least invasive, and cheapest cardiovascular test.^{15,16} It remains the procedure of first choice for evaluation of chest pain, dizziness, or syncope. In its simplest interpretation, the ECG characterizes rhythms and conduction abnormalities. However, the ECG also provides, by inference, information about the anatomy and structures of the heart, pathophysiologic changes, and hemodynamics of the CVD system.¹⁷ ECG abnormalities are often the earliest sign of adverse drug effects, ischemia, and electrolyte abnormalities.

Although few ECG recordings are highly specific or sensitive to a disease state, correlation of findings with clinical and pathologic states affords the ECG significant diagnostic and prognostic capabilities. Sensitivity and specificity of ECG changes depend primarily on the clinical setting, recording technique, and skill of interpreters. Sensitivity and specificity of findings are increased by interpretation in conjunction with patient information such as age, gender, medical history, and medications. Additionally, prior and/or serial ECGs should be obtained for comparison prior to identifying new findings on a current ECG as diagnostic. This is particularly important in patients with significant cardiac disease or on medications that alter the ECG (Table 13–2). The ECG is sensitive in detecting rhythm abnormalities, but it does not record the actual activity of the conduction tissue.^{18,19}

The ECG can be used to evaluate ischemia following angioplasty or other surgical interventions and to monitor responses to antiarrhythmic agents or in patients receiving drugs with potential cardiac effects.

Electrocardiography is based on the measurement of change in summated three-dimensional electrical vectors or forces that result from depolarization and repolarization of cells in the conduction system and heart muscle. The standard external 12-lead ECG uses two sets of leads: limb and chest (Fig. 13–6). The six limb leads look at the heart in a single frontal plane. Limb lead nomenclature is as follows: lead I, right arm/left arm; lead II, right arm/left leg; lead III, left arm/left leg. Altering resistances create the augmented limb leads, which are called aVR, aVL, and aVF. Unipolar chest leads are positioned across the chest and labeled V₁ to V₆. V₁ is positioned slightly to the right of the midline, and V₆ is positioned in the left midaxillary line (Fig. 13–7). Leads aVR and V₁ are considered right-sided leads, so they appear inverted, and leads aVL, I, II, V₅ and V₆ are left-sided leads, so they appear upright on the ECG. Leads II, III, and aVF are inferior leads. Leads V₁ to V₄ are anterior wall leads. Single-lead ECGs or ECG monitors frequently use lead II.

Recording of the ECG has several standard features. The paper is divided into squares of 1 mm; each 10 mm (10 small boxes) is equivalent to 1 mV. Paper speed is 25 mm per second. Each small box on the tracing paper equals 0.04 second (40 milliseconds), and each big box is 0.2 second. If there is one QRS complex per six big boxes (6 × 0.20 second), the patient has a heart rate of 50 beats per minute, whereas one QRS per big box indicates a heart rate of 300 beats per minute.

The ECG pattern is named alphabetically and is read from left to right, beginning with the P wave. Electrical activation (depolarization) of the right and then the left atrium as a result of discharge from the sinoatrial nodes causes an upward or positive deflection in lead II called the *P wave*. The normal duration of the P wave is up

FIGURE 13-6. The torso with the six limb leads in a single frontal plane.

to 0.12 second, and it has an amplitude of 0.25 mV (i.e., 2.5 small boxes). The *PR segment* is created by passage of the impulse through the atrioventricular node and the bundle of His and its branches, and it has a duration of 0.12 to 0.21 second. The *QRS complex* primarily traces the electrical depolarization of the ventricles. Initially, there is a negative deflection, the *Q wave*, followed by a positive deflection, the *R wave*, and finally a negative deflection, the *S wave*. Q-wave duration is normally 0.4 second or less, and the amplitude is 25% or less of the overall height of the QRS complex. Normal duration of the QRS complex is 0.12 second. The QRS complex is positive in left-sided leads and negative in right-sided leads because the left ventricle is much thicker than the right, and the forces going left during depolarization dominate.

Following the QRS complex is a plateau phase called the *ST segment*, which extends from the end of the QRS complex (called the *J point*) to the beginning of the T wave. The ST segment is evaluated from its position relevant to the baseline, configuration, and leads where changes occur. The ST segment is normally on or slightly above the baseline. Configuration changes, convexity upward or downward, identify the presence of myocardial ischemia. Lead localization of ST-segment changes indicates the area of ischemia. The *QT interval* is measured from the start of the QRS complex to the end of the T wave. This varies with heart rate and is corrected (QTc) for heart rates greater than 60 beats per minute. The normal QTc is less than 0.42 second in men and 0.43 second in women.

Repolarization of the ventricle leads to the *T wave*. The T wave usually goes in the same direction as the QRS complex. The normal axis of the ECG is 30° (above the horizontal) to +110° (away from the horizontal) (see Fig. 13–7). The six frontal plane (A) and the six horizontal plane (B) leads provide a three-dimensional representation of cardiac electrical activity.

The ECG is evaluated in a systematic manner to avoid omission of important characteristics. All ECGs are interpreted for the following elements: rate, general rhythm, intervals, voltage, axis, waveforms, abnormal features (e.g., Q waves), and technical aspects such as adequacy of lead placement and calibration.²⁰ The number of P waves and QRS complexes (*RR interval*) is also used to determine rate. QRS complexes may be more useful if heart block exists. The rhythm from the ECG is identified by the following features:

FIGURE 13-7. A. Electrode positions of the precordial leads. (MCL, midclavicular line; V₁, fourth intercostal space at the right sternal border; V₂, fourth intercostal space at the left sternal border; V₃, halfway between V₂ and V₄; V₄, fifth intercostal space at the midclavicular line; V₅, anterior axillary line directly lateral to V₄; V₆, anterior axillary space directly lateral V₅.) B. The precordial reference figure. Leads V₁ and V₂ are called right-sided precordial leads; leads V₃ and V₄, midprecordial leads; and leads V₅ and V₆, left-sided precordial leads. (Redrawn from Kinney MR, Packa DR, eds. *Andreoli's Comprehensive Cardiac Care*, 8th ed. St. Louis: Mosby, 1996, with permission.)

1. The rate of the QRS (>100/min is tachycardia and <60/min is bradycardia).
2. The regularity of the QRS. (The presence or absence of the QRS complex with each P wave helps to identify if the rhythm is atrial or ventricular in origin and if each atrial beat [P wave] is being conducted to the ventricles. The regularity of the QRS identifies conditions such as atrial fibrillation and extra beats.)
3. Configuration of the QRS—wide or narrow—indicating if it is generated from electrical activity that arose in the atria or ventricles.

Always reported are the RR, PR, QRS, and QT intervals and the duration, magnitude, and configuration of the P waves, QRS complexes, ST segments, T waves, and U waves.²¹ Computer interpretation of the ECG provides a standardized reading and records and calculates basic rhythm patterns, heart rate, and intervals but does not interpret arrhythmias. Independent review of the ECG is necessary for accurate translation of findings. In epidemiologic studies, the ECG is used to assess physical fitness, document the prevalence of ischemic heart disease (IHD), and identify subclinical heart disease. The sensitivity and specificity of ECG changes are highly dependent on the pretest probability of heart disease. As the pretest probability of heart disease increases, the sensitivity and specificity of ECG findings increase. The use and value of the ECG as a screening tool are controversial. It is only used where the diagnosis of heart disease would preclude active employment, such as in airline pilots. The ECG frequently is used in conjunction with other diagnostic tests to provide additional data, to monitor the patient, and to identify if abnormalities detected during tests correlate with ECG changes.²⁰⁻²²

Gating, or linkage of and simultaneous recording of an ECG and other diagnostic tests, such as echocardiography and computed tomography (CT) scans, allow for correlation of images with the

cardiac cycle. Gating is either prospective, where a certain portion of the cardiac cycle is predetermined as the time during which the images are obtained, or retrospective, where the ECG and image are recorded simultaneously but independently and later matched for concurrent events. This allows multiple cardiac cycles to be overlaid, thus increasing the sensitivity to detect abnormalities.

Anomalies on the ECG include abnormal intervals, altered wave-form configurations, and rate variability. Other findings give evidence for various forms of heart block, ischemia, infarction, atrial and ventricular enlargement and hypertrophy, atrial and ventricular rhythm disorders, pericarditis, metabolic abnormalities, drug-induced changes, and pacemaker-related changes. ECG patterns found on consecutive leads can help to identify where a particular conduction defect or impulse generation is occurring or anatomic problem is located. For example, ST-segment elevation in V₂ to V₆ is indicative of anterior wall myocardial infarction from occlusion of the left anterior descending coronary artery. Single-lead abnormalities most frequently are attributed to poor lead placement, position of the patient, or recording artifacts.²²

Examples of some common findings will be discussed briefly. Short PR intervals are associated with the Wolff-Parkinson-White and Lown-Ganong-Levine syndromes and reflect the presence of accessory pathways. Long PR intervals are measures of heart block. The presence of a Q wave is a marker for loss of electrically functioning myocardium and suggests a prior myocardial infarction. It also may be present in congenital heart disorders, hypertrophic cardiomyopathy, left ventricular hypertrophy, conduction defects such as Wolff-Parkinson-White syndrome, and intraventricular conduction defects. U waves are relatively nonspecific, the most common cause being hypertension. Bundle-branch blocks are frequent findings and indicate conduction defects in one of the bundles of His. Their presence confounds the interpretation of important ECG findings such as

ischemia. Right bundle-branch block is associated with an R wave and the following abnormalities: QRS complex greater than or equal to 12 milliseconds, delayed right ventricular forces resulting in terminal R waves in the right-sided leads and S wave in the left-sided lead, and right-sided ST-segment depression and T-wave inversion. Left bundle-branch block is characterized by the following: QRS complex greater than or equal to 12 milliseconds, delayed left ventricular activation, loss of the normal “septal Q wave” in the left-sided leads, and left-sided ST-segment depression and T-wave inversion. Intraventricular conduction delay usually causes a wide QRS complex, and generally there are ST-segment–T-wave abnormalities.

Myocardial ischemia, ranging from injury to necrosis, results in T-wave changes, ST-segment abnormalities, and changes in the QRS complex. Myocardial infarction results in a typical pattern of ECG changes that begins with tall, peaked T waves persisting up to several hours, followed by ST-segment elevation with a coved (convexity upward) configuration, and inverted T waves. Development of a new Q wave has a high specificity but low sensitivity for acute myocardial ischemia. Q waves that are 4 milliseconds or longer in duration and 25% or greater of the overall QRS height are considered diagnostic and occur within minutes to hours of occlusion. Although Q waves usually evolve within hours of infarction, they may not become evident for several days. The finding of new and significant Q waves on an ECG is indicative of a previous infarction. Q waves persist indefinitely in 80% to 90% of myocardial infarctions. The location of Q waves identifies the region of myocardium affected and the coronary artery blocked (e.g., inferior infarction will result in Q waves in II, III, and aVF associated with blockage in the right coronary artery). Non-Q-wave (subendocardial) myocardial infarction implies that the Q wave does not meet the diagnostic criteria for Q-wave infarction. ST-segment depression may be present.

ST-segment changes are very common and always should be compared with a previous ECG. ST-segment elevation may be seen in persons with no known coronary disease but is usually indicative of hyperacute ischemia. ST-segment depression is never considered a normal finding. ST-segment scooping (convexity downward) may be normal, but coving (convexity upward) is abnormal. Depression of the ST segment that does not return quickly to normal and changes in multiple leads suggests clinically significant heart disease. Diffuse ST-segment elevation in all leads except V_1 and aVR suggests the diagnosis of pericarditis. Exertion in normal individuals may cause J-point depression with a rapid rise of the ST segment, and this may be confused with ST-segment depression because of the configuration. Poor R-wave progression (usually increase in size moving from V_1 to V_6) suggests anterior myocardial infarction, but smaller R waves also can occur in diseases such as chronic obstructive pulmonary disease. T-wave changes are the most frequent and most sensitive abnormality on the ECG but are also the least specific and frequently are found in persons with no heart disease.

Left atrial enlargement is characterized by a P wave that is ≥ 12 mV in lead II, or the negative component of the biphasic P wave is 4 mV in duration and 0.1 mV in depth in lead V_1 . In right atrial enlargement, the P wave in lead II can exceed 0.25 mV and usually has a vertical axis. Ventricular hypertrophy results in increased deflection of the QRS complex because of the increased muscle mass. Left ventricular hypertrophy (LVH) is diagnosed from the ECG using several different sets of criteria; none are considered highly sensitive or specific. LVH often is indicative of hypertension and resulting ventricular enlargement and strain. Commonly used voltage criteria indicating LVH are summation of the S wave in V_1 and the R wave in V_5 or the S wave in V_2 and the R wave in V_6 that exceeds 3.5 mV (35 small boxes) or the R wave in lead aVL that exceeds 1.1 mV (11 small boxes). Right ventricular hypertrophy is characterized by an R wave in V_1 that is equal to or greater than the S wave in that lead. In persons who are obese, increased voltage may not be apparent,

making voltage criteria a less useful tool to identify hypertrophy. LVH also may be assessed using echocardiography.

Electrolyte abnormalities have characteristic signs on the ECG and can be used as monitoring parameters. Hypokalemia may increase ventricular ectopic beats and causes ST-segment depression, T-wave flattening, and the appearance of a U wave (usually when the serum potassium concentration is less than 3.0 mEq/L). Hyperkalemia results in very characteristic changes in the ECG. Potassium concentrations above 6.0 mEq/L produce tall, peaked T waves. As the concentration rises further, intraventricular conduction becomes blocked, with widening of the QRS complex, and ultimately, a sine wave develops. Hypercalcemia causes a short QT interval and, occasionally, ST-segment depression, sinus arrest, and atrioventricular conduction blocks. Hypocalcemia causes a long QT interval and some broadening of the T wave. A number of drugs cause characteristic changes in the ECG that may mask interpretation of other findings. Table 13–2 lists commonly used drugs that may alter the ECG. Pericardial effusion, obesity, and large breasts limit the amount of voltage that is measured on the skin surface and reduce the QRS voltage. In the presence of large pericardial effusions, rapid changes in the positive to negative deflection of the QRS complex or electrical alternans may occur because the heart is swinging on a beat-to-beat basis.

Signal-averaged ECG may be used to help elucidate the presence of low-amplitude bioelectrical potentials.²³ Derangements of ventricular activation and late potentials can be detected on the ECG after the QRS and ST segments and are thought to be associated with increased risk of ventricular arrhythmias. Traditional ECGs are unable to detect these potentials because they are “lost” in the noise of the ECG recording. Signal-averaged ECG improves the signal-to-noise ratio, enabling the low-amplitude potentials to be interpreted. Signal-averaged ECG can be used to identify patients at risk for developing sustained ventricular tachycardia after myocardial infarction. Patients with IHD and unexplained syncope who are at risk for sustained ventricular tachycardia also may be candidates for signal-averaged ECG. Other potential uses of signal-averaged ECG include patients with nonischemic cardiomyopathy with sustained ventricular tachycardia, detection of acute rejection of heart transplant, and assessment of the proarrhythmia potential of antiarrhythmic drug therapy.

AMBULATORY ELECTROCARDIOGRAM MONITORING

Ambulatory ECG monitoring (AECG), or Holter monitoring, named for its inventor, is an aid to detect, document, characterize, and evaluate arrhythmias and other ECG abnormalities over extended periods of time.^{24,25} AECG provides information regarding random abnormal cardiac electrical activity during daily activity and helps relate altered electrical activity to precipitating factors and patient symptomatology. algorithms. AECG also helps in the discovery and investigation of arrhythmias and ST-segment deviation along with more sophisticated analyses of R-R intervals, QRS-T morphology including late potentials, Q-T dispersion, and T-wave alternans. Additionally, some findings on AECG have been used to determine prognostic implications. Different types of recording systems are discussed later in this chapter in the Echocardiogram section: one version is noninvasive, which can be patient activated and varies in duration of recording from hours to days, and the other version is invasive, which can be implanted like a pacemaker and removed later and can record for years. Most of the current new recording systems are digital (recommended guidelines by AHA/ACC) and have a diagnostic frequency response range for more accurate investigation of ST-segment deviations.

Although controversial, AECG is used as a diagnostic and screening tool for asymptomatic ischemia. It is difficult to interpret

changes in the ST segment recorded during AECG owing to amplitude, and definitions of significant changes recorded with AECG are still in evolution. As a prognostic tool, it is used primarily to evaluate patients with known CVD who have symptoms that may be associated with an arrhythmia. It is also used in clinical trials to evaluate the efficacy of drug therapy.²⁶

Guidelines as to the recommended uses of AECG are available from AHA/ACC. The major class I indications for AECG include diagnosis in patients with symptoms suggestive of arrhythmias, prognostic delineation in patients with cardiac disease considered at risk for arrhythmia-related events, and measurement of efficacy of interventions in patients with known and characterized arrhythmias. Examples of indications and clinical rhythm disturbances are listed in Tables 13-3, 13-4, and 13-5.

A major limitation of AECG is the amount of data collected with ECG abnormalities that are of unknown clinical significance. High day-to-day variability of frequency and type of arrhythmias means that repeat AECG may demonstrate as much as a 90% difference in the number of premature ventricular contractions. Little correlation of arrhythmia suppression and clinical outcomes is available. No AECG study has shown a mortality advantage when used in conjunction with antiarrhythmic drugs or devices. Following an intervention (drugs or device), at least a 63% to 95% reduction in arrhythmia frequency is required for AECG to be considered a valuable arrhythmia detection and evaluation tool. Compared with electrophysiology testing in the Electrophysiologic Study Versus Electrocardiographic Monitoring (ESVEM) study, AECG was equivalent but not superior to electrophysiology testing in the ability to select initial drug therapy.²² The Asymptomatic Cardiac Ischemia Pilot (ACIP) study found that 75% of patients with asymptomatic evidence of ischemia on AECG had multivessel coronary artery disease on angiography.²⁶

During AECG, the patient wears a portable ECG recorder that weighs about 8 to 16 oz. The recorder uses two to four chest leads (V_5 and V_3 most commonly). Additional leads do not improve the sensitivity of AECG significantly. If ST-segment changes are known to occur in certain leads, these can be used during AECG. Most AECG recordings are for 24 to 48 hours, but they can extend to weeks or months where the frequency of events related to ECG abnormalities is low. Implantable devices are used when long periods of monitoring are necessary. Currently used equipment is able to detect and analyze arrhythmias, ST-segment deviations, QRS complexes, RR intervals, and late potentials.

Three types of monitors are available: (a) continuous monitors, which record an ECG strip over the duration of the test, (b) event or

TABLE 13-4 Indications for Ambulatory Electrocardiogram Arrhythmia Detection to Assess Risk for Future Cardiac Events in Patients without Symptoms from Arrhythmia

Class I
None
Class IIb
1. Post-myocardial infarction patients with left ventricular dysfunction (ejection fraction <40%)
2. Patients with congestive heart failure
3. Patients with idiopathic hypertrophic cardiomyopathy
Class III
1. Patients who have sustained myocardial contusion
2. Systemic hypertensive patients with left ventricular hypertrophy
3. Post-myocardial infarction patients with normal left ventricular function
4. Preoperative arrhythmia evaluation of patients for noncardiac surgery
5. Patients with sleep apnea
6. Patients with valvular heart disease

intermittent recorders, which continuously monitor the ECG but only record preprogrammed abnormal ECG events or are patient-activated based on occurrence of symptoms, and (c) real-time analytical recorders, which record throughout the monitoring period and analyze each beat as it occurs. Monitors digitize, encode, and store the information in a solid-state memory or on magnetic tape. Event monitors are preprogrammed to record parameters such as the number of premature ventricular contractions and heart rate. During monitoring, the patient maintains a diary, in which the occurrence, duration, and severity of symptoms (e.g., light-headedness, chest pain) are recorded, plus any specific activities undertaken, development of symptoms with the activity, and any interventions such as the taking of medication. A clocking device in the recorder allows later correlation of the patient's diary with the recorded ECG.

Evaluation and analysis of the ECG record are complex. Computer-assisted interpretation is used to scan the ECG and identify irregular rhythms, rates, and specific preprogrammed changes. The main advantage of computer analysis is to reduce interpretation of artifact recordings. Each beat recorded during AECG is evaluated for its arrhythmia potential and classified as normal or abnormal. The morphology of each QRS-T section is examined for ischemia potential, although, as indicated previously, baseline ST-segment abnormalities and adjustments in amplitude of the recording may preclude interpretation of these segments. The ACC/AHA guidelines provide detail as to the suitability of using ST segments for analysis of ischemia.²⁷ Various drugs, such as digoxin and the tricyclic antidepressants that cause baseline ECG abnormalities, may preclude patients from being evaluated with AECG.

Sections identified by the computer as abnormal or those correlating with patient symptoms are then evaluated and characterized

TABLE 13-3 Indications for Ambulatory Electrocardiogram Monitoring to Assess Symptoms Possibly Related to Rhythm Disturbances

Class I
Patients with unexplained syncope, near syncope, or episodic dizziness in whom the cause is not obvious
Patients with unexplained recurrent palpitation
Class IIb
Patients with episodic shortness of breath, chest pain, or fatigue that is not otherwise explained
Patients with neurologic events when transient atrial fibrillation or flutter is suspected
Patients with symptoms such as syncope, near syncope, episodic dizziness, or palpitation in whom a probable cause other than an arrhythmia has been identified but in whom symptoms persist despite treatment of this other cause
Class III
Patients with symptoms such as syncope, near syncope, episodic dizziness, or palpitation in whom other causes have been identified by history, physical examination, or laboratory tests
Patients with cerebrovascular accidents, without other evidence of arrhythmia

TABLE 13-5 Indication for Ambulatory Electrocardiogram Monitoring for Ischemia

Class I
None
Class IIa
1. Patients with suspected variant angina
Class IIb
1. Evaluation of patients with chest pain who cannot exercise
2. Preoperative evaluation for vascular surgery of patients who cannot exercise
3. Patients with known coronary artery disease and atypical chest pain syndrome
Class III
1. Initial evaluation of patients with chest pain who are able to exercise
2. Routine screening of asymptomatic subjects

TABLE 13-6 Confounding Factors in Ambulatory Electrocardiogram Monitoring	
Patient Factors	Equipment Factors
Electrolyte abnormalities	Battery failure
Hyperventilation	Loose lead
Lead interference by patient	Mechanical failure of recorder
Medications	Motor failure
Physiologic variations in waveforms	Overrecording
Medications	Computer inability to detect arrhythmia
Patient activities (e.g., sudden exercise)	
Presence of atrial fibrillation	

further (e.g., potentially pathologic rhythms) by technical personnel and physicians. Confounding factors when using AECG can arise from the patient and the device (Table 13–6). AECG is evolving rapidly, primarily related to improved technology with respect to data interpretation, signal quality, and improved understanding of the implications of ECG changes.

EXERCISE STRESS TESTING

5 Exercise stress (tolerance) testing (ETT) is a noninvasive test used to evaluate clinical and cardiovascular responses to exercise.^{27–29} ETT is used frequently as an initial test, in conjunction with physical examination and patient symptoms, to aid in the selection of additional testing modalities. It is a simple test that can be conducted in a physician’s office and is about 20 times less expensive than an angiogram and almost three times less expensive than stress echocardiography. Almost two-thirds of ETTs billed to Medicare in 1996 were conducted in physicians’ offices, and one-third was conducted by noncardiologists.²⁷

Central facts to remember about ETT is that its value to diagnose CAD is largely dependent on the risk of the population studied. For example, it is not very helpful in identifying CAD if one does ETT on patients who are young and without risk factors because their risk is extremely low; but if one tests a population of people that has multiple risk factors and is older, it is more useful (Table 13–7). Even though one uses these considerations, randomized trial data on the clinical value of screening exercise testing are absent and it is not known whether a strategy of routine screening exercise testing in selected subjects reduces the risk for premature mortality or major cardiac morbidity. A recent report from the U.S. Preventive Services Task Force²⁶ recommended against the use of exercise testing as a screening tool, in a large part because most studies were completed in asymptomatic patients, and because of the well-established Bayesian argument.

One of most important parts of exercising testing is functional capacity, even though it is rarely measured directly. Functional

TABLE 13-7 Comparing Pretest Likelihoods of Coronary Artery Disease in Low-Risk Symptomatic Patients with High-Risk Symptomatic Patients—Duke Database						
Age (Years)	Nonanginal Chest Pain		Atypical Angina		Typical Angina	
	Men	Women	Men	Women	Men	Women
35	3–35	1–19	8–59	2–39	30–88	10–78
45	9–47	2–22	21–70	5–43	51–92	20–79
55	23–59	4–25	45–79	10–47	80–95	38–82
65	49–69	9–29	71–86	20–51	93–97	56–84

Each value represents the percent with significant coronary artery disease (CAD). The first is the percentage for a low-risk, mid-decade patient without diabetes, smoking, or hyperlipidemia. The second is that of the same age patient with diabetes, smoking, and hyperlipidemia. Both high- and low-risk patients have normal resting electrocardiograms. If ST-T-wave changes or Q waves had been present, the likelihood of CAD would be higher in each entry of the table.

capacity can be obtained by directly measuring the oxygen consumption but this is not routinely available because of complexity and cost of equipment. If one uses functional capacity to exercise capacity, prediction of cardiovascular risk can be assessed.³⁰ It is also essential to evaluate the inability of the heart rate to increase appropriately during exercise (chronotropic incompetence) testing. Peak heart rate, age related predicted maximum heart rate have important prognostic importance. Heart rate during exercise is an expression of decreased parasympathetic tone and increased sympathetic tone. In disease states affecting electrical conduction or possibly heart failure this becomes important. The second important area is heart rate recovery after exercise testing. Normal individuals and especially athletes have a rapid fall in heart rate during the first 30 seconds after exercise vs a patient with heart disease who has slow fall in heart rate. This heart rate response is markedly influenced by parasympathetic tone.

The ETT provides diagnostic information in patients with known or suspected IHD and prognostic information in patients after myocardial infarction or revascularization. However, there are no data that support its use as a screening tool for CAD or for detection of early CAD in asymptomatic subjects.

The principle behind ETT is to increase myocardial oxygen demand above myocardial oxygen supply and coronary reserve, thereby provoking ischemia (inadequate myocardial perfusion), using exercise as a stressor. Ischemia is detected by patient symptoms, ECG changes, and/or hemodynamic changes. The type of ECG changes, leads affected, and patient performance are used as an index of severity and location of disease. ETT is a very practical test in that it can assess patients’ functional capacity.³⁰

Some examples of classes I, II, and III indications from the ACC/AHA guidelines for ETT are presented here.³¹ The major class I indications are evaluation of males older than age 40 years who have symptoms suggestive of CAD and risk factors for CAD or atypical symptoms suggestive of CAD. Another class I indication is to help assess prognosis and functional capacity in patients with confirmed CAD.³² Frequently, the ETT is performed following an acute myocardial infarction for this purpose (Table 13–8). Class II indications

TABLE 13-8 Exercise Stress Testing after Myocardial Infarction	
Class I	
1. Before discharge for prognostic assessment, activity prescription, evaluation of medical therapy (submaximal at about 4 to 76 days).	
2. Early after discharge for prognostic assessment, activity prescription, evaluation of medical therapy, and cardiac rehabilitation if the predischARGE exercise test was not done (symptom limited; about 14–21 days).	
3. Late after discharge for prognostic assessment, activity prescription, evaluation of medical therapy, and cardiac rehabilitation if the early exercise test was submaximal (symptom limited; about 3 to 6 weeks).	
Class IIa	
After discharge for activity counseling and/or exercise training as part of cardiac rehabilitation in patients who have undergone coronary revascularization.	
Class IIb	
Periodic monitoring in patients who continue to participate in exercise training or cardiac rehabilitation.	
Class III	
1. Severe comorbidity likely to limit life expectancy and/or candidacy for revascularization.	
2. At any time to evaluate patients with acute myocardial infarction who have uncompensated congestive heart failure, cardiac arrhythmia, or noncardiac conditions that severely limit their ability to exercise. (Level of Evidence: C)	
3. Before discharge to evaluate patients who have already been selected for, or have undergone, cardiac catheterization. Although a stress test may be useful before or after catheterization to evaluate or identify ischemia in the distribution of a coronary lesion of borderline severity, stress imaging tests are recommended. (Level of Evidence: C)	

Adapted from AHA/ACC guidelines.

TABLE 13-9 2002 Exercise Testing Guideline Recommendations

Class I	
1.	Patients undergoing initial evaluation with suspected or known CAD, including those with complete right bundle-branch block or less than 1 mm of resting ST depression.
2.	Patients with suspected or known CAD, previously evaluated, now presenting with significant change in clinical status.
3.	Low-risk unstable angina patients 8 to 12 hours after presentation who have been free of active ischemic or heart failure symptoms.
4.	Intermediate-risk unstable angina patients 2 to 3 days after presentation who have been free of active ischemic or heart failure symptoms.
Class IIa	
1.	Intermediate-risk unstable angina patients who have initial cardiac markers that are normal, a repeat ECG without significant change, and cardiac markers 6 to 12 hours after the onset of symptoms that are normal and no other evidence of ischemia during observation. (<i>Level of Evidence: B</i>)
Class IIb	
1.	Patients with the following resting ECG abnormalities: Preexcitation (Wolff-Parkinson-White) syndrome. Electronically paced ventricular rhythm. 1 mm or more of resting ST depression. Complete left bundle-branch block or any interventricular conduction defect with a QRS duration greater than 120 ms.
2.	Patients with a stable clinical course who undergo periodic monitoring to guide treatment.
Class III	
1.	Patients with severe comorbidity likely to limit life expectancy and/or candidacy for revascularization.
2.	High-risk unstable angina patients.

CAD, coronary artery disease; ECG, electrocardiogram.

Adapted from AHA/ACC guidelines.

are patients with variant angina or women with a history of typical or atypical chest pain (Table 13–9). Examples of class III indications are patients with simple premature ventricular contractions on a resting ECG with no other signs or symptoms of CAD. Additionally, ETT is used to assess symptoms such as chest pain or breathlessness. ETT should be used only if the results are able to alter patient management or to assess patient function.

Guidelines for conducting and interpreting the tests and details of testing equipment and environment are outlined in the 2002 ACC/AHA guidelines on ETT standards.³³ ETT is conducted on a treadmill or bicycle ergometer or by means of a handgrip. These dynamic methods are used to assess exercise tolerance because they induce both a volume and pressure load on the heart. Both modalities also allow the degree of stress to be delivered in a graded and calibrated manner. Treadmill walking is preferred over the ergometer because it involves more muscle mass and the maximal oxygen consumption (VO₂max) achieved with cycle ergometer is 10% to 15% lower than with the treadmill.

Many protocols have been designed and validated for use with ETT, but the two used most commonly are the Bruce and Naughton protocols. Protocols help to decrease inter- and inpatient variability and allow for standardization in the interpretation of the tests. Protocols may be customized for individual patients to ensure an exercise time of 6 to 12 minutes and a heart rate of 85% to 90% of maximum predicted (adjusted for age and gender). Protocols detail gradient, speed, and rates of change of these parameters during the test.

In preparation for ETT, patients fast prior to the test for a minimum of 3 hours, may not exercise 12 hours prior to the test, and must dress suitably for exercise. Baseline evaluation consists of history and physical examination, blood pressure, heart rate, and ECG. The test begins with a 1-minute warmup period to orient the patient to the equipment. Each stage of the test is maintained for at least 3 minutes. Continuous blood pressure, heart rate, and ECG

recordings are obtained, with definitive readings 2 minutes into each stage. Patients are questioned 2 to 3 minutes into each stage of the test about symptoms such as headache, dizziness, and chest pain. Clinical symptoms assessed include color of skin, level of perspiration, and evidence of peripheral cyanosis and light-headedness. Patients are encouraged to exercise as vigorously as they can to ensure an optimal test result. Onset, nature, and duration of all changes in symptoms, hemodynamics, and ECG are noted. Following the test there is a cool-down period during which the patient is seated or lying and is observed for changes as described earlier.

ETT requires considerable effort, with many patients requiring encouragement to perform to the best of their ability. Some patients use the test as a personal challenge and perform better on repeated attempts. This is referred to as a *training effect* and may be a confounding factor in using ETT to assess the effect of drug therapy or after interventions for IHD in clinical trials.

Interpretation of the test requires correlation of clinical, ECG, and other parameters measured during the test with the patient's history (e.g., age, gender, concurrent risk factors, and medical history) and concomitant therapy. Results of ETT can be used as a guide to future patient management, including suitability for interventional cardiology and selection of pharmacotherapy. A positive test is defined as 1 mm of horizontal or downsloping depression or elevation of the ST segment for 60 to 80 milliseconds after the QRS complex. For patients with baseline ST-segment depression, combinations of abnormal responses (e.g., 2 mm of ST-segment depression with hemodynamic abnormalities) would be necessary to call a test positive. ST-segment depression of 2 mm or more, especially in conjunction with heart rates of less than 120 beats per minute, low levels of stress, or depression persisting for up to 6 minutes after the cessation of the test, is associated with a poor prognosis. Depression of the ST segment in multiple leads is also significant. Other ECG changes include development of U waves and increased complexity and/or frequency of premature ventricular contractions or beats, especially if associated with bigeminy or periods of ventricular tachycardia.

Although ECG changes and heart rate responses are used as objective end points of ETT, patient and clinical end points are actually preferred. The use of the 85% to 90% maximally predicted heart rate is highly variable among patients and often is not achieved because of concomitant drug therapy and different levels of fitness. Symptom-limited or patient-directed tests are continued to the predetermined end point(s) unless the patient tires or certain characteristics are noted. Clinical symptoms, exhaustion, chest pain, and changes in blood pressure, heart rate, and the ECG (rhythm, configuration, and rate) are used as end points for such *open-ended tests*. Also, patient performance, measured as exercise duration, time until symptoms, stress at which symptoms occur, and hemodynamic parameters, is a better indicator of an adequate test than is heart rate response. *Close-ended testing* is the use of fixed end points such as time on the treadmill or maximal heart rate.

The product of blood pressure and heart rate (*double product*) is a measure of myocardial oxygen demand. In patients with stable angina, the double product is reproducible on repeat ETTs; consequently, it is used as an objective parameter to follow an individual patient's disease. Inappropriate or inadequate responses in blood pressure and/or heart rate to exercise suggest heart disease. A reduction in heart rate or a flat response (failure to increase heart rate above 120 beats per minute) with increasing levels of stress has a poor prognosis. Likewise, failure to increase the systolic blood pressure or the finding of a sustained decrease of more than 10 mm Hg is also associated with a worse prognosis. Such responses indicate that the heart has an inadequate reserve to respond to stress. Patients who are unable to progress beyond stage II of the Bruce protocol have a poor prognosis and more severe IHD. Other rating scales (e.g., Borg, which measures perceived exertion) may be

TABLE 13-10 MET Relationship to Activity and Function

METS	Level of Activity	ET Result
1	Resting	<6 METS
2	Level walking at 2 miles/h	Symptom-limited lifestyle
4	Level walking at 4 miles/h	Sedentary lifestyle tolerated
13	Cycling 9–10 miles/h	Little or no activity-limited lifestyle
20	Shoveling heavy snow	No limitations on lifestyle

ET, exercise testing; METS, metabolic equivalents of task.

used in conjunction with the objective results from the ETT to classify patients into high- and low-risk groups. Silent ischemia may confound the interpretation of ETT because blood pressure and ECG changes may occur in the absence of symptoms.

To provide standardized comparability between tests and patients, metabolic equivalents (METS) are used as a measure of VO_2max . A MET is a measure of resting oxygen uptake. Activity energy demands then can be calculated in terms of METS. For example, 4 METS is equivalent to walking at 4 miles per hour. The number of METS a patient can undertake without symptoms of ischemia correlates with prognosis and helps to guide appropriate management strategies. Table 13–10 has examples of METS and activity correlations. Exercise capacities of less than 5 METS are associated with a poor prognosis; those greater than 13 METS have a good prognosis despite the presence of disease.

Meta-analysis of more than 24,000 patients in 147 studies showed a mean sensitivity of 68% and specificity of 77% for ETT as a diagnostic test. The specificity of ETT to detect the presence of CAD, compared with angiography, is 84%. Sensitivity ranges from 40% to 90%, depending on the number of vessels affected, with a mean of 66%.

As a prognostic test, ETT is very popular after myocardial infarction and can be conducted within 3 days of an acute event. It can be used to determine functional capacity, assess the degree of rehabilitation, and identify patients at risk for further cardiovascular events. Immediately after myocardial infarction, a modified protocol is used; the test is terminated when a heart rate of 70% to 75% of age- and gender-predicted maximum is reached (e.g., 140 beats per minute for those younger than age 40 years and 130 beats per minute for those older than age 40 years) or a METS level of 5 for patients older than age 40 years or of 7 for those younger than age 40 years. Tests usually are done prior to discharge or within 6 weeks of infarction. In the periinfarction period, mortality and reinfarction rates caused by ETT are 0.02% and 0.09%, respectively. Patients may be stratified into low-, intermediate-, and high-risk categories, depending on the evidence for ischemia and the level of exercise tolerance.³³

TABLE 13-11 Exercise Testing before and after Revascularization

Class I
1. Demonstration of ischemia before revascularization.
2. Evaluation of patients with recurrent symptoms that suggest ischemia after revascularization.
Class IIa
After discharge for activity counseling and/or exercise training as part of cardiac rehabilitation in patients who have undergone coronary revascularization.
Class IIb
1. Detection of restenosis in selected, high-risk asymptomatic patients within the first 12 months after percutaneous coronary intervention.
2. Periodic monitoring of selected, high-risk asymptomatic patients for restenosis, graft occlusion, incomplete coronary revascularization, or disease progression.
Class III
1. Localization of ischemia for determining the site of intervention.
2. Routine, periodic monitoring of asymptomatic patients after percutaneous coronary intervention or coronary artery bypass grafting without specific indications.

Adapted from AHA/ACC guidelines.

TABLE 13-12 Contraindications to Exercise Testing

Absolute
Acute myocardial infarction (within 2 days)
High-risk unstable angina
Uncontrolled cardiac arrhythmias causing symptoms or hemodynamic compromise
Symptomatic severe aortic stenosis
Uncontrolled symptomatic heart failure
Acute pulmonary embolus or pulmonary infarction
Acute myocarditis or pericarditis
Acute aortic dissection
Relative
Left main coronary stenosis
Moderate stenotic valvular heart disease
Electrolyte abnormalities
Severe arterial hypertension
Tachyarrhythmias or bradyarrhythmias
Hypertrophic cardiomyopathy and other forms of outflow tract obstruction
Mental or physical impairment leading to inability to exercise adequately
High-degree atrioventricular block

Adapted from AHA/ACC guidelines.

ETT is relatively safe, with an estimated risk of acute myocardial infarction or death of 10 per 10,000 tests overall. Most adverse effects are cardiac in nature, including arrhythmias (primarily bradyarrhythmias), sudden death, hypotension, and myocardial infarction. Patients in whom ETT is contraindicated are those who are unable or who should not exercise because of physiologic or psychological limitations and indications for termination (Tables 13–11, 13–12, and 13–13). Unstable angina is usually a contraindication to ETT because of the instability of the patient's disease state and because patients cannot exercise to a satisfactory level for the test to be considered adequate. However, once such a patient is stable, ETT is excellent for prognostic evaluation. In patients with untreated life-threatening arrhythmias or congestive heart failure, ETT is also contraindicated. Patients with comorbid diseases such as chronic obstructive pulmonary disease or peripheral vascular disease may be limited in their exercise capacity, whereas lower-limb amputees are unable to perform the standard treadmill test. For patients with disabilities or other medical conditions that limit their exercise capacity independent of heart disease, pharmacologic stress testing with dipyridamole, adenosine, or dobutamine is an alternative (see Pharmacologic Stress Testing below).

Drug therapy rarely is discontinued for the test primarily because few data exist to support better test results off drug therapy. Patients on β -blockers or calcium channel blockers may not achieve maximal heart rates, but ETT helps to demonstrate patients' exercise capacity on drug therapy. Nitrates do not alter exercise capacity directly and theoretically may improve patient response because they relieve or prevent symptoms of ischemia. Digoxin interferes with interpretation of ST-segment changes, and patients rarely achieve ST-segment changes greater than 1 mm even in the face of significant ischemia.

TABLE 13-13 Indications for Terminating Exercise Testing

Absolute indications
Drop in systolic blood pressure of >10 mm Hg from baseline blood pressure despite an increase in workload, when accompanied by other evidence of ischemia
Moderate to severe angina
Increasing nervous system symptoms (e.g., ataxia, dizziness, or near syncope)
Signs of poor perfusion (cyanosis or pallor)
Technical difficulties in monitoring electrocardiogram or systolic blood pressure
Subject's desire to stop
Sustained ventricular tachycardia
ST elevation (>1.0 mm) in leads without diagnostic Q-waves (other than V1 or aVR)

Adapted from AHA/ACC guidelines.

Because of its long half-life, digoxin does not need to be discontinued prior to the test (see Table 13–2).

ECHOCARDIOGRAM

7 The echocardiogram (ECHO) is the use of ultrasound to visualize anatomic structures, such as the valves, within the heart and to describe wall motion.^{34,35} Clinically, the ECHO is the most frequently used noninvasive cardiovascular test, aside from the ECG. It competes well with invasive techniques, such as cardiac catheterization with angiography, for the evaluation of ischemia and valvular abnormalities. ECHO is relatively cheap to perform and can be done at the bedside, in the operating room, or in the physician's office. The major disadvantages of the ECHO relate to technical limitations of operator-dependent images and competition from other noninvasive technologies such as MRI and CT scanning that provide similar information with superior tissue-type resolution. The ECHO is often used as an initial evaluative tool following auscultation detection of an abnormality, thus providing a baseline visual characterization. Serial determinations in a given patient, especially following a change in clinical condition or a procedure, allow evaluation of progression of disease over time.

The ECHO remains the procedure of choice in the diagnosis and evaluation of a number of conditions such as valvular dysfunction (aortic and mitral stenosis and regurgitation and endocarditis), wall motion abnormalities associated with ischemia, and congenital abnormalities, such as ventricular or atrial septal defects. Images obtained from ECHO are used to estimate chamber wall thickness and left ventricle ejection fraction, assess ventricular function, and detect abnormalities of the pericardium such as effusions or thickening.

Echocardiography is based on the principle of differential acoustic impedance (or tissue density) and the laws of reflection and refraction. Sound waves directed across tissues from a transducer will reflect back sound waves of different frequencies. The ability of the ultrasonic beam to penetrate chest wall structures is inversely proportional to the frequency of the signal. With transthoracic echocardiography, frequencies of 2.0 to 5.0 MHz are commonly used in adults, and frequencies of 3.5 to 10.0 MHz are used in children. Serial determinations in a given patient using the same conditions and ECHO images (windows) provide the best form of internal control to allow comparisons of test results. In clinical trials, echocardiograms are read and interpreted independently by two or three clinicians to provide a means of control.

Two primary approaches to ECHO are used in clinical practice. Transthoracic echocardiography (TTE) is conducted with the transducer on the chest wall, whereas transesophageal echocardiography (TEE) is conducted with the transducer in the esophagus. In TTE, several modes of operation are possible, the most common being M-mode (motion) and two-dimensional (2D) imaging. Both M-mode and 2D echocardiography provide visualization of heart structures and can indicate numerous structural abnormalities such as aneurysms, wall thickness abnormalities, chamber collapse (e.g., tamponade), and valvular stenosis. TEE is used primarily for assessment of valvular anatomy and function or to image intracardiac masses such as tumors or thrombi and valvular vegetations.³⁶

In M-mode echocardiography, the transducer is placed at a single site on the chest (usually along the sternal border), and the ultrasound is directed posteriorly. M-mode echocardiography records only static objects in one plane, producing a single picture of a small region of the heart, or an “ice pick view.” Results depend on the exact placement of the transducer with respect to the underlying structures. Conventional M-mode echocardiography provides visualization of the right ventricle, left ventricle, and posterior left ventricular wall and pericardium. If the transducer is swept in an arc from the apex to the base of the heart, virtually the whole heart can

FIGURE 13-8. Schematic of two-dimensional echocardiography to illustrate location of cardiac structures as “seen” by the transducer. The transducer is swept in an arc so that several pictures of the heart are obtained to generate the final electrocardiogram. (Ao, aorta; AMV, anterior mitral valve; ARV, anterior right ventricle; IVS, interventricular septum; LA, left atrium; LV, left ventricle; PLV, posterior left ventricle; PMV, posterior mitral valve; PPM, posterior papillary muscle; RV, right ventricle.) (Redrawn from Coryu BC, et al. *Application of electrocardiography in acute myocardial infarction. Cardiovasc Clin* 1995;2:113, with permission.)

be visualized, including the valves and left atrium. Images are displayed as “windows.”

Two-dimensional echocardiography employs multiple windows of the heart, and each view provides a wedge-shaped image. Windows most commonly used include parasternal long- and short-axis and apical two- and four-chamber views (Fig. 13–8). These views are processed onto a videotape to produce a motion picture of the heart. Two-dimensional echocardiography renders increased accuracy in calculating ventricular volumes, wall thickness, and degree of valvular stenosis compared with M-mode echocardiography. Patient-specific calculated parameters such as ejection fraction and wall thickness are compared with standardized values (population-based) or with previously obtained values from the patient. Although ejection fraction is still commonly obtained with echocardiography, it is a derived number, so it is considered subjective. Other tests to determine ejection fraction provide different numbers and highlight the difficulty of comparing results between tests. Ejection fraction from echocardiography is also limited by the diminished views of total ventricular volume able to be visualized, especially in persons with distorted ventricles. Despite these limitations, echocardiography remains the most common modality for ejection fraction determination.

The ECHO can be used for diagnosis and prognosis and as a serial evaluation tool to assess acute and chronic ischemic heart disease and regional left ventricular function. Areas of ischemic myocardium are seen on the ECHO as aberrations in wall motion. Wall motion abnormalities are seen as altered thicknesses of various segments of the heart. Wall motion abnormalities are graded using descriptive terms such as *akinetic*, *hypokinetic*, *dyskinetic*, and *hyperkinetic*. It is possible to visualize the complete ventricle (in segments), allowing both global and regional left ventricular function to be assessed. Studies show that the locations of segmental ventricular wall motion abnormalities correspond with areas of CAD. Echocardiography can be linked with the various stress tests (ETT, dipyridamole or dobutamine) to assess stress-induced structural or functional abnormalities (e.g., changes in wall motion). As a serial

monitoring test, echocardiography is comparable with angiography as a prognostic tool and can be used as a treatment planning tool. After myocardial infarction, echocardiography is a useful noninvasive diagnostic tool for detection of ventricular aneurysms, thrombi, and pericardial effusions and can be used serially for diagnostic and prognostic information.

In TEE, the transducer is advanced into the esophagus and rests just behind the heart.³⁷ The transducer also can be passed into the fundus of the stomach to obtain better images of the ventricles. Images are obtained in either the horizontal or vertical plane.³⁸ This is a low-risk invasive procedure and does not require routine antibiotic prophylaxis for patients at risk of developing endocarditis. Complications such as esophageal tears or perforation, esophageal burns, transient ventricular tachycardia, minor throat irritation, and transient vocal cord paralysis have been reported rarely. In one series of 10,218 studies, only 1 death (0.0098%) was reported, comparable with that with esophageal gastroduodenoscopy (0.004%). TEE is contraindicated in patients with esophageal abnormalities, in whom passage of the transducer might be limited (e.g., esophageal strictures or varices).

TEE yields higher resolution and improved visualization of structures, especially pulmonary veins and valves, compared with TTE. Interference of ribs, lungs, and subcutaneous tissues is reduced, enabling TEE to be more useful in patients in whom TTE is limited because of pulmonary disease, mechanical ventilation, or obesity. A high-frequency transducer (5 MHz for adults) is used, thus producing better image resolution. TEE is used for the same indications as TTE. Visualization of the heart valves—in particular, the mitral valve—is superior, allowing more accurate evaluation of both native and prosthetic valves. Clinical studies show that it is possible to visualize valvular vegetations as small as 5 mm with TEE. The ACC/AHA guidelines recommend TEE if the TTE is equivocal and the patient has staphylococcal bacteremia. In a study comparing vegetation visualization, TEE detected vegetations in 90% of patients, compared to TTE detecting vegetations in 58%. It also can help to define complications of endocarditis such as thrombosis or valve leakage. In aortic dissection, TEE is able to identify the initial flap and origin of dissection and has an overall sensitivity and specificity of 97% and 100%, respectively. CT remains the diagnostic method of choice for aortic dissection, but TEE offers a sensitive and fast test that can be conducted in the emergency room.

Other uses of TEE include identification of cardiac thrombus, especially thrombi in the left atrium, and assessment of atrial dilation. After transient ischemic attacks or cerebrovascular accidents, TEE may enable identification of the site of cardiac emboli by providing excellent images of likely sources, namely, ventricular or atrial thrombus, valvular vegetation, cardiac shunts, cardiac tumors, or atrial and ventricular septal defects. In a study of almost 1,500 patients with cerebral ischemia or nonvalvular atrial fibrillation, atrial thrombi were seen in 183 patients when evaluated by TEE versus only in 2 patients when evaluated by TTE. TEE can be used for intraoperative cardiac imaging to ascertain development of ischemia.

Another advance with echocardiography has been the addition of Doppler and color-flow Doppler technology. The Doppler principle involves reflecting sound off a moving object—in the case of echocardiography, the red blood cell. As the red cell moves in relation to the transducer, a frequency shift occurs in the reflected wave. Assessment with Doppler echocardiography combines structural images and hemodynamic monitoring. Thus it is possible to evaluate the impact of structural disease on cardiac function and quantify the associated hemodynamics. Color enhancement allows flow direction to be visualized; different colors are used for antegrade and retrograde flow. These improve resolution of structures, identify patterns of blood flow, and allow calculation of flow gradients.

Doppler echocardiography is used primarily in conjunction with traditional echocardiography for analysis of valvular function or

blood flow patterns. It allows measurement of transvalvular pressure gradients, valve area, and pressure changes on either side of the valve. Doppler echocardiography is either continuous or pulsed; the former is used to assess pressure changes, whereas the latter is used to localize points of origin and creation of turbulent and high blood flow. Color Doppler is used to visualize blood flow (e.g., regurgitation). Turbulence associated with valvular and wall motion abnormalities can be visualized and quantified clearly. In aortic regurgitation, Doppler echocardiography is one of the best noninvasive technique to assess the pressure and severity of regurgitation. Color-flow mapping allows tracing of the jet direction and an indication of its volume, point of wall contact, and width. Because Doppler echocardiography distinguishes different types of turbulence, it can simultaneously identify more than one type of valvular abnormality (e.g., aortic regurgitation and mitral stenosis) and the source of concomitant heart murmur.

The ACC/AHA 2003 task force has published clinical guidelines for application of echocardiography. In recent years, the use of intraoperative TEE has significantly increased and standard for valvular heart surgery and other types of cardiovascular surgery (Table 13–14).

NUCLEAR CARDIOLOGY^{39,40}

Nuclear cardiology continues to be a major advance as a noninvasive testing method. Radionuclides with short half-lives, which can be

TABLE 13-14 Recommendations for Intraoperative Echocardiography

Class I

1. Evaluation of acute, persistent, and life-threatening hemodynamic disturbances in which ventricular function and its determinants are uncertain and have not responded to treatment.
2. Surgical repair of valvular lesions, hypertrophic obstructive cardiomyopathy, and aortic dissection with possible aortic valve involvement.
3. Evaluation of complex valve replacements requiring homografts or coronary reimplantation, such as the Ross procedure.
4. Surgical repair of most congenital heart lesions that require cardiopulmonary bypass.
5. Surgical intervention for endocarditis when preoperative testing was inadequate or extension to perivalvular tissue is suspected.
6. Placement of intracardiac devices and monitoring of their position during port-access and other cardiac surgical interventions.
7. Evaluation of pericardial window procedures in patients with posterior or loculated pericardial effusions.

Class IIa

1. Surgical procedures in patients at increased risk of myocardial ischemia, myocardial infarction, or hemodynamic disturbances.
2. Evaluation of valve replacement, aortic atheromatous disease, the Maze procedure, cardiac aneurysm repair, removal of cardiac tumors, intracardiac thrombectomy, and pulmonary embolectomy.
3. Detection of air emboli during cardiectomy, heart transplant operations, and upright neurosurgical procedures.

Class IIb

1. Evaluation of suspected cardiac trauma, repair of acute thoracic aortic dissection without valvular involvement, and anastomotic sites during heart and/or lung transplantation.
2. Evaluation of regional myocardial function during and after off-pump coronary artery bypass graft procedures.
3. Evaluation of pericardiectomy, pericardial effusions, and pericardial surgery.
4. Evaluation of myocardial perfusion, coronary anatomy, or graft patency.
5. Dobutamine stress testing to detect inducible demand ischemia or to predict functional changes after myocardial revascularization.
6. Assessment of residual duct flow after interruption of patent ductus arteriosus.

Class III

1. Surgical repair of uncomplicated secundum atrial septal defect.

Cheitlin MD, Armstrong WF, Aurigemma GP, et al. ACC/AHA/AHA 2003 guideline update for the clinical application of echocardiography—summary article. *J Am Coll Cardiol* 2003;42(5):954-970. Full text at <http://content.onlinejacc.org/>.⁴¹

used either alone or combined with other substances to form agents with particular properties, such as technetium-99m pyrophosphate, have expanded the role for nuclear imaging in cardiology.

Nuclear imaging techniques have demonstrated equal sensitivity and specificity to many of the invasive “gold standard” testing modalities. The major limitations of nuclear cardiology are the availability of suitable radionuclides and correlation of nuclear images with cardiovascular function.

Despite the availability of new radionuclides, technetium-99m (^{99m}Tc) and thallium-201 (^{201}Tl) remain the two most commonly used radionuclides. ^{99m}Tc is ideal for clinical imaging because it has a half-life of about 6 hours, a single 140-keV photon peak suitable for available imaging systems, primarily gamma ray emission, and the ability to be combined with multiple pharmaceuticals. It is generated in-house by a benchtop generator that reduces transportation costs and provides immediate availability. The short half-life means high doses and repeat injections can be given to evaluate efficacy of interventional therapy over a relatively short period of time. ^{201}Tl has a much longer half-life of 73 hours, which prevents the use of multiple doses close together but does mean that delayed imaging is possible following administration of the agent. Uptake into cells depends on blood flow. The energy from ^{201}Tl is x-ray, with an energy level of 69 to 83 keV. Production of ^{201}Tl requires a cyclotron. Images are obtained with a conventional gamma camera.

Technetium Scanning

Technetium scanning is used for the evaluation of blood pool and myocardial perfusion and as an infarct-avid agent to identify damaged myocardium. Analysis of the blood pool, as in multigated angiography, uses technetium either alone or as a red blood cell complex. The former obtains images following a bolus of technetium and traces its passage from the venous system through the heart to the aorta and is known as *first-pass angiography*. Equilibrium tests where technetium is bound to red blood cells provide an imaging time of several hours, which allows serial images to be obtained. These tests are used to determine right and left ventricular ejection fractions, detect cardiac shunts, estimate ventricular volumes, and view wall motion.⁴²

Infarct-avid radionuclides such as technetium-pyrophosphate ($^{99m}\text{Tc-PYP}$) are used to describe the presence and extent of damaged myocardium after myocardial infarction, in suspected myocardial contusion, and following chest wall injuries. Imaging with $^{99m}\text{Tc-PYP}$ is applicable when myocardial infarction is suspected clinically, but patient history, ECG changes, and laboratory evidence are not definitive. Uptake of $^{99m}\text{Tc-PYP}$ into infarcted tissue depends on regional blood flow, myocardial calcium concentration, the degree of irreversible myocardial injury, and time after infarction. $^{99m}\text{Tc-PYP}$ attaches to calcium deposited in the infarcted area, so the approach is known as *hot-spot scanning*. False hot spots may occur where there is necrotic myocardial tissue, as in myocarditis, myocardial abscesses, old infarctions, and myocardial trauma. Additionally, uptake has been seen during unstable angina and ventricular dyskinesia and at sites of ventricular aneurysms, suggesting that these are associated with transient low blood flow. In infarcted tissue, $^{99m}\text{Tc-PYP}$ levels can be as high as 18 to 20 times that of normal myocardium, which gives rise to very distinct borders between the infarcted and normal myocardium. Uptake of $^{99m}\text{Tc-PYP}$ into necrotic myocardium is delayed and not measurable until after about 4 hours of coronary occlusion. Scans prior to this time are usually negative and become positive about 12 hours after occlusion. Peak intensity of $^{99m}\text{Tc-PYP}$ is reached at 48 hours. Washout occurs over 5 to 7 days, so $^{99m}\text{Tc-PYP}$ is a useful late marker of infarction, especially in patients who present late or with a silent infarction. Images are viewed by comparing sternum and rib uptake with that seen in the myocardium. This type of imaging also can be used to assess graft

patency after coronary artery bypass. Certain characteristics of the images obtained have been linked with various prognostic values but await confirmation in comparative and long-term prognostic trials.

Other technetium-labeled agents used include technetium-*t*-butyl isonitrile ($^{99m}\text{Tc-TIBI}$); technetium-carboxy isopropyl isonitrile ($^{99m}\text{Tc-CPI}$); technetium-sestamibi, also known as methoxy-isobutyl isonitrile (Tc-MIBI); and technetium-teboroxime. Technetium-sestamibi has a similar myocardial uptake pattern to thallium and produces similar results but with improved image quality because it generates a much higher photon yield. This is now popular as an alternative perfusion imaging agent to thallium. Technetium-teboroxime is still primarily an investigational agent. The main advantage of the newer technetium compounds is the lack of redistribution perfusion, allowing for delayed imaging. This is particularly useful in acute clinical settings; the radiopharmaceutical can be injected during the acute event and imaging undertaken when the patient is more stable.

Thallium Scanning

Thallium is a potassium analog taken up into normal myocardium by passive diffusion and possibly by active transport via the Na^+/K^+ -adenosine triphosphatase (ATPase) pump. Uptake depends on regional blood flow and in a linear fashion up to very high blood flow rates. It is used primarily for the analysis of coronary and myocardial perfusion. High thallium uptake occurs in perfused myocardium; in ischemic myocardium, uptake is reduced significantly. Scans taken during acute ischemia or following infarction show areas of poor or nil distribution of thallium corresponding to the site of ischemia. A scan repeated 4 to 6 hours after the initial scan may show a redistribution of the thallium into areas that previously had little to no thallium uptake. These defects are referred to as *partial defects*, demonstrating areas hypoperfused during “stress” but viable myocardium at rest. Redistribution occurs because there is delayed washout of thallium from poorly perfused myocardium, resulting in less contrast between the density of thallium in different areas of the heart. This gives the appearance of “redistribution” of the radionuclide into the previously ischemic area. To enhance evaluation of potential partial defects, a second injection of thallium can be used. Areas of nil distribution are called *cold spots* or *fixed defects* and reflect infarcted myocardium.

Thallium scanning with the aid of computer analysis segregates the images into anatomic regions and specifically localizes areas of dead or necrotic myocardial tissue. In conjunction with echocardiography or single-photon emission computed tomography (SPECT), thallium scans can correlate areas of abnormal wall motion with areas of poor perfusion. Sensitivity and specificity of thallium scanning to detect IHD disease are comparable with those of ETT (75% and 80%, respectively). When used in conjunction with exercise ECG, sensitivity increases to approximately 80%. Thallium scanning also can be used in conjunction with ETT to allow detection of lower levels of ischemia than may be determined from ECG abnormalities or patient symptoms. Thallium is injected at the peak of the ETT, and exercise continues for another 30 to 60 seconds, when the initial images are taken. Repeat images are taken at 3 to 4 hours.

Thallium scanning is useful in patients with atypical chest pain and ambiguous or false-positive ETT to determine if IHD is the cause of symptoms and the ETT abnormalities. Thallium scanning is also used for postoperative evaluation of revascularization or angioplasty procedures and for preoperative evaluation for prognostic stratification for persons with IHD. A normal thallium scan heralds a benign outcome, even in patients who have angiographically evident CAD. The finding of redistribution is a marker of jeopardized but viable myocardium that has important prognostic value. Major cardiac events such as myocardial infarction in patients with normal ^{201}Tl studies average less than 1% per year. The

best predictor of coronary events, which correlates thallium scans with clinical significance, is the number of myocardial segments with transient (redistribution) defects.

A number of other radiopharmaceuticals have found some use in cardiovascular testing, such as labeled antimyosin antibodies. Theoretically, these antibodies should be more specific markers of myocyte necrosis. The currently used antibodies are a murine Fab fragment. Phase I, II, and III trials suggest that these are highly specific for irreversibly injured myocytes, but they have limitations in terms of pharmacokinetic properties. Uptake into myocardial tissues is very slow, with a prolonged blood pool activity seen for at least 24 hours. In clinical use, the antibody is given within 24 hours of the infarction, and planar or SPECT imaging is undertaken 24 to 48 hours later. Despite the supposed specificity of the antibody to myosin, localization is more dependent on blood flow than on myosin concentration, so measurement of infarction size is not as accurate as expected. Another investigational agent, [^{123}I]phenylpentadecanoic acid, is able to assess both myocardial perfusion and metabolism by virtue of its affinity for fatty acid metabolism.

Pharmacologic Stress Testing

9 Pharmacologic stress testing is an alternative to ETT and ETT with thallium in patients who are unable or unwilling to undergo ETT.^{43,44} Additionally, pharmacologic stress testing is now used more than 50% of the time to assess coronary perfusion. The pharmacologic agent produces stress by a hyperemic (vasodilator) response or by increasing myocardial oxygen demand (heart rate and myocardial contractility). Agents currently used include dipyridamole and adenosine (hyperemic stress) and dobutamine (myocardial stress). Pharmacologic stress tests can be linked to various imaging techniques such as thallium planar scanning, SPECT, MRI, and echocardiography. Dobutamine is linked most frequently to echocardiography, allowing quantification of wall motion abnormalities, which correlate well with areas of ischemia.

The principle of dipyridamole and adenosine thallium imaging is related to their coronary arteriolar vasodilator properties. Dipyridamole inhibits adenosine cellular reuptake, resulting in increased concentrations of adenosine in the blood and tissues. Adenosine is a potent coronary artery vasodilator and can increase perfusion four to five times over baseline. Areas distal to a coronary artery obstruction will show a relative hypoperfusion compared with normal coronary arteries because there is reduced perfusion pressure as a consequence of preferential perfusion of normal segments over stenotic segments. Acutely, these areas will appear as cold spots, but on the redistribution scans, the defects will fill, indicating viable but jeopardized myocardium.

Dipyridamole is given intravenously in a dose of 0.142 mg/kg per minute over 4 minutes. This dose has been shown to increase baseline coronary blood flow in the normal tissues up to four to five times over control. Some studies have used doses up to 0.84 mg/kg to enhance the vasodilator response. At the higher dose, acute adverse effects such as chest pain are more common. Adenosine for stress testing is an unlabeled use of this drug. Adenosine is given over 6 minutes at a dose of 0.140 mcg/kg per minute. At the end of infusion (dipyridamole) or after 3 minutes (adenosine), a 2.5- to 4-mCi dose of thallium is given. The maximum effect of dipyridamole occurs at 5 to 7 minutes and adenosine at approximately 30 seconds after the end of infusion. Imaging follows immediately and can be repeated at 24 hours (thallium scanning) to heighten the redistribution defects from fixed or partial defects.

Like exercise thallium scanning, dipyridamole and adenosine scanning or echocardiography is used to detect IHD, evaluate the prognosis of patients with known disease, assess patients after myocardial infarction, and as a risk-stratification method prior to vascu-

lar, cardiac, and noncardiac surgery. Pharmacologic stress testing evaluates wall motion abnormalities and perfusion defects under stress and has been shown in numerous studies to have comparable sensitivity and specificity with the traditional ETT. Using planar scanning and dipyridamole, sensitivity to detect IHD ranges from 67% to 95% with a 67% to 100% specificity. A summary of 13 studies in almost 900 patients gave a pooled sensitivity of 85% and specificity of 87%. SPECT scanning has at least comparable sensitivity and slightly lower specificity to planar imaging but produces higher-quality imaging, which may enhance quantitative interpretation.

Dipyridamole testing is safe and effective in the elderly and in those with unstable angina immediately after myocardial infarction (within days). It also may be used to assess the status of revascularization procedures.⁴³ As a prognostic test, dipyridamole testing is very useful. In several studies, abnormal scans have shown about a 10-fold increase in event rates over 1 to 2 years of followup. Abnormal scans also have been shown to be an independent risk factor for myocardial infarction and death with a relative risk ratio of 3.1. Reversible defects correlate best with events, with one study demonstrating a 4.41 relative risk ratio for cardiac events.

Adverse effects with dipyridamole thallium testing are minimal, the main adverse effects being chest pain (with or without ischemic changes on the ECG), headache, dizziness, and nausea. Adverse effects are related to the increased adenosine activity and can be ameliorated by xanthine compounds because they are direct competitive antagonists of adenosine. Caffeine products must be avoided for about 24 hours prior to the test. Adenosine is associated with a higher incidence of adverse effects (80% versus 50%), but these are very transient, and some studies have shown that patients prefer it over dipyridamole. Both agents are relatively contraindicated in patients with a history of bronchospasm.

Dobutamine, a synthetic catecholamine, raises heart rate and cardiac output, which increases myocardial oxygen demand. Ischemia develops in areas where stenosis prevents the increase in oxygen demand from being met with increased blood flow. Ischemia is detected by the ECHO as regional wall motion abnormalities or with thallium scanning.

Dobutamine, when used as a stress test, is given in doses of 10 to 40 mcg/kg per minute.⁴⁴ The dose is titrated at 3-minute intervals in increments of 10 mcg/kg per minute. If thallium is used, it is given 2 to 3 minutes before the end of infusion. Atropine 0.5 to 1 mg may be given to augment the heart rate response to 85% of the patient's calculated maximum. ECG and blood pressure are recorded continuously throughout the test, and ECHO recordings are made during the last minute of each dose level and during recovery.

β -Blocker and calcium channel blocker therapy may interfere with the heart rate response to dobutamine stress tests and is recommended to be discontinued prior to the test. Dobutamine stress testing is relatively well tolerated. Reasons to discontinue the test include development of severe chest pain, extensive new wall motion abnormalities, ST-segment elevation and depression suggestive of significant ischemia, tachyarrhythmias, and symptomatic reductions in blood pressure.⁴⁵ β -Blockers can be used to reverse most adverse effects if they persist. Dobutamine stress tests are contraindicated in patients with aortic stenosis, uncontrolled hypertension, and severe ventricular arrhythmias. Ventricular fibrillation and myocardial infarction occur at a rate of approximately 0.05%.

Dobutamine stress testing has been studied as a diagnostic, prognostic, and therapy assessment tool after myocardial infarction and for unstable and chronic angina. One study compared dobutamine, dipyridamole, and ETT with coronary angiography for diagnostic accuracy in patients with IHD and showed an overall accuracy of 87% for ETT, 82% for dobutamine, and 77% for dipyridamole. A recent review of 14 studies of 942 patients for the detection of IHD with dobutamine stress testing calculated the sensitivity to be

approximately 80% (70% to 100%) with a 75% (64% to 100%) specificity. Sensitivity is highest for detection of three-vessel disease (92%). Dobutamine-sestamibi stress testing seems to be less sensitive than thallium even for multivessel disease. Comparative studies with ETT and dipyridamole echocardiography show dobutamine to be more sensitive. After myocardial infarction, dobutamine stress testing identifies patients at high risk of subsequent cardiac events. For patients with suspected or known IHD, a positive dobutamine stress test is an independent predictor of cardiac events, and a negative test affords protection from cardiac death.⁴⁶

The current 2006 guidelines on the use of these tests in clinical practice are rather brief, only to say that cardiac imaging is currently undergoing rapid evolution. The use of these types of test in intermediate to high risk patients are markedly increasing. The identification of asymptomatic intermediate-risk patients (10% to 20% risk of cardiovascular death/myocardial infarction in 10 years) is still undergoing considerable debate. The clinical treatment of these patients with atherosclerosis *must* include appropriate risk factor treatment according to existing AHA guidelines. Patients with high-risk findings of cardiovascular disease may require more invasive testing but global risk reduction will still be required before and after there testing or invasive treatment if essential.⁴⁷

COMPUTED TOMOGRAPHY

CT scanning is becoming more popular as a primary screening procedure in the evaluation of CVD and function because it provides similar information as other diagnostic procedures (e.g., catheterization, echocardiography) and is less expensive and less invasive than a routine heart catheterization. In recent years, advancement in technology has considerably enhanced definition and spatial resolution of all cardiac structures that are useful in evaluation of many specific areas, such as coronary arteries, aortic and pericardial disease, and paracardiac and cardiac masses. Very accurate determination of chamber volume and size and mass calculations of myocardial wall thickness can be obtained from CT scanning than with other methods such as echocardiography or angiography. Additionally, CT scanning acquires three-dimensional images.⁴⁸ New techniques such as ultrafast CT (cine-CT) scanning have significantly improved problems with cardiac motion that distorted conventional CT images. In cine-CT scanning, complete tomograms are assembled within one cardiac cycle (50 msec), thus providing real-time images. For ultrafast CT scanners, a set event within the cardiac cycle (determined by ECG) usually is used as initiator for imaging to ensure standardization. Conventional CT scanning requires that images be correlated with the cardiac cycle by gating the CT to the ECG. Cine-CT scans examine the heart at 10 to 14 tomographic levels in <10-mm slices. The resolution has improved considerably in the last few years as a result of advances in many areas of computer science and now 64-section multidetector CT scans are significantly better.

Although still in its infancy, cine-CT scanning has matured significantly and is now being used as a screening tool for evaluating the risk of significant obstructive CAD and as a diagnostic tool for CAD in limited centers. Recent AHA/ACC guidelines address the current state of practice with this methodology. The CT scan will show localized areas of infarction and abnormal perfusion and allows quantification of the extent and density of coronary artery calcification.⁴⁹ Cine-CT scanning is more sensitive and specific than fluoroscopy in identifying the extent and density of coronary artery calcification. The calcium score (calcium density and volume of calcium) in patients older than 30 to 70 years with known CAD is significantly higher than in subjects with no CAD and appears to correlate well with the degree of coronary artery occlusion (Table 13–15).⁵⁰

New CT scanning may be more definitive and accurate in the diagnosis of aortic dissection and evaluation of the pericardium

TABLE 13-15 ACCF/AHA 2007 Clinical Expert Consensus Document on Coronary Artery Calcium Scoring By Computed Tomography—Conclusions

1. What is the role of coronary calcium measurement by coronary CT scanning in asymptomatic patients with intermediate CHD risk (between 10% and 20% 10-year risk of estimated coronary events)?
The Committee judged that it may be reasonable to consider use of CAC measurement in such patients based on available evidence that demonstrates incremental risk prediction information in this selected (intermediate-risk) patient group. This conclusion is based on the possibility that such patients might be reclassified to a higher risk status based on high CAC score, and subsequent patient management may be modified.
2. What is the role of coronary calcium measurement by CT scan in patients with low CHD risk (below 10% 10-year risk of estimated CHD events)?
The Committee does not recommend use of CAC measurement in this selected patient group. This patient group is similar to the “population screening” scenario, and the Committee does not recommend screening of the general population using CAC measurement.
3. What is the role of coronary calcium measurement by fast CT scan in asymptomatic patients with high CHD risk (greater than 20% estimated 10-year risk of estimated CHD events, or established coronary disease, or other high-risk diagnoses)?
The Committee does not advise CAC measurement in this selected patient stratum as they are already judged to be candidates for intensive risk-reducing therapies based on current NCEP guidelines.
4. Is the evidence strong enough to reduce the treatment intensity in patients with calcium score = 0 in patients who are considered intermediate risk before coronary calcium score?
No evidence is available that allows the Committee to make a consensus judgment on this question. Accordingly, the Committee felt that current standard recommendations for treatment of intermediate risk patients should apply in this setting.
5. Is there evidence that coronary calcium measurement is better than other potentially competing tests in intermediate risk patients for modifying cardiovascular disease risk estimate?
In general, CAC measurement has not been compared to alternative approaches to risk assessment in head-to-head studies. The question cannot be adequately answered from available data.
6. Should there be additional cardiac testing when a patient is found to have high coronary calcium score (e.g., CAC is greater than 400)?
Current clinical practice guidelines indicate that patients classified as high risk based on high-risk factor burden or existence of known high-risk disease states (e.g., diabetes) are regarded as candidates for intensive preventive therapies (medical treatments). There is no clear evidence that additional noninvasive testing in this clear patient population will result in more appropriate selection of treatments.
7. Is there a role for CAC testing in patients with atypical cardiac symptoms?
Evidence indicates that patients considered to be at low risk of coronary disease by virtue of atypical cardiac symptoms may benefit from CAC testing to help in ruling out the presence of obstructive coronary disease. Other competing approaches are available, and most of these competing modalities have not been compared head-to-head with CAC.
8. Can coronary calcium data collected to date be generalized to specific patient populations (women, African American men)?
CAC data are strongest for Caucasian, non-Hispanic men. The Committee recommends caution in extrapolating CAC data derived from studies in white men to women and to ethnic minorities.
9. What is the appropriate followup when an incidental finding in the lungs or other noncardiac tissues is found on a fast coronary CT study?
Current radiology guidelines should be considered when determining need for followup of incidental findings on a fast CT study, such as that which was recently published to guide followup of small pulmonary nodules.

CAC, coronary artery calcium; CHD, coronary heart disease; CT, computed tomography; NCEP, National Cholesterol Education Program.

Greenland, Bonow RO, Brundage BH, et al. ACCF/AHA 2007 clinical expert consensus document on coronary artery calcium scoring by computed tomography in global cardiovascular risk assessment and in evaluation of patients with chest pain. *J Am Coll Cardiol* 2007;49:378–402.

than TTE but in many expert centers, TEE maybe as good. Currently 3D echocardiography can add other important information to a critical patient's case, for example, valvular leaks and wall motion changes. Diagnostic accuracy of aortic dissections with CT scanning is >90%. CT scanning affords definition of the

edges of the intimal flap of the dissection, and true and false channels can be seen. It also demarcates the components of the myocardial wall from the inner endocardial wall through to the epicardial surface and pericardium, allowing visualization of abnormalities, such as aneurysms and thrombin. Detection of the presence of a thrombus on a CT scan is comparable in accuracy with 2D echocardiography. The pericardium appears as a distinct entity and can be evaluated for thickening and calcification. CT scanning is the most sensitive technique to differentiate types of pericarditis and estimate pericardial fluid volume. Compared with echocardiography, CT scanning is equivocal to define loculated and hemorrhagic effusions. Important advances in 3D echocardiography is currently making significant advancement as we have seen with new CT scanners.

In the evaluation of cardiac masses, CT scanning shows the mass as a distinct space-occupying entity. Tissue density differentiation as seen on a CT scan allows characterization of density, aiding in determination of the nature of masses. Masses as small as 0.5 to 1 cm can be identified on CT scans.

Like radionuclide assessment, contrast angiography, and echocardiography, CT scanning can be used to calculate ejection fraction, left ventricular volume, and stroke volume. The blood pool is defined with intravenous iodinated contrast material. Ventricular volumes, ejection fraction, and stroke volume are determined directly from the blood pool on each image. Values obtained with CT scanning are more accurate and reproducible than those obtained on angiography and ECHO. The three-dimensional image of a CT scan also allows determination of the extent and distribution of LVH in patients with hypertrophic or congestive cardiomyopathy.

CT scanning has proven to be an effective noninvasive method to visualize congenital heart disease, but its role is challenged by the higher-resolution capacity of MRI.⁵⁰ For measuring parameters in some congenital disorders, such as evaluation of ventricular function and estimation of the volume of cardiac shunts, CT scanning still remains an important choice. As patients have more procedures related to implanted metallic devices, CT scanning is a very important option and newer CT scanners are making major strides in many areas of congenital heart disease.

A few practical considerations when one considers CT for evaluating the coronary arteries. Diagnostic quality imaging may require in most cases the patient to have normal sinus rhythm, and a targeted heart rate of less than 65 beats per minute during image acquisition. The patient's heart rate should be measured during a breath-holding test to determine whether the administration of a β -blocker is necessary. If the heart rate drops after inspiration breath holding by 10 beats per minute, the study should be of good quality. However, sometimes short-acting β -blockers are needed to reduce heart rates to below 65 beats per minute.⁵¹

Recently published guidelines from the AHA⁵² on the assessment of coronary artery disease by cardiac computed tomography have an excellent review of the topic with a wonderful reference section. Table 13–16 is an overview of current considerations for scanning. Most expert panels generally agree that patients with a prior probability of a coronary event in the intermediate range (>6% in 10 years but <20% in 10 years), a calcium score of >100 would yield a posttest probability >2% per year in the majority of patients. This would place the patient in the range of a coronary heart disease risk equivalent population and within a level requiring secondary prevention strategies. Table 13–17 describes the American College of Cardiology Foundation (ACCF) results of appropriate use of cardiac computed tomography in cardiovascular disease from the Appropriateness Criteria Working Group.⁵³

In summary, CT scanning, especially cine-CT scanning, is a rapidly evolving technique for evaluation of CVD. It remains an expensive alternative to other methodologies in many instances, but

TABLE 13-16 Criteria for Cardiac Computed Tomography (CCT) and Cardiac Magnetic Resonance (CMR) ACCF/ACR/SCCT/SCMR/ASNC/NASCI/SCAI/SIR 2006 Appropriateness

Appropriate test for specific indication (Score 7–9)
Detection of CAD: Symptomatic
Intermediate pretest probability of CAD
ECG uninterpretable or unable to exercise
Evaluation of Intracardiac Structures (Use of CT Angiogram)
Evaluation of suspected coronary anomalies
Acute Chest Pain (Use of CT Angiogram)
Intermediate pretest probability of CAD
No ECG changes and serial enzymes negative
Morphology (Use of CT Angiogram)
Assessment of complex congenital heart disease including anomalies of coronary circulation, great vessels, and cardiac chambers and valves
Evaluation of coronary arteries in patients with new onset heart failure to assess etiology.
Evaluation of Intra- and Extracardiac Structures (Use of Cardiac CT)
Evaluation of cardiac mass (suspected tumor or thrombus)
Patients with technically limited images from echocardiogram, MRI, or TEE
Evaluation of pericardial conditions (pericardial mass, constrictive pericarditis, or complications of cardiac surgery)
Patients with technically limited images from echocardiogram, MRI, or TEE
Evaluation of pulmonary vein anatomy prior to invasive radiofrequency ablation for atrial fibrillation
Noninvasive coronary vein mapping prior to placement of biventricular pacemaker
Noninvasive coronary arterial mapping, including internal mammary artery prior to repeat cardiac surgical revascularization
Evaluation of Aortic and Pulmonary Disease (Use of CT Angiogram ^a)
Evaluation of suspected aortic dissection or thoracic aortic aneurysm
Evaluation of suspected pulmonary embolism
Uncertain for specific indication (Score 4–6)
Inappropriate test for that indication (Score 1–3)

^aNongated, CT angiogram which has a sufficiently large field of view for these specific indications. Hendel (Guidelines). JACC 2007;48:1475. Summary of Table 11–20.

the high resolution and spatial capabilities mean that CT scanning offers unique properties. It is important to remember that CT scanning radiation dosage on average is three times more than a routine heart catheterization. Current coronary angiography has a mean effective radiation dosage of approximately 5 mSv (millisievert) and cardiac CT varies between 6.9 and 20 mSv depending on the configuration.^{54,55}

POSITRON EMISSION TOMOGRAPHY

PET is a relatively new modality for diagnostic imaging in CVD medicine.^{56,57} PET has found a niche to characterize myocardial physiologic and metabolic activity, perfusion, and viability. PET can measure regional myocardial uptake of exogenous glucose and fatty acids, quantitate free fatty acid metabolism, define perfused myocardium energy source(s), and evaluate myocardial chemoreceptor sites.⁶¹ Although many other techniques can be used similarly to evaluate myocardial function, PET images are superior in definition. The primary advantages of PET are its noninvasive nature, the ability to do repeat scans within a short period of time, such as before and after percutaneous transluminal coronary angioplasty (PTCA), and the reproducibility of images over time. PET is very expensive because of the need for onsite cyclotrons for many of the radiotracers, and there is limited availability of sites that offer the technique. Cheaper forms of PET-like scanning are in development, but image resolution is lower.

PET uses positron-emitting isotopes such as oxygen-15, nitrogen-13, carbon-11, and fluoride-18. These are incorporated into sub-

TABLE 13-17 Interpretation and Recommendations for CT Heart Scanning and CACP Scoring

Negative test result	
A negative test (score = 0) makes the presence of atherosclerotic plaque, including unstable or vulnerable plaque, highly unlikely.	
A negative test (score = 0) makes the presence of significant luminal obstructive disease highly unlikely (negative predictive power by EBCT on the order of 95% to 99%).	
A negative test is consistent with a low risk (0.1% per year) of a cardiovascular event in the next 2 to 5 years.	
Positive test result	
A positive test (CAC 0) confirms the presence of a coronary atherosclerotic plaque.	
The greater the amount of coronary calcium, the greater the atherosclerotic burden in men and women, irrespective of age.	
The total amount of coronary calcium correlates best with the total amount of atherosclerotic plaque, although the true atherosclerotic burden is underestimated.	
High score	
A high calcium score (an Agatston score >100) is consistent with a high risk of a cardiac event within the next 2 to 5 years (2% annual risk).	
Risk prediction	
Coronary artery calcium measurement can improve risk prediction in conventional intermediate-risk patients, and CACP scanning should be considered in individuals at intermediate risk for a coronary event (1.0% per year to 2.0% per year) for clinical decision making with regard to refinement of risk assessment.	
Decisions for further testing (such as stress testing or cardiac catheterization) beyond assistance in risk stratification in patients with a positive CACP score cannot be made on the basis of coronary calcium scores alone, as calcium score correlates poorly with stenosis severity in a given individual and should be based upon clinical history and other conventional clinical criteria.	

CACP, coronary artery calcified plaque; CAC, coronary artery calcium; CT, computed tomography; EBCT, electron-beam computed tomography.

stances such as water, glucose analogs, or fatty acids, the metabolic substrates for myocardial tissue. For myocardial perfusion studies, rubidium-82 (^{82}Rb), nitrogen-13 ammonia ($^{13}\text{N}[\text{H}_3]$), and $^{15}\text{O}_2$ -labeled water are used. For myocardial substrate metabolism studies, ^{11}C palmitate, ^{11}C acetate, and ^{18}F 2-deoxyglucose (FDG) are used. All these substances have very short half-lives (<10 minutes). In the fasting state, perfused myocardium primarily uses fatty acids as energy source. Postprandially, glucose is the preferred substrate. Ischemic myocardium primarily metabolizes glucose because mitochondrial fatty acid oxidation is impaired. Hence, with PET using either a fatty acid or glucose substrate, ischemic versus nonischemic areas can be defined. Frequently, PET is used in conjunction with pharmacologic stress testing to provoke ischemia, with images obtained before and after stress application.

Uptake of ^{82}Rb occurs via the Na^+/K^+ -ATPase pump and occurs preferentially in viable tissue. Net uptake into tissue resolving from an ischemic insult and infarcted tissue is reduced. With a half-life of 1.26 minutes, serial images of myocardial perfusion can be taken as frequently as every 5 minutes, and a dobutamine stress test is completed within 45 minutes. Comparative studies with ETT, SPECT, and stress echocardiography show PET to be more accurate in the detection of IHD. The substrate $^{13}\text{N}[\text{H}_3]$ rapidly crosses capillary membranes and is trapped in the myocardium by glutamate–glutamine reactions. This product produces high-contrast images with a sensitivity of 88% to 97% and a specificity of 90% to 100% to detect IHD. $^{15}\text{O}_2$ -labeled water has a high extraction ratio into myocardial tissue, which appears to be independent of blood flow or the metabolic state of the myocardium. $^{15}\text{O}_2$ -labeled water studies are done in conjunction with ^{15}O carbon monoxide (labels red blood cells in the vascular space) studies to help eliminate some of the background activity that occurs as a result of the high extraction ratio.⁵⁸

Tracers used for assessment of myocardial metabolism are selected based on the type of metabolism of interest: FDG traces glucose metabolism, ^{11}C palmitate traces mitochondrial fatty acid metabo-

lism, and ^{11}C acetate is an indirect marker for myocardial oxygen consumption, allowing assessment of ventricular performance. ^{11}C Palmitate is a useful marker for normal myocardial oxygen consumption because baseline energy needs of the myocardium are met through fatty acid oxidation. Clearance of ^{11}C palmitate is biexponential, and studies in animals and in healthy men show clearance to be proportional to cardiac workload and myocardial oxygen consumption. In acute ischemia, the first component of clearance is reduced and the second is increased. The use of ^{11}C palmitate to assess myocardial metabolism in ischemic tissue is limited because there is altered transport and storage of the compound and significant back diffusion of the agent into the vascular space.

FDG accumulates in the heart proportional to glucose use by the myocardial cell and so is a marker of cell viability. FDG studies help to identify the affected vascular bed and allow evaluation as to whether angioplasty or surgery might be used. Detection of hibernating myocardium is possible because it predominantly uses glucose and can be seen readily on PET scans. Patients with a significant degree of jeopardized or hibernating myocardium identified on PET scanning then could be candidates for revascularization procedures. In contrast, a perfusion study would not show as good differentiation of infarcted versus hibernating tissue, and revascularization may not be considered. In studies of recovery of left ventricular function following revascularization, PET has a positive predictive value of 72% and a negative predictive value of 83%. PET with FDG has been used in the assessment of cardiomyopathies. In ischemic cardiomyopathy, discrete regional ischemia is seen as a patchy, nonhomogeneous uptake of the tracers; dilated cardiomyopathies show global decreased uptake of tracers.

In CAD, PET is used to assess and follow the physiologic significance of stenotic lesions. After infarction, PET myocardial substrate metabolism studies are used to evaluate the amount and activity of viable tissue around the infarcted area and the site and extent of infarction. Myocardial perfusion studies with PET identify more accurately the viable and nonviable myocardium compared with technetium and thallium. PET also quantifies regional myocardial perfusion more accurately than other modalities. When linked with physiologic or pharmacologic stress tests, PET enables evaluation of the myocardium under stress conditions. Studies in patients with more than 50% stenosis on angiography suggest that dipyridamole stress SPECT and ^{13}N ammonia PET are comparable tests to assess coronary artery perfusion, with respective sensitivities of 98% and 96% and specificities of 88% and 81%. SPECT analysis using FDG compared with PET with FDG shows comparable accuracy for the detection of CAD. Comparative studies with SPECT thallium in conjunction with bicycle ergometer or dipyridamole versus PET perfusion scanning showed comparative sensitivities (76% to 79%) but improved specificity (90% versus 82%, $p < 0.005$).⁵⁸

The future of PET appears promising. Improved tomographic scanners, development of new radiopharmaceuticals, and improved understanding of substrate metabolism and its relationship to myocardial tissue viability will provide new dimensions to assess and evaluate myocardial function. Research enterprises are developing agents to label receptors as a tool to determine cardiovascular physiology and how altered receptor function, biochemical abnormalities, substrate metabolism, or other as yet unrecognized abnormalities impair cardiac function. It continues to be used mostly to answer research questions than in clinical practice settings. A few specialized, large centers do offer PET scanning.

CARDIAC CATHETERIZATION AND ANGIOGRAPHY⁵⁹

4 Development of the cardiac catheterization technique was a major milestone in the diagnosis and management of CVD because

it provided a physiologic and anatomic approach to assess patency of coronary vessels and hemodynamic parameters of cardiac function. Cardiac catheterization is the technique used to gain vascular access to the coronary arteries by intravascular catheters and heart chambers. Once cardiac catheterization is complete, other diagnostic and therapeutic procedures, such as angiography, ventriculography, and PTCA, and drug administration (e.g., thrombolytics) may be undertaken. Following interventional procedures such as PTCA, catheterization with angiography can be used to evaluate efficacy of the intervention. In recurrent clinical syndromes, following a procedure, catheterization is used to help delineate a new management strategy. Catheterization is also now used commonly with PTCA and/or drug therapy in the management of acute coronary syndromes.

Additionally, catheterization allows assessment of valvular function and computation of various cardiac performance parameters such as cardiac output, stroke volume, systemic vascular resistance, cardiac chamber pressures, and blood flow. It also allows for placement of cardiac pacemakers. Drug administration during cardiac catheterization is used primarily for assessment of end points in clinical trials (e.g., thrombolytics to assess coronary artery patency), for management of events (e.g., chest pain) during catheterization, or for diagnostic purposes (e.g., ergonovine to evaluate coronary spasm). Further applications of cardiac catheterization include aortic root angiography, pulmonary angiography, retrieval of foreign bodies, and atherectomy.⁶⁰

More than 1 million cardiac catheterizations are performed in the United States each year, making it the second most frequent in-hospital procedure. Images obtained during catheterization are stored on 35-mm cineradiographic film or are digitized, allowing comparison of studies at a later date. The ACC/AHA guidelines on angiography and PTCA describe the classes I, II, and III indications for each of these procedures; examples are given in Tables 13–18 and 13–19.⁶³ The guidelines for angiography, PTCA, and catheterization also include recommendations regarding technique, procedures, facilities, personnel, and training.

The cardiac catheterization procedure requires vascular access, usually obtained percutaneously at brachial or femoral arteries or veins. Left-sided catheterization provides access to the aorta, left ventricle, and left atrium. Right-sided catheterization enables the right side of the heart, coronary sinus, pulmonary arteries, and pulmonary wedge position to be reached. Left-sided catheterization is used for coronary angiography and ventriculography, whereas right-sided catheterization is used for determination of cardiac performance parameters.

Prior to an elective procedure, the patient is given nothing by mouth (after midnight) except for oral medications. It is not necessary to stop any medications except warfarin prior to catheterization. Patients receiving warfarin may be transitioned to low-molecular-weight or unfractionated heparin or anticoagulation may be discontinued depending on the clinical scenario about 3 days prior to the procedure. Heparin products are stopped about 6 hours before the procedure to allow normalization of coagulation. There are no data to support low-molecular-weight heparin during catheterization procedures because its longer half-life may increase the risk of intra- and postprocedural bleeding. Patients who require anticoagulation prior to angiography (e.g., those with acute coronary syndromes) usually are treated with unfractionated heparin or low-molecular-weight heparin.

Patients frequently develop chest pain and/or vasospasm during introduction and manipulation of catheters and injection of angiographic dyes. Nitroglycerin/nitroprusside and/or morphine may be given for chest pain. Nitroglycerin also is used to prevent vasospasm and is given sublingually or by intravenous infusion. The use of nitroprusside has increased in recent years because it is a direct smooth muscle vasodilator. Sedatives, such as midazolam and other

TABLE 13-18 Recommendations for Coronary Angiography in Patients with Known or Suspected Coronary Artery Disease Who Are Currently Asymptomatic or Have Stable Angina

Class I

1. Canadian Cardiovascular Society (CCS) class III and class IV angina on medical treatment. (*Level of Evidence: B*)
2. High-risk criteria on noninvasive testing regardless of anginal severity. (*Level of Evidence: A*)
3. Patients who have been successfully resuscitated from sudden cardiac death or have sustained (>30 seconds) monomorphic ventricular tachycardia or nonsustained (<30 seconds) polymorphic ventricular tachycardia. (*Level of Evidence: B*)

Class IIa

1. CCS class III or IV angina, which improves to class I or II with medical therapy. (*Level of Evidence: C*)
2. Serial noninvasive testing with identical testing protocols, at the same level of medical therapy, showing progressively worsening abnormalities. (*Level of Evidence: C*)
3. Patients with angina and suspected coronary disease who, because of disability, illness, or physical challenge, cannot be adequately risk stratified by other means. (*Level of Evidence: C*)
4. CCS class I or II angina with intolerance to adequate medical therapy or with failure to respond, or patients who have recurrence of symptoms during adequate medical therapy as defined above. (*Level of Evidence: C*)
5. Individuals whose occupation involves the safety of others (e.g., pilots, bus drivers, etc.) who have abnormal but not high-risk stress test results or multiple clinical features that suggest high risk. (*Level of Evidence: C*)

Class III

1. Angina in patients who prefer to avoid revascularization even though it might be appropriate. (*Level of Evidence: C*)
2. Angina in patients who are not candidates for coronary revascularization or in whom revascularization is not likely to improve quality or duration of life. (*Level of Evidence: C*)
3. As a screening test for coronary artery disease in asymptomatic patients. (*Level of Evidence: C*)
4. After coronary artery bypass grafting or angioplasty when there is no evidence of ischemia on noninvasive testing, unless there is informed consent for research purposes. (*Level of Evidence: C*)
5. Coronary calcification on fluoroscopy, electron-beam computed tomography, or other screening tests without criteria listed above. (*Level of Evidence: C*)

Scanlon PJ, Faxon DP, Audet A-M, et al. ACC/AHA Guidelines for Coronary Angiography: Executive Summary and Recommendations. *Circulation* 1999;99:2345–2357. ©American Heart Association, Inc.

short-acting benzodiazepines, frequently are given to ensure patient comfort and safety, but the patient is awake and aware of the procedure. Patient cooperation is necessary to obtain the angiographic views and assess symptoms. The patient is required to remain still for about 6 to 8 hours to reduce the risk of bleeding from the catheter entry site(s). Depending on the procedure, patients may be discharged the same day or within 24 hours, if stable.

Heparin products are used during procedures such as angiography, left-sided heart catheterization, and PTCA to prevent thrombotic complications. Depending on the procedure undertaken,

TABLE 13-19 Recommendations for Coronary Angiography in Patients with Nonspecific Chest Pain

Class I

1. High-risk findings on noninvasive testing. (*Level of Evidence: B*)

Class IIa

1. None.

Class IIb

1. Patients with recurrent hospitalizations for chest pain who have abnormal (but not high-risk) or equivocal findings on noninvasive testing. (*Level of Evidence: B*)

Class III

1. All other patients with nonspecific chest pain. (*Level of Evidence: C*)

Scanlon PJ, Faxon DP, Audet A-M, et al. ACC/AHA Guidelines for Coronary Angiography: Executive Summary and Recommendations. *Circulation* 1999;99:2345–2357. ©American Heart Association, Inc.

heparin is either discontinued almost immediately following the procedure or continued for 12 to 24 hours. Heparin administration during the procedure is measured with the activated clotting time, not the partial thromboplastin time. For patients undergoing percutaneous coronary intervention, aspirin, and clopidogrel are used prior to and following the procedure. Despite the invasive nature of the procedure, there are no data to support the need for prophylactic antibiotics in patients at risk for bacterial endocarditis because of valvular prostheses or a prior history of rheumatic fever. At present, the infectious risk of this procedure is extremely low. With the advent of classes IIb/IIIa receptor antagonists such as tirofiban, eptifibatide, and abciximab, which improve short- and long-term coronary artery patency rates with high-risk percutaneous coronary intervention, patients who receive a stent also will receive one of these agents prior to, during, and/or after the procedure. Abciximab is usually preferred.

During the procedure, hemodynamic parameters, blood pressure, and heart rate are monitored continuously. ECG monitoring and intermittent 12-lead ECGs are also maintained. Measurements taken during catheterization are obtained only after hemodynamic stabilization: at baseline, following catheter movement, or during pharmacologic intervention. Information obtained during catheterization is in real time and is assumed to reflect the ongoing status of the coronary circulation. Procedurally related vasospasm may be misleading because the catheter itself is a powerful stimulus for spasm.

Complications associated with cardiac catheterization procedures and attending angiographic or interventional activities are related to the expertise and experience of the operator, with case load being a good indicator of the latter. The incidence of significant complications related to catheterization with angiography is reported to be less than 2%, with mortality approximately 0.11%. Patient factors such as hemodynamic stability and renal function increase risk. There are no absolute contraindications to coronary angiography, and the relative contraindications are not well substantiated (Table 13-20). In essence, clinical stability of the patient and potential benefit of the procedure in terms of future patient management predicate the importance of relative contraindications. Complication rates, especially those of a thrombotic nature, increase with the dwell time of the catheters, duration of catheterization, catheter type, and operator technique. Bleeding complications can be reduced by ensuring that patients have normal coagulation studies prior to the procedure and remain at bedrest for several hours after the procedure, and that the nursing staff undertakes good care of the catheter entry and exit sites. In the event of bleeding complications, direct pressure is required with sandbags, followed by emergency surgery if there is no resolution, to prevent further complications. Heart perforation is an uncommon but potentially lethal complication requiring emergency surgical intervention. Other complications,

such as a vagal reflex with hypotension, bradycardia, and nausea, can occur. These occur most frequently in conjunction with patient anxiety and can be prevented or treated with atropine. An increased predisposition to myocardial infarction during and after the procedure is seen in patients with unstable angina, recent subendocardial infarction, and type 1 diabetes mellitus. After catheterization, patients may have elevated creatine phosphokinase and troponins as a consequence of tissue damage during the procedure. There is some controversy as to how to interpret these values with respect to what they indicate regarding myocardial damage. Acute closure of a coronary vessel or myocardial ischemia is managed by return to the catheterization laboratory or cardiac surgery. All facilities should be in close liaison with a cardiothoracic surgery unit.

Angiography, which accompanies most cardiac catheterization procedures, is defined as the “radiographic visualization of coronary vessels after injection of radiopaque contrast medium.” Despite the expanding role of cardiac catheterization, angiography is used most frequently to describe the presence and extent of CAD and to allow planning for medical or surgical intervention. Cardiac catheterization with angiography is the “gold standard” in the diagnosis and assessment of CAD, against which all new invasive and noninvasive tests are measured. Unlike most other procedures, angiography determines the morphology of a stenotic lesion and the degree of luminal obstruction. However, this does not relate well to physiologic or functional significance of the lesion.⁵⁹ For example, a 50% luminal occlusion not considered significant by radiologic standards may still be the lesion producing symptomatic chest pain, and a diabetic patient with significant microvascular CAD may appear to have unaffected larger arteries at angiography and yet still be at risk of a cardiac event. Angiography also assesses the presence of collateral circulation and dynamic abnormalities such as vasospasm.

The extent of disease by angiography is defined as the number of vessels, and the vessels affected are named. Angiography is able to detect lesions that occlude the vessel by as little as 20%. Occlusions of 75% or more are almost always seen on angiography. Significant narrowing is usually assumed to be 50% or more, although some studies use 70% narrowing as the cutoff point. The lesion can be measured in several ways. Considerable controversy exists as to the best methodology. During angiography, the lesion is compared visually with surrounding vessels. Inherent difficulties include individual evaluator variability and also the assumption that surrounding vessels are normal. Calipers can be used to document physical size, but generally, the degree of stenosis is reported as a percentage of narrowing. Various grading scales, such as the coronary artery score and myocardial jeopardy scores, are used, and these scores predict long-term outcomes. Coronary artery lesions most prone to rupture and thrombosis are those with 40% to 60% narrowing, so lesions with less than 50% narrowing are not benign.

Multiple views are required to obtain a good image of the vessel; the right anterior oblique planes are used most commonly (two views at 90° to each other). Lesions may be described as concentric and smooth (simple lesions) or eccentric and broad with a rough surface (complicated lesions). The number of lesions is also considered of importance to the severity and prognosis of IHD, although there is considerable variation in the accuracy of such predictions because angiographic and pathologic correlation of lesions is imperfect. The occurrence of spasm, variants in anatomy, and collateral filling also complicate interpretation of the angiogram.

Angiographic films are used to plan interventions, in particular coronary artery bypass grafting and percutaneous coronary intervention. They are also used during both surgery and percutaneous coronary intervention to guide the procedure. Ventriculographic studies may be performed during cardiac catheterization to obtain information about the contours of the heart and to assess global and segmental function. Regional wall motion, filling defects, and the

TABLE 13-20 Contraindications of Cardiac Catheterization and Other Procedures^a

Recent stroke	Patient noncompliance ^b
Advanced physiologic age	Digoxin intoxication
Severe anemia	Anaphylaxis to radiographic dyes
Severe hypertension	Active infection
Active gastrointestinal bleed	Severe electrolyte imbalances
Fever	Unstable condition
Other comorbid illnesses, e.g., COPD ^{c,d}	

COPD, chronic obstructive pulmonary disease; PTCA, percutaneous transluminal coronary angioplasty.

^aPrimarily contraindications to procedures such as arteriography and PTCA.

^bPatient not willing to undergo further treatment (e.g., surgery based on results of catheterization).

^cDisease states that may prohibit or increase risk of other interventions (e.g., surgery).

^dPatients in whom emergency cardiac surgery would pose a high risk (e.g., during acute asthma or acute exacerbation of COPD).

FIGURE 13-9. Intravascular ultrasound (IVUS) imaging demonstrating mild to severe atherosclerosis. Optical coherence tomography demonstrating a lipid pool inside of a plaque.

presence of mural thrombi also may be visualized. During this procedure, radiopaque dye is injected into the heart chambers, and serial films are taken to follow the dye passage. Left ventricular ventriculography is a routine part of left-sided catheterization unless ventricular function information is already available from other noninvasive studies or there are specific contraindications to the procedure.

Cardiac performance is also best assessed during catheterization procedures as direct visualization of performance along with calculated parameters that can be obtained simultaneously and represent real-time values. Measured and observed parameters obtained during catheterization are used to determine cardiac performance. Contractility, as judged by wall motion and ejection fraction, can be used to assess global cardiac performance and to plan and evaluate or assess therapy.

Invasive cardiology is growing rapidly not only in terms of the numbers of patients undergoing such procedures but also in terms of the diversity of procedures. The development of electrophysiologic studies for the assessment and treatment of arrhythmias was made possible because of catheterization. The diversity of techniques is “limited only by the imagination of the physician and inventiveness of the microtechnologist.”

INTRAVASCULAR ULTRASOUND

Intravascular ultrasound (IVUS) is a procedure that uses a very small ultrasound transducer on the tip of a coronary catheter to construct detailed images of the inner wall of a coronary artery. It combines braided polyethylene catheter technology with miniaturized ultrasound transducers that can be inserted into a variety of vascular beds within the body, including the coronary artery vasculature.^{60–63} Catheter configurations vary and may include over-the-wire, monorail, and fixed-guidewire tip configurations, resulting in different torqueability, steerability, and pushability characteristics for each type of catheter. There are two basic types of transducers: the solid-state phased array and a rotating mechanical transducer. In general, the phased-array transducers are smaller and may be mounted on more flexible catheters so that smaller vessels (such as

coronary arteries) can be visualized, but they require a more complex system for image reconstruction and show more artifacts in imaging. Recently, new software packages have allowed detailed images identifying calcium, fibrofatty, and lipid plaques. This could be a major advance in IVUS clinical use (Fig. 13–9).

In contrast to angiography, IVUS provides quantitative information from within the vessel on diameter, circumference, luminal diameter, plaque volume, and percent stenosis. Qualitative information regarding the amount of plaque stenosis, plaque composition (e.g., calcific, fibrous, or fatty plaque), and the presence of plaque versus thrombus, thrombus versus tumor, and aneurysm and hematoma can be provided by IVUS. IVUS is also used as a therapeutic adjunct with PTCA, atherectomy, stent or graft placement, and fibrinolysis, although routine use may not be justified. These combination procedures may be monitored in real time as the procedure (e.g., atherectomy) is being performed. In current trials, IVUS has been very helpful in evaluation of disease progression or regression. Many current trials are underway to test medication for atherosclerosis regression, plaque morphology changes and other.⁶⁶

Another new development in imaging the inner wall of the coronary is the recently developed, intravascular optical coherence tomography providing high-resolution, cross-sectional images of tissue with an axial resolution of 10 microns and a lateral resolution of 20 microns.⁶³ Optical coherence tomography images of human coronary atherosclerotic plaques are much more structurally detailed than IVUS.⁶³ Clinically, the detection of thin fibrous caps (vulnerable atheromas) (<65 microns) is below the resolution of the current 40-MHz IVUS (100 to 200 microns).⁶⁰ A summary of tests used in cardiovascular medicine is provided in Appendices 13–1 and 13–2.

JEFFREY F. BARLETTA AND JEFFREY L. WILT

KEY CONCEPTS

- 1 High-quality cardiopulmonary resuscitation (CPR) with minimal interruptions in chest compressions should be emphasized in all patients following cardiac arrest.
- 2 Chest compressions before a defibrillation attempt might be warranted especially with cardiac arrests that are not witnessed.
- 3 The purpose of using vasopressors following cardiac arrest is to increase both coronary and cerebral perfusion pressures.
- 4 Either epinephrine or vasopressin is an appropriate drug of first choice in patients with ventricular fibrillation (VF)/pulseless ventricular tachycardia (PVT).
- 5 Amiodarone is preferred over lidocaine as the antiarrhythmic drug of choice in patients with VF/PVT.
- 6 Therapy for pulseless electrical activity (PEA) or asystole is aimed at identifying the precipitating cause of the arrest.
- 7 Intraosseous administration is the preferred alternative for drug delivery if intravenous access cannot be obtained.

INTRODUCTION

Cardiopulmonary arrest is the abrupt cessation of spontaneous and effective ventilation and circulation following a cardiac or respiratory event.¹ CPR provides artificial ventilation and circulation until it is possible to provide advanced cardiac life support (ACLS) and reestablish spontaneous circulation. In the United States, there are more than 460,000 victims of sudden cardiac arrest each year with most occurring outside the hospital.²⁻⁴ The annual incidence of sudden cardiac arrest has been estimated to be approximately 0.55 per 1,000 population and in the United States, sudden cardiac death represents up to 15% of total mortality.⁵⁻⁷

Early attempts at resuscitation date back to the biblical era.⁸ Modern-day resuscitation began in the late 1950s when it was discovered that expired air delivered via a mouth-to-mouth technique can maintain adequate oxygenation of blood.⁹ Later, in 1960, Kouwenhoven and colleagues described “closed chest cardiac massage,” and together with mouth-to-mouth ventilation, modern-day CPR was born.¹⁰

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

EPIDEMIOLOGY

In an adult patient, cardiopulmonary arrest usually results from the development of an arrhythmia.¹¹ Most cardiac arrests take place outside the hospital, and most patients have underlying acute or chronic heart disease.⁶ In more than two-thirds of patients, cardiac arrest occurs as the first manifested clinical event with no preceding symptoms or warning.^{6,12} Although the most common arrhythmia is either VF or PVT, the number of patients with out-of-hospital cardiac arrests presenting with VF as the initial rhythm has changed dramatically.^{4,13} In one study, the number of patients with VF was 61% in 1980 compared with only 41% in 2000, a reduction of greater than 30%.¹³ A similar trend was noted with in-hospital cardiac arrest as one study reported the number of patients presenting with VF or PVT as the initial rhythm to be only 23%.¹⁴ Hospital survival for in-hospital cardiac arrest related to VF or PVT is approximately 36% with 75% having a good neurologic outcome.¹⁴ Survival for out-of-hospital cardiac arrest caused by VF or PVT is 25% to 40%, with higher survival rates being observed in communities that have a rapid response system.^{6,15,16}

In contrast to adult patients, only 15% of pediatric patients present with VF or PVT as the initial rhythm.² This is probably because most pediatric arrests are respiratory-related as opposed to the primary cardiac etiology seen in adult patients. Unfortunately, survival following pediatric out-of-hospital cardiopulmonary arrest ranges only from 2% to 10%, with most survivors having a poor neurologic status.²

ETIOLOGY

The most common cause of cardiopulmonary arrest in adult patients is an acute myocardial infarction (MI) or pulmonary embolism (PE) representing more than 70% of victims.¹⁷ In pediatric patients, conversely, cardiopulmonary arrest is often the terminal event of progressive shock or respiratory failure.² The cause of cardiac arrest varies with age, the underlying health of the child, and the location of the event. Out-of-hospital arrests frequently are associated with events such as trauma, sudden infant death syndrome, drowning, poisoning, choking, severe asthma, and pneumonia.³ In-hospital pediatric arrests are associated with sepsis, respiratory failure, drug toxicity, metabolic disorders, and arrhythmias. Pediatric out-of-hospital arrest generally presents with hypoxia and hypercarbia progressing to respiratory arrest and bradycardia and finally to asystolic cardiac arrest.

PATHOPHYSIOLOGY OF CPR

There are two proposed theories describing the mechanism of blood flow during CPR.^{1,18,19} The first theory, known as the cardiac pump

theory, states that the active compression of the heart between the sternum and vertebrae creates an “artificial systole” in which intraventricular pressure increases, the atrioventricular valves close, the aortic valve opens, and blood is forced out of the ventricles. When ventricular compression ends, the decline in intraventricular pressure causes the mitral and tricuspid valves to open, and ventricular filling begins. The second, more recent theory is the thoracic pump theory. The basis for this theory is the belief that blood flow results from intrathoracic pressure alterations induced by chest compressions. During compression or systole, a pressure gradient develops between the intrathoracic arteries and the extrathoracic veins, causing forward blood flow from the lungs into the systemic circulation. The heart merely acts as a passive conduit for flow. After compression ends, or diastole, intrathoracic pressure declines, and blood flow returns to the lungs.

The concept of cough CPR supports the importance of changes in intrathoracic pressure as a means of generating forward blood flow.^{18,19} During vigorous coughing, intrathoracic pressures increase secondary to contractions of the diaphragm, abdominal muscles, and intracostal muscles. These pressure changes occur without direct chest compression and are sufficient to maintain consciousness. The observation that cough alone can maintain consciousness led many investigators to question the cardiac pump theory and accept the thoracic pump theory. In reality, it is likely that both models apply to the mechanism of blood flow during CPR.¹⁹

CLINICAL PRESENTATION

Symptoms

- Anxiety, change in mental status or unconscious
- Cold, clammy extremities
- Dyspnea, shortness of breath or no respiration
- Chest pain
- Diaphoresis
- Nausea and vomiting

Signs

- Hypotension
- Tachycardia, bradycardia, irregular or no pulse
- Cyanosis
- Hypothermia
- Distant or absent heart and lung sounds

TREATMENT

Cardiopulmonary Resuscitation

■ DESIRED OUTCOME

The goal of CPR is the return of spontaneous circulation (ROSC), with effective perfusion (and similarly, ventilation) as quickly as possible to minimize hypoxic damage to vital organs. It is not sufficient to restore spontaneous circulation if the patient is left neurologically devastated or incurs severe morbidity in the process. Factors proven to enhance survival to hospital discharge include the occurrence of a witnessed arrest, rapid implementation of bystander CPR, presence of VF as the initial rhythm, and early defibrillation therapy for VF.^{4,20} In one report, the rate of survival to hospital discharge was 74% when defibrillation was performed within 3 minutes of a witnessed cardiac arrest compared with 49% when defibrillation was performed after 3 minutes ($P = 0.02$).²¹

Several patient-specific factors exist that can affect resuscitation survival, but few have been evaluated in clinical trials. In one study,

a 3% decrease in survival was noted for each 1-year increment in age.²² Other proposed risk factors include concomitant diseases, initial pH, duration of resuscitation, and end-tidal carbon dioxide.¹¹

■ GENERAL APPROACH TO TREATMENT

National conferences and organized committees have played a major role in encouraging widespread competency in CPR technique. The first national conference took place in 1966 and recommended the training of healthcare professionals in the techniques of CPR.⁸ Since then, the American Heart Association (AHA) has organized seven additional national conferences to update philosophies for providing CPR and emergency cardiovascular care (ECC) to the general population. The most recent conference was held in 2005, which provides the latest set of recommendations for CPR and ECC.²

The Guidelines 2005 Conference recommendations were built on the same edifice that led to the ECC 2000 guidelines in that they are internationally developed as well as evidence-based. The classification system used was consistent with that used by the AHA/American College of Cardiology for evidence-based guidelines [i.e., class I through class III or indeterminate (Table 14–1)]. These guidelines differ from previous years although, as they have been streamlined to simplify the treatment algorithms, to reduce the amount of information clinicians need to learn, and to clarify the most important issues. Additionally, a new process for disclosure and conflicts of interest was implemented.

The AHA continues to use the “chain of survival” to highlight the treatment approach and illustrate the importance of a timely response.² Based on the concept that “a chain is only as strong as its weakest link,” each element in the chain is essential for a successful resuscitation outcome. The four links of the chain of survival are as follows:

1. Early recognition of the emergency and activation of emergency medical services (EMS)
2. Early bystander basic life support (BLS) and CPR
3. Early delivery of a shock with a defibrillator
4. Early ACLS followed by postresuscitation care delivered by healthcare professionals

Although all four links of the chain of survival are important, the most crucial may be the first three, particularly early CPR.² Cardiopulmonary resuscitation provides critical blood flow to the heart and brain, prolongs the time VF is present (prior to the deterioration to asystole), and increases the likelihood that a shock will terminate VF resulting in a rhythm compatible with life.² In one study of out-of-hospital cardiac arrest, early recognition of cardiac arrest (odds ratio [OR] 4.4, 95% confidence interval [CI] 3.1–6.4), early CPR (OR 3.7, 95% CI 2.5–5.4), and defibrillation within 8 minutes (OR 3.4, 95% CI 1.4–8.4) were associated with an increase in survival to hospital discharge.²⁰ Advanced cardiac life support, conversely, did not improve survival (OR 1.1, 95% CI 0.8–1.5).¹ Henceforth, the guidelines for CPR and ECC emphasize the provision of high-quality CPR with minimal interruptions in chest compressions.² The use of drug therapy as part of ACLS, however, has evolved to a minimal role because survival to hospital discharge does not appear to be impacted.

GENERAL MANAGEMENT OF CARDIAC ARREST

■ BASIC LIFE SUPPORT

The general management of cardiac arrest is based on algorithms developed by the AHA, and are published for widespread dissemination.

TABLE 14-1 Evidence-Based Treatment Recommendations

Recommendations	Recommendation (Grades)
Immediate bystander CPR High-quality CPR should be performed with minimal interruption in chest compressions and defibrillation as soon as it can be accomplished.	Class I
Epinephrine 1 mg IV/IO should be administered every 3 to 5 minutes in patients with VF, PVT, PEA, or asystole.	Class IIb
Vasopressin 40 units IV/IO can replace either the first or second dose of epinephrine in patients with VF, PVT, or asystole. There is insufficient evidence to recommend either for or against its use in PEA.	Class indeterminate
Amiodarone 300 mg IV/IO can be followed by 150 mg IV/IO in patients with VF/PVT unresponsive to CPR, shock, and a vasopressor.	Class IIb
Lidocaine Lidocaine can be considered an alternative to amiodarone in patients with VF/PVT. The initial dose is 1 to 1.5 mg/kg IV. Additional doses of 0.5 to 0.75 mg/kg can be administered at 5 to 10 minute intervals to a maximum dose of 3 mg/kg if VF/PVT persists.	Class indeterminate
Magnesium Magnesium is recommended for VF/PVT that is caused by torsade de pointes. 1 to 2 g diluted in 10 mL D5W should be administered IV/IO push over 5 to 20 minutes. Clinical studies have not demonstrated a benefit when magnesium was routinely administered during CPR when torsade de pointes was not present.	Class IIa
Fibrinolysis Thrombolytics should be considered on a case-by-case basis when pulmonary embolism is suspected.	Class IIa
Hypothermia Hypothermia should be implemented in unconscious adult patients with ROSC after out-of-hospital cardiac arrest when the initial rhythm was VF. These patients should be cooled to 32°C (89.6°F) to 34°C (93.2°F) for 12 to 24 hours.	Class IIa
Hypothermia may be beneficial for patients with non-VF arrest out-of-hospital or for in-hospital cardiac arrest.	Class IIb
Atropine Atropine 1 mg IV/IO every 3 to 5 minutes (maximum total of 3 doses or 3 mg) can be considered for patients with asystole or PEA.	Class indeterminate

CPR, cardiopulmonary resuscitation; D5W, 5% dextrose in water; IO, intraosseous; IV, intravenous; PEA, pulseless electrical activity; PVT, pulseless ventricular tachycardia; ROSC, return of spontaneous circulation; VF, ventricular fibrillation.

Key for evidence-based classifications²:

Class I: High-level prospective studies support the action or therapy and the benefit substantially outweighs the potential for harm. The treatment should be administered.

Class IIa: The weight of evidence supports the action or therapy, and the therapy is considered acceptable and useful. It is reasonable to administer the treatment.

Class IIb: The evidence documented only short-term benefits, or positive results were documented with lower levels of evidence. Class IIb recommendations can be considered either optional or recommended by experts despite the absence of high-level supporting evidence.

Class III: The risk outweighs the benefit for a particular treatment. The treatment should not be administered and can be harmful.

Class indeterminate: This is either a continuing area of research or an area where research is just beginning. No recommendation (either for or against) can be made.

nation.² The initial algorithm is BLS, and the first action is to determine responsiveness of the patient. If there is no response, the rescuer should immediately activate the emergency medical response team, and obtain an automated external defibrillator (AED) if one is available. Next, the victim's airway should be opened, with an assessment of effective breathing. If the victim is not breathing, then two rescue breaths should be administered.

Subsequent to this, the rescuer should determine if there is an effective pulse. If there is an effective pulse, then rescue breathing with frequent assessments of effective circulation should be continued until help arrives. If there is no pulse, then chest compressions need to be immediately instituted. The recommended rate is 100 beats/min, with cycles of 30 compressions followed by 2 rescue breaths. The 2005 guidelines for CPR and ECC stress that there should be minimal interruptions in chest compressions. If there is no AED available, then cycles of compressions/breaths should continue, with pulse checks every 2 minutes (5 cycles) until help arrives or the patient regains spontaneous circulation. If there is an AED available, then the rhythm should be checked to determine if defibrillation is advised. If so, then one shock should be delivered with the immediate resumption of chest compressions/rescue breaths. After five cycles, the rhythm should be reevaluated to determine the need for defibrillation. This algorithm should be repeated until help arrives, or the rhythm is no longer "shockable." If the rhythm is not shockable, then chest compressions/rescue breath cycles should be continued until help arrives, or the victim recovers spontaneous circulation (Fig. 14-1).

■ ADVANCED CARDIAC LIFE SUPPORT

Once ACLS providers arrive, then further definitive therapy is given. If the rhythm is not shockable, then it is likely to be either asystole or pulseless electrical activity (PEA) (Fig. 14-2). The general management of these rhythms is CPR and pharmacologic therapy as listed below. For PEA, the rescuer must consider reversible causes (Table 14-2). If the person is in VF or PVT, then one shock should be delivered (appropriate to the available electrical device), with the immediate resumption of 30 compressions and 2 breaths for 5 cycles prior to rechecking the rhythm or pulse. If there is still a shockable rhythm, then one shock should be delivered and at this time pharmacologic intervention can be considered. After the first unsuccessful shock, vasopressors are the initially recommended pharmacologic intervention (before or after the second shock), and after the second unsuccessful shock, antiarrhythmics can be considered (before or after the third shock). Five cycles of chest compressions/breaths should be performed in between attempts at defibrillation. This algorithm will repeat until either a pulse is obtained with effective circulation, the rhythm changes, or the patient expires. For completeness, please refer to the guidelines published by the AHA.²

VENTRICULAR FIBRILLATION/ VENTRICULAR TACHYCARDIA

■ NONPHARMACOLOGIC THERAPY

Electrical defibrillation is the only effective method of restoring a perfusing cardiac rhythm, therefore it is a crucial link in the "chain of survival" especially for a witnessed arrest.² The probability of successful defibrillation is directly related to the time interval between the onset of VF and the delivery of the first shock.² Generally, with each passing minute, the rate of survival decreases by 8% to 10% when CPR is not provided.²³ In one study, a 23% relative improvement in survival was observed with each 1-minute reduction in the time to defibrillation (OR 0.77, 95% CI 0.73–0.81).²⁴

② Although early defibrillation is crucial for survival following cardiac arrest, several studies have suggested that CPR prior to defibrillation can lead to more successful outcomes.²³ One study (published after the 2005 guidelines) cites the concept of "cardio-cerebral" resuscitation, based on applying appropriate cardiac resuscitation principles to the three phases of cardiac arrest: First, the "electrical" phase (0–4 minutes) when defibrillation is most likely to

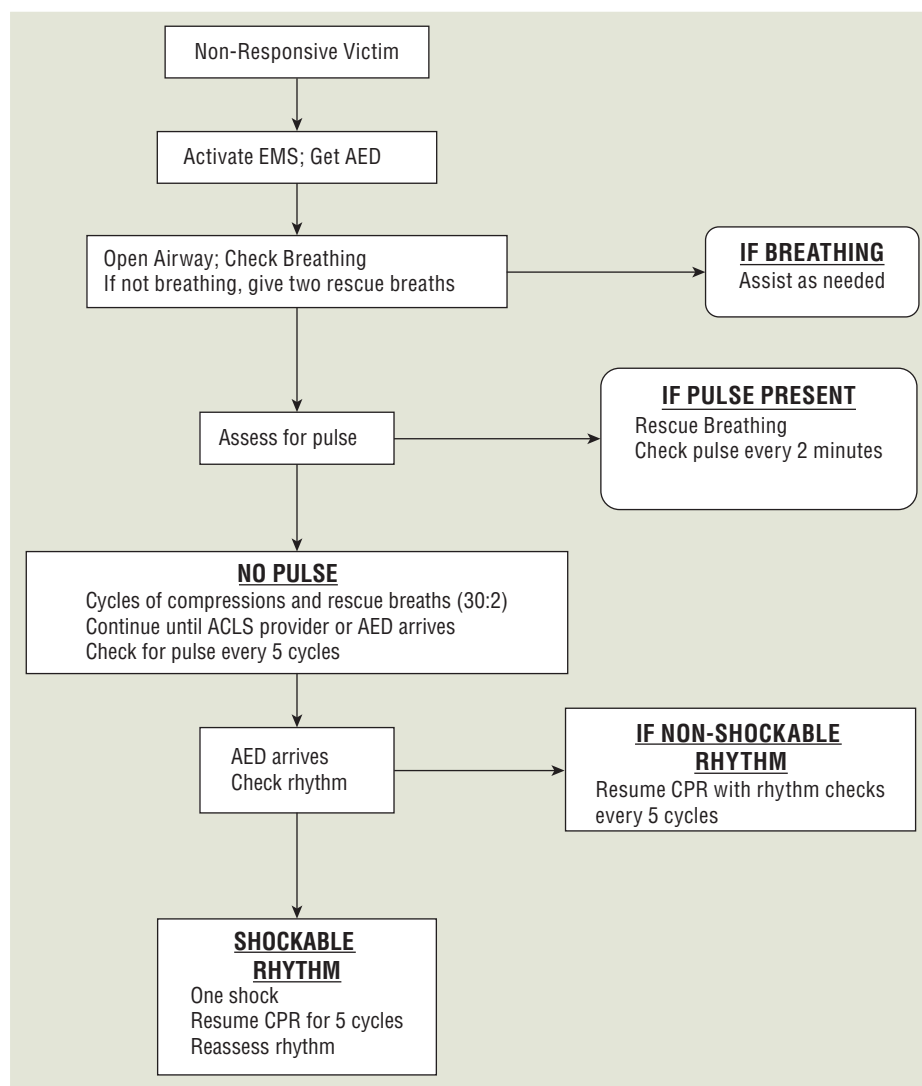

FIGURE 14-1. Treatment algorithm for adult cardiopulmonary arrest. (BLS, basic life support.)

be effective; second, the “circulatory” phase (4–10 minutes or longer) where adequate coronary or cerebral perfusion prior to defibrillation is likely to be helpful; and, third, the “metabolic” phase (greater than 10 minutes) in which survival is very low, and hypothermia is likely to be the most beneficial approach.^{23,25} Using a protocol where each defibrillation, including the first, was preceded by 200 uninterrupted chest compressions, an increase in total survival (57% [19/33] vs. 20% [18/92], $P = 0.001$) and neurologically normal survival (48% [16/33] vs. 15% [14/92], $P = 0.001$) was noted compared to standard CPR practices.²⁵

Other clinical trials have evaluated the impact of delaying defibrillation to allow for CPR in patients with out-of-hospital VF.^{26,27} In one trial, the provision of roughly 90 seconds of CPR prior to defibrillation was associated with an increased rate of hospital survival (compared with a historical control group) when response intervals were 4 minutes or longer (27% vs. 17%; $P < 0.007$).²⁶ In a second trial, hospital survival rates were higher in patients with response intervals greater than 5 minutes when 3 minutes of CPR was administered prior to defibrillation (22% vs. 4%; $P = 0.006$).²⁷

Collectively, these trials support the theory of a three-phase time-sensitive model for resuscitation after cardiac arrest mentioned above. Successful defibrillation most likely will occur when cardiac arrest victims are in the electrical phase because there is enough tissue oxygenation still present to support metabolic demands. Conversely, when cardiac arrest victims are in the circulatory phase, global ischemia has already occurred, and immediate defibrillation

could lead to asystole. It can be more important to first provide some blood flow and cardiac perfusion via CPR to “flush out” the deleterious metabolic factors that have accumulated during ischemia.²³ Because of this, the recent guidelines offer that EMS personnel can give 2 minutes of chest compressions prior to attempting defibrillation. Recommendations are similar for victims in the metabolic phase recognizing the likelihood of achieving ROSC, however, is drastically lower. Further trials are needed to evaluate this resuscitation technique.²⁵

As opposed to the previous guidelines, where “stacked,” multiple shocks were initially given, persons in VF or PVT should receive electrical defibrillation with one shock.² The defibrillation attempt should be with 360 joules (monophasic defibrillator) or 150 to 200 joules (biphasic defibrillator). Automatic external defibrillators are reliable, computerized defibrillators that can be useful for both healthcare providers and lay personnel. These devices are effective, easy to use, and have led to the development of public access defibrillation programs in many communities.^{15,28} When an arrest is witnessed, and AED is immediately available, it should be used as soon as possible. However, CPR should be started immediately (after EMS activation), as the AED is being prepared. If early CPR is provided to a witnessed VF arrest, and defibrillation is able to be provided within 3 to 5 minutes, survival rates have been reported to be as high as 41% to 74%.^{2,15,21,29–31}

After defibrillation is attempted, CPR should be immediately restarted and continued for 2 minutes without checking a pulse.

TABLE 14-2 Potentially Reversible Causes of PEA and Asystole (Think: 6 H's; 6 T's)

Condition	Clues	Treatment
Hypovolemia	History, flat neck veins	Intravenous fluids
Hypoxia	Cyanosis, blood gases, airway problems	Ventilation, oxygen
Hydrogen ion (acidosis)	History of bicarbonate-responsive preexisting acidosis	Sodium bicarbonate, hyperventilation
Hyper (Hypo) kalemia	History of renal failure, diabetes, recent dialysis, dialysis fistulas, medications	Calcium chloride, insulin, glucose, sodium bicarbonate, sodium polystyrene sulfonate, dialysis
Hypothermia	History of exposure to cold, central body temperature	Rewarming, oxygen, intravenous fluids
Hypoglycemia	History of diabetes	Glucose infusion
Toxin (Drug overdose)	Bradycardia, history of ingestion, empty bottles at the scene, pupils, neurologic exam	Drug screens, intubation, lavage, activated charcoal
Tamponade (Cardiac)	History (trauma, renal failure, thoracic malignancy), no pulse with CPR, vein distension, impending tamponade-tachycardia, hypotension, low pulse pressure changing to sudden bradycardia as terminal event	Pericardiocentesis
Tension pneumothorax	History (asthma, ventilator, chronic obstructive pulmonary disease, trauma), no pulse with CPR, neck vein distension, tracheal deviation	Needle decompression
Thrombosis, coronary	History, ECG, enzymes	Thrombolytics, oxygen, nitroglycerin, heparin, aspirin, morphine
Thrombosis, pulmonary	History, no pulse with CPR, distended neck veins	Pulmonary arteriogram, surgical embolectomy, thrombolytics
Trauma	History, examination	Volume infusion, intracranial pressure monitoring, bleeding control, surgical intervention

CPR, cardiopulmonary resuscitation; ECG, electrocardiogram; PEA, pulseless electrical activity.

Data from American Heart Association² and Ornato and Peberdy.⁴

The omission of the pulse check after defibrillation is a paradigm shift in the algorithm, and is related to myocardial stunning with resultant poor perfusion and diminished cardiac output immediately after electrical therapy.² After 2 minutes of chest compressions, the rhythm and pulse should be rechecked. If there is still evidence of VF or PVT, then pharmacologic therapy with repeat attempts at single-discharge defibrillation should be attempted.

Endotracheal intubation and intravenous (IV) access should be obtained when feasible, but not at the expense of stopping chest compressions. The 2005 guidelines for CPR and ECC strongly stress the need for uninterrupted CPR.² Once an airway is achieved, patients should be ventilated with 100% oxygen. The recent guidelines suggest that lower tidal volumes and rates can be beneficial.² There are several airway adjuncts that are potentially available, such as laryngeal mask airways and esophageal-tracheal combination tubes. However, the definitive airway is an endotracheal tube placed with direct laryngoscopy.

■ PHARMACOLOGIC THERAPY

Sympathomimetics

The use of sympathomimetics is a major part of drug therapy in CPR. Animal studies have demonstrated that coronary perfusion pressures above 30 mm Hg are associated with adequate forward blood flow and improved survival.³² In humans, even with properly performed chest compressions, coronary perfusion pressures are only 10 to 15 mm Hg, the systolic arterial pressure is rarely above 80 mm Hg, the diastolic pressure is low, and the carotid mean pressure

is rarely above 40 mm Hg.^{2,33} Although this amount of pressure is often enough to provide vital perfusion and oxygenation, sympathomimetic therapy is indicated to augment both the coronary and cerebral perfusion pressures seen during this low-flow state.

Epinephrine continues to be a drug of first choice for the treatment of VF, PVT, asystole, and PEA despite a paucity of evidence demonstrating improved survival in humans² (Table 14-3). Epinephrine is both an α - and β -receptor agonist, although its effectiveness is primarily through its α effects. The β effects can in fact be harmful as β -stimulation increases myocardial oxygen demand and can increase the severity of postresuscitation myocardial dysfunction.³⁴ This has led some investigators to evaluate simultaneous β -blocker administration in conjunction with sympathomimetic therapy using an animal model.^{32,35,36} Unfortunately, these studies have produced mixed results.

Several studies have compared the effects of pure α_1 -agonists, such as phenylephrine and methoxamine, with epinephrine as these agents lack any β -activity.^{37,38} These studies have shown the use of α_1 -agonists to have no long-term survival advantage over epinephrine. One reason that selective α_1 -agonists are not superior to epinephrine is related to the α_2 effects. Agents that have potent α_2 effects (e.g., epinephrine and norepinephrine) can be more effective because the α_2 -adrenergic receptors lie extrajunctionally in the intima of the blood vessels, making them more accessible to circulating catecholamines—even in low-flow states that occur during CPR.³⁸ Furthermore, during ischemia, the number of postsynaptic α_1 -receptors decreases, which suggests a greater role for α_2 -agonist activity during CPR.³⁹

Several investigators have compared norepinephrine with epinephrine in both human and animal models.^{33,40–43} Norepinephrine is a potent α -agonist (both α_1 and α_2) but also has β_1 -agonist effects. In the only large-scale randomized, double-blind, prospective trial that compared norepinephrine with epinephrine in the prehospital cardiac arrest setting, there were no significant differences in ROSC (norepinephrine, 13% [35:260] vs. epinephrine, 8% [22:270]; $P = 0.19$), hospital admission (norepinephrine, 13% [36:260] vs. epinephrine, 10% [27:270]; $P = 0.37$), or discharge (norepinephrine, 2.6% [7:260] vs. epinephrine, 1.2% [3:270]; $P = 0.37$).⁴¹ A second, smaller study demonstrated higher resuscitation rates with norepinephrine compared to epinephrine (64% [16:25] vs. 32% [8:25]) but no significant difference in hospital discharge.⁴² Consequently, epinephrine remains the first-line sympathomimetic for CPR.

The recommended dose for epinephrine is 1 mg administered by intravenous (IV) or by intraosseous (IO) injection every 3 to 5 minutes.² This epinephrine dose was derived from animal studies (0.1 mg/kg in a 10-kg dog) and equates to approximately 0.015 mg/kg for a 70-kg human.⁴⁴ Both animal and human studies have demonstrated a positive dose-response relationship with epinephrine suggesting that higher doses might be necessary to improve hemodynamics and achieve successful resuscitation.^{45–48} These results, however, have not been replicated in human studies^{41,49–56} (see Table 14–3). Collectively, these studies have shown that high-dose epinephrine can increase the initial resuscitation success rate, but that overall survival is not significantly different. The discrepancy between animal and human studies can be caused by the fact that most victims of cardiac arrest have coronary artery disease, a condition not present in an animal model. In a human model, however, atherosclerotic plaques can aggravate the balance between myocardial oxygen supply and demand. Moreover, the interval from arrest to treatment in animal studies is shorter than the interval frequently reported in human studies. Because time to CPR and defibrillation are crucial variables for success, prolonging this time period can lower resuscitation rates.

Vasopressin

Vasopressin, also known as *antidiuretic hormone*, is a potent, non-adrenergic vasoconstrictor that increases blood pressure and sys-

temic vascular resistance. Although it acts on various receptors throughout the body, its vasoconstrictive properties are caused primarily by its effects on the V_1 receptor.⁵⁷ Measurement of vasopressin levels in patients undergoing CPR has shown a high correlation between the levels of endogenous vasopressin released and the potential for ROSC.⁵⁸ In fact, in one study, plasma vasopressin concentrations were approximately three times as high in survivors compared with nonsurvivors, suggesting that vasopressin is released as an adjunct vasopressor to epinephrine in life-threatening events such as cardiac arrest.⁵⁹

Vasopressin may have several advantages over epinephrine. First, the metabolic acidosis that frequently accompanies cardiopulmonary arrest can blunt the vasoconstrictive effect of adrenergic agents such as epinephrine. This effect does not occur with vasopressin. Second, the stimulation of β -receptors caused by epinephrine can increase myocardial oxygen demand and complicate the postresuscitative phase of CPR. Because vasopressin does not act on β -receptors, this effect does not occur with its use. Vasopressin also can have a beneficial effect on renal blood flow by stimulating V_2 receptors in the kidney, causing vasodilation and increased water reabsorption. With regard to splanchnic blood flow, however, vasopressin has a detrimental effect when compared to epinephrine.⁶⁰

Clinical experience with vasopressin in humans is limited, and comparative trials evaluating vasopressin and epinephrine have produced mixed results⁵⁷ (Table 14–4). Potential reasons include the setting in which cardiac arrest was evaluated (in-hospital versus out-of-hospital), variability in the quality of CPR performed, the average time from collapse to study drug administration, and the number of patients presenting with VF as the initial rhythm.

In the largest comparative trial with vasopressin and epinephrine for out-of-hospital cardiac arrest conducted to date, no significant differences were noted in ROSC, hospital admission rate, or discharge rate.⁶¹ Furthermore, when patients were stratified according to their initial presenting rhythm, no significant differences were noted for patients with VF or PEA. Interestingly, patients with asystole had a significantly higher rate of hospital admission (29% vs. 20%; $P = 0.02$) and discharge (4.7% vs. 1.5%; $P = 0.04$) when vasopressin was administered compared with epinephrine. In addition, a subgroup analysis of 732 patients who required additional

^aAll study groups received epinephrine following the initial study drug.

^b $P < 0.05$.

Data from Wenzel et al.,⁶¹ Guyette, et al.,¹⁰⁹ Lindner et al.,¹¹⁰ Stiell et al.,¹¹¹ and Grmec, et al.¹¹²

epinephrine therapy despite the two doses of study drug revealed significant benefits in ROSC (37% vs. 26%; $P = 0.002$), hospital admission rate (26% vs. 16%; $P = 0.002$), and discharge rate (6.2% vs. 1.7%; $P = 0.002$) with vasopressin. There was a trend, however, toward a poorer neurologic state or coma among the patients who survived to discharge and received vasopressin.

The effectiveness of vasopressin for cardiac arrest has also been evaluated in a systematic review/meta-analysis.⁶² No significant differences were noted between vasopressin and epinephrine in failure of ROSC (relative risk [RR] 0.81, 95% CI 0.58–1.12), death before hospital admission (RR 0.72, 95% CI 0.38–1.39), death within 24 hours (RR 0.74, 95% CI 0.38–1.43) or death before hospital discharge (RR 0.96, 95% CI 0.87–1.05). Similarly, no differences were noted in death before hospital discharge when patients were stratified according to their initial rhythm (VF/PVT, RR 0.97, 95% CI 0.79–1.19; PEA, RR 1.02, 95% CI 0.95–1.10; asystole, RR 0.97, 95% CI 0.94–1.00).

4 Overall, these studies suggest that vasopressin is effective as part of ACLS following cardiac arrest, but its superiority to epinephrine remains questionable. Vasopressin can be more beneficial when used for out-of-hospital cardiac arrests, arrests secondary to asystole, or situations when the effect of catecholamines may be diminished because of profound acidosis than when it is used for in-hospital cardiac arrest secondary to VF or PVT. Further research is needed to define the role of vasopressin in cardiac arrest.

Antiarrhythmics

The purpose of antiarrhythmic drug therapy following unsuccessful defibrillation and vasopressor administration is to prevent the development or recurrence of VF and PVT by raising the fibrillation threshold. Clinical evidence demonstrating improved survival to hospital discharge, however, is lacking. As the role of antiarrhythmics during CPR remains limited, only two individual agents are currently recommended in the 2005 guidelines for CPR and ECC: amiodarone and lidocaine.

The use of lidocaine has been beneficial in animal studies and in patients with arrhythmias following an acute myocardial infarction, but its benefit in cardiac arrest remains questionable. In the only published case-control trial where patients were classified according to whether they received lidocaine, no significant difference was noted in ROSC, admission to the hospital, or survival to hospital discharge between groups.⁶³ Similarly, a prospective study comparing the effectiveness of lidocaine with that of standard-dose epinephrine showed not only a lack of benefit with lidocaine but also a higher tendency to promote asystole.⁶⁴ In contrast, a retrospective analysis in patients with VF indicated that lidocaine was associated with a higher rate of ROSC and hospitalization ($P < 0.01$) but not an increase in the hospital discharge rate.⁶⁵

Amiodarone is classified as a class III antiarrhythmic but possesses electrophysiologic characteristics of all four Vaughan Williams classifications. The most frequent adverse effect is hypotension, which has occurred in approximately 20% of clinical trials. This hypotension appears to be related to the diluent used for the amiodarone solution (i.e., polysorbate 80) and the rate of IV administration. An aqueous formulation is available, which has not been associated with these deleterious effects.⁶⁶

In a large, randomized, double-blind trial in out-of-hospital cardiac arrest secondary to VF or PVT, patients were randomized to receive either amiodarone 300 mg or placebo.⁶⁷ Recipients of amiodarone were more likely to be resuscitated and survive to hospital admission than were recipients of placebo (44% and 34%, respectively; $P = 0.03$) for a relative improvement of 29%. There was no difference in survival to hospital discharge for those patients who received amiodarone compared to placebo (13.4% vs. 13.2%, respectively; $P =$ not significant). This was the first trial to demon-

strate the benefit of an antiarrhythmic agent over placebo in patients with out-of-hospital cardiac arrest.

A subsequent trial compared amiodarone 5 mg/kg with lidocaine 1.5 mg/kg in patients with out-of-hospital cardiac arrest caused by VF.⁶⁸ In this trial, amiodarone was associated with a relative improvement of 90% in survival to hospital admission compared with lidocaine (22.8% vs. 12%; OR 2.17, 95% CI 1.21–3.83; $P = 0.009$). Similar to the previous trial, there was no difference in survival to hospital discharge (amiodarone, 5% vs. lidocaine, 3%; $P = 0.34$).

Amiodarone and lidocaine have also been compared following in-hospital cardiac arrest secondary to VF or PVT. In a multicentered, retrospective review, 194 patients who received amiodarone ($n = 74$), lidocaine ($n = 79$), or both ($n = 41$) were evaluated.⁶⁹ The rate of survival at 24 hours was 55%, 63%, and 50% for patients receiving amiodarone, lidocaine, or both, respectively ($P = 0.39$). There was no difference in survival to hospital discharge (39% for amiodarone, 45% for lidocaine, and 42% for patients receiving both agents; $P = 0.72$). After adjusting for multiple covariates, Cox regression analysis revealed higher mortality for those patients who received amiodarone (as opposed to lidocaine) (survival to 24 hours: hazard ratio 3.15, 95% CI 1.68–5.92, $P < 0.001$; survival to hospital discharge: hazard ratio 3.25, 95% CI 1.22–8.65, $P = 0.02$) and in those patients with VF/PVT as the initial rhythm (as opposed to bradycardia followed by VF/PVT) (survival to 24 hours: hazard ratio 3.36, 95% CI 1.98–5.71, $P < 0.001$; survival to hospital discharge: hazard ratio 3.6, 95% CI 1.2–10.6, $P = 0.021$). The mean initial dose of amiodarone, however, was 190 mg, and only 25% of patients received the recommended dose of 300 mg. Additionally, the time to first dose of antiarrhythmic was significantly longer in the amiodarone group than in the lidocaine group (14 minutes vs. 6 minutes, $P < 0.001$). Although these differences could have biased the results in favor of lidocaine, they provide a “real-world” experience with the use of amiodarone. Further large-scale trials are needed to determine the preferred antiarrhythmic for both in-hospital and out-of-hospital cardiac arrest. 5 In the meantime, amiodarone remains the preferred antiarrhythmic during cardiac arrest according to the 2005 guidelines for CPR and ECC with lidocaine considered as an alternative.²

Thrombolytics

Because most cardiac arrests are related to either MI or PE, several investigators have evaluated the role of thrombolytics during CPR. Several studies have demonstrated successful use of thrombolytics, but few have shown improvements to hospital discharge^{70–76} (Table 14–5). Of note, an increase in bleeding, which is especially concerning in the setting of traumatic or prolonged CPR, has not been noted. Thrombolytics, therefore, should be considered on a case-by-case basis when PE is suspected.² A large, international, multicentered, randomized controlled trial is currently underway to better address the efficacy and safety of thrombolytic therapy during CPR.¹⁷

Magnesium

Although severe hypomagnesemia has been associated with VF/PVT, clinical trials have not demonstrated any benefit with the routine administration of magnesium during a cardiac arrest. Two observation trials, however, have shown an improvement in ROSC in patients with arrests associated with torsade de pointes.² Therefore, magnesium administration should be limited to these patients.

POSTRESUSCITATIVE CARE

Therapeutic Hypothermia

Restoration of blood flow following cardiac arrest can lead to several chemical cascades and destructive enzymatic reactions that can result in cerebral injury. These reactions include free-radical production,

Data from Abu-Laban et al.,⁷⁰ Bottiger et al.,⁷¹ Fatovich et al.,⁷² Janata et al.,⁷³ Kurkciyan et al.,⁷⁴ Lederer et al.,⁷⁵ Ruiz-Bailen et al.,⁷⁶ and Stadlbauer et al.¹¹³

excitatory amino acid release, and calcium shifts, leading to mitochondrial damage and apoptosis (programmed cell death).⁷⁷ Hypothermia can protect from cerebral injury by suppressing these chemical reactions, thereby reducing the production of free radicals. Various animal models have demonstrated improved functional recovery and reduced cerebral deficits with the induction of mild therapeutic hypothermia.⁷⁷ Clinical trials in humans have shown similar results.^{78,79}

One trial was conducted in nine centers in five European countries.⁷⁸ In this study, patients who had been resuscitated after cardiac arrest caused by VF but remained comatose were assigned randomly to undergo therapeutic hypothermia, targeting a temperature of 32°C (89.6°F) to 34°C (93.2°F), for 24 hours. The primary end point was neurologic outcome within 6 months of cardiac arrest. Secondary end points were mortality (within 6 months) and complication rate within 7 days. A favorable neurologic outcome was achieved in 55% of patients in the hypothermia group as opposed to 39% in the normothermia group ($P = 0.009$). Additionally, mortality rates were improved significantly in the hypothermia group (41% vs. 55%; $P = 0.02$). Based on this difference, seven patients would need to be treated with hypothermia to prevent one death. The rate of complications (e.g., bleeding, pneumonia, sepsis, and renal failure) did not differ between the two groups (73% for the hypothermia group and 70% for the normothermia group; $P = 0.70$).

A second trial was conducted in four hospitals in Melbourne, Australia.⁷⁹ Entry criteria were similar to the previous trial, but the target temperature for hypothermia was 33°C (91.4°F), which was maintained for 12 hours. The primary outcome measure was survival to hospital discharge with good neurologic function. Forty-nine percent of patients in the hypothermia group had good neurologic function on discharge (to either home or a rehabilitation facility) compared with 26% of patients in the normothermia group ($P = 0.046$). Mortality rates were similar between the two groups (51% for the hypothermia group and 68% for the normothermia group; $P = 0.145$). Hypothermia was associated with a lower cardiac index, higher systemic vascular resistance, and hyperglycemia. It is important to note that only 8% of patients with cardiac arrest were selected for therapeutic hypothermia in these two studies. Thus, further research needs to focus on the subset of arrest patients who are most likely to benefit from this strategy.

In light of these trials, unconscious adult patients with spontaneous circulation after out-of-hospital cardiac arrest should be cooled to 32°C (89.6°F) to 34°C (93.2°F) for 12 to 24 hours when the initial rhythm is VF.^{2,77} Such cooling also can be of benefit for other rhythms or in-hospital cardiac arrests. There is insufficient evidence to make a recommendation on the use of therapeutic hypothermia in children, however, an evaluation in neonates with asphyxiation suggested that hypothermia in this select population may be beneficial.⁸⁰

Hypothermia must be used with caution, however, as there are several complications that can develop. Coagulopathy, dysrhythmias, hyperglycemia, increased incidence of pneumonia, as well as sepsis have been described.^{79,81} Further research is needed in this area.

Glucose Control

Electrolyte abnormalities are frequent after cardiac arrest, and can be very deleterious to outcome. Although no controlled evidence exists regarding glucose control post-cardiac arrest, there is growing consensus among critical care practitioners that tight glucose control improves outcome among critically ill patients. Studies have documented increased survival, as well as less infectious complications using insulin drips to obtain tight glucose control (i.e., 80 to 110 mg/dL).⁸² Because hyperglycemia is common after cardiac arrest, it would seem reasonable for post-arrest providers to maintain normoglycemia, albeit further study is warranted to determine the role of tight glycemic control in these patients.

Cardiovascular Perfusion

The patient who has achieved ROSC often has myocardial stunning/dysfunction, either caused by reperfusion injury or the direct effects of defibrillation.² Postresuscitation support involves adequate fluid and vasopressor support in order to maintain sufficient cardiac output with acceptable organ perfusion. Evaluation should thus include electrocardiographic and echocardiographic analysis. Patients often develop a delayed vasodilatation that is responsive to fluids and vasoactive support. Invasive monitoring can be required; however the optimal target numbers for either mean arterial pressure or hemodynamic indices have not been ascertained. It is also unclear whether antiarrhythmics are beneficial in the post-arrest timeframe, despite the fact that many arrests are precipitated by

dysrhythmias. Relative adrenal insufficiency has also been shown to develop in the post-arrest period, but adrenal replacement has not been shown to date to be efficacious. However, again borrowing on critical care literature in sepsis, adrenal replacement in the correct situation has been shown to be beneficial.⁸³ Whether or not this is true in post-cardiac arrest requires further study.

NON-VF/PVT RHYTHMS: PEA AND ASYSTOLE

■ NONPHARMACOLOGIC THERAPY

Pulseless electrical activity is defined as the absence of a detectable pulse and the presence of some type of electrical activity other than VF or PVT. Several studies have documented that patients with PEA actually have mechanical cardiac contractions, but they are too weak to produce a palpable pulse or blood pressure. Asystole is defined as the presence of a flat line on the electrocardiogram (ECG) monitor. Although PEA is still classified as a “rhythm of survival,” the success rate of treatment is much lower than the rates seen with VF/PVT.¹⁴ PEA is often caused by treatable conditions, and the resuscitation team needs to identify and correct these conditions emergently if the resuscitation is to be successful. The rate of survival among patients with out-of-hospital cardiac arrest secondary to asystole is 1% to 2% but can be up to 10% in patients with in-hospital arrest.^{13,14,20} Successful treatment of both PEA and asystole depends almost entirely on diagnosis of the underlying cause (see Table 14–2). **6** The algorithm for treatment of PEA is the same as the treatment of asystole. Both conditions require CPR, airway control, and IV access. Asystole should be reconfirmed by checking a second lead on the cardiac monitor. Defibrillation should be avoided in patients with asystole because the parasympathetic discharge that occurs with defibrillation can reduce the chance of ROSC and worsen the chance of survival. The emphasis in resuscitation is good quality CPR without interruption and to try to identify a correctable cause. If available, transcutaneous pacing can be attempted. Asystole often represents confirmation of death rather than a rhythm to be treated; therefore, withdrawal of efforts must be strongly considered if there is not a rapid ROSC.²

Much like VF/PVT, there is an interest in hypothermia in these post-arrest patients. Metabolic parameters (e.g., lactate and oxygen [O₂] extraction) have been shown to be improved when post-arrest comatose adults survived their arrest and were treated with hypothermia.⁸⁴ Further studies are warranted in this area.

■ PHARMACOLOGIC THERAPY

The primary pharmacologic agents used in the treatment of asystole are vasopressors (i.e., epinephrine and vasopressin) and atropine. Studies comparing epinephrine and vasopressin in patients with PEA and asystole have not demonstrated an advantage with one agent over the other. In one large trial of patients with out-of-hospital cardiac arrest, a post hoc, subgroup analysis was conducted for those patients with asystole.⁶¹ In these patients, ROSC was 16% with vasopressin and 17% with epinephrine (OR 1.00, 95% CI 0.7–1.6; *P* = 0.87), survival to hospital admission was 29% with vasopressin and 20% with epinephrine (OR 0.6, 95% CI 0.4–0.9, *P* = 0.02) and survival to hospital discharge was 4.7% with vasopressin and 1.5% with epinephrine (OR 0.3, 95% CI 0.1–1.0, *P* = 0.04). An increase in intact neurologic survival, however, was not noted. In contrast, 40% (8/20) of patients who received vasopressin and subsequently required additional treatment with epinephrine were discharged in a coma or vegetative state compared to 0% (0/5) of patients who received epinephrine only (*P* = 0.14). Nevertheless, vasopressin can be substituted for the first or second dose of epinephrine in patients with asystole.² There is insufficient data to recommend for or against

its use in PEA. Epinephrine should be administered similarly to its use in VF/PVT; that is, 1 mg every 3 to 5 minutes.

Atropine is an antimuscarinic agent that blocks the depressant effect of acetylcholine on both the sinus and atrioventricular nodes, thus decreasing parasympathetic tone. During asystole, parasympathetic tone may increase because of the vagal stimulation that occurs secondary to intubation, the effects of hypoxia and acidosis, or alterations in the balance of parasympathetic and sympathetic control.⁸⁵ Unfortunately, there are no prospective controlled trials showing benefit from atropine for the treatment of asystole or PEA.

Earlier small observational reports found some response to atropine in asystole or pulseless idioventricular rhythm but little evidence to suggest that long-term outcomes were altered.⁸⁶ In one retrospective case-control study, a success rate of 14% (6/43) was noted with atropine compared with to a 0% (0/41) rate with a control but no patients survived to hospital discharge.⁸⁶ In a second retrospective study, asystole was terminated in only 4 of 22 patients (18%) when atropine was administered.⁸⁷ Once again, none survived to hospital discharge. Finally, a third retrospective review evaluated 101 patients who received atropine for asystole.⁸⁸ Twenty-four patients (24%) survived 24 hours after resuscitation. It is unclear how many survived to hospital discharge. These results show that although atropine can achieve ROSC in some instances, asystolic arrest is almost always fatal. Given the relative safety of atropine, the ease of administration, low cost, and theoretical advantages, atropine should be considered for asystole or PEA.² The beneficial effects, however, are limited.

■ ACID/BASE MANAGEMENT

Acidosis seen during cardiac arrest is the result of decreased blood flow and inadequate ventilation. Chest compressions generate approximately 20% to 30% of normal cardiac output, leading to inadequate organ perfusion, tissue hypoxia, and metabolic acidosis. In addition, the lack of ventilation causes retention of carbon dioxide, leading to respiratory acidosis. This combined acidosis produces not only reduced myocardial contractility and negative inotropic effect, but also the appearance of arrhythmias because of a lower fibrillation threshold. In early cardiac arrest, adequate alveolar ventilation is the mainstay of control to limit the accumulation of carbon dioxide and control the acid–base imbalance.² With arrests of long duration, buffer therapy is often considered, however, few data supports its use during cardiac arrest.

Although sodium bicarbonate was once given routinely to reduce the detrimental effects associated with acidosis (e.g., reduced myocardial contractility), enhance the effect of epinephrine, and improve the rate of defibrillation, there are few clinical data supporting its use.⁸⁹ In fact, sodium bicarbonate can have some detrimental effects.^{89,90} The effect of sodium bicarbonate can be described by the following reaction:

When sodium bicarbonate is added to an acidic environment, this reaction will shift to the right, thereby increasing tissue and venous hypercarbia. The carbon dioxide generated by this reaction will diffuse into the cell and decrease intracellular pH. The accumulation of intracellular carbon dioxide, specifically within the myocardium, is inversely correlated with coronary perfusion pressure produced by CPR. Intracellular acidosis also will decrease myocardial contractility, further complicating the low-flow state associated with CPR.⁸⁹ Furthermore, treatment with sodium bicarbonate often overcorrects extracellular pH because sodium bicarbonate has a greater effect when the pH is closer to normal.⁹⁰ The induced alkalosis, causes an increase in the affinity of oxygen to hemoglobin (“left shift”), thus interfering with oxygen release into the tissues.

Sodium bicarbonate can be used in special circumstances (i.e., underlying metabolic acidosis, hyperkalemia, salicylate overdose, or tricyclic antidepressant overdose), however, the dosage should be guided by laboratory analysis if possible. There has been clinical interest in other buffering agents (an equimolar mixture of sodium bicarbonate and sodium carbonate [Carbicarb]; tris(hydroxymethyl)aminomethane [THAM]; a mixture of THAM, acetate, sodium bicarbonate, and phosphate [Tribonat]) as they have shown less potential for the adverse effects seen with sodium bicarbonate.² However, there is a dearth of clinical experience with these agents, and outcome studies are not available.

MODIFICATIONS FOR SPECIAL SITUATIONS

■ DROWNING

Drowning is a process resulting in primary respiratory impairment from immersion in a liquid. It is a common, preventable cause of morbidity and mortality. The most important inciting event is the hypoxia induced by submersion. Thus, early care of the drowning patient includes immediate rescue breathing, even before he or she is removed from the water. This is performed much in the same way as for other victims of cardiac arrest. Prompt initiation of this therapy increases chance of survival.⁹¹ Once victims are removed from the water, immediate chest compressions should be started if they are pulseless. Drowning victims can present with any of the pulseless rhythms; standard guidelines need to be followed for therapy of these rhythms.

■ HYPOTHERMIA

Unintentional hypothermia (as opposed to the therapeutic hypothermia used post-arrest, described above) is defined by a body temperature $<30^{\circ}\text{C}$ (86°F), and is associated with marked derangements in body function. Because it can depress virtually every body system, including pulse and respiration, the patient may appear to be dead on the initial evaluation. Hypothermia can lead to benefit on brain recovery after cardiac arrest (discussed earlier), thus aggressive intervention is clearly indicated when there is a hypothermic arrest victim.

If the patient still has a perfusing rhythm, therapy is mainly based on rewarming techniques. For mild hypothermia (i.e., $>34^{\circ}\text{C}$ [$>93.2^{\circ}\text{F}$]), passive rewarming is recommended. For moderate hypothermia (i.e., 30°C to 34°C [86°F to 93.2°F]), active external rewarming is recommended, and for severe hypothermia (i.e., $<30^{\circ}\text{C}$ [$<86^{\circ}\text{F}$]) active internal rewarming is recommended. These patients need to be manipulated very gently as VF is sometimes precipitated by movement.⁹²

If the patient is in cardiac arrest, then the standard BLS algorithm should be followed. However, there are some modifications that the rescuer needs to consider. The rescuer should evaluate for respiration and pulse for a longer time frame, as these can be slow or very difficult to realize. If there is no breathing, then rescue breaths should ensue. If there is any doubt about the presence of a pulse, then chest compressions should be started immediately. If the patient is in VF or PVT then electrical therapy should be given in a standard manner. However, the hypothermic heart may be less responsive to medications or defibrillation, and thus there have been worries about the optimal temperature at which to start defibrillation attempts.² There are no published consensus guidelines regarding this. Immediately after defibrillation, CPR should resume as in the standard manner. During CPR, continued attempts at rewarming are of paramount importance. Included in this concept is preventing further heat loss (i.e., removal of wet clothing, protection from the environment, etc.). Patients often require significant vol-

ume challenges during the rewarming process. The use of steroids, antibiotics, and barbiturates has been proposed, but none of these agents have ever been shown to increase survival rates.²

It is debatable when to stop resuscitative efforts in the hypothermic patient. Many authors have proposed that a patient should not be pronounced until the core temperature has been restored to near normal.² Once the patient is in the hospital, it is still the judgment of the treating physician when efforts should be terminated.

■ PREGNANCY

Pregnancy is a unique situation in that survival of both the fetus and the mother depend on CPR. The best hope for survival of the fetus is maternal survival. Because of the gravid uterus, resuscitation needs to be modified. Because the vena cava and aorta can be obstructed by a uterus of approximately 20 weeks of gestation or later, it is appropriate to position the patient approximately 15 to 30 degrees back from the left lateral decubitus position, or to pull the uterus to the side.⁹³

Airway control is important in the pregnant patient. The airway may be smaller because of the hormonal changes and edema that accompany pregnancy. Similarly, because of increased intraabdominal pressure exerted by the uterus, as well as hormonal changes that change the resting state of the gastroesophageal sphincter, clinicians need to be acutely aware of the increased risk of aspiration. Because of this, cricoid pressure needs to be maintained continuously during airway manipulation. The rescuer may need to give smaller tidal volumes than normal because of the diaphragm elevation that accompanies the later stages of pregnancy. Similarly, circulatory support also has to be adjusted. In particular, chest compressions need to be administered slightly above the center of the sternum to adjust for the anatomic changes of the pregnant uterus.²

In an arrest situation during pregnancy the ACLS provider needs to follow the standard guidelines, including the same use of defibrillation and medications. Although it is true that vasoactive agents, such as epinephrine, can diminish uterine blood flow, safer alternatives do not exist.²

Although etiologies of arrest in pregnancy are often the same as in the nonpregnant patient, there are several unique situations that need to be considered in the differential diagnosis of a pregnancy arrest. These include: excess magnesium sulfate institution (i.e., iatrogenic from treating eclampsia) in which case the therapeutic administration of calcium gluconate can be lifesaving; amniotic embolism, which is associated with complete cardiovascular collapse during labor and delivery (cardiopulmonary bypass has been reportedly successful in salvaging this condition); preeclampsia/eclampsia developing after 20 weeks of gestation producing hypertension and multiple organ dysfunction; as well as vascular events including acute coronary syndromes and acute pulmonary embolism.^{94,95}

It is paramount to remember that unless circulation is restored to the mother, both the mother and the fetus will succumb especially if standard therapy is not used correctly and promptly. Because of this the resuscitation leader should consider the need for emergent hysterotomy (i.e., Cesarean delivery) and delivery as soon as the arrest happens. The best survival reported for infants >24 weeks of gestation happens when delivery occurs no more than 5 minutes after the arrest of the mother.^{2,96}

■ TRAUMA

Cardiac resuscitation of the trauma arrest patient is basically performed with the same guidelines as any other arrest. There are some specific etiologies to rapidly consider however, as the survival of an out-of-hospital cardiac arrest caused by trauma is rare.² The rescuer needs to consider airway obstruction, pneumothorax, tracheobronchial injury, cardiac or large arterial injury, cardiac tamponade,

severe head injury with secondary cardiac collapse, and other injuries specific to the particular trauma.² The best survival seems to be in young patients with treatable penetrating injuries.

Trauma patients often suffer head or cervical injuries; thus cervical spine precautions should be used in these patients. A jaw thrust maneuver is the preferred way to open the airway, with in-line stabilization during attempts at advanced airway placement.² The rescuer must be vigilant for the development of tension pneumothorax during ventilation. Inadequate ventilation of one side is usually caused by tube malposition, tension pneumothorax, or hemothorax. These conditions are usually treated by medical personnel at the hospital after transport.

Chest compressions should be performed in a standard manner. Any visible hemorrhage should be controlled with direct pressure. Fluid resuscitation is done with a goal of adequate blood pressure and organ perfusion. The specific details of fluid resuscitation are highly controversial however, and the optimal volume infusion for trauma resuscitation is a subject of ongoing debate.

Open thoracotomy for trauma-induced arrest has been performed in many instances. For penetrating chest trauma patients who arrest immediately before arrival or in the emergency department, open thoracotomy can allow relief of tamponade, control of major vessel hemorrhage, or direct repair of cardiac insult.⁹⁷ In the case of blunt trauma however, open thoracotomy does not improve outcome.

For definitive post-arrest care, trauma patients should be rapidly transferred to a facility with expertise in the provision of trauma care.

■ ELECTRICAL SHOCK

There are many etiologies of electrical shock injuries, from lightning strike (mortality estimated to be 30%, with 70% of survivors sustaining significant morbidity) to high-tension current, to household current.^{98,99} The severity of injury depends on the site, type of current, duration of contact, pathway, and the magnitude of delivered electricity.

Cardiac arrest is common in electrical injury caused by current passing through the heart during the “vulnerable period” of the cardiac cycle. In large-current events, such as lightning strike, the heart undergoes massive depolarization simultaneously.¹⁰⁰ Sometimes the intrinsic pacemaker can restore an organized cardiac electrical cycle, but because of injury to other muscles, specifically the thoracic musculature, the patient cannot retain or sustain viable circulation because of the lack of ventilation and oxygenation.¹⁰¹

When approaching a victim of electrocution, the rescuer must first be certain of his or her own safety. Thereafter, standard BLS, prompt CPR, and ACLS when available is indicated. Electric shock is often associated with multiple trauma, including spinal injury, multiple injuries to the skeletal muscles, as well as fractures. These factors need to be evaluated by the resuscitation team.

Airway control can be difficult because of the edema that often accompanies such injuries; thus an advanced airway early in the treatment process is recommended.² With soft tissue swelling, there is often a need for aggressive fluid resuscitation in these patients. The underlying tissue, or visceral organ damage, is often worse than the external appearance. It is usually recommended that these patients be transferred to centers with expertise in dealing with these types of injuries.

GUIDELINES FOR DRUG ADMINISTRATION

The routes of administration that are available for drug delivery during CPR include IV (both central and peripheral access), IO, and endotracheal. The chosen route represents a compromise between

the availability of access and their apparent efficacy in introducing the drug into the central circulation. When selecting a route for drug administration, it is of utmost importance to minimize any interruptions in chest compressions during CPR.

Central venous access will result in a faster and higher peak drug concentration than peripheral access, but central line access is not needed in most resuscitation attempts. If a central line is already present, however, it should be the access site of choice. Central lines located above the diaphragm are preferable to those located below the diaphragm because of poor blood flow during CPR.¹⁰² If IV access (either central or peripheral) has not been established a large peripheral venous catheter should be inserted. Peripheral drug administration yields a peak concentration in the major systemic arteries in roughly 1.5 to 3 minutes but circulation time can be shortened by up to 40% if the drug is followed by a 20-mL fluid bolus with elevation of the extremity.¹⁰²

7 The 2005 guidelines for CPR and ECC now recommend IO administration as the preferred alternative if IV administration cannot be achieved.² Drug administration using the IO route is as quick and effective as drug administration via central access and superior to that achieved with peripheral access. Several studies have documented the effectiveness and safety of this administration route in both adults and children.² Potential anatomic sites for insertion for an IO needle are the distal tibia, the proximal tibia, and the distal femur.¹⁰³ Intraosseous infusion devices are available that allow for rapid insertion (i.e., within 90 seconds) and are easy to use.¹⁰⁴

In the event that neither IV nor IO access can be established, then a few drugs can be administered endotracheally. These drugs are atropine, lidocaine, epinephrine, naloxone, and vasopressin.² Medications administered through the endotracheal route, however, will have both a lower and delayed peak concentration than when they are administered by the IV or IO routes.² Furthermore, clinical trials have failed to demonstrate any benefit with using the endotracheal route.^{105,106} In fact, one clinical trial noted lower rates of ROSC (15% [15:101] vs. 27% [134:495], $P \leq 0.01$), hospital admission (9% [9:101] vs. 20% [97:495], $P \leq 0.02$), and hospital discharge (0% [0:101] vs. 5% [27:495], $P \leq 0.02$) with endotracheal drug administration compared to IV.¹⁰⁶ Currently, the recommended endotracheal dose is 2 to 2.5 times larger than the IV/IO dose.² Given the unpredictable absorption and the lack of clinical effectiveness, however, either the IV or IO routes are preferred.

ETHICAL AND ECONOMIC CONSIDERATIONS

The primary objective of CPR is to obtain neurologic survival. Because this is often unobtainable, many healthcare professionals are attempting to identify patients unlikely to benefit from cardiac resuscitation. One difficulty in accomplishing this task is defining medical futility. The two major determinants of medical futility are length of life and quality of life.² An intervention that cannot increase length or quality of life is considered futile. Key factors in CPR are the disease underlying the cardiac arrest and the expected state of health after resuscitation. One important question that is debated often is how low should the chance of survival be before medical therapy is considered futile? Is the chance of 1 or 2 months of life for a patient an acceptable goal? These are important questions that must be addressed when determining resuscitation status. Ethically, healthcare providers are obligated to respect patient autonomy, which is easiest in the arrest situation if the patient has an advance directive. If the patient loses the ability to make informed decisions regarding medical care, then a spouse or a designated healthcare advocate must act as a surrogate decision maker, invoking what has been termed substituted judgment: following the predetermined wishes of the patient.

Unfortunately, there is no scientific evidence or scoring system that can predict the outcome following CPR. Therefore, all patients

in cardiac arrest should receive resuscitation unless the patient has a “do not attempt resuscitation” (DNAR) order, signs of irreversible death, or vital organ function deterioration that makes it impossible to expect any benefit from CPR—despite maximum therapy.² Withholding CPR attempts in these futile cases not only would decrease the number of patients left in a vegetative state with poor neurologic status but also would improve the cost-effectiveness of CPR programs. CPR is of minimal economic benefit if the only outcome following ROSC is a prolonged, expensive hospital stay.

The decision to terminate resuscitative efforts usually rests with the treating medical team in the hospital. This is often based on many factors, including time to CPR, time of CPR, time to ROSC, premorbid conditions, and so forth. None of these is clearly predictive of outcome however. In a prehospital arrest, it is the duty of the treating team to provide BLS and ACLS unless there is clear evidence of death (i.e., signs of rigor mortis), the provision of CPR would place the rescuer at personal risk, or there is clear evidence of a DNAR order.

CLINICAL CONTROVERSIES

Some clinicians feel that vasopressin should be the vasopressor of first choice in patients with VF/PVT although others prefer epinephrine.

Although amiodarone is considered the preferred antiarrhythmic in patients with VF/PVT, there is conflicting data regarding its effect on outcome when compared to lidocaine.

Some clinicians feel that CPR should be performed before defibrillation is attempted in patients who have had an unwitnessed arrest. Others feel that defibrillation should be attempted as soon as possible.

EVALUATION OF THERAPEUTIC OUTCOMES

To measure the success of resuscitation outcomes, therapeutic outcome monitoring should occur both during the resuscitation attempt and in the postresuscitation phase. The optimal outcome following CPR is an awake, responsive, spontaneously breathing patient. Patients must remain neurologically intact with minimal morbidity following the resuscitation if it is to be truly classified as a success.

Unfortunately, there are no reliable criteria for clinicians to use to gauge the efficacy of CPR. Nonetheless, heart rate, cardiac rhythm, and blood pressure should be assessed and documented throughout the resuscitation attempt and subsequent to each intervention. Coronary perfusion pressure (CPP; CPP is the aortic diastolic pressure minus right atrial diastolic pressure) should be assessed in patients for whom intraarterial monitoring is in place. Determination of the presence or absence of a pulse is paramount to deciding which interventions are appropriate. Palpating a pulse to determine the efficacy of blood flow during CPR, however, has not been shown to be useful.

End-tidal carbon dioxide monitoring is a safe and effective method to assess cardiac output during CPR and has been associated with ROSC.² The main determinant for carbon dioxide excretion is the rate of delivery from the peripheral sites (where it's produced) to the lungs. Increasing cardiac output (through effective CPR), will yield higher end-tidal carbon dioxide levels as delivery of carbon dioxide to the lungs increases.

Clinicians should also consider the precipitating cause of the cardiac arrest, such as an MI, electrolyte imbalance, or primary arrhythmia. Pre-arrest status should be carefully reviewed, particularly if the patient was receiving drug therapy. Altered cardiac, hepatic, and renal function resulting from ischemic damage during the cardiopulmonary arrest warrant special attention and can

require advanced care. Neurologic function should be assessed by means of the Cerebral Performance Category and the Glasgow Coma Scale.^{107,108} Nonresponse to an array of suitable interventions can indicate that resuscitation is impossible.

ABBREVIATIONS

ACLS: advanced cardiac life support
 AHA: American Heart Association
 BLS: basic life support
 CPP: coronary perfusion pressure
 CPR: cardiopulmonary resuscitation
 ECC: emergency cardiovascular care
 EMS: emergency medical services
 IO: intraosseous
 IV: intravenous
 MI: myocardial infarction
 PEA: pulseless electrical activity
 PE: pulmonary embolism
 ROSC: return of spontaneous circulation
 PVT: pulseless ventricular tachycardia
 VF: ventricular fibrillation

JOSEPH J. SASEEN AND ERIC J. MACLAUGHLIN

KEY CONCEPTS

- 1 The risk of cardiovascular (CV) morbidity and mortality is directly correlated with blood pressure (BP). Even patients with prehypertension have an increased risk of CV disease.
- 2 Outcome trials have shown that antihypertensive drug therapy substantially reduces the risks of CV events and death in patients with hypertension.
- 3 Essential hypertension is usually an asymptomatic condition. A diagnosis cannot be made based on one elevated BP measurement. Elevated values from the average of two or more measurements on two or more clinical encounters are needed to diagnose hypertension.
- 4 The overall goal of treating hypertension is to reduce hypertension-associated morbidity and mortality from CV events. The selection of specific drug therapy is based on evidence that demonstrates CV risk reduction.
- 5 A goal BP of less than 140/90 mm Hg is appropriate for general prevention of CV events or CV disease. However, achieving BP of less than 130/80 mm Hg goal is recommended in patients with diabetes, significant chronic kidney disease, known coronary artery disease (myocardial infarction, stable angina, unstable angina), noncoronary atherosclerotic vascular disease (ischemic stroke, transient ischemic attack, peripheral arterial disease, abdominal aortic aneurism), or a 10% or greater 10-year risk of fatal coronary heart disease or nonfatal myocardial infarction based on Framingham risk scoring. Patients with left ventricular dysfunction (systolic heart failure) have a BP goal of less than 120/80 mm Hg.
- 6 Lifestyle modifications should be prescribed in all patients with hypertension and prehypertension. However, they should never be used as a replacement for antihypertensive drug therapy in patients with hypertension, especially patients with additional CV risk factors.
- 7 Thiazide-type diuretics have traditionally been classified as first-line agents for treating most patients with hypertension. This recommendation is supported by clinical trials showing reduced CV morbidity and mortality with thiazide diuretic therapy. Comparative data from the landmark Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) confirm the first-line role of thiazide-type diuretics.
- 8 An angiotensin-converting enzyme (ACE) inhibitor, angiotensin II receptor blocker (ARB), or calcium channel blocker (CCB) may be used as first-line agents in patients without compelling indications. Clinical trials have demonstrated that these agents reduce the risk of CV events when used to treat hypertension.
- 9 β -Blockers do not reduce CV events to the extent that thiazide-type diuretics, ACE inhibitors, ARBs, or CCBs do when used as the primary antihypertensive agent in patients with hypertension but without a compelling indication for β -blocker therapy.
- 10 Compelling indications are comorbid conditions where specific drug therapies have been shown in outcome trials to provide unique long-term benefits (reducing the risk of CV events).
- 11 Patients with diabetes are at very high risk for CV events. All patients with diabetes and hypertension should be managed with either an ACE inhibitor or an ARB. These are typically in combination with one or more other antihypertensive agents because multiple agents frequently are needed to lower BP to less than 130/80 mm Hg.
- 12 Older patients with isolated systolic hypertension are often at risk for orthostatic hypotension when antihypertensive drug therapy is started, particularly with diuretics, ACE inhibitors, and ARBs. Although overall treatment should be the same, low initial doses should be used and dosage titrations should be gradual to minimize risk of orthostatic hypotension.
- 13 Alternative antihypertensive agents have not been proven to reduce the risk of CV events compared with first-line antihypertensive agents. They should be used primarily in combination with first-line agents to provide additional BP lowering.
- 14 Hypertensive urgency is ideally managed by adjusting maintenance therapy (adding a new antihypertensive and/or increasing the dose of a present medication). This provides a gradual reduction in BP, which is a safer treatment approach than very rapid reductions in BP.
- 15 Most patients require combination therapy to achieve goal BP values. Combination regimens should include a diuretic, preferably a thiazide-type. If a diuretic was not the first drug used, it should be the second drug add-on therapy for most patients.
- 16 Patients have resistant hypertension when they fail to attain goal BP values while adherent with an appropriate three drug-regimen. This three-drug regimen must include full doses and include a diuretic.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

Hypertension is a common disease that is simply defined as persistently elevated arterial blood pressure (BP). Although elevated BP was perceived to be “essential” for adequate perfusion of essential

organs during the early and middle 1900s, it is now identified as one of the most significant risk factors for cardiovascular (CV) disease. Increasing awareness and diagnosis of hypertension, and improving control of BP with appropriate treatment, are considered critical public health initiatives to reduce CV morbidity and mortality.

The Seventh Report of the Joint National Committee on the Detection, Evaluation, and Treatment of High Blood Pressure (JNC7) is the most prominent evidence-based clinical guideline in the United States for the management of hypertension,¹ supplemented by the 2007 American Heart Association (AHA) Scientific Statement on the treatment of hypertension.² This chapter reviews relevant components of these guidelines and additional evidence from clinical trials, with a focus on the pharmacotherapy of hypertension. Data from the National Health and Nutrition Examination Survey from 1999 to 2000 indicate that of the population of Americans with hypertension, 68.9% are aware that they have hypertension, only 58.4% are on some form of antihypertensive treatment, and only 34% of all patients have controlled BP.³ Therefore, there are ample opportunities for clinicians to improve the care of patients with hypertension.

EPIDEMIOLOGY

Approximately 31% of the population (72 million Americans) have high BP ($\geq 140/90$ mm Hg).⁴ The percentage of men with high BP is higher than that of women before the age of 45 years, but between the ages of 45 and 54 years the percentage is slightly higher with women.⁴ After age 55 years, a much higher percentage of women have high BP than men.⁴ Prevalence rates are highest in non-Hispanic blacks (33.5%) followed by non-Hispanic whites (28.9%) and Mexican Americans (20.7%).³

BP values increase with age, and hypertension (persistently elevated BP values) is very common in the elderly. The lifetime risk of developing hypertension among those 55 years of age and older who are normotensive is 90%.¹ Most patients have prehypertension before they are diagnosed with hypertension, with most diagnoses occurring between the third and fifth decades of life. In the population age ≥ 60 years, the prevalence of hypertension in 2000 was estimated at 65.4%, which is significantly higher than the 57.9% prevalence estimated in 1988.³

ETIOLOGY

In most patients, hypertension results from an unknown pathophysiologic etiology (*essential or primary hypertension*). This form of hypertension cannot be cured, but it can be controlled. A small percentage of patients have a specific cause of their hypertension (*secondary hypertension*). There are many potential secondary causes that are either concurrent medical conditions or are endogenously induced. If the cause can be identified, hypertension in these patients has the potential to be cured.

ESSENTIAL HYPERTENSION

More than 90% of individuals with hypertension have essential hypertension.¹ Numerous mechanisms have been identified that may contribute to the pathogenesis of this form of hypertension, so identifying the exact underlying abnormality is not possible. Genetic factors may play an important role in the development of essential hypertension. There are monogenic and polygenic forms of BP dysregulation that may be responsible for essential hypertension.⁵ Many of these genetic traits feature genes that affect sodium balance, but genetic mutations altering urinary kallikrein excretion, nitric oxide release, and excretion of aldosterone, other adrenal

steroids, and angiotensinogen are also documented.⁵ In the future, identifying individuals with these genetic traits could lead to alternative approaches to preventing or treating hypertension; however, this is not currently recommended.

SECONDARY HYPERTENSION

Fewer than 10% of patients have secondary hypertension where either a comorbid disease or drug is responsible for elevating BP (Table 15–1).^{1,6} In most of these cases, renal dysfunction resulting from severe chronic kidney disease or renovascular disease is the most common secondary cause. Certain drugs, either directly or indirectly, can cause hypertension or exacerbate hypertension by increasing BP. Table 15–1 lists the most common agents. Some of these agents are herbal products. Although these are not technically drugs, they have been identified as secondary causes. When a secondary cause is identified, removing the offending agent (when feasible) or treating/correcting the underlying comorbid condition should be the first step in management.

PATHOPHYSIOLOGY^{5,7}

Multiple factors that control BP are potential contributing components in the development of essential hypertension. These include malfunctions in either humoral (i.e., the renin–angiotensin–aldosterone system [RAAS]) or vasodepressor mechanisms, abnormal

TABLE 15-1 Secondary Causes of Hypertension

Diseases	Drugs Associated with Hypertension in Humans ^a
Chronic kidney disease	Prescription drugs
Cushing's syndrome	• Adrenal steroids (e.g., prednisone, fludrocortisone, triamcinolone)
Coarctation of the aorta	• Amphetamines/anorexiant (e.g., phendimetrazine, phentermine, sibutramine)
Obstructive sleep apnea	• Antivascular endothelin growth factor agents (bevacizumab, sorafenib, sunitinib), estrogens (usually oral contraceptives)
Parathyroid disease	• Calcineurin inhibitors (cyclosporine and tacrolimus)
Pheochromocytoma	• Decongestants (phenylpropanolamine and analogs)
Primary aldosteronism	• Erythropoiesis stimulating agents (erythropoietin and darbepoietin)
Renovascular disease	• Nonsteroidal antiinflammatory drugs, cyclooxygenase-2 inhibitors
Thyroid disease	• Others: venlafaxine, bromocriptine, bupropion, buspirone, carbamazepine, clozapine, desulfurane, ketamine, metoclopramide
	Situations: β -blocker or centrally acting α -agonists (when abruptly discontinued); β -blocker without α -blocker first when treating pheochromocytoma
	Street drugs and other natural products
	Cocaine and cocaine withdrawal
	Ephedra alkaloids (e.g., Ma-huang), "herbal ecstasy," other phenylpropanolamine analogs ^a
	Nicotine withdrawal, anabolic steroids, narcotic withdrawal, methylphenidate, phencyclidine, ketamine, ergotamine and other ergot-containing herbal products, St. John's wort
	Food substances
	Sodium
	Ethanol
	Licorice
	Tyramine-containing foods if taking a monoamine oxidase inhibitor

^aAgents of most clinical importance.

neuronal mechanisms, defects in peripheral autoregulation, and disturbances in sodium, calcium, and natriuretic hormones. Many of these factors are cumulatively affected by the multifaceted RAAS, which ultimately regulates arterial BP. It is probable that none of these factors is solely responsible for essential hypertension; however, most antihypertensives specifically target these mechanisms and components of the RAAS.

ARTERIAL BLOOD PRESSURE

Arterial BP is the pressure in the arterial wall measured in millimeters of mercury (mm Hg). The two typical arterial BP values are *systolic BP* (SBP) and *diastolic BP* (DBP). SBP is achieved during cardiac contraction and represents the peak value. DBP is achieved after contraction when the cardiac chambers are filling, and represents the nadir value. The difference between SBP and DBP is called the pulse pressure and is a measure of arterial wall tension. Mean arterial pressure is the average pressure throughout the cardiac cycle of contraction. It is sometimes used clinically to represent overall arterial BP, especially in hypertensive emergency. During a cardiac cycle, two-thirds of the time is spent in diastole and one-third in systole. Consequently, the mean arterial pressure can be estimated by using the following equation:

$$\text{mean arterial pressure} = (\text{SBP} \times 1/3) + (\text{DBP} \times 2/3)$$

Arterial BP is hemodynamically generated by the interplay between blood flow and the resistance to blood flow. It is mathematically defined as the product of cardiac output and total peripheral resistance according to the following equation:

$$\text{BP} = \text{cardiac output} \times \text{total peripheral resistance}$$

Cardiac output is the major determinant of SBP, whereas total peripheral resistance largely determines DBP. In turn, cardiac output is a function of stroke volume, heart rate, and venous capacitance. Table 15–2 lists physiologic causes of increased cardiac output and total peripheral resistance and correlates them to potential mechanisms of pathogenesis.

Under normal physiologic conditions, arterial BP fluctuates throughout the day. It typically follows a circadian rhythm, where it

TABLE 15-3 Classification of Blood Pressure in Adults (Age ≥18 Years)^a

Classification	Systolic Blood Pressure (mm Hg)	and	Diastolic Blood Pressure (mm Hg)
Normal	<120		<80
Prehypertension ^b	120–139	or	80–89
Stage 1 hypertension	140–159	or	90–99
Stage 2 hypertension	≥160	or	≥100

^aClassification determined based on the average of two or more properly measured seated blood pressure measurements from two or more clinical encounters. If systolic and diastolic blood pressure values yield different classifications, the highest category is used for the purpose of determining a classification.

^bFor patients with diabetes mellitus, significant chronic kidney disease, known coronary artery disease (myocardial infarction, stable angina, unstable angina), noncoronary atherosclerotic vascular disease (ischemic stroke, transient ischemic attack, peripheral arterial disease, abdominal aortic aneurism), or a Framingham risk score of 10% or greater, values ≥130/80 mm Hg are considered above goal; patients with left ventricular dysfunction have a blood pressure goal of less than 120/80 mm Hg.

decreases to its lowest daily values during sleep. This is followed by a sharp rise starting a few hours prior to awakening with the highest values occurring midmorning. BP is also increased acutely during physical activity or emotional stress.

Classification

The JNC7 classification of BP in adults (age ≥18 years) is based on the average of two or more properly measured BP readings from two or more clinical encounters (Table 15–3).¹ It includes four categories: normal, prehypertension, stage 1 hypertension, and stage 2 hypertension. Prehypertension is not considered a disease category, but identifies patients whose BP is likely to increase into the classification of hypertension in the future.

Hypertensive crises are clinical situations where BP values are very elevated, typically greater than 180/120 mm Hg.⁷ They are categorized as either a *hypertensive emergency* or *hypertensive urgency*. Hypertensive emergencies are extreme elevations in BP that are accompanied by acute or progressing target-organ damage. Hypertensive urgencies are high elevations in BP without acute or progressing target-organ injury. Recommendations for managing hypertensive crises are described later in this chapter.

1 Cardiovascular Risk and Blood Pressure

Epidemiologic data clearly indicate a strong correlation between BP and CV morbidity and mortality.⁸ Risk of stroke, myocardial infarction, angina, heart failure, kidney failure, or early death from a CV cause are directly correlated with BP. Starting at a BP of 115/75 mm Hg, risk of CV disease doubles with every 20/10 mm Hg increase.¹ Even patients with prehypertension have an increased risk of CV disease.

2 Treating patients with hypertension with antihypertensive drug therapy provides significant benefits. Large-scale, placebo-controlled, outcome trials show that the increased risks of CV events and death associated with elevated BP are reduced substantially by antihypertensive drug therapy.^{9–12}

SBP is a stronger predictor of CV disease than DBP in adults ≥50 years of age and is the most important clinical BP parameter for most patients.¹ Patients with DBP values less than 90 mm Hg and SBP values ≥140 mm Hg have *isolated systolic hypertension*. Isolated systolic hypertension is believed to result from pathophysiologic changes in the arterial vasculature consistent with aging. These changes decrease the compliance of the arterial wall and portend an increased risk of CV morbidity and mortality. Pulse pressure is the difference between the SBP and the DBP. It is believed to reflect extent of atherosclerotic disease in the elderly and is a measure of increased arterial stiffness. Higher pulse pressure values are correlated with an increased risk of CV mortality, especially in those with isolated systolic hypertension.

TABLE 15-2 Potential Mechanisms of Pathogenesis

Blood pressure is the mathematical product of cardiac output and peripheral resistance. Elevated blood pressure can result from increased cardiac output and/or increased total peripheral resistance.	
Increased cardiac output	<p>Increased cardiac preload:</p> <ul style="list-style-type: none"> Increased fluid volume from excess sodium intake or renal sodium retention (from reduced number of nephrons or decreased glomerular filtration) <p>Venous constriction:</p> <ul style="list-style-type: none"> Excess stimulation of the RAAS Sympathetic nervous system overactivity

RAAS, renin–angiotensin–aldosterone system.

HUMORAL MECHANISMS

Several humoral abnormalities may be involved in the development of essential hypertension. These abnormalities may involve the RAAS, natriuretic hormones, and hyperinsulinemia.

The Renin–Angiotensin–Aldosterone System

The RAAS is a complex endogenous system that is involved with most regulatory components of arterial BP. Activation and regulation are primarily governed by the kidney (Fig. 15–1). The RAAS regulates sodium, potassium, and fluid balance. Consequently, this system significantly influences vascular tone and sympathetic nervous system activity and is the most influential contributor to the homeostatic regulation of BP.

Renin is an enzyme that is stored in the juxtaglomerular cells, which are located in the afferent arterioles of the kidney. The release of renin is modulated by several factors: intrarenal factors (e.g., renal perfusion pressure, catecholamines, angiotensin II), and extrarenal factors (e.g., sodium, chloride, and potassium).

Juxtaglomerular cells function as a baroreceptor-sensing device. Decreased renal artery pressure and kidney blood flow are sensed by these cells and stimulate secretion of renin. The juxtaglomerular apparatus also includes a group of specialized distal tubule cells referred to collectively as the *macula densa*. A decrease in sodium

and chloride delivered to the distal tubule stimulates renin release. Catecholamines increase renin release probably by directly stimulating sympathetic nerves on the afferent arterioles that in turn activate the juxtaglomerular cells. Decreased serum potassium and/or intracellular calcium are detected by the juxtaglomerular cells resulting in renin secretion.

Renin catalyzes the conversion of angiotensinogen to angiotensin I in the blood. Angiotensin I is then converted to angiotensin II by angiotensin-converting enzyme (ACE). After binding to specific receptors (classified as either AT₁ or AT₂ subtypes), angiotensin II exerts biologic effects in several tissues. The AT₁ receptor is located in brain, kidney, myocardium, peripheral vasculature, and the adrenal glands. These receptors mediate most responses that are critical to CV and kidney function. The AT₂ receptor is located in adrenal medullary tissue, uterus, and brain. Stimulation of the AT₂ receptor does not influence BP regulation.

Circulating angiotensin II can elevate BP through pressor and volume effects. Pressor effects include direct vasoconstriction, stimulation of catecholamine release from the adrenal medulla, and centrally mediated increases in sympathetic nervous system activity. Angiotensin II also stimulates aldosterone synthesis from the adrenal cortex. This leads to sodium and water reabsorption that increases plasma volume, total peripheral resistance, and ultimately BP. Aldosterone also has a deleterious role in the pathophysiology of other CV diseases (heart failure, myocardial infarction [MI] and kidney dis-

FIGURE 15-1. Diagram representing the renin–angiotensin–aldosterone system. The interrelationship between the kidney, angiotensin II, and regulation of blood pressure are depicted. There are three major regulators of renin secretion from the juxtaglomerular cells in this system. The primary sites of action for major antihypertensive agents are included. (①, angiotensin-converting enzyme inhibitors; ②, angiotensin II receptor blockers; ③, β -blockers; ④, calcium channel blockers; ⑤, diuretics; ⑥, aldosterone antagonists; ⑦, direct renin inhibitor; CNS, central nervous system.)

ease) by promoting tissue remodeling leading to myocardial fibrosis and vascular dysfunction. Clearly, any disturbance in the body that leads to activation of the RAAS could explain chronic hypertension.

The heart and brain contain a local RAAS. In the heart, angiotensin II is also generated by a second enzyme, angiotensin I convertase (human chymase). This enzyme is not blocked by ACE inhibition. Activation of the myocardial RAAS increases cardiac contractility and stimulates cardiac hypertrophy. In the brain, angiotensin II modulates the production and release of hypothalamic and pituitary hormones, and enhances sympathetic outflow from the medulla oblongata.

Peripheral tissues can locally generate biologically active angiotensin peptides, which may explain the increased vascular resistance seen in hypertension. Some evidence suggests that angiotensin produced by local tissue may interact with other humoral regulators and endothelium-derived growth factors to stimulate vascular smooth muscle growth and metabolism. These angiotensin peptides may, in fact, instigate increased vascular resistance in low plasma renin forms of hypertension. Components of the tissue RAAS may also be responsible for the long-term hypertrophic abnormalities seen with hypertension (left ventricular hypertrophy, vascular smooth muscle hypertrophy, and glomerular hypertrophy).

Natriuretic Hormone

Natriuretic hormone inhibits sodium and potassium-adenosine triphosphatase and thus interferes with sodium transport across cell membranes. Inherited defects in the kidney's ability to eliminate sodium can cause an increased blood volume. A compensatory increase in the concentration of circulating natriuretic hormone theoretically could increase urinary excretion of sodium and water. However, this same hormone is also thought to block the active transport of sodium out of arteriolar smooth muscle cells. The increased intracellular sodium concentration ultimately would increase vascular tone and BP.

Insulin Resistance and Hyperinsulinemia

The development of hypertension and associated metabolic abnormalities is referred to as the metabolic syndrome.¹³ Hypothetically, increased insulin concentrations may lead to hypertension because of increased renal sodium retention and enhanced sympathetic nervous system activity. Moreover, insulin has growth hormone-like actions that can induce hypertrophy of vascular smooth muscle cells. Insulin also may elevate BP by increasing intracellular calcium, which leads to increased vascular resistance. The exact mechanism by which insulin resistance and hyperinsulinemia occur in hypertension is unknown. However, this association is strong because many of the criteria used to define this population (elevated BP, abdominal obesity, dyslipidemia, and elevated fasting glucose) are often present in patients with hypertension.¹³

NEURONAL REGULATION

Central and autonomic nervous systems are intricately involved in the regulation of arterial BP. A number of receptors that either enhance or inhibit norepinephrine release are located on the presynaptic surface of sympathetic terminals. The α and β presynaptic receptors play a role in negative and positive feedback to the norepinephrine-containing vesicles located near the neuronal ending. Stimulation of presynaptic α -receptors (α_2) exerts a negative inhibition on norepinephrine release. Stimulation of presynaptic β -receptors facilitates norepinephrine release.

Sympathetic neuronal fibers located on the surface of effector cells innervate the α - and β -receptors. Stimulation of postsynaptic α -receptors (α_1) on arterioles and venules results in vasoconstriction. There are two types of postsynaptic β -receptors, β_1 and β_2 .

Both are present in all tissue innervated by the sympathetic nervous system. However, in some tissues β_1 -receptors predominate and in other tissues β_2 -receptors predominate. Stimulation of β_1 -receptors in the heart results in an increase in heart rate and contractility, whereas stimulation of β_2 -receptors in the arterioles and venules causes vasodilation.

The baroreceptor reflex system is the major negative-feedback mechanism that controls sympathetic activity. Baroreceptors are nerve endings lying in the walls of large arteries, especially in the carotid arteries and aortic arch. Changes in arterial pressure rapidly activate baroreceptors that then transmit impulses to the brainstem through the ninth cranial nerve and vagus nerves. In this reflex system, a decrease in arterial BP stimulates baroreceptors, causing reflex vasoconstriction and increased heart rate and force of cardiac contraction. These baroreceptor reflex mechanisms may be blunted (less responsive to changes in BP) in the elderly and those with diabetes.

Stimulation of certain areas within the central nervous system (nucleus tractus solitarius, vagal nuclei, vasomotor center, and the area postrema) can either increase or decrease BP. For example, α_2 -adrenergic stimulation within the central nervous system decreases BP through an inhibitory effect on the vasomotor center. However, angiotensin II increases sympathetic outflow from the vasomotor center, which increases BP.

The purpose of these neuronal mechanisms is to regulate BP and maintain homeostasis. Pathologic disturbances in any of the four major components (autonomic nerve fibers, adrenergic receptors, baroreceptors, or central nervous system) could conceivably lead to chronically elevated BP. These systems are physiologically interrelated. A defect in one component may alter normal function in another, and such cumulative abnormalities may then explain the development of essential hypertension.

PERIPHERAL AUTOREGULATORY COMPONENTS

Abnormalities in renal or tissue autoregulatory systems could cause hypertension. It is possible that a renal defect in sodium excretion may first develop, which can then cause resetting of tissue autoregulatory processes resulting in a higher arterial BP. The kidney usually maintains normal BP through a volume-pressure adaptive mechanism. When BP drops, the kidneys respond by increasing retention of sodium and water. These changes lead to plasma volume expansion that increases BP. Conversely, when BP rises above normal, renal sodium and water excretion are increased to reduce plasma volume and cardiac output. This ultimately will maintain homeostatic BP conditions.

Local autoregulatory processes maintain adequate tissue oxygenation. When tissue oxygen demand is normal to low, the local arteriolar bed remains relatively vasoconstricted. However, increases in metabolic demand trigger arteriolar vasodilation that lowers peripheral vascular resistance and increases blood flow and oxygen delivery through autoregulation.

Intrinsic defects in these renal adaptive mechanisms could lead to plasma volume expansion and increased blood flow to peripheral tissues, even when BP is normal. Local tissue autoregulatory processes that vasoconstrict would then be activated to offset the increased blood flow. This effect would result in increased peripheral vascular resistance, and if sustained, would also result in thickening of the arteriolar walls. This pathophysiologic component is plausible because increased total peripheral resistance is a common underlying finding in patients with essential hypertension.

VASCULAR ENDOTHELIAL MECHANISMS

Vascular endothelium and smooth muscle play important roles in regulating blood vessel tone and BP. These regulating functions are

mediated through vasoactive substances that are synthesized by endothelial cells. It has been postulated that a deficiency in the local synthesis of vasodilating substances (prostacyclin and bradykinin) or excess vasoconstricting substances (angiotensin II and endothelin I) contribute to essential hypertension, atherosclerosis, and other CV diseases.

Nitric oxide is produced in the endothelium, relaxes the vascular epithelium, and is a very potent vasodilator. The nitric oxide system is an important regulator of arterial BP. Patients with hypertension may have an intrinsic deficiency in nitric oxide, resulting in inadequate vasodilation.

ELECTROLYTES AND OTHER CHEMICALS

Epidemiologic and clinical data have associated excess sodium intake with hypertension. Population-based studies indicate that high salt diets are associated with a high prevalence of stroke and hypertension. Conversely, low salt diets are associated with a low prevalence of hypertension. Clinical studies consistently show that dietary sodium restriction lowers BP in many (but not all) patients with elevated BP. The exact mechanisms by which excess sodium leads to hypertension are unknown. However, they may be linked to increased circulating natriuretic hormones, which would inhibit intracellular sodium transport causing increased vascular reactivity and increased BP.

Altered calcium homeostasis also may play an important role in the pathogenesis of hypertension. A lack of dietary calcium hypothetically can disturb the balance between intracellular and extracellular calcium, resulting in an increased intracellular calcium concentration. This imbalance can alter vascular smooth muscle function by increasing peripheral vascular resistance. Some studies show that dietary calcium supplementation results in a modest BP reduction in patients with hypertension.

The role of potassium fluctuations is also inadequately understood. Potassium depletion may increase peripheral vascular resistance, but the clinical significance of small serum potassium concentration changes is unclear. Furthermore, data demonstrating reduced CV risk with dietary potassium supplementation is very limited.

CLINICAL PRESENTATION

CLINICAL PRESENTATION OF HYPERTENSION

General

- The patient may appear very healthy, or may have the presence of additional CV risk factors:
 - Age (≥ 55 years for men and 65 years for women)
 - Diabetes mellitus
 - Dyslipidemia (elevated low-density lipoprotein-cholesterol, total cholesterol, and/or triglycerides; low high-density lipoprotein-cholesterol)
 - Microalbuminuria
 - Family history of premature CV disease
 - Obesity (body mass index ≥ 30 kg/m²)
 - Physical inactivity
 - Tobacco use

Symptoms

- Most patients are asymptomatic.

Signs

- Previous BP values in the prehypertension or hypertension category.

Laboratory Tests

- Blood urea nitrogen/serum creatinine, fasting lipid panel, fasting blood glucose, serum electrolytes, spot urine albumin-to-creatinine ratio. The patient may have normal values and still have hypertension. However, some may have abnormal values consistent with either additional CV risk factors or hypertension-related damage.

Other Diagnostic Tests

- 12-lead electrocardiogram (to detect left ventricular hypertrophy), estimated glomerular filtration rate (using Modification of Diet in Renal Disease equation).
- 10-year risk of fatal coronary heart disease or non-fatal myocardial infarction, based on Framingham scoring.

Target-Organ Damage

- The patient may have a previous medical history or diagnostic findings that indicate the presence of hypertension-related target-organ damage:
 - Brain (stroke, transient ischemic attack)
 - Eyes (retinopathy)
 - Heart (left ventricular hypertrophy, angina or prior MI, prior coronary revascularization, heart failure)
 - Kidney (chronic kidney disease)
 - Peripheral vasculature (peripheral arterial disease)

3 DIAGNOSTIC CONSIDERATIONS

Hypertension is termed the “silent killer” because most patients do not have symptoms. The primary physical finding is elevated BP. The diagnosis of hypertension cannot be made based on one elevated BP measurement. The average of two or more measurements taken during two or more clinical encounters should be used to diagnose hypertension.¹ Thereafter, this BP average can be used to establish a diagnosis, and then classify the stage of hypertension present using Table 15–3.

Measuring Blood Pressure

Indirect measurement of BP using a sphygmomanometer is a common routine medical screening tool that should be conducted at every healthcare encounter.¹

Sphygmomanometry—American Heart Association Procedure¹⁴ The appropriate procedure to measure BP has been described by the AHA.¹⁴ It is imperative that the measurement equipment (inflation cuff, stethoscope, manometer) meet certain national standards to ensure maximum quality and precision with the auscultatory measurement of BP.

The AHA stepwise technique is recommended:

- Patients should refrain from nicotine or caffeine ingestion for 30 minutes and be seated with the lower back supported in a chair and with their bare arm supported and resting near heart level. Feet should be flat on the floor (with legs not crossed). Measuring BP in the supine or standing position may be required under special circumstances (suspected orthostatic hypotension, volume depletion, or dehydration). The measurement environment should be relatively quiet and provide privacy.
- Measurement should begin only after a 5-minute period of rest.
- A properly sized cuff (pediatric, small, regular, large, or extra large) should be used. If the cuff is too small, the measured BP can be overestimated. The inflatable rubber bladder inside the cuff should encircle at least 80% of the arm of the upper arm in length and 40% in width.

- The palpatory method should be used to estimate the SBP:
 - Place the cuff on the upper arm 2 to 3 cm above the antecubital fossa and attach it to the manometer (either a mercury or aneroid)
 - Close the inflation valve with the thumb and index finger, and inflate the cuff to 70 mm Hg
 - Simultaneously palpate the radial pulse with the index and middle fingers of the opposite hand
 - Inflate in increments of 10 mm Hg by pumping the inflation bulb (as it is resting in the palm of your hand) with the pinky, ring, and middle fingers (the last three) until the radial pulse disappears
 - Note the pressure at which radial pulse disappears; this is the estimated SBP
 - Release pressure from the cuff by turning the valve counter-clockwise
- The bell (not the diaphragm) of the stethoscope should be placed on the skin of the antecubital fossa, directly over where the brachial artery is palpated. The stethoscope earpieces should be inserted appropriately. The valve should be closed with the cuff then inflated rapidly to about 30 mm Hg above the estimated SBP from the palpatory method. The valve should be only slightly opened to release pressure at a very slow rate of 2 to 3 mm Hg per second.
- The clinician should listen for Korotkoff sounds with the stethoscope. The first phase of Korotkoff sounds are the initial presence of clear tapping sounds. Note the pressure at the first recognition of these sounds. This is the SBP. As pressure continues to deflate, note the pressure when all sounds disappear (also known as the fifth Korotkoff phase). This is the DBP.
- Measurements should be taken to the nearest 2 mm Hg.
- A second measurement should be obtained after a minimum of 1 minute, and the average should be documented. If these values differ by more than 5 mm Hg, additional measurements should be collected and averaged.
- Neither the patient nor the observer should talk during measurement.
- At the first visit, BP should be measured in both arms. When consistent interarm differences exist, the higher number should be used for diagnostic and treatment purposes.

It is recommended that the stethoscope bell, rather than the diaphragm, be used for measurement, although some studies suggest little difference between two.¹⁴ Low-frequency Korotkoff sounds, however, may not be heard clearly and accurately with the diaphragm. This is especially problematic in patients with faint or “distant” sounds.

Inaccuracies with indirect measurements result from inherent biologic variability of BP, inaccuracies related to suboptimal technique, and the white coat effect.¹⁴ Variations in BP occur with environmental temperature, the time of day and year, meals, physical activity, posture, alcohol, nicotine, and emotions. In the clinic setting, standard BP measurement procedures (e.g., appropriate rest period, poor technique, minimal number of measurements) are often not followed, which results in poor estimation of true BP. Approximately 15% to 20% of patients have *white coat hypertension*, where BP values rise in a clinical setting but return to normal in nonclinical environments using home or ambulatory BP measurements.¹⁴ Interestingly, the rise in BP dissipates gradually over several hours after leaving the clinical setting. It may or may not be precipitated by other stresses in the patient’s daily life.

CLINICAL CONTROVERSY

Aggressive treatment of white coat hypertension is controversial. However, patients with white coat hypertension may have increased CV risk compared with those without such BP changes.¹⁵

Several additional factors can result in erroneous BP measurements. *Pseudohypertension* is a falsely elevated BP measurement. It may be seen in the elderly, those with long-standing diabetes, or in those with chronic kidney disease caused by rigid, calcified brachial arteries.¹⁴ In these patients, the true arterial BP when measured directly with intraarterial measurement (the most accurate measurement of BP) is much lower than that measured using the indirect cuff method. The Osler maneuver can be used to test for pseudohypertension. In this maneuver, the BP cuff is inflated above peak SBP. If the radial artery remains palpable, the patient has a positive Osler sign (rigid artery), which may indicate pseudohypertension.

Elderly patients with a wide pulse pressure may have an auscultatory gap which can lead to underestimated SBP or overestimated DBP measurements.¹⁴ In this situation, as the cuff pressure falls from the true SBP value, the Korotkoff sound may disappear (indicating a false DBP measurement), reappear (a false SBP measurement), and then disappear again at the true DBP value. This is often identified by using the palpatory method to estimate SBP and then inflating the cuff an additional 30 mm Hg above this estimate because the “gap” is usually less than 30 mm Hg. When an auscultatory gap is present, Korotkoff sounds are usually heard when pressure in the cuff first starts to decrease after inflation. This may be eliminated by raising the arm overhead for 30 seconds before bringing it to the proper position and inflating the cuff. This maneuver decreases the intravascular volume and improves inflow thereby allowing Korotkoff sounds to be heard.¹⁴

Patients with irregular ventricular heart rates (e.g., atrial fibrillation, atrial flutter) may have misleading BP values when measured indirectly. In this situation, SBP and DBP values may vary from one heartbeat to the next.

Ambulatory and Self Blood Pressure Monitoring

Ambulatory BP monitoring using an automated device can document BP at frequent time intervals (e.g., every 15 to 30 minutes) throughout a 24-hour period.¹⁴ Ambulatory BP values are usually lower than clinic-measured values. The upper limit for normal ambulatory BP is 140/90 mm Hg during the day, 125/75 mm Hg at night, and 135/85 mm Hg during 24 hours. Home BP measurements are collected by patients, preferably in the morning, using home monitoring devices. Either of these may be warranted in patients with suspected white coat hypertension (without hypertension-related target-organ damage) to differentiate white coat from essential hypertension.¹ Moreover, ambulatory BP monitoring may be helpful in patients with apparent drug resistance, hypotensive symptoms while on antihypertensive therapy, episodic hypertension (e.g., white coat hypertension), autonomic dysfunction, and to identify “nondippers” whose BP does not decrease by >10% during sleep and which may portend increased risk of BP-related complications.^{1,14}

Some data suggest that 24-hour and home BP measurements correlate better with CV risk than do conventional office-based BP measurements.^{14,16} However, one controlled study found that ambulatory BP and self BP monitoring are complementary to conventional clinic-based measurements.¹⁷ Limitations of these measurements that may prohibit routine use of such technology include lack of validated devices, complexity of use, costs, and lack of prospective outcomes data describing normal ranges for these measurements. Although self-monitoring of BP at home is less complicated and less costly than ambulatory monitoring, patients may omit or fabricate readings. Thus, devices that have a memory or printouts are recommended.¹⁴

CLINICAL EVALUATION

Frequently, the only sign of essential hypertension is elevated BP. The rest of the physical examination may be completely normal. However, a complete medical evaluation (a comprehensive medical history, physical examination, and laboratory and/or diagnostic tests) is recommended after diagnosis to (a) identify secondary causes, (b) identify other CV risk factors or comorbid conditions that may define prognosis and/or guide therapy, and (c) assess for the presence or absence of hypertension-associated target-organ damage.¹ All patients with hypertension should have the following measured prior to initiating therapy: 12-lead electrocardiogram; spot urine albumin-to-creatinine ratio; blood glucose and hematocrit; serum potassium, creatinine (with estimated glomerular filtration rate [GFR]), and calcium; and a fasting lipid panel.^{1,18} For patients without a history of coronary artery disease, noncoronary atherosclerotic vascular disease (also referred to as coronary artery disease risk equivalents), left ventricular dysfunction, or diabetes, it is also important to estimate a 10-year risk of fatal coronary heart disease or nonfatal myocardial infarction using Framingham Risk scoring (http://www.nhlbi.nih.gov/guidelines/cholesterol/risk_tbl.htm).²

Secondary Causes

Table 15–1 lists the most common secondary causes of hypertension. A complete medical evaluation may provide clues for identifying secondary hypertension.

Patients with secondary hypertension may complain of symptoms suggestive of the underlying disorder, but some are asymptomatic. Patients with pheochromocytoma may have a history of paroxysmal headaches, sweating, tachycardia, and palpitations. Over half of these patients suffer from episodes of orthostatic hypotension. In primary aldosteronism, symptoms related to hypokalemia usually include muscle cramps and muscle weakness. Patients with Cushing's syndrome may complain of weight gain, polyuria, edema, menstrual irregularities, recurrent acne, or muscular weakness and have several classic physical features (e.g., moon face, buffalo hump, hirsutism, abdominal striae). Patients with coarctation of the aorta may have diminished or even absent femoral pulses, and patients with renal artery stenosis may have an abdominal systolic–diastolic bruit.

Routine laboratory tests may also help identify secondary hypertension. Baseline hypokalemia may suggest mineralocorticoid-induced hypertension. Protein, blood cells, and casts in the urine may indicate renovascular disease. Some laboratory tests are used specifically to diagnose secondary hypertension. These include plasma norepinephrine and urinary metanephrine for pheochromocytoma, plasma and urinary aldosterone concentrations for primary aldosteronism, and plasma renin activity, captopril stimulation test, and renal artery angiography for renovascular disease.

Certain medications and herbal products can result in drug-induced hypertension (see Table 15–1). For some patients, the addition of these agents can be the cause of hypertension or can exacerbate underlying hypertension. Identifying a temporal relationship between starting the suspected agent and developing elevated BP is most suggestive of drug-induced BP elevation.

NATURAL COURSE OF DISEASE

Essential hypertension is usually preceded by elevated BP values that are in the prehypertension category. BP values may fluctuate between elevated and normal levels for an extended period of time. These changes may begin as early as the second decade of life. During this stage, many patients have a hyperdynamic circulation with increased cardiac output and normal or even low peripheral vascular resistance. As the disease progresses, peripheral vascular resistance increases, and BP elevation is sustained to the point where essential hypertension is diagnosed.

Target-Organ Damage

Target-organ damage (see Clinical Presentation of Hypertension above) can develop as a complication of hypertension. The primary organs involved are the eye, brain, heart, kidneys, and peripheral blood vessels. Clinical CV events (e.g., MI, stroke, kidney failure) are clinical end points of target-organ damage and are the primary causes of CV morbidity and mortality in patients with hypertension. The probability of CV events and CV morbidity and mortality in patients with hypertension is directly correlated with the severity of BP elevation and additional CV risk factors.

Hypertension accelerates atherosclerosis and stimulates left ventricular and vascular hypertrophy. These pathologic changes are thought to be secondary to both a chronic pressure overload and a variety of nonhemodynamic stimuli. Some of the nonhemodynamic disturbances that have been implicated in these effects include the adrenergic system, RAAS, increased synthesis and secretion of endothelin I, and a decreased production of prostacyclin and nitric oxide. Accelerated atherogenesis in hypertension is accompanied by proliferation of smooth muscle cells, lipid infiltration into the vascular endothelium, and an enhancement of vascular calcium accumulation.

Cerebrovascular disease is a consequence of hypertension. A neurologic assessment can detect either gross neurologic deficits or a slight hemiparesis with some incoordination and hyperreflexia that are indicative of cerebrovascular disease. Stroke can result from lacunar infarcts caused by thrombotic occlusion of small vessels or intracerebral hemorrhage resulting from ruptured microaneurysms. Transient ischemic attacks secondary to atherosclerotic disease in the carotid arteries are possible long-term complications of hypertension.

Retinopathies can occur in hypertension and may manifest as a variety of different findings. A fundoscopic examination can detect hypertensive retinopathy and can be categorized according to the Keith-Wagener-Barker retinopathy classification. Retinopathy manifests as arteriolar narrowing, focal arteriolar constrictions, arteriovenous crossing changes (nicking), retinal hemorrhages and exudates, and disk edema. Accelerated arteriosclerosis, a long-term consequence of essential hypertension, can cause nonspecific changes such as increased light reflex, increased tortuosity of vessels, and arteriovenous nicking. Focal arteriolar narrowing, retinal infarcts, and flame-shaped hemorrhages usually are suggestive of accelerated or malignant phase of hypertension. Papilledema is swelling of the optic disk and is caused by a breakdown in autoregulation of capillary blood flow in the presence of high pressure. It is usually only present in hypertensive emergencies.

Heart disease is the best identified form of target-organ damage. A thorough cardiac and pulmonary examination can identify cardiopulmonary abnormalities. Clinical manifestations include left ventricular hypertrophy, coronary heart disease (angina, prior MI, and prior coronary revascularization), and heart failure. These complications may lead to cardiac arrhythmias, angina, MI, and sudden death. Coronary disease (also called coronary heart disease or coronary artery disease) and associated CV events are the most common causes of death in patients with hypertension.

The kidney damage caused by hypertension is characterized pathologically by hyaline arteriosclerosis, hyperplastic arteriosclerosis, arteriolar hypertrophy, fibrinoid necrosis, and atheroma of the major renal arteries. Glomerular hyperfiltration and intraglomerular hypertension are early stages of hypertensive nephropathy. Microalbuminuria is followed by a gradual decline in renal function. The primary renal complication in hypertension is nephrosclerosis, which is secondary to arteriosclerosis. Atheromatous disease of a major renal artery may give rise to renal artery stenosis. Although overt kidney failure is an uncommon complication of essential hypertension, it is an important cause of end-stage kidney disease, especially in African Americans, Hispanics, and Native Americans. It is not completely understood why these ethnic groups are more at risk for kidney decline than other ethnic groups.

The peripheral vasculature is a target organ. Physical examination of the vascular system can detect evidence of atherosclerosis, which may present as arterial bruits (aortic, abdominal, or peripheral), distended veins, diminished or absent peripheral arterial pulses, or lower-extremity edema. Peripheral arterial disease is a clinical condition that can result from atherosclerosis, which is accelerated in hypertension. Other CV risk factors (e.g., smoking) can increase the likelihood of peripheral arterial disease as well as all other forms of target-organ damage.

TREATMENT

Hypertension

■ DESIRED OUTCOMES

④ Overall Goal of Therapy

The overall goal of treating hypertension is to reduce hypertension-associated morbidity and mortality.¹ This morbidity and mortality is related to target-organ damage (e.g., CV events, heart failure, and kidney disease). Reducing risk remains the primary purpose of hypertension therapy and the specific choice of drug therapy is significantly influenced by evidence demonstrating such risk reduction.

⑤ Surrogate Goal of Therapy

Treating patients with hypertension to achieve a desired target BP value is simply a surrogate goal of therapy. Reducing BP to goal does not guarantee that target-organ damage will not occur. However, attaining goal BP values is associated with lower risk of CV disease and target-organ damage.^{1,19} Targeting a goal BP value is a tool that clinicians can easily use to evaluate response to therapy and is the primary method used to determine the need for titration and regimen modification.

Most patients have a goal BP of less than 140/90 mm Hg for the general prevention of CV events or CV disease (e.g., coronary artery disease).^{1,2} However, this goal is lowered to less than 130/80 mm Hg for patients with diabetes, significant chronic kidney disease, known coronary artery disease (myocardial infarction, stable angina, unstable angina), noncoronary atherosclerotic vascular disease (ischemic stroke, transient ischemic attack, peripheral arterial disease, abdominal aortic aneurism), or a 10% or greater 10-year risk of fatal coronary heart disease or nonfatal myocardial infarction based on Framingham risk scoring (http://www.nhlbi.nih.gov/guidelines/cholesterol/risk_tbl.htm).² Moreover, patients with left ventricular dysfunction (heart failure) have a BP goal of less than 120/80 mm Hg.²

GOAL BLOOD PRESSURE VALUES RECOMMENDED BY THE AMERICAN HEART ASSOCIATION IN 2007²

- | | |
|---|---------------|
| • Most patients for general prevention | <140/90 mm Hg |
| • Patients with diabetes (referred to as coronary artery disease risk equivalent), significant chronic kidney disease, known coronary artery disease (myocardial infarction, stable angina, unstable angina), noncoronary atherosclerotic vascular disease (ischemic stroke, transient ischemic attack, peripheral arterial disease, abdominal aortic aneurism [referred to as coronary artery disease risk equivalents]), or a Framingham risk score of 10% or greater | <130/80 mm Hg |
| • Patients with left ventricular dysfunction (heart failure) | <120/80 mm Hg |

Significant chronic kidney disease is considered to be moderate-to-severe chronic kidney disease, defined as estimated GFR <60 mL/min/1.73 m² (correlating to a serum creatinine >1.3 mg/dL in women and >1.5 in men) or albuminuria (>300 mg/day or >200 mg/g creatinine).

Framingham risk score is calculated using the risk calculator available at http://www.nhlbi.nih.gov/guidelines/cholesterol/risk_tbl.htm

Some clinicians advocate attaining BP goal values that are lower than what is recommended as a modality to further reduce CV risk following the myth that “lower is better.” Contrary to this, a *J-curve hypothesis*, where lowering BP too much might increase the risk of CV events, has been described.²⁰ However, these data are based off of observational studies and cannot establish a cause-and-effect relationship because of confounding variables.

Lower goal BP values have been evaluated prospectively in the Hypertension Optimal Treatment (HOT) trial.¹⁹ In this study, more than 18,700 patients were randomized to target DBP values of 90 mm Hg or less, 85 mm Hg or less, or 80 mm Hg or less. Although the actual DBP values achieved were 85.2, 83.2, and 81.1 mm Hg, respectively, the risk of major CV events was the lowest with a BP of 139/83 mm Hg, and the lowest risk of stroke was with a BP of 142/80 mm Hg. Risk of events in subjects with either diabetes or ischemic heart disease were lowest at DBP values of less than 80 mm Hg. No J-curve relationship was seen.

CLINICAL CONTROVERSY

There is increasing evidence suggesting that ambulatory BP measurements may be more accurate and better predict target-organ damage than manual BP measurements using a sphygmomanometer in a clinic setting (considered the gold standard).¹⁴ Studies document that large numbers of individuals may be misdiagnosed or misclassified based on clinic BP measurements as a result of a variety of factors such as poor technique, daily variability of BP, and white coat hypertension. Validated ambulatory BP monitoring may obviate some of these factors, but their role in the routine management of hypertension is unclear.

■ AVOIDING CLINICAL INERTIA

Although hypertension is one of the most common medical conditions, BP control rates are poor. Many patients, especially older patients, with hypertension are at goal DBP values but continue to have elevated SBP values. It has been estimated that of the hypertensive population that is treated, yet not controlled, 76.9% have SBP ≥140 mm Hg with DBP values less than 90 mm Hg.²¹ For most patients with hypertension, attaining the SBP goal almost always assures achievement of the DBP goal. When coupled with the fact that SBP is a better predictor of CV risk than DBP, SBP must be used as the primary clinical marker of disease control in hypertension.

Clinical inertia in hypertension has been defined as an office visit at which no therapeutic move was made to lower BP in a patient with uncontrolled hypertension.²² Clinical inertia is not the entire reason why most patients with hypertension do not have at-goal BP values. However, it is certainly a major reason that can be simply remedied through more aggressive treatment with drug therapy. This can involve initiating, titrating, or changing drug therapy.

■ GENERAL APPROACH TO TREATMENT

After a definitive diagnosis of hypertension is made, most patients should be placed on both lifestyle modifications and drug therapy concurrently. Lifestyle modification alone is considered appropriate therapy for patients with prehypertension. However, lifestyle modi-

FIGURE 15-2. Algorithm for treatment of hypertension. Drug therapy recommendations are graded with strength of recommendation and quality of evidence in brackets. Strength of recommendations: A, B, C = good, moderate, and poor evidence to support recommendation, respectively. Quality of evidence: 1 = Evidence from more than 1 properly randomized, controlled trial. 2 = Evidence from at least one well-designed clinical trial with randomization; from cohort or case-controlled analytic studies; or dramatic results from uncontrolled experiments or subgroup analyses. 3 = Evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities. (ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; CCB, calcium channel blocker; DBP, diastolic blood pressure; SBP, systolic blood pressure.) (Adapted from references 1 and 2.)

fications alone are not considered adequate for patients with hypertension and additional CV risk factors, especially patients with BP goals of less than 130/80 mm Hg (e.g., diabetes, coronary artery disease, chronic kidney disease) or less than 120/80 mm Hg (i.e., left ventricular dysfunction), who have not attained this goal BP.

The choice of initial drug therapy depends on the degree of BP elevation and presence of compelling indications (see Patients with Compelling Indications section). Most patients with stage 1 hypertension should be initially treated with a thiazide-type diuretic, ACE inhibitor, ARB, or CCB. For patients with more severe BP elevation (stage 2 hypertension), combination drug therapy, with one of the agents being preferably a thiazide type-diuretic, is recommended. Figure 15–2 outlines this general approach. There are six compelling indications where specific antihypertensive drug classes have evidence showing unique benefits in patients with the compelling indication (Fig. 15–3).

■ 6 NONPHARMACOLOGIC THERAPY

All patients with prehypertension and hypertension should be prescribed lifestyle modifications. Table 15–4 lists modifications that lower BP. These approaches are recommended by the JNC7 and the AHA.^{1,23} They can provide small to moderate reductions in SBP. Aside from lowering BP in patients with known hypertension, lifestyle modification can decrease the progression to hypertension in patients with prehypertension BP values.²³ In a portion of patients with hypertension that have relatively good BP control while on single antihypertensive drug therapy, sodium reduction and weight loss may allow withdrawal of drug therapy.²⁴

A sensible dietary program is one that is designed to reduce weight gradually, for overweight and obese patients, and one that restricts sodium intake with only moderate alcohol consumption. Successful implementation of dietary lifestyle modifications by clinicians requires aggressive promotion through reasonable patient education, encouragement, and continued reinforcement. Patients may better understand the rationale for dietary intervention in hypertension if they are provided the following observations and facts²³:

1. Hypertension is two to three times more likely in overweight than in lean persons.
2. More than 60% of patients with hypertension are overweight.

3. As little as 10 pounds of weight loss can decrease BP significantly in overweight patients.
4. Abdominal obesity is associated with the metabolic syndrome, which is a precursor to diabetes, dyslipidemia, and, ultimately, CV disease.¹³
5. Diets rich in fruits and vegetables and low in saturated fat lower BP in patients with hypertension.
6. Most people experience some degree of SBP reduction with sodium restriction.

The Dietary Approaches to Stop Hypertension (DASH) eating plan is a diet that is rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated and total fat. It is advocated by the JNC7 as a reasonable and feasible diet that is proven to lower BP. Intake of sodium should be minimized as much as possible, ideally to 1.5 g/day, although an interim goal of less than 2.3 g/day may be reasonable considering the difficulty in achieving these low intakes. Patients should be aware of the multiple sources of dietary sodium (e.g., processed foods, soups, table salt) so that they may follow these recommendations. Potassium intake should be encouraged through fruits and vegetables with high content (ideally 4.7 g/day) in those with normal kidney function. Excessive alcohol use can either cause or worsen hypertension. Patients with hypertension who drink alcoholic beverages should restrict their daily intake (see Table 15–4). Patients should be counseled that 1 drink is equivalent to 1.5 oz of 80-proof distilled spirits (e.g., whiskey), a 5 oz glass of wine (12%), or 12 oz of beer.²³

Carefully designed programs of physical activity can lower BP. Regular physical activity for at least 30 minutes most days of the week is recommended for all adults, with at least 60 minutes recommended for adults attempting to lose weight or maintain weight loss.²⁵ Studies show that aerobic exercise can reduce BP, even in the absence of weight loss. Patients should consult their physicians before starting an exercise program, especially those with CV and/or target-organ disease.

Cigarette smoking is a major, independent, modifiable risk factor for CV disease. Patients with hypertension who smoke should be thoroughly counseled regarding the additional health risks that result from smoking. Moreover, the potential benefits that cessation can provide should be explained to encourage cessation. Several smoking-cessation programs, pharmacotherapy options, and aids are available to assist patients.

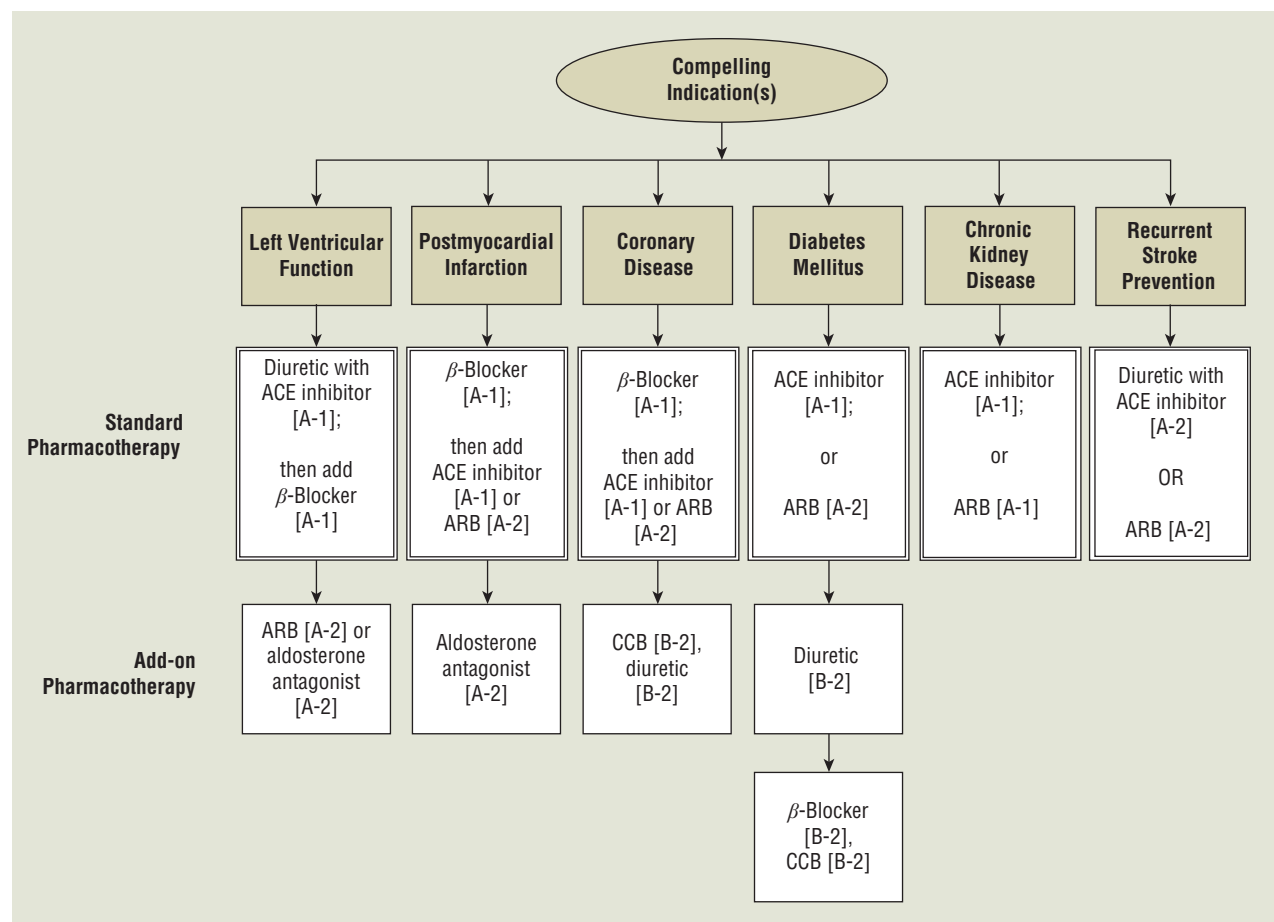

FIGURE 15-3. Compelling indications for individual drug classes. Compelling indications for specific drugs are evidence-based recommendations from outcome studies or existing clinical guidelines. The order of drug therapies serves as a general guidance that should be balanced with clinical judgment and patient response; however, standard pharmacotherapy should be considered first-line recommendations, preferably in the order depicted. Add-on pharmacotherapy recommendations then are intended to be used to further reduce risk of cardiovascular events and to lower blood pressure to goal values. Blood pressure control should be managed concurrently with the compelling indication. Drug therapy recommendations are graded with strength of recommendation and quality of evidence in brackets. Strength of recommendations: A, B, C = good, moderate, and poor evidence to support recommendation, respectively. Quality of evidence: 1 = Evidence from more than one properly randomized, controlled trial. 2 = Evidence from at least one well-designed clinical trial with randomization; from cohort or case-controlled analytic studies or multiple time series; or dramatic results from uncontrolled experiments or subgroup analyses. 3 = Evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities. (ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; CCB, calcium channel blocker.) (Adapted from references 1, 2, 58, and 74.)

■ PHARMACOTHERAPY

A diuretic (primarily a thiazide-type), ACE inhibitor, angiotensin II receptor blocker (ARB), or calcium channel blocker (CCB) are considered primary antihypertensive agents that are acceptable first-line options (Table 15-5). These agents should be used to treat the majority of patients with hypertension because evidence from out-

comes data have demonstrated CV risk reduction benefits with these classes. Several have subclasses where significant differences in mechanism of action, clinical use, side effects, or evidence from outcomes studies exist. β -Blockers are effective antihypertensive agents that previously were considered primary agents. They are now preferred either to treat a specific compelling indication, or in combination with one of the aforementioned primary antihypertensive agents for

TABLE 15-4 Lifestyle Modifications to Prevent and Manage Hypertension

Modification	Recommendation	Approximate Systolic Blood Pressure Reduction (mm Hg) ^a
Weight loss	Maintain normal body weight (body mass index 18.5–24.9 kg/m ²)	5–20 per 10-kg weight loss
DASH-type dietary patterns	Consume a diet rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated and total fat	8–14
Reduced salt intake	Reduce daily dietary sodium intake as much as possible, ideally to \approx 65 mmol/day (1.5 g/day sodium, or 3.8 g/day sodium chloride)	2–8
Physical activity	Regular aerobic physical activity (at least 30 min/day, most days of the week)	4–9
Moderation of alcohol intake	Limit consumption to \leq 2 drinks/day in men and \leq 1 drink/day in women and lighter-weight persons	2–4

DASH, Dietary Approaches to Stop Hypertension.

^aEffects of implementing these modifications are time and dose dependent and could be greater for some patients.

Data from Chobanian et al.,¹ and Kostis et al.²⁴

TABLE 15-5 Primary Antihypertensive Agents

Class	Subclass	Drug (Brand Name)	Usual Dose Range (mg/day)	Daily Frequency	Comments
Diuretics	Thiazides	Chlorthalidone (Hygroton)	12.5–25	1	Dose in the morning to avoid nocturnal diuresis; thiazides are more effective antihypertensives than loop diuretics in most patients; use usual doses to minimize adverse metabolic effects; ideally maintain potassium concentration between 4.0–5.0 mEq/L to minimize metabolic effects; hydrochlorothiazide and chlorthalidone are generally preferred, with 25 mg/day generally considered the maximum effective dose; chlorthalidone is nearly twice as potent as hydrochlorothiazide; have additional benefits in osteoporosis; may require additional monitoring in patients with a history of gout or hyperglycemia
		Hydrochlorothiazide (Microzide)	12.5–25	1	
		Indapamide (Lozol)	1.25–2.5	1	
		Metolazone (Zaroxolyn)	2.5–5	1	
	Loops	Bumetanide (Bumex)	0.5–4	2	Dose in the morning and afternoon to avoid nocturnal diuresis; higher doses may be needed for patients with severely decreased glomerular filtration rate or left ventricular dysfunction
		Furosemide (Lasix)	20–80	2	
		Torsemide (Demadex)	5–10	1	
	Potassium sparing	Amiloride (Midamor)	5–10	1 or 2	Dose in the morning or afternoon to avoid nocturnal diuresis; weak diuretics that are generally used in combination with thiazide-type diuretics to minimize hypokalemia; avoid in patients with severe chronic kidney disease (estimated glomerular filtration rate <30 mL/min/1.73 m ²); may cause hyperkalemia, especially in combination with an ACE inhibitor, ARB, direct renin inhibitor or potassium supplements
		Amiloride/hydrochlorothiazide (Moduretic)	5–10/50–100	1	
		Triamterene (Dyrenium)	50–100	1 or 2	
		Triamterene/hydrochlorothiazide (Dyazide)	37.5–75/25–50	1	
	Aldosterone antagonists	Eplerenone (Inspra)	50–100	1 or 2	Dose in the morning or afternoon to avoid nocturnal diuresis; eplerenone contraindicated in patients with an estimated creatinine clearance <50 mL/min, elevated serum creatinine (>1.8 mg/dL in women, >2 mg/dL in men), and type 2 diabetes with microalbuminuria; avoid spironolactone in patients with chronic kidney disease (estimated glomerular filtration rate <30 mL/min/1.73 m ²); may cause hyperkalemia, especially in combination with an ACE inhibitor, ARB, direct renin inhibitor or potassium supplements
		Spironolactone (Aldactone)	25–50	1 or 2	
		Spironolactone/hydrochlorothiazide (Aldactazide)	25–50/25–50	1	
ACE inhibitors		Benazepril (Lotensin)	10–40	1 or 2	Starting dose may be reduced 50% in patients who are on a diuretic, are volume depleted, or are very elderly because of risks of hypotension; may cause hyperkalemia in patients with chronic kidney disease or in those receiving potassium-sparing diuretics, aldosterone antagonists, ARB, or direct renin inhibitors; can cause acute kidney failure in patients with severe bilateral renal artery stenosis or severe stenosis in artery to solitary kidney; do not use in pregnancy or in patients with a history of angioedema
		Captopril (Capoten)	25–150	2 or 3	
		Enalapril (Vasotec)	5–40	1 or 2	
		Fosinopril (Monopril)	10–40	1	
		Lisinopril (Prinivil, Zestril)	10–40	1	
		Moexipril (Univasc)	7.5–30	1 or 2	
		Perindopril (Aceon)	4–16	1	
		Quinapril (Accupril)	10–80	1 or 2	
		Ramipril (Altace)	2.5–10	1 or 2	
		Trandolapril (Mavik)	1–4	1	
ARBs		Candesartan (Atacand)	8–32	1 or 2	Starting dose may be reduced 50% in patients who are on a diuretic, are volume depleted, or are very elderly because of risks of hypotension; may cause hyperkalemia in patients with chronic kidney disease or in those receiving potassium-sparing diuretics, aldosterone antagonists, ACE inhibitors, or direct renin inhibitor; can cause acute kidney failure in patients with severe bilateral renal artery stenosis or severe stenosis in artery to solitary kidney; do not cause a dry cough like ACE inhibitors may; do not use in pregnancy
		Eprosartan (Teveten)	600–800	1 or 2	
		Irbesartan (Avapro)	150–300	1	
		Losartan (Cozaar)	50–100	1 or 2	
		Olmesartan (Benicar)	20–40	1	
		Telmisartan (Micardis)	20–80	1	
		Valsartan (Diovan)	80–320	1	
Calcium channel blockers	Dihydropyridines	Amlodipine (Norvasc)	2.5–10	1	Short-acting dihydropyridines should be avoided, especially immediate-release nifedipine and nicardipine; dihydropyridines are more potent peripheral vasodilators than nondihydropyridines and may cause more reflex sympathetic discharge (tachycardia), dizziness, headache, flushing, and peripheral edema; have additional benefits in Raynaud's syndrome
		Felodipine (Plendil)	5–20	1	
		Isradipine (DynaCirc)	5–10	2	
		Isradipine SR (DynaCirc SR)	5–20	1	
		Nicardipine SR (Cardene SR)	60–120	2	
		Nifedipine long-acting (Adalat CC, Procardia XL)	30–90	1	
		Nisoldipine (Sular)	10–40	1	

(continued)

TABLE 15-5 Primary Antihypertensive Agents (continued)

Class	Subclass	Drug (Brand Name)	Usual Dose Range (mg/day)	Daily Frequency	Comments
β -Blockers	Nondihydropyridines	Diltiazem SR (Cardizem SR)	180–360	2	Extended-release and sustained-release products are preferred for hypertension; these agents block slow channels in the heart and reduce heart rate; may produce heart block, especially in combination with β -blockers; these products are not AB rated as interchangeable on a equipotent mg-per-mg basis because of different release mechanisms and different bioavailability parameters; Cardizem LA, Covera HS, and Verelan PM have delayed drug release for several hours after dosing; when dosed in the evening can provide chronotherapeutic drug delivery starting shortly before patients awake from sleep; have additional benefits in patients with atrial tachyarrhythmia
		Diltiazem SR (Cardizem CD, Cartia XT, Dilacor XR, Diltia XT, Tiazac, Taztia XT)	120–480	1	
		Diltiazem ER (Cardizem LA)	120–540	1 (morning or evening)	
		Verapamil SR (Calan SR, Isoptin SR, Verelan)	180–480	1 or 2	
		Verapamil ER (Covera HS)	180–420	1 (in the evening)	
		Verapamil oral drug absorption system ER (Verelan PM)	100–400	1 (in the evening)	
	Cardioselective	Atenolol (Tenormin)	25–100	1	Abrupt discontinuation may cause re-bound hypertension; inhibit β_1 -receptors at low to moderate dose, higher doses also block β_2 -receptors; may exacerbate asthma when selectivity is lost; have additional benefits in patients with atrial tachyarrhythmia or preoperative hypertension
		Betaxolol (Kerlone)	5–20	1	
		Bisoprolol (Zebeta)	2.5–10	1	
		Metoprolol tartrate (Lopressor)	100–400	2	
		Metoprolol succinate (Toprol XL)	50–200	1	
		Nadolol (Corgard)	40–120	1	Abrupt discontinuation may cause rebound hypertension; inhibit β_1 - and β_2 -receptors at all doses; can exacerbate asthma; have additional benefits in patients with essential tremor, migraine headache, thyrotoxicosis
		Propranolol (Inderal)	160–480	2	
		Propranolol long-acting (Inderal LA, InnoPran XL)	80–320	1	
		Timolol (Blocadren)	10–40	1	Abrupt discontinuation may cause rebound hypertension; partially stimulate β -receptors while blocking against additional stimulation; no clear advantage for these agents; contraindicated in patients with coronary disease or post-myocardial infarction
		Acebutolol (Sectral)	200–800	2	
	Intrinsic sympathomimetic activity	Carteolol (Cartrol)	2.5–10	1	
		Penbutolol (Levitol)	10–40	1	
		Pindolol (Visken)	10–60	2	Abrupt discontinuation may cause rebound hypertension; additional α -blockade produces more orthostatic hypotension
		Carvedilol (Coreg)	12.5–50	2	
	Mixed α - and β -blockers	Carvedilol phosphate (Coreg CR)	20–80	1	
		Labetalol (Normodyne, Trandate)	200–800	2	

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; ER, extended-release; SR, sustained-release.

patients without a compelling indication. Other antihypertensive drug classes are considered alternative drug classes that may be used in select patients after primary agents (Table 15–6).

CLINICAL CONTROVERSY

Prehypertension is a BP classification that identifies patients who do not have hypertension, but are at risk for developing it. The Trial of Preventing Hypertension (TROPHY) showed that treating patients with prehypertension with the ARB candesartan decreased progression to stage 1 hypertension.²⁶ However, it is not known whether managing prehypertension with antihypertensive drug therapy, in addition to lifestyle modifications, decreases CV events or whether this treatment approach is cost-effective.

7 Thiazide-Type Diuretics as Traditional First-Line Therapy for Most Patients

JNC7 guidelines recommend thiazide-type diuretics whenever possible, as first-line therapy for most patients, which is consistent with the traditional pharmacotherapy of hypertension.¹ However, AHA guidelines do not recommend thiazide-type diuretics as preferred over an ACE inhibitor, ARB, or CCB for first-line therapy. Figure 15–2 displays the algorithm for the treatment of hypertension. This recommendation is specifically for patients without compelling indications and is based on best available evidence demonstrating reductions in CV morbidity and mortality.

Landmark placebo-controlled clinical trials—SHEP (Systolic Hypertension in the Elderly Program),⁹ STOP (Swedish Trial in Old Patients),¹⁰ and MRC (Medical Research Council)¹¹—showed significant reductions in stroke, MI, all-cause CV disease, and mortality with thiazide-type diuretic-based therapy versus placebo. These trials allowed for β -blockers as add-on therapy for BP control. Newer agents (ACE inhibitors, ARBs, and CCBs) were not available at the time of these studies. However, subsequent clinical trials have compared these newer antihypertensive agents to thiazide-type diuretics.^{27–32} These data show similar effects, but most trials used a prospective open-label, blinded end point study methodology that is not double-blinded and limited their ability to prove equivalence of newer drugs to diuretics. Other prospective trials have compared different primary antihypertensive agents to each other.^{29,33,34} Although these studies used head-to-head comparisons, they did not use a thiazide-type diuretic as their comparator treatment. Consequently, their results cannot be easily used to justify an antihypertensive drug class other than a thiazide-type diuretic as first-line therapy.

The ALLHAT Study³⁰ The result of the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) was the deciding evidence that the JNC7 used to justify thiazide-type diuretics as first-line therapy.³⁰ It was designed to test the hypothesis that newer antihypertensive agents (an α -blocker, ACE inhibitor, or dihydropyridine CCB) would be superior to thiazide-type diuretic-based therapy. The primary objective was to compare the combined end point of fatal coronary heart disease and nonfatal MI. Other hypertension-related complications (e.g., heart failure,

TABLE 15-6 Alternative Antihypertensive Agents

Class	Drug (Brand Name)	Usual Dose Range (mg/day)	Daily Frequency	Comments
α_1 -Blockers	Doxazosin (Cardura)	1–8	1	First dose should be given at bedtime; counsel patients to rise from a sitting or laying position slowly to minimize risk of orthostatic hypotension; have additional benefits in men with benign prostatic hyperplasia
	Prazosin (Minipress)	2–20	2 or 3	
	Terazosin (Hytrin)	1–20	1 or 2	
Direct renin inhibitor	Aliskiren (Tekturna)	150–300	1	May cause hyperkalemia in patients with chronic kidney disease and diabetes or in those receiving a potassium-sparing diuretic, aldosterone antagonist, ACE inhibitor, or ARB; may cause acute kidney failure in patients with severe bilateral renal artery stenosis or severe stenosis in artery to solitary kidney; do not use in pregnancy
Central α_2 -agonists	Clonidine (Catapres)	0.1–0.8	2	Abrupt discontinuation may cause rebound hypertension; most effective if used with a diuretic to diminish fluid retention; clonidine patch is replaced once per week; not recommended in very elderly
	Clonidine patch (Catapres-TTS)	0.1–0.3	1 weekly	
	Methyldopa (Aldomet)	250–1000	2	
Peripheral adrenergic antagonist	Reserpine (generic only)	0.05–0.25		A very useful agent that has been used in many of the major clinical trials; should be used with a diuretic to diminish fluid retention
Direct arterial vasodilators	Minoxidil (Loniten)	10–40	1 or 2	Should be used with diuretic and β -blocker to diminish fluid retention and reflex tachycardia
	Hydralazine (Apresoline)	20–100	2 to 4	

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker.

stroke) were evaluated as secondary end points. This was the largest hypertension trial ever conducted and included 42,418 patients ages 55 and older with hypertension and one additional CV risk factor. This prospective, double-blind trial randomized patients to chlorthalidone-, amlodipine-, doxazosin-, or lisinopril-based therapy for a mean of 4.9 years.

The doxazosin arm was terminated early when a significantly higher risk of heart failure versus chlorthalidone was observed.³⁵ The other arms were continued as scheduled and no significant differences in the primary end point were seen between the chlorthalidone and lisinopril or amlodipine treatment groups. However, chlorthalidone had statistically fewer secondary end points than amlodipine (heart failure) and lisinopril (combined CV disease, heart failure, and stroke). The study conclusions were that chlorthalidone-based therapy was superior in preventing one or more major forms of CV disease and was less expensive than amlodipine or lisinopril-based therapy.

ALLHAT was designed as a superiority study with the hypothesis that amlodipine, doxazosin, and lisinopril would be better than chlorthalidone.³⁶ It did not prove this hypothesis because the primary end point was no different between chlorthalidone, amlodipine, and lisinopril. Many subgroup analyses of specific populations (e.g., black patients, chronic kidney disease, diabetes) from the ALLHAT have been conducted to assess response in certain unique patient populations.^{37–39} Surprisingly, none of these analyses demonstrated superior CV event reductions with lisinopril or amlodipine versus chlorthalidone. Overall, thiazide-type diuretics remain unsurpassed in their ability to reduce CV morbidity and mortality in most patients.

Most patients require two or more agents to control BP. Therefore, a thiazide-type diuretic should be one of these agents unless contraindicated.

8 Other First-Line Treatment Options for Most Patients

Clinical trials data cumulatively demonstrate that ACE inhibitor-, CCB-, or ARB-based antihypertensive therapy reduces CV events. These agents may be used in patients without compelling indications, similarly to thiazide-type diuretics, as first-line therapy. The Blood Pressure Lowering Treatment Trialists' Collaboration evaluated the incidence of major CV events and death among different antihypertensive drug classes from 29 major randomized trials in 162,341 patients.⁴⁰ In placebo-controlled trials, the incidences of major CV events were significantly lower with ACE inhibitor- and CCB-based regimens than with placebo. Although there were differ-

ences in the incidences of certain CV events in some comparisons (e.g., stroke was lower with diuretic- or CCB-based regimens versus ACE inhibitor-based regimens), there were no differences in total major CV events when ACE inhibitors, CCBs, or diuretics were compared to each other. In studies evaluating ARB-based therapy to control regimens, the incidence of major CV events was lower with ARB-based regimens. However, the control regimens used in these comparisons included both active antihypertensive drug therapies and placebo.

Data from meta-analyses may not be as influential as data from well-designed, prospective, randomized, controlled trials (e.g., the ALLHAT). However, they provide clinically useful data that support using ACE inhibitor-, CCB-, or ARB-based treatment for hypertension as first-line therapy. Clinicians can use meta-analyses data as supporting evidence when selecting an alternative first-line antihypertensive regimen for hypertension in most patients, in addition to the 2007 AHA recommendations.⁴¹

Other major consensus guidelines recommend multiple first-line options for treating hypertension in most patients. The 2007 European Society of Hypertension–European Society of Cardiology guidelines and the 2006 United Kingdom's National Institute for Health and the Clinical Excellence guidelines list more than one drug therapy option as an acceptable first-line treatment approach.^{42,43} The European Society of Hypertension–European Society of Cardiology guidelines are founded on the principle that CV risk reduction is a function of BP control that is largely independent of specific antihypertensives.⁴² The United Kingdom guidelines stratify patients based on age and race; they recommend an ACE inhibitor first-line for patients younger than age 55 years, and either a CCB or thiazide-type diuretic first-line for patients age 55 years or older and for black patients.⁴³

9 β -Blockers versus Other First-Line Drug Therapies

Clinical trials data cumulatively suggests that β -blockers may not reduce CV events to the extent that ACE inhibitors, CCBs, or ARBs do. These data are from three meta-analyses of clinical trials evaluating β -blocker-based therapy for hypertension.^{44–47} Overall, these analyses demonstrated fewer reductions in CV events with β -blocker-based antihypertensive therapy compared mostly with ACE inhibitor- and CCB-based therapy. Although comparative data with ARB-based therapy are more limited, a similar trend was observed.

Meta-analyses data evaluating β -blockers and their ability to reduce CV events have limitations. Most studies that were included used atenolol as the β -blocker studied. Thus it is possible that atenolol is the only β -blocker that does not reduce risk of CV events as well as the other primary antihypertensive drug classes. However,

it is acceptable to extrapolate these findings to the β -blocker drug class in general. Interestingly, the 2006 United Kingdom guidelines recommend a β -blocker only after other primary antihypertensive agents (thiazide-type diuretics, CCBs, ACE inhibitors, or ARBs) have been used. These findings also call in question the validity of results from prominent prospective, controlled clinical trials evaluating antihypertensive drug therapy that use β -blocker–based therapy, especially atenolol, as the primary comparator.^{29,34,47}

β -Blocker therapy in patients without compelling indications still has a prominent role in the management of hypertension. It is important for clinicians to remember that β -blocker–based antihypertensive therapy does not increase risk of CV events; β -blocker–based therapy reduces risk of CV events compared to no antihypertensive therapy. Using a β -blocker as a primary antihypertensive agent is optimal when a thiazide-type diuretic, ACE inhibitor, ARB, or CCB cannot be used as the primary agent. Additionally, using a β -blocker in a young patient with hypertension that is thought to have high adrenergic drive, as evidenced by an elevated heart rate, may still be clinically reasonable.⁴⁶ β -Blockers still have an important role as an alternative add-on agent to reduce BP in patients with hypertension but without compelling indications.

10 Patients with Compelling Indications¹

The JNC7 report identifies six compelling indications. Compelling indications represent specific comorbid conditions where evidence from clinical trials supports using specific antihypertensive classes to treat both the compelling indication and hypertension (see Fig. 15–3). Data from these clinical trials demonstrate a reduction in CV morbidity and/or mortality that justifies use in patients with hypertension and with such a compelling indication. Some compelling indications include recommendations that are provided by other national treatment guidelines, or from newer clinical trials, which are complementary to the JNC7 guidelines.

Left Ventricular Dysfunction: Systolic Heart Failure⁴⁸ Five drug classes are listed as compelling indications for heart failure. These recommendations specifically refer to left ventricular dysfunction (also known as systolic heart failure), where the primary physiologic abnormality is decreased cardiac output. ACE inhibitor with diuretic therapy is recommended as the first-line regimen of choice. ACE inhibitor therapy is recommended based on numerous outcome studies showing reduced CV morbidity and mortality⁴⁸; diuretics are also a part of this first-line regimen because they provide symptomatic relief of edema by inducing diuresis. Loop diuretics are often needed, especially in patients with more advanced disease. Patients with left ventricular dysfunction have a BP goal of less than 120/80 mm Hg, so multiple drug therapies are typically needed.

Evidence from clinical trials shows that ACE inhibitors significantly modify disease progression by reducing morbidity and mortality. Although left ventricular dysfunction was the primary disease in these studies, ACE inhibitor therapy will also control BP. ACE inhibitors should be started with low-doses in patients with heart failure, especially those in acute exacerbation. Heart failure induces a compensatory high renin condition, and starting ACE inhibitors under these conditions can cause a pronounced first-dose effect and possible orthostatic hypotension.

β -Blocker therapy is appropriate to further modify disease in left ventricular dysfunction, and is a component of this first-line regimen (standard therapy) for these patients. In patients on an initial regimen of diuretics and ACE inhibitors, β blockers reduce CV morbidity and mortality.^{49,50} It is of paramount importance that β -blockers be dosed appropriately because of the risk of inducing an acute exacerbation of heart failure. They must be started in very low doses, doses much lower than that used to treat hypertension, and titrated slowly to high-doses based on tolerability. Bisoprolol,

carvedilol, and metoprolol succinate are the only β -blockers proven to be beneficial in left ventricular dysfunction.⁴⁸

After diuretics, ACE inhibitors, and β -blockers (collectively considered standard therapy), other agents may be added to further reduce CV morbidity and mortality, and reduce BP if needed. Early data suggested that ARBs may be better than ACE inhibitors in left ventricular dysfunction.⁵¹ However, when directly compared in a well-designed prospective trial, ACE inhibitors were found to be better.⁵² ARBs are acceptable as an alternative therapy for patients who cannot tolerate ACE inhibitors, and possibly as add-on therapy to those already on a standard three-drug regimen based on data from the CHARM (Candesartan in Heart Failure: Assessment of Reduction in Mortality and Morbidity) studies.^{53,54}

The addition of aldosterone antagonists can reduce CV morbidity and mortality in left ventricular dysfunction.^{55,56} Spironolactone has been studied in severe left ventricular dysfunction and has shown benefit in addition to diuretic and ACE inhibitor therapy.⁵⁵ Eplerenone has been studied in patients with symptomatic left ventricular dysfunction within 3 to 14 days after an acute MI in addition to standard therapy.⁵⁶ An aldosterone antagonist may be considered in addition to a diuretic, ACE inhibitor or ARB, and β -blocker. It is not currently recommended to use both an aldosterone inhibitor and an ARB as add-on therapy to a standard therapy, because of the potential increase in risk of severe hyperkalemia.⁴⁸

Post-Myocardial Infarction⁵⁷ β -Blocker (those without intrinsic sympathomimetic activity [ISA]) and ACE inhibitor therapy are recommended in the AHA/American College of Cardiology and JNC7 guidelines.^{1,2,57} β -Blockers decrease cardiac adrenergic stimulation and reduce the risk of a subsequent MI or sudden cardiac death, as demonstrated in clinical trials. ACE inhibitors improve cardiac remodeling, cardiac function, and reduce CV events post-MI. These two drug classes, with β -blockers first, are considered the first drugs of choice for patients who have experienced a MI. One study, the Valsartan in Acute Myocardial Infarction Trial (VALLIANT), demonstrated that ARB therapy is similar to ACE inhibitor therapy in patients post-MI with left ventricular dysfunction.⁵⁸ However, ARBs are considered alternatives to ACE inhibitors in post-MI patients with left ventricular dysfunction. These patients have coronary artery disease, and have a BP goal of less than 130/80 mm Hg. Framingham risk scoring is not needed.

Eplerenone reduces CV morbidity and mortality in patients soon after an acute MI (within 3 to 14 days).⁵⁶ However, this supporting evidence was in patients with symptoms of acute left ventricular dysfunction. Considering that this drug has the propensity to cause significant hyperkalemia and the patient population studied, eplerenone should only be used in selected patients following a MI with very diligent monitoring of potassium.

Coronary Artery Disease^{57,59} Chronic stable angina and acute coronary syndrome (unstable angina and acute MI) are forms of coronary disease (also called coronary artery disease or ischemic heart disease). This compelling indication is also referred to as high coronary disease risk and high CV disease risk in the JNC7 report.¹ These are the most common forms of hypertension-associated target-organ disease. β -Blocker therapy has the most evidence demonstrating benefits in these patients. β -Blockers (those without ISA) are first-line therapy in chronic stable angina and have the ability to reduce BP, improve myocardial oxygen consumption and decrease demand. These patients have coronary artery disease, and have a BP goal of less than 130/80 mm Hg. Framingham risk scoring is not needed.

Long-acting CCBs are either alternatives (the nondihydropyridine CCBs diltiazem and verapamil) or add-on therapy (dihydropyridine CCBs) to β -blockers in chronic stable angina.⁵⁹ The International Verapamil-Trandolapril Study (INVEST) demonstrated no difference in CV risk reduction when β -blocker–based therapy was compared to

nondihydropyridine CCB-based therapy in this population.⁶⁰ Nonetheless, the preponderance of data are with β -blockers and they remain therapy of choice.^{1,2,57,59}

For acute coronary syndromes (ST-elevation MI and unstable angina/non-ST-segment MI), first-line therapy should consist of a β -blocker and ACE inhibitor.^{61,62} This regimen will lower BP, control acute ischemia, and reduce CV risk.

CCBs (especially nondihydropyridine CCBs) and β -blockers provide antiischemic effects; they lower BP and reduce myocardial oxygen demand in patients with hypertension and coronary disease. However, cardiac stimulation may occur with dihydropyridine CCBs or β -blockers with ISA, making these agents less desirable. Consequently, β -blockers with ISA should be avoided, nondihydropyridine CCBs should be alternatives to β -blockers, and dihydropyridines should be add-on therapy to β -blockers.

Once ischemic symptoms are controlled with β -blocker and/or CCB therapy, other antihypertensive drugs can be added to provide additional CV risk reduction. Clinical trials have demonstrated that the addition of an ACE inhibitor, or alternatively an ARB further reduces risk CV events in patients with chronic stable angina.⁶³ Thiazide-type diuretics can be added thereafter to provide additional BP lowering and to further reduce CV risk. Neither ACE inhibitors, nor thiazide-type diuretics provide anti-ischemic effects.

There has been concern that overtreating high BP in patients with coronary artery disease may bring about more harm than good (termed the *J-curve phenomenon*). Coronary blood flow occurs during diastole and the rate of flow is directly influenced by the DBP. Therefore, excessively reducing DBP may compromise coronary perfusion, especially in patients with fixed coronary artery stenosis, and lead to myocardial infarction. This concern has been theoretical based on retrospective analyses, and prospective studies have not found a J-curve until DBPs were very low (<60 mm Hg).

Diabetes Mellitus^{1,64–67} The primary cause of mortality in diabetes is CV disease, and hypertension management is a very important risk-reduction strategy. The BP goal in diabetes is less than 130/80 mm Hg. Diabetes is considered a coronary artery disease risk equivalent and Framingham risk scoring is not needed. Five antihypertensive agents have evidence supporting their compelling indications in diabetes (see Fig. 15–3). All of these agents have been shown to reduce CV events in patients with diabetes. However, risk reduction may not be equal when comparing these agents.

① All patients with diabetes and hypertension should be treated with either an ACE inhibitor or an ARB.⁶⁴ Pharmacologically, both of these agents should provide nephroprotection as a result of vasodilation in the efferent arteriole of the kidney. Moreover, ACE inhibitors have overwhelming data demonstrating CV risk reduction in patients with established forms of heart disease. Evidence from outcome studies have demonstrated reductions in both CV risk (mostly with ACE inhibitors) and reduction in risk of progressive kidney dysfunction (mostly with ARBs) in patients with diabetes.⁶⁴ There is controversy surrounding which agent is better because data support both drug classes. Nonetheless, either drug class should be used to control BP as one of the drugs in the antihypertensive regimen for patients with diabetes because multiple agents are often needed to attain goal BP values.

A thiazide-type diuretic is recommended as the second agent to lower BP and provide additional CV risk-reduction. A subgroup analysis of patients with diabetes from the ALLHAT trial showed no difference in long term risk of CV events in the chlorthalidone and lisinopril treatment groups.³⁸ Therefore, some argue that thiazide-type diuretics, used in low-doses, are equally effective in patients with hypertension and diabetes. Nonetheless, the entire body of evidence evaluating pharmacotherapy in patients with hypertension and diabetes, and consensus guidelines, support an ACE inhibitor or ARB first-line, with a thiazide-type diuretic as add-on therapy.^{1,64,65}

CCBs are useful add-on agents for BP control in patients with diabetes. Several studies have compared an ACE inhibitor with either a dihydropyridine CCB or a β -blocker. In the studies comparing a dihydropyridine with an ACE inhibitor, the ACE inhibitor group had significantly lower rates of CV end points, including MIs and all CV events.⁶⁷ These data do not suggest that CCBs are harmful in diabetic patients, but indicate that they are not as protective as ACE inhibitors. Although data are limited, nondihydropyridine CCBs (diltiazem and verapamil) appear to have more renal protective effects than the dihydropyridines.⁶⁵

β -Blockers reduce CV risk in patients with diabetes. These agents should be used when needed as add-on therapy with other standard agents, or to treat another compelling indication (e.g., post-MI). β -Blockers have been shown in at least one study to be as effective as ACE inhibitors in protection against morbidity and mortality in patients with diabetes.⁶⁶

β -Blockers (especially nonselective agents) may mask the signs and symptoms of hypoglycemia in patients with tightly controlled diabetes because most of the symptoms of hypoglycemia (i.e., tremor, tachycardia, and palpitations) are mediated through the sympathetic nervous system. Sweating, a cholinergically mediated symptom of hypoglycemia, should still occur during a hypoglycemic episode despite β -blocker therapy. Patients may also have a delay in hypoglycemia recovery time because compensatory recovery mechanisms need the catecholamine inputs that are antagonized by β -blocker therapy. Finally, unopposed α -receptor stimulation during the acute hypoglycemic recovery phase (as a consequence of endogenous epinephrine release intended to reverse hypoglycemia) may result in acutely elevated BP because of vasoconstriction. Despite these potential problems, β -blockers can be safely used in patients with diabetes.

Based on the weight of all evidence, ACE inhibitors or ARBs are preferred first-line agents for treating patients with hypertension and diabetes. The need for combination therapy should be anticipated, and thiazide-type diuretics should be the second agent added. Based on scientific evidence, β -blockers and CCBs are useful evidence-based agents in this population, but are considered add-on therapies to the aforementioned agents.

Chronic Kidney Disease⁶⁸ Patients with hypertension may develop damage to either the renal tissue (parenchyma) or the renal arteries. Chronic kidney disease initially presents as microalbuminuria (30 to 299 mcg/mg albumin-to-creatinine ratio on a spot urine sample or ≥ 30 mg albumin in a 24-hour urine collection) that can progress to overt kidney failure. The rate of kidney function deterioration is accelerated when both hypertension and diabetes are present. Once patients have an estimated GFR of less than 60 mL/min/1.73 m² or albuminuria, they have significant chronic kidney disease and the risk of CV disease and progression to severe chronic kidney disease increases.¹ Strict BP control to a goal of less than 130/80 mm Hg can slow the decline in kidney function. Although this strict BP goal is recommended in significant chronic kidney disease, long-term benefits of this lower BP goal have mostly been demonstrated in patients with both significant chronic kidney disease and diabetes.⁶⁹ This strict control often requires two or more antihypertensive agents.

In addition to lowering BP, ACE inhibitors and ARBs reduce intraglomerular pressure, which can theoretically provide additional benefits by further reducing the decline in kidney function. ACE inhibitors and ARBs have been shown to reduce progression of chronic kidney disease in diabetes⁶⁴ and in those without diabetes.^{65,70} It is difficult to differentiate whether the kidney protection benefits are from RAAS blockade or BP lowering. A recent meta-analysis failed to demonstrate any unique long-term kidney-protective effects of RAAS-blocking drugs compared with other antihypertensive drugs.⁷¹ Moreover, a subgroup analysis of patients from the ALLHAT stratified by different baseline GFR values also did not show a difference in long-term outcomes with chlorthalidone versus

lisinopril.³⁷ Nonetheless, consensus guidelines recommend either an ACE inhibitor or ARB as first-line therapy to control BP and preserve kidney function in chronic kidney disease.

Some data indicate that the combination of an ACE inhibitor with an ARB may be more effective than either agent alone.⁷² However, routine use of this combination in all patients with chronic kidney disease is controversial. Because these patients typically require multiple antihypertensive agents, diuretics and a third antihypertensive drug class (e.g., β -blocker, CCB) are often needed.

CLINICAL CONTROVERSY

Thiazide-type diuretics traditionally have been viewed as less effective than loop diuretics in patients with severe chronic kidney disease. Some clinicians routinely replace thiazide-type diuretics with a loop diuretic in patients who have estimated creatinine clearances below 30 mL/min. However, limited data demonstrate that the antihypertensive effects of hydrochlorothiazide are equal to that of furosemide in patients with chronic renal failure and hypertension.⁷³

Patients may rarely experience acute kidney failure when given an ACE inhibitor or ARB. The potential to produce acute kidney failure is particularly problematic in patients with bilateral renal artery stenosis or a solitary functioning kidney with stenosis. Patients with renal artery stenosis are usually older, and the condition is more common in patients with diabetes and in those who smoke. Patients with renal artery stenosis do not necessarily have evidence of kidney disease unless sophisticated tests are performed. Evaluating kidney function shortly after starting the drug can minimize this risk.

Recurrent Stroke Prevention Ischemic stroke is considered target-organ damage caused by hypertension. Attaining goal BP values in patients who have experienced a stroke, or a transient ischemic attack, is considered a primary modality to reduce risk of a second stroke. In general, these patients have noncoronary atherosclerotic vascular disease, are considered a coronary artery disease risk equivalent, and have a BP goal of less than 130/80 mm Hg. However, BP lowering should only be attempted after patients have stabilized following an acute cerebrovascular event. One clinical trial, PROGRESS (Perindopril Protection Against Recurrent Stroke Study), showed that the incidence of recurrent stroke in patients with a history of ischemic stroke can be reduced when a thiazide-type diuretic is used in combination with an ACE inhibitor.³¹ Reduction in recurrent stroke was seen with this combination therapy, even in those who had BP values less than 140/90 mm Hg. Recurrent stroke was not reduced with ACE inhibitor monotherapy in the PROGRESS, it was only reduced when the thiazide-type diuretic was added.

Reductions in risk of recurrent stroke have also been seen with ARBs.⁷⁴ In another clinical trial, the MOSES (Morbidity and Mortality After Stroke, Eprosartan Compared with Nitrendipine for Secondary Prevention), patients with a history of stroke or transient ischemic attack had a lower risk of a recurrent stroke when treated with ARB-based therapy compared to dihydropyridine CCB-based therapy. Therefore, both an ACE inhibitor with a thiazide-type diuretic,^{1,75} or ARB-based therapy are evidence-based antihypertensive regimens for patients with a history of cerebrovascular disease, specifically ischemic stroke or transient ischemic attack, to prevent recurrent stroke. These recommendations do not apply to patients with a history of hemorrhagic stroke.

Alternative Drug Treatments

It is necessary to use other agents such as α -blockers, central α_2 -agonists, a direct renin inhibitor, adrenergic inhibitors, and vasodila-

tors in some patients. Although these agents are potent, many of them have a much greater incidence of adverse effects. Moreover, they do not have compelling outcomes data showing reduced morbidity and mortality in hypertension. They are generally reserved for patients with resistant hypertension, and should only be used as add-on therapy with other primary antihypertensive agents.

Special Populations¹

Selection of drug therapy should follow the guidelines provided by the JNC7, which are summarized in Figures 15–2 and 15–3. These should be maintained as the guiding principles of drug therapy. However, there are some patient populations where the approach to drug therapy may be slightly different or necessitate tailored dosing strategies. In some cases this is because other agents have unique properties that benefit a coexisting condition, but may not be based on evidence from outcomes studies in hypertension.

Hypertension in Older People Hypertension often presents as isolated systolic hypertension in the elderly. Epidemiologic data indicate that CV morbidity and mortality are more closely related to SBP than to DBP in patients ages 50 years and older, so this population is at high risk for hypertension-related target-organ damage.¹ Although several placebo-controlled trials have specifically demonstrated risk reduction in this form of hypertension, many older people with hypertension are either not treated, or treated yet not controlled.²¹

The SHEP was a landmark, double-blind, placebo-controlled trial that evaluated chlorthalidone-based treatment (with atenolol or reserpine as add-on therapy) for isolated systolic hypertension.⁹ A 36% reduction in total stroke, a 27% reduction in coronary artery disease, and 55% reduction in heart failure were demonstrated versus placebo. The Syst-Eur (Systolic Hypertension in Europe) was another placebo-controlled trial that evaluated treatment with a long-acting dihydropyridine CCB.¹² Treatment resulted in a 42% reduction in stroke, 26% reduction in coronary artery disease, and 29% reduction in heart failure. These data clearly demonstrate reductions in CV morbidity and mortality in older patients with isolated systolic hypertension, especially with thiazide-type diuretics and long-acting dihydropyridine CCBs.

The very-elderly population (age ≥ 80 years) has been underrepresented in clinical trials, including the SHEP and Syst-Eur studies. This population often is not treated to goal either because of a fear of lowering BP too much or because of limited data demonstrating benefit. The best available data in the very elderly comes from meta-analyses.^{76,77} Although these data do not show reductions in mortality, they consistently show fewer strokes with antihypertensive drug therapy. However, care should be taken that BP not be excessively lowered in this population, as it this is associated with increased risk of mortality.⁷⁸ The HYVET (Hypertension in the Very Elderly Trial), a prospective controlled clinical trial was recently stopped early due to significant reductions in stroke and total mortality with antihypertensive treatment in the very elderly versus placebo.⁷⁹

Thiazide-type diuretics or β -blockers have been compared with either ACE inhibitors or CCBs in elderly patients with either systolic or diastolic hypertension or both.⁸⁰ In the Swedish Trial in Old Patients with Hypertension-2 (STOP-2) study, no significant differences were seen between conventional drugs and either ACE inhibitors or CCBs. However, there were significantly fewer MIs and cases of heart failure in the ACE inhibitor group compared with the CCB group. These data suggest that overall treatment may be more important than specific antihypertensive agents in this population.

Elderly patients are more sensitive to volume depletion and sympathetic inhibition than younger individuals. This may lead to orthostatic hypotension (see Patients at Risk for Orthostatic Hypotension below). In the elderly, this can increase the risk of falls

as a consequence of the associated dizziness and risk of fainting. Centrally acting agents and α -blockers should generally be avoided or used with caution in the elderly because they are frequently associated with dizziness and postural hypotension. Diuretics and ACE inhibitors provide significant benefits and can safely be used in the elderly, but smaller-than-usual initial doses might be needed.

The JNC7 and AHA goal BP recommendations are independent of age.^{1,2} Age-adjusted goals are inappropriate. Moreover, treatment of hypertension in older patients should follow the same principles that are outlined for general care of hypertension. However, initial drug doses may be lower, and dosage titrations should occur over a longer period of time to minimize the risk of hypotension. An interim goal of a SBP of below 160 mm Hg may be necessary for those with very high initial SBP, but the ultimate goal should still be less than 140 mm Hg, less than 130 mm Hg, or less than 120 mm Hg, depending on CV risk and comorbid conditions of the patient.

12 Patients at Risk for Orthostatic Hypotension *Orthostatic hypotension* is a significant drop in BP when standing and can be associated with dizziness and/or fainting. It is defined as a SBP decrease of greater than 20 mm Hg or DBP decrease of greater than 10 mm Hg when changing from supine to standing.¹ Older patients (especially those with isolated systolic hypotension), patients with diabetes, severe volume depletion, baroreflex dysfunction, autonomic insufficiency, and use of venodilators (α -blockers, mixed α/β -blockers, nitrates, and phosphodiesterase inhibitors) all increase risk of orthostatic hypotension. In patients with these risks, antihypertensive agents should be started in low doses, especially diuretics, ACE inhibitors, and ARBs.

Hypertension in Children and Adolescents⁸¹ Detecting hypertension in children requires special attention to BP measurement, and is defined as SBP and/or DBP that is greater than 95th percentile for sex, age, and height on at least three occasions.⁸¹ BP between the 90th and 95th percentile, or equal to or greater than 120/80 mm Hg in adolescents, is considered prehypertension. Hypertensive children often have a family history of high BP, and many are overweight, predisposing them to insulin resistance and associated CV disease. Unlike hypertension in adults, secondary hypertension is more common in children and adolescents. An appropriate workup for secondary causes is essential if elevated BP is identified. Kidney disease (e.g., pyelonephritis, glomerulonephritis) is the most common cause of secondary hypertension in children. Coarctation of the aorta can also produce secondary hypertension. Medical or surgical management of the underlying disorder usually normalizes BP.

Nonpharmacologic treatment, particularly weight loss in those who are overweight, is the cornerstone of therapy for essential hypertension in children.⁸¹ The goal is to reduce the BP to below the 95th percentile for sex, age, and height, or below the 90th percentile if concurrent conditions, such as chronic kidney disease, diabetes, or target-organ damage, are present. ACE inhibitors, ARBs, β -blockers, CCBs, and thiazide-type diuretics are all acceptable choices in children. ACE inhibitors, ARBs, and direct renin inhibitors are contraindicated in sexually active girls because of potential teratogenic effect, and in those who might have bilateral renal artery stenosis or unilateral stenosis in a solitary kidney. As with adults, consideration for initial agents should be based on the presence of compelling indications or concurrent conditions that may warrant their use (e.g., ACE inhibitor or ARB for those with diabetes or microalbuminuria).

Pregnancy^{1,82} Hypertension during pregnancy is a major cause of maternal and neonatal morbidity and mortality. Hypertension during pregnancy is categorized as preeclampsia, eclampsia, gestational, chronic, and superimposition of preeclampsia on chronic hypertension. Preeclampsia, defined as a elevated BP greater than or equal to 140/90 mm Hg that appears after 20 weeks gestation accompanied by new-onset proteinuria (≥ 300 mg/24 hours), can lead to life-threaten-

ing complications for both mother and fetus. Eclampsia, the onset of convulsions in preeclampsia, is a medical emergency. Gestational hypertension is defined as new-onset hypertension arising after midpregnancy in the absence of proteinuria, and chronic hypertension is elevated BP that is noted before the pregnancy began. It is controversial whether treating elevated BP in patients with chronic hypertension in pregnancy is beneficial. However, women with chronic hypertension prior to pregnancy are at increased risk of a number of complications, including superimposed preeclampsia, preterm delivery, fetal growth restriction or demise, placental abruption, heart failure, and acute kidney failure.⁸²

Definitive treatment of preeclampsia is delivery. Delivery is indicated if pending or frank eclampsia is present. Otherwise, management consists of restricting activity, bedrest, and close monitoring. Salt restriction, or any other measures that contract blood volume, should not be employed. Antihypertensive agents are used prior to induction of labor if DBP is greater than 105 to 110 mm Hg with a target DBP of 95 to 105 mm Hg. Intravenous hydralazine is most commonly used, and intravenous labetalol is also effective. Immediate-release oral nifedipine has been used, but it is not approved by the Food and Drug Administration (FDA) for hypertension and untoward fetal and maternal effects (hypotension with fetal distress) have been reported.

Many agents can be used to treat chronic hypertension in pregnancy (Table 15-7). Unfortunately, there is little consensus and few data regarding the most appropriate therapy in pregnancy. Methyl-dopa is still considered the drug of choice.¹ Data indicate that uteroplacental blood flow and fetal hemodynamics are stable with methyldopa. Moreover, it is viewed as very safe, based on long-term followup data (7.5 years) that has not demonstrated adverse effects on childhood development. β -Blockers, labetalol and CCBs are also reasonable alternatives. ACE inhibitors and ARBs are known teratogens and are absolutely contraindicated.⁸³ Aliskiren also should not be used in pregnancy.

African Americans^{1,84} Hypertension affects African American patients at a disproportionately higher rate, and hypertension-related target-organ damage is more prevalent than in other populations. Reasons for these differences are not fully understood, but may be related to differences in electrolyte homeostasis, GFR, sodium excretion and transport mechanisms, plasma renin activity, and BP response to plasma volume expansion.

African Americans have an increased need for combination therapy to attain and maintain BP goals.⁸⁴ The Hypertension in African American Working Group of the International Society on Hypertension in Blacks has published treatment guidelines that are similar to the JNC7.⁸⁴ Lifestyle modifications are recommended to

TABLE 15-7 Treatment of Chronic Hypertension in Pregnancy

Drug/Class	Comments
Methyldopa	Preferred agent based on long-term followup data supporting safety
β -Blockers	Generally safe, but intrauterine growth retardation reported
Labetalol	Increasingly preferred over methyldopa because of fewer side effects
Clonidine	Limited data available
Calcium channel blockers	Limited data available; no increase in major teratogenicity with exposure
Diuretics	Not first-line agents but probably safe in low doses if used chronically prior to conception
Angiotensin-converting enzyme inhibitors, angiotensin II receptor blockers and direct renin inhibitors	Contraindicated; major teratogenicity reported with exposure (fetal toxicity and death)

augment drug therapy. They also support thiazide-type diuretics as first-line for most patients and selecting specific drug therapy to treat compelling indications, if present. These guidelines aggressively promote combination therapy. They recommend starting with two drugs in patients with SBP values ≥ 15 mm Hg from goal. This aggressive approach is reasonable considering that overall goal BP attainment rates are low in African Americans.

BP-lowering effects of antihypertensive classes varies in African Americans. Thiazide diuretics and CCBs seem to be particularly effective at lowering BP in African Americans. When either of these two classes (especially thiazides) is used in combination with a β -blocker, ACE inhibitor, or ARB, antihypertensive response is significantly increased. This may be a result of the low renin pattern of hypertension, which can result in less BP lowering with β -blockers, ACE inhibitors, or ARBs when used as monotherapy compared to the effect in white patients. Interestingly, African Americans have a higher risk of angioedema and cough from ACE inhibitors than do whites.⁸⁴

Despite potential differences in antihypertensive effects, drug therapy selection should be based on evidence. Thiazide-type diuretics are first-line agents based on the preponderance of evidence. A subgroup analysis of African American patients from the ALLHAT also supports the first-line role of thiazide-type diuretics in treating African American patients with hypertension.³⁹ These agents just so happen to also be very effective at controlling BP in this population. ACE inhibitors, ARBs, and CCBs may also be used as first-line options. Other drug therapies should be used if a compelling indication is present, even if the antihypertensive effect may not be as great as with another drug class (e.g., a β -blocker is first-line therapy for BP control in an African American patient who is post-MI).

Other Concomitant Conditions

Most patients with hypertension have some other coexisting condition(s) that may influence selection or use of drug therapy. The influence of concomitant conditions should only be complementary to, and never in replacement of, drug therapy choices indicated by compelling indications. Under some circumstances, these are helpful in deciding on a particular antihypertensive agent when more than one antihypertensive class is recommended. In some cases, an agent should be avoided because it may aggravate a concomitant disorder. In other cases, an antihypertensive can be used to treat hypertension, a compelling indication, and another concomitant condition.

Pulmonary Disease and Peripheral Arterial Disease⁸⁵ β -Blockers, especially nonselective agents, have been generally avoided in patients with hypertension and reactive airway disease (asthma or chronic obstructive pulmonary disease with a reversible obstructive component) because of a fear of inducing bronchospasm. This precaution is more of a myth than a fact. Data suggests that cardioselective β -blockers can safely be used in patients with asthma or chronic obstructive pulmonary disease.⁸⁶ Consequently, cardioselective β -blockers should be used to treat a compelling indication (i.e., post-MI, coronary disease, or heart failure) in patients with reactive airway disease.

Peripheral arterial disease, noncoronary atherosclerotic vascular disease, is a coronary artery disease risk equivalent. The 2007 AHA guidelines now recommend a BP goal of less than 130/80 mm Hg in this population. ACE inhibitors may be ideal in patients with symptomatic lower-extremity peripheral arterial disease who also have hypertension, as they decrease CV events in these patients.⁸⁵ CCBs may also be beneficial because of their vasodilatory effects on the peripheral arteries. β -Blockers have traditionally been considered problematic in patients with peripheral arterial disease because of possible decreased peripheral blood flow secondary to unopposed stimulation of α -receptors that results in vasoconstriction. However, β -blockers are not contraindicated in peripheral arterial disease and have not been shown to adversely affect walking capability.⁸⁵

Dyslipidemia Dyslipidemia is considered a major CV risk factor. Controlling dyslipidemia is important to the overall care of patients with hypertension. Thiazide-type diuretics and β -blockers without ISA may adversely affect serum cholesterol values, although these effects generally are transient and of no clinical consequence.⁸⁷ α -Blockers have favorable effects (decreased low-density lipoprotein cholesterol and increased high-density lipoprotein cholesterol). However, because data from the ALLHAT show that α -blocker therapy does not reduce CV risk as much as thiazide-type diuretic therapy, this benefit is not clinically applicable.³⁵

Metabolic Syndrome^{13,88,89} Metabolic syndrome is a cluster of multiple cardiometabolic risk factors. It was most recently defined as the presence of three of the following five criteria: abdominal obesity (waist circumference >40 inches in men, >35 inches in women), elevated triglycerides (≥ 150 mg/dL or receiving drug treatment for elevated triglycerides), low high-density lipoprotein cholesterol (<40 mg/dL in men, <50 mg/dL in women or receiving drug treatment for low high-density lipoprotein), elevated BP ($\geq 130/\geq 85$ mm Hg or receiving drug treatment for high BP), and elevated fasting blood glucose (≥ 100 mg/dL or receiving drug treatment for elevated glucose).¹³

Regardless of the debate regarding whether or not metabolic syndrome is a true “disease,” it is widely accepted that patients with metabolic syndrome are at significant increased risk of developing CV disease and/or type 2 diabetes. Using an ACE inhibitor or ARB to treat patients with hypertension and the metabolic syndrome, especially patients with elevated fasting glucose but not yet type 2 diabetes, may be beneficial. A recent meta-analysis demonstrated that ARBs and ACE inhibitors are less likely than β -blockers or thiazide-diuretics to be associated with progression to new-onset type 2 diabetes.⁸⁹ However, studies specifically evaluating the most effective antihypertensive regimen in patients with metabolic syndrome have not been done. In addition, an ALLHAT subgroup analysis of patients with impaired fasting glucose showed that CV events were reduced more with chlorthalidone compared to lisinopril.³⁸ Thus, thiazides-type diuretics can be used in patients with metabolic syndrome, similar to ACE inhibitors, ARBs, or CCBs. In patients with elevated fasting glucose, or any patient at risk for developing type 2 diabetes, close monitoring of serum potassium should occur when treated with thiazide-type diuretics. If hypokalemia develops, or even subclinical hypokalemia (serum potassium within the normal range, but at the low end of the normal range), in thiazide treated patients, the risk of developing type 2 diabetes significantly increases.⁹⁰ Therefore, treatment of thiazide-induced hypokalemia, or even subclinical hypokalemia, should be considered to maintain serum potassium in the mid to high end of the normal range (e.g., 4.0–5.0 mEq/L). This may reverse thiazide-induced glucose intolerance or possibly prevent onset of type 2 diabetes. This can be accomplished though the addition of an ACE inhibitor, ARB, or potassium sparing diuretic, or with potassium supplementation for cases of more severe hypokalemia.

Erectile Dysfunction⁹¹ Most antihypertensive agents are associated with erectile dysfunction in men. However, it is not clear if erectile dysfunction associated with antihypertensive treatment is solely a result of drug therapy or is a symptom of underlying CV disease. Traditionally, β -blockers have been labeled as agents that significantly cause sexual dysfunction, and many practitioners have avoided prescribing them as a result. However, data supporting this notion are limited. A systematic review of 15 studies involving 35,000 patients assessing β -blocker use for MI, heart failure, and hypertension found only a very slight increased risk erectile dysfunction.⁹² In addition, prospective long-term data from the TOMHS (Treatment of Mild Hypertension Study) show no difference in the incidence of erectile dysfunction between diuretics and

β -blockers versus ACE inhibitors and CCBs.⁹³ Centrally acting agents are associated with higher rates of sexual dysfunction and should be avoided in men with erectile dysfunction.

Hypertensive men frequently have atherosclerotic vascular disease, which frequently results in erectile dysfunction. Consequently, erectile dysfunction may be mostly associated with chronic arterial changes resulting from elevated BP and lack of control may increase the risk of erectile dysfunction. These changes are even more pronounced in hypertensive men with diabetes.

Erectile dysfunction in hypertension may be an important marker for CV disease. A study of men prospectively screened for erectile dysfunction after being referred for nuclear stress test imaging showed that erectile dysfunction was a stronger predictor of severe coronary heart disease than traditional risk factors (age, smoking, hypertension, diabetes, and dyslipidemia).⁹⁴

Individual Antihypertensive Agents^{1,7}

Diuretics^{9-11,30} Diuretics, preferably a thiazide, are first-line agents for hypertension.^{1,2} The best available evidence justifying this recommendation is from ALLHAT.³⁰ Moreover, when combination therapy is needed in hypertension to control BP, a diuretic is recommended to be one of the agents used.¹ There are four subclasses of diuretics that are used in the treatment of hypertension: thiazides, loops, potassium-sparing agents, and aldosterone antagonists (see Table 15-5). Potassium-sparing diuretics are weak antihypertensive agents but provide an additive effect when used in combination with a thiazide or loop diuretic. Moreover, they counteract the potassium- and magnesium-losing properties of the other diuretic agents and possible glucose intolerance. Aldosterone antagonists (spironolactone and eplerenone) may be technically considered potassium-sparing agents, but are more potent antihypertensives. However, they are viewed by the JNC7 as an independent class because of evidence supporting compelling indications.

The exact hypotensive mechanisms of action of diuretics are multifaceted. The drop in BP seen when diuretics are first started is caused by an initial diuresis. Diuresis causes reductions in plasma and stroke volume, which decreases cardiac output and BP. This initial drop in cardiac output causes a compensatory increase in peripheral vascular resistance. With chronic diuretic therapy, extracellular fluid and plasma volume return to near pretreatment values. However, peripheral vascular resistance decreases to values that are lower than the pretreatment baseline. This reduction in peripheral vascular resistance is responsible for chronic antihypertensive effects.

Thiazide-type diuretics have additional actions that may further explain their antihypertensive effects. Thiazides mobilize sodium and water from arteriolar walls. This effect would lessen the amount of physical encroachment on the lumen of the vessel created by excessive accumulation of intracellular fluid. As the diameter of the lumen relaxes and increases, there is less resistance to the flow of blood and peripheral vascular resistance further drops. High dietary sodium intake can blunt this effect and a low salt intake can enhance this effect. Thiazides are also postulated to cause direct relaxation of vascular smooth muscle.

Thiazides are the preferred type of diuretic for treating hypertension. In patients requiring diuresis to treat concurrent edema, such as in heart failure, a loop diuretic should be considered. Diuretics should ideally be dosed in the morning if given once daily, and in the morning and afternoon when dosed twice daily to minimize risk of nocturnal diuresis. However, with chronic use, thiazide-type diuretics, potassium sparing diuretics, and aldosterone antagonists rarely cause a pronounced diuresis.

The major pharmacokinetic differences between the various thiazide-type diuretics are serum half-life and duration of diuretic effect. The clinical relevance of these differences is unknown because the

serum half-life of most antihypertensive agents does not correlate with the hypotensive duration of action. Moreover, diuretics lower BP primarily through extrarenal mechanisms. Hydrochlorothiazide and chlorthalidone are the two most frequently used thiazide diuretics in landmark clinical trials that have demonstrated reduced morbidity and mortality. These agents are not equipotent on a milligram-per-milligram basis; chlorthalidone is 1.5 to 2.0 times more potent than hydrochlorothiazide.⁹⁵ This is attributed to a longer half-life (45 to 60 hours vs. 8 to 15 hours) and longer duration of effect (48 to 72 hours vs. 16 to 24 hours) with chlorthalidone. These differences in BP lowering do not appear to result in differences in CV outcomes. A small meta-analysis of five outcome-based clinical trials evaluating CV events suggests there is no difference in long-term CV outcomes with chlorthalidone compared with other thiazide-type diuretics, including hydrochlorothiazide.⁹⁶ It is well accepted that CV benefits in hypertension apply to all thiazide-type diuretics, and benefits are considered a class effect.²

Diuretics are very effective in lowering BP when used in combination with most other antihypertensives. This additive response is explained by two independent pharmacodynamic effects. First, when two drugs cause the same overall pharmacologic effect (BP lowering) through different mechanisms of action, their combination usually results in an additive or synergistic effect. This is especially relevant when a β -blocker, ACE inhibitor, or ARB is indicated in an African American, but does not elicit sufficient antihypertensive effect. Adding a diuretic in this situation can often significantly lower BP. Second, a compensatory increase in sodium and fluid retention may be seen with antihypertensive agents. This problem is counteracted with the concurrent use of a diuretic.

Side effects of thiazide-type diuretics include hypokalemia, hypomagnesemia, hypercalcemia, hyperuricemia, hyperglycemia, dyslipidemia, and sexual dysfunction. Many of these side effects were identified when high-doses of thiazides were used in the past (e.g., hydrochlorothiazide 100 mg/day). Current guidelines recommend limiting the dose of hydrochlorothiazide or chlorthalidone to 12.5 to 25 mg/day, which markedly reduces the risk for most metabolic side effects. Loop diuretics may cause the same side effects, although the effect on serum lipids and glucose is not as significant, and hypocalcemia may occur.

Hypokalemia and hypomagnesemia may cause muscle fatigue or cramps. However, serious cardiac arrhythmias can occur in patients with severe hypokalemia and hypomagnesemia. Patients at greatest risk for this are patients with left ventricular hypertrophy, coronary disease, post-MI, a history of arrhythmia, or those concurrently receiving digoxin. Low-dose therapy (i.e., 25 mg hydrochlorothiazide or 12.5 mg chlorthalidone daily) rarely causes significant electrolyte disturbances. Efforts should be made to keep potassium in the therapeutic range by careful monitoring.

Diuretic-induced hyperuricemia can precipitate gout. This side effect may be especially problematic in patients with a previous history of gout and with thiazide-type diuretics. However, acute gout is unlikely in patients with no previous history of gout. If gout does occur in a patient who requires diuretic therapy, allopurinol can be given to prevent gout and will not compromise the antihypertensive effects of the diuretic. High doses of thiazide-type and loop diuretics may increase fasting glucose and serum cholesterol values. Diligent monitoring and treatment of diuretic-induced hypokalemia, even if subclinical, will lessen the associated increase in fasting glucose, and perhaps onset of type 2 diabetes.⁹⁰

Potassium-sparing diuretics can cause hyperkalemia, especially in patients with chronic kidney disease or diabetes and in patients receiving concurrent treatment with an ACE inhibitor, nonsteroidal antiinflammatory drugs, or potassium supplements. Hyperkalemia is especially problematic for the newest aldosterone antagonist eplerenone. This agent is a very selective aldosterone antagonist, and

its propensity to cause hyperkalemia is greater than with the other potassium sparing agents, and even spironolactone. Because of this increased risk of hyperkalemia, eplerenone is contraindicated in patients with impaired kidney function or type 2 diabetes with proteinuria (see Table 15–5). Although spironolactone may cause gynecomastia in up to 10% of patients, this occurs rarely with eplerenone.

Diuretics can be used safely with most other agents. However, concurrent administration with lithium may result in increased lithium serum concentrations. This interaction can predispose patients to lithium toxicity.

ACE Inhibitors^{27,32,80} ACE inhibitors are a first-line agents for hypertension.^{1,2} The ALLHAT demonstrated less heart failure and stroke with chlorthalidone than with lisinopril.³⁰ However, other outcome studies have demonstrated similar, if not better outcomes with ACE inhibitors than with thiazide diuretics.^{27,32}

ACE facilitates production of angiotensin II which has a major role in arterial BP regulation as depicted in Fig. 15–1. ACE is distributed in many tissues and is present in several different cell types, but its principal location is in endothelial cells. Thus the major site for angiotensin II production is in the blood vessels, not the kidney. ACE inhibitors block the ACE (also termed *bradykinase*), thus inhibiting conversion of angiotensin I to angiotensin II. Angiotensin II is a potent vasoconstrictor that also stimulates aldosterone secretion, causing an increase in sodium and water reabsorption with accompanying potassium loss. By blocking the ACE, vasodilation and a decrease in aldosterone occur. ACE inhibitors also block degradation of bradykinin and stimulate the synthesis of other vasodilating substances (prostaglandin E₂ and prostacyclin). The observation that ACE inhibitors lower BP in patients with normal plasma renin activity suggests that bradykinin and perhaps tissue production of ACE are important in hypertension. Increased bradykinin enhances the BP-lowering effects of ACE inhibitors, but also is responsible for the side effect of dry cough. ACE inhibitors effectively prevent or regress left ventricular hypertrophy by reducing the direct stimulation by angiotensin II on myocardial cells.

There are many evidence-based uses for ACE inhibitors (see Fig. 15–3). ACE inhibitors reduce CV morbidity and mortality in patients with left ventricular dysfunction,⁴⁸ and decrease progression of chronic kidney disease.⁶⁵ They should be first-line as disease modifying therapy in all of these patients unless absolutely contraindicated. ACE inhibitors, or ARBs in certain patients, are first-line in patients with diabetes and hypertension because of demonstrated CV disease and kidney benefits. A regimen including an ACE inhibitor with a thiazide-type diuretic is considered first-line in recurrent stroke prevention base on proven benefits from the PROGRESS trial showing reduced risk of secondary stroke.³¹ In combination with β -blocker therapy, evidence shows that ACE inhibitors further reduce CV risk in coronary disease, and in patients post-MI.^{57,59,61,62} These benefits of ACE inhibitors occur in patients with atherosclerotic vascular even in the absence of left ventricular systolic dysfunction or heart failure, and have the potential to reduce the development of new-onset type 2 diabetes.⁶³

There are 10 ACE inhibitors on the U.S. market (see Table 15–5). All except captopril, which has a much shorter half-life than the others, can be dosed once daily; captopril is dosed two or three times daily. In some patients, especially when higher doses are used, twice daily dosing is needed to maintain 24-hour effects with enalapril, benazepril, moexipril, quinapril, and ramipril. The absorption of captopril, but not other ACE inhibitors, is reduced when given with food.

ACE inhibitors are well tolerated,⁹⁸ but are not absent of side effects. ACE inhibitors decrease aldosterone and can increase serum potassium concentrations. Although this increase is usually small, and beneficial in thiazide-treated patients, hyperkalemia is possible. Patients with

chronic kidney disease or those on concomitant nonsteroidal antiinflammatory drugs, potassium supplements, or potassium-sparing diuretics are at risk for hyperkalemia. Judicious monitoring of serum potassium and creatinine values within 4 weeks of starting or increasing the dose of an ACE inhibitor can often identify these abnormalities before they evolve into serious hyperkalemia.

A worrisome adverse effect of ACE inhibitor is acute kidney failure. Fortunately, this serious adverse effect is rare, occurring in less than 1% of patients. Preexisting kidney disease increases the risk of this side effect. Bilateral renal artery stenosis or unilateral stenosis of a solitary functioning kidney render patients dependent on the vasoconstrictive effect of angiotensin II on the efferent arteriole of the kidney, thus explaining why these patients are particularly susceptible to acute kidney failure from ACE inhibitors. Slowly titrating the dose of ACE inhibitor and judicious kidney function monitoring can minimize risk and allow for early detection of those with renal artery stenosis.

It is important to note that GFR decreases in patients treated with ACE inhibitors or ARBs.⁶⁵ This is attributed to the inhibition of angiotensin II vasoconstriction on the efferent arteriole. This decrease in GFR often increases serum creatinine, and small increases should be anticipated when monitoring patients on ACE inhibitors. Modest elevations of either up to a 35% (for baseline creatinine values less than or equal to 3 mg/dL) or absolute increases less than 1 mg/dL, do not warrant changes.⁶⁵ If larger increases occur, ACE inhibitor therapy should be stopped or the dose reduced.

Angioedema is a serious potential complication of ACE inhibitor therapy. It occurs in less than 1% of the population, and is more likely in African Americans and smokers. Symptoms include lip and tongue swelling and possibly difficulty breathing. Drug discontinuation is needed for ACE inhibitor-associated angioedema. However, angioedema associated with laryngeal edema and/or pulmonary symptoms occasionally occurs and requires treatment with epinephrine, corticosteroids, antihistamines and/or emergent intubations to support respiration. A history of angioedema, even if not from an ACE inhibitor, precludes use of another ACE inhibitor (it is a contraindication). Cross-reactivity between ACE inhibitors and ARBs is small, but has been reported.^{53,99} An ARB can be used in a patient with a history of ACE inhibitor-induced angioedema when there is a compelling indication for an ARB with careful monitoring for a repeat occurrence of angioedema.

A persistent dry cough develops in up to 20% of patients, and is pharmacologically explained by the inhibition of bradykinin breakdown. This cough does not cause clinical illness, but is annoying to patients. It should be clearly differentiated from a wet cough because of pulmonary edema, which may be a sign of uncontrolled heart failure versus an ACE inhibitor-induced cough.

ACE inhibitors, in addition to ARBs, are absolutely contraindicated in pregnancy.^{1,83} Female patients of child-bearing age should be counseled regarding effective forms of birth control as ACE inhibitors are associated major congenital malformations when exposed in the first trimester and fetopathy (group of conditions that includes renal failure, renal dysplasia, hypotension, oligohydramnios, pulmonary hypotension, hypocalvaria, and death) when exposed in the second and third trimester.⁸³ Similar to diuretics, ACE inhibitors can increase lithium serum concentrations in patients on lithium therapy. Concurrent use of an ACE with a potassium-sparing diuretic (including aldosterone antagonists), potassium supplements, or an ARB may result in excessive increases in potassium.

Starting doses of ACE inhibitors should be low, with even lower doses in patients at risk for orthostatic hypotension, or severe renal dysfunction (e.g., elderly, chronic kidney disease). Acute hypotension may occur at the onset of ACE inhibitor therapy. Patients who are sodium or volume depleted, in heart failure exacerbation, very elderly, or on concurrent vasodilators or diuretics are at high risk

for this effect. It is important to start with half the normal dose of an ACE inhibitor for all patients with these risk factors, and use slow dose titration.

Angiotensin Receptor Blockers ARBs are first-line agents for hypertension.^{1,2} Angiotensin II is generated by two enzymatic pathways: the RAAS, which involves ACE, and an alternative pathway that uses other enzymes such as chymases (also known as “tissue ACE”). ACE inhibitors inhibit only the effects of angiotensin II produced through the RAAS, whereas ARBs inhibit angiotensin II from all pathways. It is unclear how these differences affect tissue concentrations of ACE. ACE inhibitors only partially block the effects of angiotensin II, though the clinical significance of this is not known.

ARBs directly block the angiotensin II receptor subtype 1 receptor that mediates the known effects of angiotensin II in humans: vasoconstriction, aldosterone release, sympathetic activation, antidiuretic hormone release, and constriction of the efferent arterioles of the glomerulus. Because they do not block the angiotensin II receptor subtype 2 receptor, the beneficial effects of angiotensin II receptor subtype 2 stimulation (vasodilation, tissue repair, and inhibition of cell growth) remain intact when ARBs are used. Unlike ACE inhibitors, ARBs do not block the breakdown of bradykinin. Therefore, some of the beneficial effects of bradykinin, such as vasodilation (which can enhance treatment of left ventricular dysfunction), regression of myocyte hypertrophy and fibrosis, and increased levels of tissue plasminogen activator, are not present with ARB therapy.

ARBs have outcomes data showing long-term reductions in progression of target-organ damage in patients with hypertension and certain compelling indications. In patients with type 2 diabetes and nephropathy, progression of nephropathy has been shown to be significantly reduced with ARB therapy.⁶⁴ Some benefits appear to be independent of BP lowering, suggesting that the pharmacologic effects of ARBs on the efferent arteriole may result in progression of kidney disease. For patients with left ventricular dysfunction, the CHARM studies showed that ARB therapy reduces risk of CV events when added to a stable regimen of a diuretic, ACE inhibitor, and β -blocker, or as alternative therapy in ACE-intolerant patients.^{53,54} Importantly, the ELITE (Evaluation of Losartan in the Elderly) studies show that losartan is not superior to captopril in left ventricular dysfunction when compared head-to-head.^{51,52} One outcome study, the VALLIANT, also showed that an ARBs can reduce CV events in patients post-MI with left ventricular dysfunction, but would be used mostly as an alternative to an ACE inhibitor for this use.⁵⁸

ARBs have been compared head-to-head with CCBs. The MOSES demonstrated that eprosartan reduces the occurrence of recurrent stroke more than nitrendipine does in patients with a past medical history of cerebrovascular disease.⁷⁴ Using nitrendipine was a reasonable comparator because the Syst-Eur had already demonstrated that nitrendipine reduces the occurrence of CV events, particularly stroke, in older patients with isolated systolic hypertension.¹² These data support the common notion that ARBs may have cerebroprotective effects that may explain CV event reductions. Another outcome study, the VALUE (Valsartan Long-term Use Evaluation) trial, showed that valsartan-based therapy is equivalent to amlodipine-based therapy for the primary composite outcome of first CV event in patients with hypertension and additional CV risk factors.³³ However, occurrence of certain components of the primary end point (stroke and MI) and new-onset type 2 diabetes was lower in the valsartan group. Although patients treated with amlodipine had slightly lower mean BP values than valsartan treated patients, there was no difference in the primary end point.

Data from pooled analyses and direct comparisons have demonstrated that ARBs have a fairly flat dose–response curve, suggesting that increasing the dose above low or moderate doses is unlikely to result in a large degree of BP lowering.⁹⁸ The addition of low doses

of a thiazide-type diuretic to an ARB significantly increases antihypertensive efficacy. Similar to ACE inhibitors, most ARBs have long enough half-lives to allow for once-daily dosing. However, candesartan, eprosartan, losartan, and valsartan have the shortest half-lives and may require twice-daily dosing for sustained BP lowering.

ARBs have the lowest incidence of side effects compared to other antihypertensive agents.⁹⁸ Because they do not affect bradykinin, they do not have the potential to illicit a dry cough like ACE inhibitors. Although these drugs have been termed “ACE inhibitors without the cough,” pharmacologic differences highlight that they could have very different effects on vascular smooth muscle and myocardial tissue that can correlate to different effects on target-organ damage and CV risk reduction when compared with ACE inhibitors. It is possible that their effects may be superior to ACE inhibitors in patients with type 2 diabetic nephropathy, but may be inferior to ACE inhibitors in patients with more advanced heart disease (e.g., heart failure, post-MI). Unfortunately, there are no direct comparisons looking at long-term effects in patients with just hypertension. Regardless, their role in patients with type 2 diabetic nephropathy is well established and they also are very reasonable alternatives in patients requiring an ACE inhibitor but who experience intolerable side effects.

CLINICAL CONTROVERSY

Data demonstrates that risk of CV events is further reduced when an ARB is added to an ACE inhibitor in patients with left ventricular dysfunction. Other data support this combination in patients with severe forms of nephrotic syndrome. However, using the combination of an ACE with an ARB has not been well studied as a standard treatment regimen in hypertension and incurs a significantly higher risk of side effects (e.g., hyperkalemia).¹⁰⁰

Like ACE inhibitors, ARBs may cause renal insufficiency, hyperkalemia, and orthostatic hypotension. The same precautions that apply to ACE inhibitors for patients with suspected bilateral renal artery stenosis, those on drugs that can raise potassium, and those on drugs that increase risk of hypotension apply to ARBs. ARBs can be used with caution in patients with a history of angioedema, but unlike ACE inhibitors are not contraindicated. Angioedema is also less likely to occur than with ACE inhibitors, but cross-reactivity has been reported.^{53,99} An ARB should only be used in a patient with a history of ACE inhibitor-induced angioedema when there is a compelling indication for an ARB with careful monitoring for a repeat occurrence of angioedema. ARBs should not be used in pregnancy.⁸³

Calcium Channel Blockers^{12,27} CCBs, both dihydropyridine CCBs and nondihydropyridine CCBs, are first-line agents for hypertension.^{1,2} They have compelling indications in coronary disease and in diabetes. However, with these compelling indications, they are essentially in addition to, or in replacement of, other antihypertensive drug classes.

Previous data indicated that dihydropyridine CCBs may not provide as much protection against CV events when compared with conventional therapy (diuretics and β -blockers) or ACE inhibitors in uncomplicated hypertension.²⁷ However, newer data shows that CCBs are likely to be as effective at lowering CV events as other agents. In ALLHAT there was no difference in the primary outcome between chlorthalidone and amlodipine, and only the secondary outcome of heart failure was higher with amlodipine.³⁰ A subgroup analysis of ALLHAT directly compared amlodipine to lisinopril and demonstrated that there was no difference in the primary outcome.¹⁰¹ As discussed previously, the VALUE study also showed no difference in the primary outcome of first CV event in high-risk patients between valsartan and amlodipine.³³

There may be differences in CV event reduction between dihydropyridine CCBs and nondihydropyridine CCBs. In patients with hypertension and diabetes, dihydropyridine CCBs appear to be less cardioprotective than ACE inhibitors.⁶⁴ Studies with the nondihydropyridine CCBs (diltiazem and verapamil) are limited, but the NORDIL (Nordic Diltiazem) study found diltiazem to be equivalent to diuretics and β -blockers in reducing CV events.²⁷ It is possible that these differences (beneficial with diltiazem and neutral with dihydropyridines) may relate to the sympathetic stimulation that can occur with dihydropyridines.

Dihydropyridine CCBs are very effective in older patients with isolated systolic hypertension. The Syst-Eur demonstrated that a long-acting dihydropyridine CCB reduced the risk of CV events markedly in isolated systolic hypertension.¹² A long-acting dihydropyridine CCB should be strongly considered in isolated systolic hypertension.

Contraction of cardiac and smooth muscle cells requires an increase in free intracellular calcium concentrations from the extracellular fluid. When cardiac or vascular smooth muscle is stimulated, voltage-sensitive channels in the cell membrane are opened, allowing calcium to enter the cells. The influx of extracellular calcium into the cell releases stored calcium from the sarcoplasmic reticulum. As intracellular free calcium concentration increases, it binds to a protein, calmodulin, which then activates myosin kinase enabling myosin to interact with actin to induce contraction. CCBs work by inhibiting influx of calcium across the cell membrane. There are two types of voltage-gated calcium channels: a high-voltage channel (L type) and a low-voltage channel (T type). Currently available CCBs only block the L-type channel, which leads to coronary and peripheral vasodilation.

The two subclasses of CCBs, dihydropyridines and nondihydropyridines (see Table 15–5) are pharmacologically very different from each other. Antihypertensive effectiveness is similar with both subclasses, but they differ in other pharmacodynamic effects. Nondihydropyridines decrease heart rate and slow atrioventricular nodal conduction. Similar to β -blockers, these drugs may also treat supraventricular tachyarrhythmias (e.g., atrial fibrillation). Verapamil produces negative inotropic and chronotropic effects that are responsible for its propensity to precipitate or cause systolic heart failure in high-risk patients. Diltiazem also has these effects but to a lesser extent than verapamil. All CCBs (except amlodipine and felodipine) have negative inotropic effects. Dihydropyridines may cause a baroreceptor-mediated reflex tachycardia because of their potent peripheral vasodilating effects. This effect appears to be more pronounced with the first generation dihydropyridines (e.g., nifedipine) and is significantly diminished with the newer agents (e.g., amlodipine) and when given in sustained-release dosage forms. Dihydropyridines do not alter conduction through the atrioventricular node and thus are not effective agents in supraventricular tachyarrhythmias.

Among dihydropyridines, short-acting nifedipine may rarely cause an increase in the frequency, intensity, and duration of angina in association with acute hypotension. This effect is most likely due to a reflex sympathetic stimulation, and is likely obviated by using sustained-release formulations of nifedipine. For this reason, all other dihydropyridines have an intrinsically long-half-life or are provided in sustained release formulations. Immediate-release nifedipine has been associated with an increased incidence of adverse CV effects, is not approved for treatment of hypertension, and should not be used to treat hypertension. Other side effects with dihydropyridines include dizziness, flushing, headache, gingival hyperplasia, and peripheral edema. Side effects caused by vasodilation, such as dizziness, flushing, headache, and peripheral edema, occur more frequently with all dihydropyridines than with the nondihydropyridines because they are less-potent vasodilators.

Diltiazem and verapamil can cause cardiac conduction abnormalities such as bradycardia or atrioventricular block. These prob-

lems occur mostly with high-doses or when used in patients with preexisting abnormalities in the cardiac conduction system. Heart failure has been reported in otherwise healthy patients as a consequence of negative inotropic effects. Both drugs can cause anorexia, nausea, peripheral edema, and hypotension. Verapamil causes constipation in approximately 7% of patients. This side effect also occurs with diltiazem, but to a lesser extent.

Verapamil and to a lesser extent diltiazem, can cause drug interactions because of their ability to inhibit the cytochrome P450 3A4 isoenzyme system. This inhibition can increase serum concentrations of other drugs that are metabolized by this isoenzyme system (e.g., cyclosporine, digoxin, lovastatin, simvastatin, tacrolimus, theophylline). Verapamil and diltiazem should be given very cautiously with a β -blocker because there is an increased risk of heart block with these combinations. When a CCB is needed in combination with a β -blocker for BP lowering, a dihydropyridine should be selected, because it will not increase risk of heart block. The hepatic metabolism of CCBs, especially felodipine, nicardipine, nifedipine, and nisoldipine, may be inhibited by ingesting large quantities of grapefruit juice (≥ 1 quart daily).

Many different formulations of verapamil and diltiazem are currently available (see Table 15–5). Although certain sustained-release verapamil and diltiazem products may contain the same active drug (e.g., Calan SR and Verelan), they are usually not AB rated by the FDA as interchangeable on a mg-per-mg basis because of different biopharmaceutical release mechanisms. However, the clinical significance of these differences is likely negligible.

Two sustained-release verapamil products (Covera HS and Verelan PM) and one diltiazem product (Cardizem LA) are chronotherapeutically designed to target the circadian BP rhythm. These agents are primarily dosed in the evening (with the exception of Cardizem LA which may be dosed in the morning or evening) so that drug is released during the early morning hours when BP first starts to increase. The rationale behind chronotherapy in hypertension is that blunting the early morning BP surge may result in greater reductions in CV events than conventional dosing of regular antihypertensive products in the morning. However, evidence from the CONVINCe (Controlled Onset Verapamil Investigation of Cardiovascular End Points) trial showed that chronotherapeutic verapamil was similar, but not better than, a thiazide-type diuretic/ β -blocker-based regimen with respect to CV events.²⁸

β -Blockers^{27,28,48,59,62} β -Blockers have been used in several large outcome trials in hypertension. However, in most of these trials, a thiazide-type diuretic was the primary agents with a β -blocker added on for additional BP lowering. Therefore, β -blockers are now only considered appropriate first-line agents to treat specific compelling indications (post-MI, coronary disease). They also are evidence-based as additional therapy for other compelling indications (heart failure and diabetes). Numerous trials have shown reduced CV risk when β -blockers are used following an MI, during an acute coronary syndrome, or in chronic stable angina. Although once considered contraindicated in heart failure, multiple studies have shown that carvedilol and metoprolol succinate reduce mortality in patients with left ventricular dysfunction who are treated with a diuretic and ACE inhibitor.

For patients with hypertension but without compelling indications, other primary agents (thiazide-type diuretics, ACE inhibitors, ARBs, and CCBs) should be used as the initial first-line agent before β -blockers. While this may be surprising to experienced clinicians, this recommendation is consistent with the 2007 AHA guidelines, the 2007 European Society of Hypertension guidelines, and the 2006 United Kingdom's National Institute for Health and the Clinical Excellence guidelines.^{2,92,93} It is based on meta-analyses data that suggest β -blocker-based therapy may not reduce CV events as well

as these other agents when used as the initial drug to treat patients with hypertension and without a compelling indication for a β -blocker.

Several mechanisms of action have been proposed for β -blockers, but none of them alone is consistently associated with a reduction in arterial BP. β -Blockers have negative chronotropic and inotropic cardiac effects that reduce cardiac output and explains some of the antihypertensive effect. However, cardiac output falls equally in patients treated with β -blockers regardless of BP lowering.

β -Adrenoceptors are located on the surface membranes of juxtaglomerular cells, and β -blockers inhibit these receptors and thus the release of renin. However, there is a weak association between plasma renin and antihypertensive efficacy of β -blocker therapy. Some patients with low plasma renin concentrations do respond to β -blockers. Therefore, additional mechanisms must also account for the antihypertensive effect of β -blockers. However, the ability of β -blockers to reduce plasma renin and thus angiotensin II concentrations may play a major role in their ability to reduce CV risk.

There are important pharmacodynamic and pharmacokinetic differences among β -blockers, but all agents provide a similar degree of BP lowering. There are two pharmacodynamic properties of the β -blockers that differentiate this class: cardioselectivity and ISA. β -Blockers that possess a greater affinity for β_1 -receptors than β_2 -receptors are *cardioselective*.

The β_1 - and β_2 -adrenoceptors are distributed throughout the body, but they concentrate differently in certain organs and tissues. There is a preponderance of β_1 -receptors in the heart and kidney, and a preponderance of β_2 -receptors in the lungs, liver, pancreas, and arteriolar smooth muscle. β_1 -Receptor stimulation increases heart rate, contractility, and renin release. β_2 -Receptor stimulation results in bronchodilation and vasodilation. Cardioselective β -blockers are not likely to provoke bronchospasm and vasoconstriction. Insulin secretion and glycogenolysis are mediated by β_2 -receptors. Blocking β_2 -receptors may reduce these processes and cause hyperglycemia or blunt recovery from hypoglycemia.

Cardioselective β -blockers (e.g., atenolol, metoprolol) have clinically significant advantages over nonselective β -blockers (e.g., propranolol, nadolol), and are generally preferred to treat hypertension. Cardioselective agents are safer than nonselective agents in patients with asthma or diabetes. However, cardioselectivity is a dose-dependent phenomenon; at higher doses, cardioselective agents lose their relative selectivity for β_1 -receptors and block β_2 -receptors as effectively as they block β_1 -receptors. The dose at which cardioselectivity is lost varies from patient to patient.

Some β -blockers (e.g., acebutolol, pindolol) have ISA and act as partial β -receptor agonists. When they bind to the β -receptor, they stimulate it, but far less than a pure β -agonist. If sympathetic tone is low, as it is during resting states, β -receptors are partially stimulated by ISA β -blockers. Therefore, resting heart rate, cardiac output, and peripheral blood flow are not reduced when these type of β -blockers are used. Theoretically, ISA agents would appear to have advantages over β -blockers in certain patients with heart failure, or sinus bradycardia. Unfortunately, they do not appear to reduce CV events as well as other β -blockers. In fact, they may increase risk post-MI or in those with coronary disease. Thus, agents with ISA are rarely needed and have little to no clinical utility.

Pharmacokinetic differences among β -blockers relate to first-pass metabolism, route of elimination, degree of lipophilicity, and serum half-lives. Propranolol and metoprolol undergo extensive first-pass metabolism, so the dose needed to attain β -blockade with either drug varies from patient to patient. Atenolol and nadolol have are renally excreted. The dose of these agents may need to be reduced in patients with moderate to severe chronic kidney disease.

β -Blockers, especially those with highly lipophilic properties, penetrate the central nervous system penetration and may cause

other effects. Propranolol is the most lipophilic drug and atenolol is the least lipophilic. It is unclear whether higher lipophilicity is associated with more central nervous system side effects (dizziness, drowsiness). However, the lipophilic properties can provide better effects for non-CV conditions such as migraine headache prevention, essential tremor, and thyrotoxicosis. BP lowering is equal among β -blockers regardless of lipophilicity.

CLINICAL CONTROVERSY

Many of the clinical trials included in the meta-analyses data that suggest β -blocker-based therapy may not reduce CV events as well as these other agents used atenolol dosed once daily.^{44–47} Atenolol has a half life of 6 to 7 hours and is nearly always dosed once daily, whereas immediate-release forms of carvedilol and metoprolol tartrate have 6- to 10- and 3- to 7-hour half-lives respectively, and are always dosed at least twice daily. Consequently, it is possible that these findings might only apply to atenolol and also that these findings may be a result of using atenolol once daily instead of twice daily.

Most side effects of β -blockers are an extension of their ability to antagonize β -adrenoceptors. β -Blockade in the myocardium can be associated with bradycardia, atrioventricular conduction abnormalities (e.g., second- or third-degree heart block), and the development of acute heart failure. The decreases in heart rate may actually benefit certain patients with atrial arrhythmias (atrial fibrillation, atrial flutter) and hypertension by both providing rate control and BP lowering. β -Blockers usually only produce heart failure if they are used in high initial doses in patients with preexisting left ventricular dysfunction or if started in these patients during an acute heart failure exacerbation. Blocking β_2 -receptors in arteriolar smooth muscle may cause cold extremities and may aggravate peripheral arterial disease or Raynaud's phenomenon as a result of decreased peripheral blood flow. In addition, there is an increase of sympathetic tone during periods of hypoglycemia that may result in an increase in BP because of unopposed α -receptor-mediated vasoconstriction.

Abrupt cessation of β -blocker therapy can produce unstable angina, MI, or even death in patients with coronary disease. Abrupt cessation may also lead to rebound hypertension (a sudden increase in BP to above pretreatment values). To avoid this, β -blockers should always be tapered gradually over 1 to 2 weeks before eventually discontinuing the drug. This acute withdrawal syndrome is believed to be secondary to progression of underlying coronary disease and hypersensitivity of β -adrenergic receptors as a result of upregulation. In patients without coronary disease, abrupt discontinuation may present as tachycardia, sweating, and generalized malaise, in addition to increased BP.

Like diuretics, β -blockers have been shown to increase serum cholesterol and glucose values, but these effects are transient and of questionable clinical significance. In patients with diabetes or dyslipidemia, the reduction in CV events was as great with β -blockers as with an ACE inhibitor in the United Kingdom Prospective Diabetes Study,⁶⁶ and far superior to placebo in the SHEP trial.⁹ In the GEMENI (Glycemic Effects in Diabetes Mellitus: Carvedilol-Metoprolol Comparison in Hypertension) trial, patients with diabetes and hypertension who were randomized to metoprolol had an increase in hemoglobin A_{1c} values, whereas patients randomized to carvedilol did not.¹⁰² This suggests that mixed α - and β -blocking effects of carvedilol may be preferential to metoprolol in patients with uncontrolled diabetes. However, differences in hemoglobin A_{1c} values were too small to make this application clinically relevant in all patients with diabetes that need treatment with a β -blocker.

β -Blockers can slightly increase serum triglycerides and decrease high-density lipoprotein cholesterol. β -Blockers with α -blocking properties produce no changes in these lipid values. Because these are of questionable clinical significance, cardioselective agents, which have less overall side effects, remain the β -blockers of choice for most patients.

13 Alternative Agents The primary role of an alternative antihypertensive agent is to provide additional BP lowering in patients who are already treated with an agent from a drug class proven to reduce CV events (diuretics, ACE inhibitors, ARBs, CCBs, or even β -blockers).

α_1 -Blockers.³⁵ Prazosin, terazosin, and doxazosin are selective α_1 -receptor blockers. They work in the peripheral vasculature and inhibit the uptake of catecholamines in smooth muscle cells resulting in vasodilation and BP lowering.

Doxazosin was one of the original treatment arms of the ALLHAT. However, it was stopped prematurely when statistically more secondary end points of stroke, heart failure, and CV events were seen with doxazosin compared with chlorthalidone.³⁵ There were no differences in the primary end point of fatal coronary heart disease and nonfatal MI. These data suggest that thiazide-type diuretics are superior to α_1 -blockers in preventing CV events in patients with hypertension. Therefore, α_1 -blockers are alternative agents that should be used in combination with primary antihypertensive agents.

α_1 -Blockers can provide symptomatic benefits in men with benign prostatic hypertrophy. These agents block postsynaptic α_1 -adrenergic receptors located on the prostate capsule, causing relaxation and decreased resistance to urinary outflow. However, when used to lower BP, they should only be in addition to primary antihypertensive agents.

A potentially severe side effect of α_1 -blockers is a “first-dose” phenomenon that is characterized by transient dizziness or faintness, palpitations, and even syncope within 1 to 3 hours of the first dose. This adverse reaction can also happen after dose increases. These episodes are accompanied by orthostatic hypotension and can be obviated by taking the first dose and subsequent first increased doses at bedtime. Because orthostatic hypotension and dizziness may persist with chronic administration, these agents should be used cautiously in elderly patients. Even though antihypertensive effects are achieved through a peripheral α_1 -receptor antagonism, these agents cross the blood-brain barrier and may cause central nervous system side effects. α_1 -Blockers also may cause priapism. Sodium and water retention can occur with chronic administration. Consequently, these agents are most effective when given in combination with a diuretic to maintain antihypertensive efficacy and minimize potential edema.

Aliskiren.^{103,104} Aliskiren is the first oral agent within a new antihypertensive drug class that directly inhibits renin.¹⁰³ This drug blocks the RAAS at its point of activation, which results in reduced plasma renin activity and BP lowering. It has a 24-hour half-life, is primarily eliminated through biliary excretion unchanged, and provides 24-hour antihypertensive effects with once-daily dosing.

The exact role of this drug class in the management of hypertension is unclear. Aliskiren is approved as monotherapy or in combination therapy. However, because of the lack of long-term studies evaluating CV event reduction and significant drug cost compared to generic agents with outcomes data, it should clearly be used as an alternative therapy for the treatment of hypertension. Studies evaluating the ability of aliskiren to lower CV events and decrease progression of diabetic nephropathy are planned to start in 2007, but will not be completed for many years. Aliskiren provides BP reductions comparable to an ACE inhibitor, ARB, or CCB. It also has additive antihypertensive effects when used in combination with thiazides, ACE inhibitors, ARBs, or a

CCB, although its effectiveness in combination with maximum doses of ACE inhibitors has not been adequately studied.

Many of the cautions and adverse effects seen with ACE inhibitors and ARBs apply to direct renin inhibitors (i.e., aliskiren). Aliskiren should never be used in pregnancy because of the known teratogenic effects of using other drugs that block the RAAS system. Angioedema has also been reported in patients treated with aliskiren. Increases in serum creatinine and serum potassium values have been observed. The mechanisms of these adverse effects are likely similar to those with ACE inhibitors and ARBs. It is reasonable to use similar monitoring strategies by measuring serum creatinine and serum potassium in patients treated with aliskiren. This is particularly important in patients treated with the combination of aliskiren and an ACE inhibitor or an ARB who are at higher risk for hyperkalemia (e.g., chronic kidney disease).

Central α_2 -Agonists. Clonidine, guanabenz, guanfacine, and methyldopa lower BP primarily by stimulating α_2 -adrenergic receptors in the brain. This stimulation reduces sympathetic outflow from the vasomotor center in the brain and increases vagal tone. It is also believed that peripheral stimulation of presynaptic α_2 -receptors may further reduce sympathetic tone. Reduced sympathetic activity together with enhanced parasympathetic activity can decrease heart rate, cardiac output, total peripheral resistance, plasma renin activity, and baroreceptor reflexes. Clonidine is often used in resistant hypertension, and methyldopa is a first-line agent for pregnancy-induced hypertension.

Chronic use of centrally acting α_2 -agonists results in sodium and water retention. As with other centrally acting antihypertensives, depression can occur, especially with high doses. The incidence of orthostatic hypotension and dizziness is high, so they should be used very cautiously in the elderly. Lastly, clonidine has a relatively high incidence of anticholinergic side effects (sedation, dry mouth, constipation, urinary retention, and blurred vision). Thus it should generally be avoided for chronic antihypertensive therapy in the elderly.

Abrupt cessation of central α_2 -agonists may lead to rebound hypertension. This effect is thought to be secondary to a compensatory increase in norepinephrine release after abrupt discontinuation. In addition, other effects such as nervousness, agitation, headache, and tremor can also occur, which may be exacerbated by concomitant β -blocker use, particularly with clonidine. Thus, if clonidine is to be continued it should be tapered. In patients who are receiving concomitant β -blocker therapy, the β -blocker should be gradually discontinued first several days before gradual discontinuation of clonidine.

Methyldopa can cause hepatitis or hemolytic anemia, although this is rare. Transient elevations in serum hepatic transaminases are occasionally seen with methyldopa therapy but are clinically irrelevant unless they are greater than three times the upper limit of normal. Methyldopa should be quickly discontinued if persistent increases in serum hepatic transaminases or alkaline phosphatase are detected because this may indicate the onset of a fulminate life-threatening hepatitis. A Coombs-positive hemolytic anemia occurs in less than 1% of patients receiving methyldopa, although 20% of patients exhibit a positive direct Coombs test without anemia. For these reasons, methyldopa has limited use in routine management of hypertension except in pregnancy.

Reserpine. Reserpine lowers BP by depleting norepinephrine from sympathetic nerve endings, and blocking transport of norepinephrine into its storage granules. Norepinephrine release into the synapse following nerve stimulation is reduced and results in reduced sympathetic tone, peripheral vascular resistance, and BP. Reserpine also depletes catecholamines in the brain and the myocardium.

Reserpine has a slow onset of action and long-half life that allows for once-daily dosing. However, it may take 2 to 6 weeks before the

maximal antihypertensive effect is seen. Because reserpine can cause significant sodium and water retention, it should only be given in combination with a diuretic (preferably a thiazide). Reserpine's strong inhibition of sympathetic activity results in increased parasympathetic activity. This effect explains why side effects such as nasal stuffiness, increased gastric acid secretion, diarrhea, and bradycardia can occur. Depression has been reported, which is a consequence of central nervous system depletion of catecholamines and serotonin. The initial reports of depression with reserpine were in the 1950s and are inconsistent with current definitions of depression. Regardless, reserpine-induced depression is dose-related. Moreover, very high doses (above 1 mg daily) were frequently used in the 1950s, resulting in more depression. When reserpine is used in doses between 0.05 and 0.25 mg daily (recommended doses), the rate of depression is equal to that seen with β -blockers, diuretics, or placebo.⁹

Reserpine was used as a third-line agent in many of the landmark clinical trials that have documented the benefit in treating hypertension, including the VA Cooperative trials and most importantly, the SHEP trial.⁹ An analysis of the SHEP data found that reserpine was very well tolerated.

Direct Arterial Vasodilators. Hydralazine and minoxidil directly relax arteriolar smooth muscle resulting in vasodilation and BP lowering. Both agents cause potent reductions in perfusion pressure that activates the baroreceptor reflexes. Activation of baroreceptors results in a compensatory increase in sympathetic outflow, which leads to an increase in heart rate, cardiac output, and renin release. Consequently, tachyphylaxis can develop resulting in a loss of hypotensive effect with continued use. This compensatory baroreceptor response can be counteracted by concurrent use of a β -blocker.

All patients receiving hydralazine or minoxidil long-term for hypertension should first receive both a diuretic and a β -blocker. Direct arterial vasodilators can precipitate angina in patients with underlying coronary disease unless the baroreceptor reflex mechanism is completely blocked with a β -blocker. Nondihydropyridine CCBs can be used as an alternative to β -blockers in these patients, but a β -blocker is preferred. The side effect of sodium and water retention is significant with these drugs, and is minimized by using a diuretic concomitantly.

One side effect unique to hydralazine is a dose-dependent drug-induced lupus-like syndrome. Hydralazine is eliminated by hepatic *N*-acetyltransferase. This enzyme displays genetic polymorphism, and "slow acetylators" are especially prone to develop drug-induced lupus with hydralazine. This syndrome is more common in women and is reversible upon discontinuation. Drug-induced lupus may be avoided by using less than 200 mg of hydralazine daily. Other side effects of hydralazine include dermatitis, drug fever, peripheral neuropathy, hepatitis, and vascular headaches. For these reasons, hydralazine has limited usefulness in the treatment of hypertension. However, it is still especially useful in patients with severe chronic kidney disease and in kidney failure.

Because minoxidil is a more potent vasodilator than hydralazine, the compensatory increases in heart rate, cardiac output, renin release, and sodium retention are even more dramatic. Sodium and water retention can be so severe with minoxidil that heart failure can be precipitated. It is even more important to coadminister a β -blocker and a diuretic with minoxidil. A loop diuretic is often more effective than a thiazide in patients treated with minoxidil. A troublesome side effect of minoxidil is hypertrichosis (hirsutism), presenting as increased hair growth on the face, arms, back, and chest. This usually ceases when the drug is discontinued. Minoxidil is reserved for very-difficult-to-control hypertension and in patients requiring hydralazine who experience drug-induced lupus.

Other Agents. Guanethidine and guanadrel are postganglionic sympathetic inhibitors. Because of significant complications, these

drugs have little to no role in the management of hypertension. They deplete norepinephrine from postganglionic sympathetic nerve terminals and inhibit the release of norepinephrine in response to sympathetic nerve stimulation, resulting in reduced cardiac output and peripheral vascular resistance. Orthostatic hypotension is common because reflex-mediated vasoconstriction is blocked. Long-term norepinephrine depletion leads to postsynaptic receptor supersensitivity. Consequently, concomitant use of sympathomimetics or tricyclic antidepressants may provoke hypertensive crisis. Erectile dysfunction, diarrhea, and weight gain are also common.

Agents in Development.¹⁰⁴ Darusentan, clevidipine, and nebivolol are new agents under study that provide significant reductions in BP and may be approved for hypertension in the near future. Darusentan is an endothelin (A) selective endothelin receptor antagonist. There currently are no antihypertensive agents available that target the endothelin receptor. If this agent is approved, it will likely be used in patients with resistant hypertension. Nebivolol is a "third-generation" cardioselective β -blocker. It produces vasodilation and improves endothelial function via the L-arginine-nitric oxide pathway. Clevidipine is an ultrashort-acting, vascular-selective, dihydropyridine calcium antagonist. It is being developed for intravenous use in patients with hypertensive crisis.

PHARMACOECONOMIC CONSIDERATIONS

The cost of effectively treating hypertension is substantial. However, these costs can be offset by savings that would be realized by reducing CV morbidity and mortality. Cost related to treating target-organ damage (e.g., MI, end-stage kidney failure) can drastically increase healthcare costs. The cost per life-year saved from treating hypertension is estimated to be \$40,000 for younger adults and even less for older adults.¹⁰⁵ Treatments that cost less than \$50,000 per quality-adjusted life-year saved generally are considered favorable by health economists.

In a cost-minimization study that included the cost of drug acquisition, supplemental drugs, laboratory tests, clinic visits, and complications, the total costs of treating hypertension with either a diuretic, ACE-inhibitor, or CCB was under \$1,500.¹⁰⁶ Another cost-minimization analysis found that 86 middle-age or 29 elderly patients with hypertension would need to be treated to prevent 1 MI, stroke, or death.¹⁰⁷

A comparative analysis of 133,624 patients with hypertension ages 65 and older from a state prescription drug-assistance program demonstrated that 40% of patients were prescribed pharmacotherapy that was not necessarily recommended by the JNC7 guidelines recommendations.¹⁰⁸ If these 40% had drug-therapy modifications made to follow evidence-based treatment, a reduction in costs of \$11.6 million would have been realized in the 2001 calendar year based on discounted prices. This was projected to increase to \$20.5 million using usual Medicaid pricing limits.

Thus it is crucial to identify ways to control the cost of care without increasing the morbidity and mortality associated with uncontrolled hypertension. Using evidence-based pharmacotherapy will save costs not only by using the most effective agents. Thiazide-type diuretics are first-line treatment options in most patients without compelling indications, and are very inexpensive. Just using thiazides, either as monotherapy or in combination, is appropriate under almost all circumstances and aspects of hypertension management. When needed, using other generic primary antihypertensive agents that can be administered once daily should be considered.

HYPERTENSIVE URGENCIES AND EMERGENCIES^{1,7}

Both hypertensive urgencies and emergencies are characterized by the presence of very elevated BP—greater than 180/120 mm Hg.

However, the need for urgent or emergent antihypertensive therapy should be determined based on the presence of acute or immediately progressing target-organ injury, but not elevated BP alone. Urgencies are not associated with acute or immediately progressing target-organ injury, whereas emergencies are. Examples of acute target-organ injury include encephalopathy, intracranial hemorrhage, acute left ventricular failure with pulmonary edema, dissecting aortic aneurysm, unstable angina, and eclampsia or severe hypertension during pregnancy.

14 Hypertensive Urgency

A common error with treating hypertensive urgency is initiating overly aggressive antihypertensive therapy. This treatment likely has been caused by the classification terminology “urgency.” Hypertensive urgencies are ideally managed by adjusting maintenance therapy by adding a new antihypertensive and/or increasing the dose of a present medication. This is the preferred approach to these patients as it provides a more gradual reduction in BP. Very rapid reductions in BP to goal values should be discouraged because of potential risks. Because autoregulation of blood flow in patients with hypertension occurs at a much higher range of pressure than in normotensive persons, the inherent risks of reducing BP too precipitously include cerebrovascular accidents, MI, and acute kidney failure. Hypertensive urgency requires BP reductions with oral antihypertensive agents to stage 1 values over a period of several hours to several days. All patients with hypertensive urgency should be reevaluated within 7 days (preferably after 1 to 3 days).

Acute administration of a short-acting oral antihypertensive (captopril, clonidine or labetalol) followed by careful observation for several hours to assure a gradual reduction in BP is an option for hypertensive urgency. However, there are no data supporting this approach as being absolutely needed. Oral captopril is one of the agents of choice and can be used in doses of 25 to 50 mg at 1- to 2-hour intervals. The onset of action of oral captopril is 15 to 30 minutes, and a marked fall in BP is unlikely to occur if no hypotensive response is observed within 30 to 60 minutes. For patients with hypertensive rebound following withdrawal of clonidine, 0.2 mg clonidine can be given initially, followed by 0.2 mg hourly until the

DBP falls below 110 mm Hg or a total of 0.7 mg clonidine has been administered. A single dose may be all that is necessary. Labetalol can be given in a dose of 200 to 400 mg, followed by additional doses every 2 to 3 hours.

Oral or sublingual immediate-release nifedipine for acute BP lowering is dangerous. This approach produces a rapid reduction in BP. Use of immediate-release and should never be used for hypertensive urgencies because of reports of severe adverse events such as nifedipine as MIs and strokes.¹⁰⁹

Hypertensive Emergency

Hypertensive emergencies are those rare situations that require immediate BP reduction to limit new or progressing target-organ damage (see Arterial Blood Pressure: Classification above). Hypertensive emergencies require parenteral therapy, at least initially, with one of the agents listed in Table 15–8. The goal in hypertensive emergencies is not to lower BP to less than 140/90 mm Hg; rather, a reduction in mean arterial pressure of up to 25% within minutes to hours is the initial target. If then stable, BP can be reduced to 160/100–110 mm Hg within the next 2 to 6 hours. Precipitous drops in BP may lead to end-organ ischemia or infarction. If patients tolerate this reduction, additional gradual reductions toward goal BP values can be attempted after 24 to 48 hours. The exception to this guideline is for patients with an acute ischemic stroke where maintaining an elevated BP is needed for a much longer period of time.

The clinical situation should dictate which intravenous medication is used to treat hypertensive emergencies. Regardless, therapy should be provided in a hospital or emergency room setting with intraarterial BP monitoring. Table 15–8 lists special indications for agents that can be used. Some of these agents are discussed in further detail below.

Nitroprusside is widely considered the agent of choice for most cases, but can be problematic in patients with chronic kidney disease. It is a direct-acting vasodilator that decreases peripheral vascular resistance but does not increase cardiac output unless left ventricular failure is present. Nitroprusside can be given to treat most hypertensive emergencies, but in aortic dissection, propranolol should be given first to prevent reflex sympathetic activation. Nitroprusside is

TABLE 15-8 Parenteral Antihypertensive Agents for Hypertensive Emergency

Drug	Dose	Onset (min)	Duration (min)	Adverse Effects	Special Indications
Sodium nitroprusside	0.25–10 mcg/kg/min intravenous infusion (requires special delivery system)	Immediate	1–2	Nausea, vomiting, muscle twitching, sweating, thiocyanate and cyanide intoxication	Most hypertensive emergencies; caution with high intracranial pressure, azotemia, or in chronic kidney disease
Nicardipine hydrochloride	5–15 mg/h intravenous	5–10	15–30; may exceed 240	Tachycardia, headache, flushing, local phlebitis	Most hypertensive emergencies except acute heart failure; caution with coronary ischemia
Fenoldopam mesylate	0.1–0.3 mcg/kg/min intravenous infusion	<5	30	Tachycardia, headache, nausea, flushing	Most hypertensive emergencies; caution with glaucoma
Nitroglycerin	5–100 mcg/min intravenous infusion	2–5	5–10	Headache, vomiting, methemoglobinemia, tolerance with prolonged use	Coronary ischemia
Hydralazine hydrochloride	12–20 mg intravenous 10–50 mg intramuscular	10–20 20–30	60–240 240–360	Tachycardia, flushing, headache, vomiting, aggravation of angina	Eclampsia
Labetalol hydrochloride	20–80 mg intravenous bolus every 10 min; 0.5–2.0 mg/min intravenous infusion	5–10	180–360	Vomiting, scalp tingling, bronchoconstriction, dizziness, nausea, heart block, orthostatic hypotension	Most hypertensive emergencies except acute heart failure
Esmolol hydrochloride	250–500 mcg/kg/min intravenous bolus, then 50–100 mcg/kg/min intravenous infusion; may repeat bolus after 5 minutes or increase infusion to 300 mcg/min	1–2	10–20	Hypotension, nausea, asthma, first-degree heart block, heart failure	Aortic dissection; perioperative

metabolized to cyanide and then to thiocyanate, which is eliminated by the kidneys. Therefore, serum thiocyanate levels should be monitored when infusions are continued longer than 72 hours. Nitroprusside should be discontinued if the concentration exceeds 12 mg/dL. The risk of thiocyanate accumulation and toxicity is increased in patients with impaired kidney function.

Intravenous nitroglycerin dilates both arterioles and venous capacitance vessels, thereby reducing both cardiac afterload and preload which can decrease myocardial oxygen demand. It also dilates collateral coronary blood vessels and improves perfusion to ischemic myocardium. These properties make intravenous nitroglycerin ideal for the management of hypertensive emergency in the presence of myocardial ischemia. Intravenous nitroglycerin is associated with tolerance when used over 24 to 48 hours, and can cause severe headache.

Fenoldopam and nicardipine are newer and more expensive alternative agents. Fenoldopam is a dopamine-1 agonist. It can improve renal blood flow and may be especially useful in patients with kidney insufficiency. Nicardipine provides arterial vasodilation, and can treat cardiac ischemia similar to nitroglycerin, but may provide more predictable reductions in BP.

The hypotensive response of hydralazine is less predictable than with other parenteral agents. Consequently, its major role is in the treatment of eclampsia or hypertensive encephalopathy associated with renal insufficiency.

EVALUATION OF THERAPEUTIC OUTCOMES

ACHIEVING GOALS

The most important strategy to prevent CV morbidity and mortality in hypertension is BP control to goal values. Routine goal BP values should be attained in elderly patients and in those with isolated systolic hypertension, but actual BP lowering can occur at a very gradual pace over a period of several months to avoid orthostatic

hypotension. Modifying other CV risk factors (e.g., smoking, dyslipidemia, and diabetes) is also important.

15 COMBINATION ANTIHYPERTENSIVE THERAPY

Starting therapy with a combination of two drugs is recommended in patients who are far from their BP goal, for patients where goal achievement may be difficult (e.g., those with BP goals of less than 130/80 mm Hg, African Americans), and in patients with multiple compelling indications for different antihypertensive agents. Moreover, combination therapy is often needed to control BP and most patients require two or more agents.^{1,21,42,65}

Combination regimens for hypertension should ideally include a diuretic, preferably a thiazide-type. This method will provide additional BP lowering as most patients respond well to a combination regimen that includes a diuretic. Clinicians should anticipate the need for three drugs to control BP in patients with aggressive BP goals of <130/80 mm Hg.⁶⁵ Using low-dose combinations also provides greater reductions in BP compared to high doses of single agents, with fewer drug-related side effects.⁹⁸

Diuretics, when combined with several agents (especially an ACE inhibitor, ARB or β -blocker), can result in additive antihypertensive effects. BP lowering from certain antihypertensive agents can activate the RAAS as a compensatory mechanism to counteract BP changes, and regulate fluid loss. Most alternative antihypertensive agents (i.e., reserpine, arterial vasodilators, and centrally acting agents) need to be given with a diuretic to avoid sodium and water retention.

Many fixed-dose combination products are commercially available (Table 15-9). Most of these products contain a thiazide-type diuretic and have multiple dose strengths available. Individual dose titration is more complicated with fixed-dose combination products, but this strategy can reduce the number of daily tablets/capsules and can simplify regimens to improve adherence. This alone may increase the likelihood of achieving or maintaining goal BP values.

TABLE 15-9 Fixed-Dose Combination Products

Combination	Drugs (Brand Name)	Strengths (mg/mg)	Daily Frequency
ACE inhibitor with a thiazide diuretic	Benazepril/hydrochlorothiazide (Lotensin HCT)	5/6.25, 10/12.5, 20/12.5, 20/25	1
	Captopril/hydrochlorothiazide (Capozide)	25/15, 25/25, 50/15, 50/25	1 to 3
	Enalapril/hydrochlorothiazide (Vaseretic)	5/12.5, 10/25	1
	Lisinopril/hydrochlorothiazide (Prinzide, Zestoretic)	10/12.5, 20/12.5, 20/25	1
	Moexipril/hydrochlorothiazide (Uniretic)	7.5/12.5, 15/25	1 or 2
	Quinapril/hydrochlorothiazide (Accuretic)	10/12.5, 20/12.5, 20/25	1
	Quinapril/hydrochlorothiazide (Accuretic)	10/12.5, 20/12.5, 20/25	1
ARB with a thiazide diuretic	Candesartan/hydrochlorothiazide (Atacand HCT)	600/12.5, 600/25	1
	Eprosartan/hydrochlorothiazide (Teveten HCT)	16/12.5, 32/12.5	1
	Irbesartan/hydrochlorothiazide (Avalide)	75/12.5, 150/12.5, 300/12.5	1
	Losartan/hydrochlorothiazide (Hyzaar)	50/12.5, 100/25	1
	Olmesartan/hydrochlorothiazide (Benicar HCT)	20/12.5, 40/12.5, 40/25	1
	Telmisartan/hydrochlorothiazide (Micardis HCT)	40/12.5, 80/12.5	1
	Valsartan/hydrochlorothiazide (Diovan HCT)	80/12.5, 160/12.5	1
β -Blocker with a thiazide diuretic	Atenolol/chlorthalidone (Tenoretic)	50/25, 100/25	1
	Bisoprolol/hydrochlorothiazide (Ziac)	2.5/6.25, 5/6.25, 10/6.25	1
	Propranolol/hydrochlorothiazide (Inderide)	40/25, 80/25	2
	Propranolol LA/hydrochlorothiazide (Inderide LA)	80/50, 120/50, 160/50	1
	Metoprolol/hydrochlorothiazide (Lopressor HCT)	50/25, 100/25	1 or 2
	Nadolol/bendroflumethiazide (Corzide)	40/5, 80/5	1
	Timolol/hydrochlorothiazide (Timolide)	10/25	1 or 2
ACE inhibitor with calcium channel blocker	Amlodipine/benazepril (Lotrel)	2.5/10, 5/10, 10/20	1
	Enalapril/pelodipine (Lexxel)	5/5	1
	Trandolapril/verapamil (Tarka)	2/180, 1/240, 2/240, 4/240	1 or 2
ARB with calcium channel blocker	Valsartan/amlodipine (Exforge)	5/160, 10/160, 5/320, 10/320	1
	Olmesartan/amlodipine (AZOR)	5/20, 10/20, 5/40, 10/40	1

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker.

TABLE 15-10 Causes of Resistant Hypertension

Improper blood pressure measurement
Volume overload
• Excess sodium intake
• Volume retention from kidney disease
• Inadequate diuretic therapy
Drug-induced or other causes
• Nonadherence
• Inadequate doses
• Agents listed in Table 15-1
Associated conditions
• Obesity, excess alcohol intake
Secondary hypertension

16 RESISTANT HYPERTENSION

Resistant hypertension is the failure to achieve goal BP in patients who are adhering to full doses of an appropriate three-drug regimen that includes a diuretic.¹ Patients with newly diagnosed hypertension or who are not receiving drug therapy should not be considered to have resistant hypertension.¹¹⁰ Difficult-to-control hypertension is persistently elevated BP despite treatment with two or three drugs that does not meet the criteria for resistant hypertension (e.g., maximum doses that includes a diuretic).

Table 15-10 lists several causes of resistant hypertension. Volume overload is a common cause, thus highlighting the importance of diuretic therapy in the management of hypertension. In addition, nonadherence to drug therapy and lifestyle modifications plays an important role. Patients should be closely evaluated to see if any of these causes can be reversed. If nothing is identified, the principle of drug therapy selection from the JNC7 and AHA guidelines should still apply. Compelling indications, if present, should guide selection assuming these patients are on a diuretic.

Medications that have additive or synergistic effects when given in combination should ideally be used. In patients with severe chronic kidney disease (e.g., estimated GFR <30 mL/min 1.73 m²), a loop diuretic might be considered over a thiazide.

CLINICAL MONITORING

Routine ongoing monitoring to assess disease progression, the desired effects of antihypertensive therapy (efficacy), and undesired adverse side effects (toxicity) is needed in all patients treated with antihypertensive drug therapy.

Disease Progression

Patients should be monitored for signs and symptoms of progressive target-organ disease (see Table 15-1). A careful history for chest pain (or pressure), palpitations, dizziness, dyspnea, orthopnea, headache, sudden change in vision, one-sided weakness, slurred speech, and loss of balance should be taken to assess for the presence of hypertensive complications. Other clinical monitoring parameters that may be used to assess target-organ disease include funduscopic changes on eye examination, left ventricular hypertrophy on electrocardiogram, proteinuria, and changes in kidney function. These parameters should be monitored periodically because any sign of deterioration requires immediate assessment and followup.

Efficacy

Clinic-based BP monitoring remains the standard for managing hypertension. BP response should be evaluated 2 to 4 weeks after initiating or making changes in therapy. Once goal BP values are attained, assuming no signs or symptoms of acute target-organ disease are present, BP monitoring can be done every 3 to 6 months.

More frequent evaluations are required in patients with a history of poor control, nonadherence, progressive target-organ damage, or symptoms of adverse drug effects.

Self-measurements of BP or automatic ambulatory BP monitoring can be useful clinically to establish effective 24-hour control. This type of monitoring may become the standard of care in the future, but the JNC7 and AHA recommends that ambulatory BP monitoring only be used in select situations such as suspected white coat hypertension. If patients are measuring their BP at home, it is important that they measure during the early morning hours for most days, and then at different times of the day on alternative days of the week. Additionally, patients should be instructed to measure BP two to three times each time they measure BP, and to document all values accurately.

Toxicity

Patients should be monitored routinely for adverse drug effects (Table 15-11). Monitoring should typically occur 2 to 4 weeks after starting a new agent or dose increases, and then every 6 to 12 months in stable patients. Additional monitoring may be needed for other concomitant diseases if present (e.g., diabetes, dyslipidemia, gout). Moreover, patients treated with an aldosterone antagonist (eplerenone or spironolactone), should have potassium concentrations and kidney function assessed within 3 days and again at 1 week after initiation to detect potential hyperkalemia.⁴⁸ The occurrence of an adverse drug event may require dosage reduction or substitution with an alternative antihypertensive agent.

ADHERENCE

Lack of persistence with hypertension treatment is a major problem in the United States and is associated with significant increases in costs as a result of development of complications. Because hypertension is a relatively asymptomatic disease, poor adherence is frequent, particularly in patients newly treated. It has been estimated that only up to 50% of patients with newly diagnosed hypertension are continuing treatment at 1 year.¹¹¹ Therefore, it is imperative to assess patient adherence on a regular basis.

Identification of nonadherence should be followed up with appropriate patient education, counseling, and intervention. Once-daily regimens are preferred in most patients to improve adherence. Although some may believe that aggressive treatment may negatively impact quality of life and thus adherence, several studies have found that most patients actually feel better once their BP is controlled. Patients on antihypertensive therapy should be questioned periodically about changes in their general health perception, energy level, physical functioning, and overall satisfaction with treatment. Lifestyle modifications should always be recommended to provide additional BP lowering and other potential health benefits. Persistence with lifestyle modifications should be continually encouraged in patients engaging in such endeavors.

TABLE 15-11 Select Monitoring for Antihypertensive Pharmacotherapy

Class	Parameters
Diuretics	Blood pressure, blood urea nitrogen (BUN)/serum creatinine, serum electrolytes (potassium, magnesium, sodium), uric acid (for thiazides)
Aldosterone antagonists	Blood pressure, BUN/serum creatinine, serum potassium
Angiotensin-converting enzyme inhibitors	Blood pressure, BUN/serum creatinine, serum potassium
Angiotensin receptor blockers	Blood pressure, BUN/serum creatinine, serum potassium
Calcium channel blockers	Blood pressure; heart rate
β -Blockers	Blood pressure, heart rate

CONCLUSIONS

Hypertension is a very common medical condition in the United States. Treatment of patients with hypertension should include both lifestyle modifications and pharmacotherapy. Outcome-based studies have definitively demonstrated that treating hypertension reduces the risk of CV events and subsequently reduces morbidity and mortality. Moreover, evidence evaluating individual drug classes has resulted in an evidence-based approach to selecting pharmacotherapy in an individual patient, which is outlined in the JNC7 and 2007 AHA guidelines. Diuretics, ACE inhibitors, ARBs, and CCBs are all first-line agents. However, diuretics, specifically thiazide-type diuretics, are unsurpassed in their ability to reduce risk of CV events in hypertension based on an extensive body of supportive evidence. If patients with hypertension have a comorbid condition that is considered a compelling indication, a different set of drugs may be recommended for first-line therapy. Data suggests that using a β -blocker as the primary agent to treat patients with hypertension, without the presence of a compelling indication, may not be as beneficial on reducing risk of CV events compared to diuretic-, ACE inhibitor-, ARB-, or CCB-based therapy. Therefore, β -blockers are not first-line therapy options unless an appropriate compelling indication is present.

An often overlooked concept in managing hypertension is to treat patients to a goal BP value. In addition to selecting the most appropriate agent, attaining a goal BP is also of paramount importance to ensure maximum reduction in risk for CV events is provided. A BP goal of less than 140/90 mm Hg is recommended for general prevention of CV events or disease; however, this goal is less than 130/80 mm Hg for patients with diabetes, significant chronic kidney disease, coronary artery disease, noncoronary atherosclerotic vascular disease or a Framingham risk score of 10% or greater, and is less than 120/80 mm Hg for patients with left ventricular dysfunction (i.e., systolic heart failure). Most patients with hypertension require more than one pharmacologic agent to attain goal BP values; therefore, combination therapy is often needed.

ABBREVIATIONS

ACE: angiotensin-converting enzyme

ARB: angiotensin II receptor blocker

AHA: American Heart Association

BP: blood pressure

CCB: calcium channel blocker

CV: cardiovascular

DBP: diastolic blood pressure

GFR: glomerular filtration rate

ISA: intrinsic sympathomimetic activity

JNC 7: Seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure

MI: myocardial infarction

RAAS: renin-angiotensin aldosterone system

SBP: systolic blood pressure

ROBERT B. PARKER, JO E. RODGERS, AND LARISA H. CAVALLARI

KEY CONCEPTS

- 1 Heart failure is a clinical syndrome caused by the inability of the heart to pump sufficient blood to meet the metabolic needs of the body. Heart failure can result from any disorder that reduces ventricular filling (diastolic dysfunction) and/or myocardial contractility (systolic dysfunction). The leading causes of heart failure are coronary artery disease and hypertension. The primary manifestations of the syndrome are dyspnea, fatigue, and fluid retention.
- 2 Heart failure is a progressive disorder that begins with myocardial injury. In response to the injury, a number of compensatory responses are activated in an attempt to maintain adequate cardiac output, including activation of the sympathetic nervous system (SNS) and the renin–angiotensin–aldosterone system (RAAS), resulting in vasoconstriction and sodium and water retention, as well as ventricular hypertrophy/remodeling. These compensatory mechanisms are responsible for the symptoms of heart failure and contribute to disease progression.
- 3 Our current understanding of heart failure pathophysiology is best described by the neurohormonal model. Activation of endogenous neurohormones, including norepinephrine, angiotensin II, aldosterone, vasopressin, and numerous proinflammatory cytokines, plays an important role in ventricular remodeling and the subsequent progression of heart failure. Importantly, pharmacotherapy targeted at antagonizing this neurohormonal activation has slowed the progression of heart failure and improved survival.
- 4 Most patients with symptomatic heart failure should be routinely treated with an angiotensin-converting enzyme (ACE) inhibitor, a β -blocker, and a diuretic. The benefits of these medications on slowing heart failure progression, reducing morbidity and mortality, and improving symptoms are clearly established. Patients should be treated with a diuretic if there is evidence of fluid retention. Treatment with digoxin may also be considered to improve symptoms and reduce hospitalizations.
- 5 In patients with heart failure, ACE inhibitors improve survival, slow disease progression, reduce hospitalizations, and improve quality of life. The doses for these agents should be targeted at those shown in clinical trials to improve survival. When ACE inhibitors are contraindicated or not tolerated, an angiotensin II receptor blocker or the combination of hydralazine and isosorbide dinitrate are reasonable alternatives. Patients with asymptomatic left ventricular dysfunction and/or a previous myocardial infarction (stage B of the American College of Cardiologists/American Heart Association [ACC/AHA] classification scheme) should also receive ACE inhibitors, with the goal of preventing symptomatic heart failure and reducing mortality.
- 6 The β -blockers carvedilol, metoprolol CR/XL, and bisoprolol prolong survival, decrease hospitalizations and the need for transplantation, and cause “reverse remodeling” of the left ventricle. These agents are recommended for all patients with a reduced left ventricular ejection fraction. Therapy must be instituted at low doses, with slow upward titration to the target dose.
- 7 Although chronic diuretic therapy frequently is used in heart failure patients, it is not mandatory. Diuretic therapy along with sodium restriction is required only in those patients with peripheral edema and/or pulmonary congestion. Many patients will need continued diuretic therapy to maintain euvolemia after fluid overload is resolved.
- 8 Digoxin does not improve survival in patients with heart failure but does provide symptomatic benefits. Digoxin doses should be adjusted to achieve plasma concentrations of 0.5 to 1.0 ng/mL; higher plasma concentrations are not associated with additional benefits but may be associated with increased risk of toxicity.
- 9 Aldosterone antagonism with low-dose spironolactone reduces mortality in patients with New York Heart Association (NYHA) classes III and IV heart failure and thus should be strongly considered in these patients, provided that potassium and renal function can be carefully monitored. Aldosterone antagonists should also be considered soon after myocardial infarction in patients with left ventricular dysfunction and either heart failure or diabetes.
- 10 The combination of hydralazine and nitrates improves the composite end point of mortality, hospitalizations for heart failure, and quality of life in African Americans who receive standard therapy. The addition of hydralazine and nitrates is reasonable in patients with persistent symptoms despite optimized therapy with an ACE inhibitor (or angiotensin receptor blocker) and β -blocker.
- 11 No therapy for acute decompensated heart failure studied to date has been shown conclusively to influence mortality. Treatment goals are directed toward restoration of systemic oxygen transport and tissue perfusion, relief of pulmonary edema, and limitation of further cardiac damage. Maximizing oral therapy and using combinations of short-acting intravenous medica-

tions with different cardiovascular actions are often needed to optimize cardiac output, relieve pulmonary edema, and limit myocardial ischemia. Invasive hemodynamic monitoring may be required to provide immediate feedback on treatment efficacy and adverse effects.

- 12
- Pharmacists should play an important role as part of a multidisciplinary team to optimize therapy in heart failure. The pharmacist should be responsible for such activities as optimizing regimens for heart failure drug therapy (namely, ensuring that appropriate drugs at appropriate doses are used), educating patients about the importance of adherence to their heart failure regimen (including pharmacologic and dietary interventions), screening for drugs that may exacerbate or worsen heart failure, and monitoring for adverse drug effects and drug interactions.

1 2

Heart failure is a progressive clinical syndrome that can result from any disorder that impairs the ability of the ventricle to fill with or eject blood, thus rendering the heart unable to pump blood at a rate sufficient to meet the metabolic demands of the body.¹ Heart failure is the final common pathway for numerous cardiac disorders including those affecting the pericardium, heart valves, and myocardium. Diseases that adversely affect ventricular diastole (filling), ventricular systole (contraction), or both can lead to heart failure. For many years it was believed that reduced myocardial contractility, or systolic dysfunction (i.e., reduced left ventricular ejection fraction [LVEF]), was the sole disturbance in cardiac function responsible for heart failure. However, it is now recognized that large numbers of patients with the heart failure syndrome have relatively normal systolic function (i.e., normal LVEF). This is now referred to as heart failure with preserved LVEF and is believed to be primarily caused by diastolic dysfunction of the heart.¹ Recent estimates suggest 20% to 60% of patients with heart failure have preserved LVEF with disturbances in relaxation (lusitropic) properties of the heart, or diastolic dysfunction.² However, regardless of the etiology of heart failure, the underlying pathophysiologic process and principal clinical manifestations (fatigue, dyspnea, and volume overload) are similar and appear to be independent of the initial cause. Historically, this disorder was commonly referred to as *congestive heart failure*; the preferred nomenclature is now *heart failure* because a patient can have the clinical syndrome of heart failure without having symptoms of congestion. This chapter focuses on treatment of patients with systolic dysfunction (with or without concurrent diastolic dysfunction), whereas Chap. 20 focuses on the treatment of heart failure with preserved LVEF (diastolic dysfunction).

EPIDEMIOLOGY

Heart failure is an epidemic public health problem in the United States. Approximately 5 million Americans have heart failure with an additional 550,000 cases diagnosed each year. Unlike most other cardiovascular diseases, the incidence, prevalence, and hospitalization rates associated with heart failure are increasing and are expected to continue to increase over the next few decades as the population ages. A large majority of patients with heart failure are elderly, with multiple comorbid conditions that influence morbidity and mortality.^{3,4} The incidence of heart failure doubles with each decade of life and affects nearly 10% of individuals older than age 75 years. Heart failure is more common in men than in women until age 65 years, reflecting the greater incidence of coronary artery disease in men.⁴ As such, improved survival of patients after myocardial infarction is a likely contributor to the increased incidence and prevalence of heart failure.³ Recent results from the Framingham Heart Study showed that the incidence of heart failure

in men has not changed over the last 40 years, but has decreased by approximately one-third in women.⁵ These differences in heart failure incidence may be a result of sex-based differences in the cause of heart failure as myocardial infarction is the leading cause in men, whereas hypertension is the leading etiology in women.

Heart failure is the most common hospital discharge diagnosis in individuals older than age 65 years. Annual hospital discharges for heart failure now total more than 1 million, a 174% increase over the last two decades.⁴ Heart failure also has a tremendous economic impact, which is expected to increase markedly as the baby boom generation ages. Current estimates suggest annual expenditures for heart failure of approximately \$33 billion, with the majority of these costs spent on hospitalized patients.⁴ Thus, heart failure is a major medical problem, with substantial economic impact that is expected to become even more significant as the population ages.

Despite prodigious advances in our understanding of the etiology, pathophysiology, and pharmacotherapy of heart failure, the prognosis for patients with this disorder remains grim. Although the mortality rates have declined over the last 50 years, the overall 5-year survival remains approximately 50% for all patients with a diagnosis of heart failure, with mortality increasing with symptom severity.⁵ For heart failure patients younger than age 65 years, 80% of men and 70% of women will die within 8 years. Death is classified as sudden in approximately 40% of patients,^{1,6} implicating serious ventricular arrhythmias as the underlying cause in many patients with heart failure. Factors affecting the prognosis of patients with heart failure include, but are not limited to, age, gender, LVEF, renal function, blood pressure, heart failure etiology, and drug or device therapy. Recent models incorporating these and other factors enable clinicians to develop reliable estimates of an individual patient's prognosis.⁷

ETIOLOGY

1 2

Heart failure can result from any disorder that affects the ability of the heart to contract (systolic function) and/or relax (diastolic dysfunction); Table 16–1 lists the common causes of heart failure.⁸ Heart failure with impaired systolic function (i.e., reduced LVEF) is the classic, more familiar form of the disorder, but current estimates suggest up to 50% of patients with heart failure have preserved left ventricular systolic function with presumed diastolic dysfunction.² In contrast to systolic heart failure that is usually caused by previous myocardial infarction (MI), patients with preserved LVEF typically are elderly, female, obese, and have hypertension, atrial fibrillation, or diabetes.² Recent data indicate that survival

TABLE 16-1 Causes of Heart Failure

Systolic dysfunction (decreased contractility)

- Reduction in muscle mass (e.g., myocardial infarction)
- Dilated cardiomyopathies
- Ventricular hypertrophy
 - Pressure overload (e.g., systemic or pulmonary hypertension, aortic or pulmonic valve stenosis)
 - Volume overload (e.g., valvular regurgitation, shunts, high-output states)

Diastolic dysfunction (restriction in ventricular filling)

- Increased ventricular stiffness
 - Ventricular hypertrophy (e.g., hypertrophic cardiomyopathy, other examples above)
 - Infiltrative myocardial diseases (e.g., amyloidosis, sarcoidosis, endomyocardial fibrosis)
 - Myocardial ischemia and infarction
- Mitral or tricuspid valve stenosis
- Pericardial disease (e.g., pericarditis, pericardial tamponade)

Data from Colucci W, Braunwald E. Pathophysiology of heart failure. In: Zipes DP, Libby P, Bonow RO, Braunwald E, eds. Heart Disease: A Textbook of Cardiovascular Medicine, 7th ed. Philadelphia: Elsevier Saunders, 2005:509–538.

is similar in patients with impaired or preserved LVEF.² Frequently, systolic and diastolic dysfunction coexist. The common cardiovascular diseases, such as MI and hypertension, can cause both systolic and diastolic dysfunction; thus many patients have heart failure as a result of reduced myocardial contractility and abnormal ventricular filling. Heart failure with preserved LVEF is discussed in Chap. 20.

1 Coronary artery disease is the most common cause of systolic heart failure, accounting for nearly 70% of cases.³ Myocardial infarction leads to reduction in muscle mass as a consequence of death of affected myocardial cells. The degree to which contractility is impaired will depend on the size of the infarction. In an attempt to maintain cardiac output, the surviving myocardium undergoes a compensatory remodeling, thus beginning the maladaptive process that initiates the heart failure syndrome and leads to further injury to the heart. This is discussed in greater detail in Pathophysiology below. Myocardial ischemia and infarction also affect the diastolic properties of the heart by increasing ventricular stiffness and slowing ventricular relaxation. Thus, myocardial infarction frequently results in systolic and diastolic dysfunction.

Impaired systolic function is a cardinal feature of dilated cardiomyopathies. Although the cause of reduced contractility frequently is unknown, abnormalities such as interstitial fibrosis, cellular infiltrates, cellular hypertrophy, and myocardial cell degeneration are seen commonly on histologic examination. Genetic causes of dilated cardiomyopathies may also occur.⁹

Pressure or volume overload causes ventricular hypertrophy, which attempts to return contractility to a near-normal state. If the pressure or volume overload persists, the remodeling process results in alterations in the geometry of the hypertrophied myocardial cells and is accompanied by increased collagen deposition in the extracellular matrix. Thus, both systolic and diastolic function may be impaired.⁸ Examples of pressure overload include systemic or pulmonary hypertension and aortic or pulmonic valve stenosis.

Hypertension remains an important cause and/or contributor to heart failure in many patients, particularly women, the elderly, and African Americans.¹ The role of hypertension should not be underestimated because hypertension is an important risk factor for ischemic heart disease and thus is also present in a high percentage of the patients with this disorder. Volume overload may occur in the presence of valvular regurgitation, shunts, or high-output states such as anemia or pregnancy. Table 16-1 lists less-common causes of diastolic dysfunction, which include infiltrative myocardial diseases, mitral or tricuspid valve stenosis, and pericardial disease.

Because ischemic heart disease and/or hypertension contribute so significantly to the development of heart failure in the majority of patients, it is important to emphasize that heart failure is a largely preventable disorder. Thus, control of blood pressure and appropriate management of other risk factors for cardiovascular disease (e.g., smoking cessation, treatment of lipid disorders, diabetes management, dietary modification) are important strategies for clinicians to implement to reduce their patients' risk of heart failure.

PATHOPHYSIOLOGY

NORMAL CARDIAC FUNCTION

To understand the pathophysiologic processes in heart failure, a basic understanding of normal cardiac function is necessary. *Cardiac output* (CO) is defined as the volume of blood ejected per unit time (L/min) and is the product of heart rate (HR) and stroke volume (SV):

$$\text{CO} = \text{HR} \times \text{SV}$$

The relationship between CO and mean arterial pressure (MAP) is:

$$\text{MAP} = \text{CO} \times \text{systemic vascular resistance (SVR)}$$

Heart rate is controlled by the autonomic nervous system. Stroke volume, or the volume of blood ejected during systole, depends on preload, afterload, and contractility.⁸ As defined by the Frank-Starling mechanism, the ability of the heart to alter the force of contraction depends on changes in preload. As myocardial sarcomere length is stretched, the number of cross-bridges between thick and thin myofilaments increases, resulting in an increase in the force of contraction. The length of the sarcomere is determined primarily by the volume of blood in the ventricle; therefore, left ventricular end-diastolic volume is the primary determinant of preload. In normal hearts, the preload response is the primary compensatory mechanism such that a small increase in end-diastolic volume results in a large increase in cardiac output. Because of the relationship between pressure and volume in the heart, left ventricular end-diastolic pressure is often used in the clinical setting to estimate preload. The hemodynamic measurement used to estimate left ventricular end-diastolic pressure is the pulmonary artery occlusion pressure (PAOP). Afterload is a more complex physiologic concept that can be viewed pragmatically as the sum of forces preventing active forward ejection of blood by the ventricle. Major components of global ventricular afterload are ejection impedance, wall tension, and regional wall geometry. In patients with left ventricular systolic dysfunction, an inverse relationship exists between afterload (or SVR) and stroke volume such that increasing afterload causes a decrease in stroke volume (Fig. 16-1). Contractility is the intrinsic property of cardiac muscle describing fiber shortening and tension development.

COMPENSATORY MECHANISMS IN HEART FAILURE

2 Heart failure is a progressive disorder initiated by an event that impairs the ability of the heart to contract and/or relax. The index event may have an acute onset, as with myocardial infarction, or the onset may be slow, as with long-standing hypertension. Regardless of the index event, the decrease in the heart's pumping capacity results in the heart having to rely on compensatory responses to maintain an adequate cardiac output.¹⁰ These compensatory responses include (a) tachycardia and increased contractility through sympathetic nervous system (SNS) activation, (b) the Frank-Starling mechanism, whereby an increase in preload results in an increase in stroke volume, (c) vasoconstriction, and (d) ventricular hypertrophy and remodeling. These compensatory responses are intended to be short-term responses to maintain circulatory homeostasis after acute reductions in blood pressure or renal perfusion. However, the

FIGURE 16-1. Relationship between stroke volume and systemic vascular resistance. In an individual with normal left ventricular (LV) function, increasing systemic vascular resistance has little effect on stroke volume. As the extent of LV dysfunction increases, the negative, inverse relationship between stroke volume and systemic vascular resistance becomes more important (B to A).

TABLE 16-2 Beneficial and Detrimental Effects of the Compensatory Responses in Heart Failure

Compensatory Response	Beneficial Effects of Compensation	Detrimental Effects of Compensation
Increased preload (through Na ⁺ and water retention)	Optimize stroke volume via Frank-Starling mechanism	Pulmonary and systemic congestion and edema formation Increased MVO ₂
Vasoconstriction	Maintain BP in face of reduced CO Shunt blood from nonessential organs to brain and heart	Increased MVO ₂ Increased afterload decreases stroke volume and further activates the compensatory responses
Tachycardia and increased contractility (because of SNS activation)	Helps maintain CO	Increased MVO ₂ Shortened diastolic filling time β_1 -receptor downregulation, decreased receptor sensitivity Precipitation of ventricular arrhythmias
Ventricular hypertrophy and remodeling	Helps maintain CO Reduces myocardial wall stress Decreases MVO ₂	Increased risk of myocardial cell death Diastolic dysfunction Systolic dysfunction Increased risk of myocardial cell death Increased risk of myocardial ischemia Increased arrhythmia risk Fibrosis

BP, blood pressure; CO, cardiac output; MVO₂, myocardial oxygen demand; SNS, sympathetic nervous system.

persistent decline in cardiac output in heart failure results in long-term activation of these compensatory responses resulting in the complex functional, structural, biochemical, and molecular changes important for the development and progression of heart failure. The beneficial and detrimental effects of these compensatory responses are described below and are summarized in Table 16–2.

Tachycardia and Increased Contractility

The change in heart rate and contractility that rapidly occurs in response to a drop in cardiac output is primarily a result of release of norepinephrine (NE) from adrenergic nerve terminals, although parasympathetic nervous system activity is also diminished. Cardiac output increases with heart rate until diastolic filling becomes compromised, which in the normal heart is at 170 to 200 beats per minute. Loss of atrial contribution to ventricular filling also can occur (atrial fibrillation, ventricular tachycardia), reducing ventricular performance even more. Because ionized calcium is sequestered into the sarcoplasmic reticulum and pumped out of the cardiac myocyte during diastole, shortened diastolic time also results in a higher average intracellular calcium concentration during diastole, increasing actin–myosin interaction, augmenting the active resistance to fibril stretch, and reducing lusitropy. Conversely, the higher average calcium concentration translates into greater filament interaction during systole, generating more tension.⁸ In addition, polymorphisms in genes coding for adrenergic receptors (e.g., β_1 and α_{2c} receptors) appear to alter the response to endogenous NE and increase the risk for the development of heart failure.¹¹

Increasing heart rate greatly increases myocardial oxygen demand. If ischemia is induced or worsened, both diastolic and systolic function may become impaired, and stroke volume can drop precipitously.

Fluid Retention and Increased Preload

Augmentation of preload is another compensatory response that is rapidly activated in response to decreased cardiac output. Renal perfusion in heart failure is reduced because of depressed cardiac output and redistribution of blood away from nonvital organs. The kidney interprets the reduced perfusion as an ineffective blood volume, resulting in activation of the renin–angiotensin–aldosterone system (RAAS) in an attempt to maintain blood pressure and increase renal sodium and water retention. Reduced renal perfusion and increased sympathetic tone also stimulate renin release from juxta-

glomerular cells in the kidney. As shown in Fig. 16–2, renin is responsible for conversion of angiotensinogen to angiotensin I. Angiotensin I is converted to angiotensin II by angiotensin-converting enzyme (ACE). Angiotensin II may also be generated via non-ACE-dependent pathways. Angiotensin II feeds back on the adrenal gland to stimulate aldosterone release, thereby providing an additional mechanism for sodium and water retention in the kidney. As intravascular volume increases secondary to sodium and water retention, left ventricular volume and pressure (preload) increase, sarcomeres are stretched, and the force of contraction is enhanced.⁸ While the preload response is the primary compensatory mechanism in normal hearts, the chronically failing heart usually has exhausted its preload reserve.⁸ As shown in Fig. 16–3, increases in preload will increase stroke volume only to a certain point. Once the flat portion of the curve is reached, further increases in preload will only lead to pulmonary or systemic congestion, a detrimental result.⁸ Figure 16–3 also shows that the curve is flatter in patients with left ventricular dysfunction. Consequently, a given increase in preload in a patient with heart failure will produce a smaller increment in stroke volume than in an individual with normal ventricular function.

Vasoconstriction and Increased Afterload

Vasoconstriction occurs in patients with heart failure to help redistribute blood flow away from nonessential organs to coronary and cerebral circulations to support blood pressure, which may be reduced secondary to a decrease in cardiac output (mean arterial pressure = CO \times SVR).⁸ A number of neurohormones likely contribute to the vasoconstriction, including NE, angiotensin II, endothelin-1, and arginine vasopressin (AVP).⁸ Vasoconstriction impedes forward ejection of blood from the ventricle, further depressing cardiac output and heightening the compensatory responses. Because the failing ventricle usually has exhausted its preload reserve (unless the patient is intravascularly depleted), its performance is exquisitely sensitive to changes in afterload (see Fig. 16–1). Thus, increases in afterload often potentiate a vicious cycle of continued worsening and downward spiraling of the heart failure state.

Ventricular Hypertrophy and Remodeling^{8,10}

③ Although the signs and symptoms of heart failure are closely associated with the items described above, the progression of heart failure appears to be independent of the patient's hemodynamic status. It is now recognized that ventricular hypertrophy and

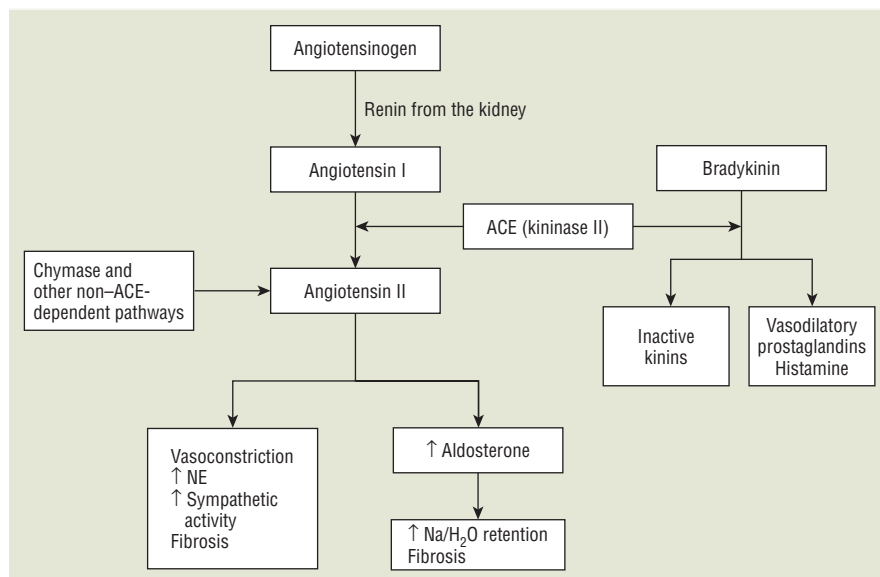

FIGURE 16-2. Physiology of the renin–angiotensin–aldosterone system. Renin produces angiotensin I from angiotensinogen. Angiotensin I is cleaved to angiotensin II by angiotensin-converting enzyme (ACE). Angiotensin II has a number of physiologic actions that are detrimental in heart failure. Note that angiotensin II can be produced in a number of tissues, including the heart, independent of ACE activity. ACE is also responsible for the breakdown of bradykinin. Inhibition of ACE results in accumulation of bradykinin that, in turn, enhances the production of vasodilatory prostaglandins. (NE, norepinephrine.)

remodeling are key components in the pathogenesis of progressive myocardial failure. *Ventricular hypertrophy* is a term used to describe an increase in ventricular muscle mass. *Cardiac or ventricular remodeling* is a broader term describing changes in both myocardial cells and extracellular matrix that result in changes in the size, shape, structure, and function of the heart. Ventricular hypertrophy and remodeling can occur in association with any condition that causes myocardial injury including MI, cardiomyopathy, hypertension, and valvular heart disease.

Cardiac remodeling is a complex process that affects the heart at the molecular and cellular levels. Figure 16-4 shows key elements in the process. Collectively, these events result in progressive changes in myocardial structure and function such as cardiac hypertrophy, myocyte loss, and alterations in the extracellular matrix. The progression of the remodeling process leads to reductions in myocardial systolic and/or diastolic function that, in turn, result in further myocardial injury, perpetuating the remodeling process and the decline in ventricular dysfunction. Angiotensin II, NE, endothelin, aldosterone, vasopressin and numerous inflammatory cytokines, as well as substances under investigation, that are activated both systemically and locally in the heart play an important role in initiating the signal–transduction cascade responsible for ventricu-

lar remodeling. Although these mediators produce deleterious effects on the heart, their increased circulating and tissue concentrations also serve as an important reminder that heart failure is a systemic, as well as cardiac, disorder.

Pressure overload (and probably hormonal activation) associated with hypertension produces a concentric hypertrophy (increase in the ventricular wall thickness without chamber enlargement). Conversely, eccentric left ventricular hypertrophy (myocyte lengthening with increased chamber size with minimal increase in wall thickness) characterizes the hypertrophy seen in patients with systolic dysfunction or previous MI. As the myocytes undergo change, so do various components of the extracellular matrix. For example, there is evidence for collagen degradation, which may lead to slippage of myocytes, fibroblast proliferation, and increased fibrillar collagen synthesis, resulting in fibrosis and stiffening of the entire myocardium. Thus, a number of important ventricular changes that occur with remodeling include changes in the geometry of the heart from elliptical to spherical, increases in ventricular mass (from myocyte hypertrophy), and changes in ventricular composition (especially the extracellular matrix) and volumes, all of which likely contribute to the impairment of cardiac function. If the event that produces cardiac injury is acute (e.g., MI), the ventricular remodeling process begins immediately. However, it is the progressive nature of this process that results in continual worsening of the heart failure state, and thus is now the major focus for identification of therapeutic targets. In fact, it is believed that all the heart failure therapies that are associated with decreased mortality and/or slowing the progression of the disease produce this effect largely through their ability to slow or reverse the ventricular remodeling process, a process often referred to as *reverse remodeling*. Thus, although ventricular hypertrophy and remodeling may have some beneficial effects by helping maintain cardiac output, they also are believed to play an essential role in the progressive nature of heart failure.

FIGURE 16-3. Relationship between cardiac output (shown as cardiac index which is cardiac output [CO]/body surface area [BSA]) and preload (shown as pulmonary artery occlusion pressure).

THE NEUROHORMONAL MODEL OF HEART FAILURE AND THERAPEUTIC INSIGHTS IT PROVIDES^{8,10}

2 3 Over the years, several different paradigms have guided our understanding of the pathophysiology and treatment of heart failure. The early paradigm is often called the *cardiorenal model*, where the problem was viewed as excess sodium and water retention, and diuretic therapy was the main therapeutic approach. The next para-

FIGURE 16-4. Key components of the pathophysiology of cardiac remodeling. Myocardial injury (e.g., myocardial infarction) results in the activation of a number of hemodynamic and neurohormonal compensatory responses in an attempt to maintain circulatory homeostasis. Chronic activation of the neurohormonal systems results in a cascade of events that affect the myocardium at the molecular and cellular levels. These events lead to the changes in ventricular size, shape, structure, and function known as ventricular remodeling. The alterations in ventricular function result in further deterioration in cardiac systolic and diastolic function which further promotes the remodeling process. (LV, left ventricle.)

digm was the *cardiocirculatory model*, which focused on impaired cardiac output (viewed as being a result of both reduced pumping capacity of the heart and systemic vasoconstriction). This paradigm focused on positive inotropes and, later, vasodilators as the primary therapies to overcome reductions in cardiac output. Although the therapeutic approaches associated with these paradigms provided some symptomatic benefits to patients with heart failure, they did little to slow progression of the disease. In fact, the detrimental effects of positive inotropic drugs on survival highlighted the inadequacy of the cardiocirculatory model to explain the progressive nature of heart failure. The first studies with ACE inhibitors were initiated with the thought that they might be effective because of their balanced (arterial and venous) vasodilation. Subsequent realization that ACE inhibitors were providing benefit beyond their vasodilating effects, followed by the positive results with β -adrenergic receptor blockers and aldosterone antagonists, has led to the current paradigm used to describe heart failure: the *neurohormonal model*. This model recognizes that there is an initiating event (e.g., MI, long-standing hypertension) that leads to decreased cardiac output and begins the “heart failure state,” but then the problem moves beyond the heart, and it essentially becomes a systemic disease whose progression is mediated largely by neurohormones and autocrine/paracrine factors. Although the former paradigms still guide us to some extent in the symptomatic management of the disease (e.g., diuretics and digoxin), it is the latter paradigm that helps us understand disease progression and, more importantly, the ways to slow disease progression. In the sections that follow, important neurohormones and autocrine/paracrine factors are described with respect to their role in heart failure and its progression. The benefits of current and investigational drug therapies can be better understood through a solid understanding of the neurohormones they regulate/affect. Although the neurohormonal model provides a logical framework for our current understanding of heart failure progression and the role of various

medications in attenuating this progression, it must be emphasized that this model does not completely explain heart failure progression. For example, drug therapies that target the neurohormonal perturbations in heart failure usually only slow the progressive nature of the disorder rather than completely stop it. Ongoing research will likely identify additional targets for drug therapy.

Angiotensin II¹⁰

Of the neurohormones and autocrine/paracrine factors that play an important role in the pathophysiology of heart failure, angiotensin II is probably the best understood. Although circulating angiotensin II produced from ACE activity is the most familiar route for generation of angiotensin II, recent evidence indicates that this hormone is synthesized directly in the myocardium through non-ACE-dependent pathways. This tissue production of angiotensin II also plays an important role in heart failure pathophysiology. Angiotensin II has multiple actions that contribute to its detrimental effects in heart failure. Angiotensin II increases systemic vascular resistance directly by promoting potent vasoconstriction and indirectly by causing release of AVP and endothelin-1. Angiotensin II also facilitates release of NE from adrenergic nerve terminals, heightening SNS activation. It promotes sodium retention through direct effects on the renal tubules and by stimulating aldosterone release. Its vasoconstriction of the efferent glomerular arteriole helps to maintain perfusion pressure in patients with severe heart failure or impaired renal function. Thus, in patients dependent on angiotensin II for maintenance of perfusion pressure, initiation of an ACE inhibitor or angiotensin receptor type I blocker (ARB) causes efferent arteriole vasodilation, decreased perfusion pressure, and decreased glomerular filtration. This explains the risk of transient impairment in renal function associated with initiation of ACE inhibitor or ARB therapy. Finally, angiotensin II, and many of the

neurohormones released in response to angiotensin II, play a central role in stimulating ventricular hypertrophy, remodeling, myocyte apoptosis (programmed cell death), oxidative stress, inflammation, and alterations in the extracellular matrix. Clinical data suggest that blocking angiotensin II-mediated effects contributes substantially to the prolonged survival of ACE inhibitor- and ARB-treated heart failure patients.^{12,13} The favorable effects of ACE inhibitors and ARBs on hemodynamics, symptoms, quality of life, and survival in heart failure highlight the importance of angiotensin II in the pathophysiology of heart failure.

Norepinephrine^{8,10}

Many of the detrimental effects of NE in heart failure are described above. It plays a central role in the tachycardia, vasoconstriction, and increased contractility observed in heart failure. Plasma NE concentrations are elevated in correlation with the degree of heart failure, and patients with the highest plasma NE concentrations have the poorest prognosis. In addition to the detrimental effects described, excessive SNS activation causes downregulation of β_1 -receptors, with a subsequent loss of sensitivity to receptor stimulation. Evidence suggests that genetic variations in the β_1 - and α_2 -receptors, which are targets for NE's actions, may modify the extent of receptor downregulation and increase the risk of heart failure.¹¹ Excess catecholamines increase the risk of arrhythmias and can cause myocardial cell loss by stimulating both necrosis and apoptosis. Finally, NE contributes to ventricular hypertrophy and remodeling. The detrimental effects of SNS activation are further highlighted by the clinical trials of chronic therapy with β -agonists, phosphodiesterase inhibitors, and other drugs that cause SNS activation, as they have been shown uniformly to increase mortality in heart failure. Conversely, β -blockers, ACE inhibitors, and digoxin all help to decrease SNS activation through various mechanisms, and are beneficial in heart failure. Thus, it is clear that NE plays a critical role in the pathophysiology of the heart failure state.

Aldosterone^{14,15}

Aldosterone-mediated sodium retention and its key role in volume overload and edema has long been recognized as an important component of the heart failure syndrome. Circulating aldosterone is increased in heart failure as a consequence of stimulation of its synthesis and release from the adrenal cortex by angiotensin II and because of decreased hepatic clearance secondary to reduced hepatic perfusion. Although its enhancement of sodium retention is an important component of heart failure symptoms, recent studies indicate direct effects of aldosterone on the heart that may be even more important in heart failure pathophysiology. Chief among these is the ability of aldosterone to produce interstitial cardiac fibrosis through increased collagen deposition in the extracellular matrix of the heart. This cardiac fibrosis may decrease systolic function, and also impair diastolic function by increasing the stiffness of the myocardium. Current research shows that extraadrenal production of aldosterone in the heart, kidneys, and vascular smooth muscle also contributes to the progressive nature of heart failure through target organ fibrosis and vascular remodeling. Induction of a systemic proinflammatory state and increased oxidative stress are other important direct detrimental actions of aldosterone. Aldosterone also may increase the risk of ventricular arrhythmias through a number of mechanisms, including creation of reentrant circuits as a result of fibrosis, inhibition of cardiac NE reuptake, depletion of intracellular potassium and magnesium, and impairment of parasympathetic traffic. Recent studies demonstrate that the aldosterone antagonists spironolactone¹⁶ and eplerenone¹⁷ produce significant reductions in mortality in patients with heart failure, without appreciable effects on diuresis or hemodynamics, providing substantial

evidence that the direct cardiac effects of aldosterone play an important role in heart failure pathophysiology.

Natriuretic Peptides¹⁸

The natriuretic peptide family has three members, atrial natriuretic peptide, B-type natriuretic peptide (BNP), and C-type natriuretic peptide. Atrial natriuretic peptide is stored mainly in the right atrium, whereas BNP is found primarily in the ventricles. Both are released in response to pressure or volume overload. C-type natriuretic peptide is found mainly in the brain and has very low plasma concentrations. Atrial natriuretic peptide and BNP plasma concentrations are elevated in patients with heart failure and are thought to balance the effects of the renin-angiotensin system by causing natriuresis, diuresis, vasodilation, decreased aldosterone release, decreased hypertrophy, and inhibition of the SNS and RAAS.

The development of easily performed commercial assays for BNP and the related biologically inactive peptide, N-terminal prohormone BNP, resulted in significant attention to the role of these peptides as a biomarker for prognostic, diagnostic, and therapeutic use. In patients with chronic heart failure, the degree of elevation in BNP levels is closely associated with increased mortality, risk of sudden death, symptoms, and hospital readmission. Current data indicate BNP is more sensitive than NE for predicting morbidity and mortality in heart failure patients. Accurate diagnosis of acute decompensated heart failure in acute care settings is often difficult because many of the symptoms (e.g., dyspnea) mimic those of other disorders, such as pulmonary disease or obesity. The best-established clinical application of BNP testing is in the urgent care setting where the BNP assay is useful when combined with clinical evaluation for discriminating dyspnea secondary to heart failure from other causes. The BNP assay may also be useful in the diagnosis of heart failure in the outpatient setting and used as a marker to guide titration of heart failure drug therapy. However, the usefulness of the assay in these situations remains uncertain and the results of ongoing studies may help clarify the role of BNP testing in these patients. Finally, administration of recombinant human BNP (nesiritide) for short-term management of acute heart failure resulted in hemodynamic and symptomatic improvement, further supporting the role of BNP in heart failure pathophysiology.

Arginine Vasopressin¹⁹

AVP is a pituitary peptide hormone that plays an important role in regulation of renal water and solute excretion. AVP secretion is directly linked to changes in plasma osmolality, thus attempting to maintain body fluid homeostasis. The physiologic effects of AVP are mediated through the V_{1a} and V_2 receptors. V_{1a} receptors are located in vascular smooth muscle and in myocytes where AVP stimulation results in vasoconstriction and increased cardiac contractility, respectively. V_2 receptors are located in the collecting duct of the kidney where AVP stimulation causes reabsorption of free water.

Plasma concentrations of AVP are elevated in patients with heart failure supporting current research that indicates AVP plays a role in the pathophysiology of heart failure. Important effects associated with increased circulating AVP concentrations include (a) increased renal free water reabsorption in the face of plasma hyposmolality resulting in volume overload and hyponatremia; (b) increased arterial vasoconstriction which contributes to reduced cardiac output; and (c) stimulation of remodeling by cardiac hypertrophy and extracellular matrix collagen deposition.

Given the importance of AVP in heart failure, recent efforts have focused on the development of AVP antagonist drugs for treatment of acute and chronic heart failure. By blocking the AVP receptor, these agents primarily increase free water excretion (i.e., an "aquaretic" effect). The oral V_2 receptor antagonist tolvaptan increased serum sodium and urine output without affecting heart

rate, blood pressure, renal function, or other electrolytes in patients hospitalized for hyponatremia from various causes (hyponatremia due to heart failure in approximately 33% of patients).²⁰ In another clinical trial, the addition of oral tolvaptan to diuretic therapy in patients hospitalized for worsening heart failure had no effect on mortality or the composite end point of cardiovascular death or hospitalization for heart failure.²¹ However, tolvaptan did produce short-term reductions in body weight, edema, and patient-assessed dyspnea without causing any serious adverse events.²² These results suggest that AVP antagonists may be useful in the treatment of heart failure patients with volume overload. Unlike diuretics, they appear to reduce excess fluid volume without affecting hemodynamics, renal function, or electrolytes. Thus, these agents may offer a new therapeutic approach to currently available drug therapies.

Other Circulating Mediators²³

In addition to neurohormones, several proinflammatory cytokines are under extensive investigation for their role in heart failure pathophysiology. Tumor necrosis factor- α (TNF- α), interleukin (IL)-6, and IL-1 β have all been shown to be elevated in heart failure, with a direct relationship between the degree of elevation and the severity of heart failure. Of these cytokines, TNF- α is best studied for its pathophysiologic role in heart failure. TNF- α produces multiple deleterious actions including negative inotropic effects, uncoupling α -adrenergic receptors from adenylyl cyclase (thus reducing β -receptor-mediated responses), increasing myocardial cell apoptosis, and stimulating remodeling via several mechanisms. Although these findings clearly implicate a role for TNF- α in the pathophysiology of heart failure, clinical trials evaluating anti-TNF- α therapies (e.g., etanercept and infliximab) have been disappointing, with no improvement in outcomes demonstrated.

The endothelin peptides are potent vasoconstrictors that may be involved in heart failure pathophysiology through a number of mechanisms. Endothelin-1, the best characterized of these peptides, is synthesized by endothelial and vascular smooth muscle cells with the release of endothelin-1 enhanced by NE, angiotensin II, and inflammatory cytokines. Like other peptides and hormones described earlier, endothelin-1 plasma concentrations are elevated in heart failure and are correlated directly with the severity of hemodynamic abnormality, symptoms, and mortality. Its arterial and venous constrictive effects increase preload and afterload, and its vasoconstriction of both efferent and afferent renal arterioles may decrease renal plasma flow and induce sodium retention. Endothelin-1 has direct cardiotoxic and arrhythmogenic effects and is a potent stimulator of cardiac myocyte hypertrophy. The putative role of endothelin in heart failure led to the development of a number of endothelin-receptor antagonists. Although these agents improved hemodynamics, no benefit on morbidity or mortality has been demonstrated and further clinical development is unlikely.

The role of inflammation and endothelial dysfunction has generated significant interest in the use of statins in patients with heart failure. In addition to lowering cholesterol and reducing the risk of death and other atherosclerotic vascular diseases, the proposed pleiotropic effects (e.g., antiinflammatory, improved endothelial function, promotion of angiogenesis) may be beneficial in heart failure.²⁴ Although some observational studies and short-term prospective clinical trials indicate beneficial effects, others have failed to demonstrate significant improvement with statin therapy. Ongoing trials to assess effects on mortality will help clarify the role of statin therapy.

FACTORS PRECIPITATING/EXACERBATING HEART FAILURE

Although significant advancements have been made in treatment, symptom exacerbations, to the point that hospitalization is required,

TABLE 16-3 Drugs That May Precipitate or Exacerbate Heart Failure

Negative inotropic effect

Antiarrhythmics (e.g., disopyramide, flecainide, propafenone, and others)
 β -Blockers (e.g., propranolol, metoprolol, atenolol, and others)
 Calcium channel blockers (e.g., verapamil, diltiazem)
 Itraconazole
 Terbinafine

Cardiotoxic

Doxorubicin
 Daunomycin
 Cyclophosphamide
 Trastuzumab
 Imatinib
 Ethanol
 Amphetamines (e.g., cocaine, methamphetamine)

Sodium and water retention

Nonsteroidal antiinflammatory drugs
 Cyclooxygenase-2 inhibitors
 Rosiglitazone and pioglitazone
 Glucocorticoids
 Androgens and estrogens
 Salicylates (high dose)
 Sodium-containing drugs (e.g., carbenicillin disodium, ticarcillin disodium)

are a common and growing problem in patients with heart failure. Hospitalization for heart failure exacerbation consumes large amounts of healthcare dollars and significantly impairs the patient's quality of life, thus there is great interest in identifying, and then remedying, factors that increase the risk of decompensation. In patients with heart failure, appropriate therapy can often maintain them in a "compensated" state, indicating that they are relatively symptom-free. However, there are many aggravating or precipitating factors that may cause a previously compensated patient to develop worsened symptoms necessitating hospitalization. Factors that may precipitate or exacerbate heart failure typically do so by one or more of the following mechanisms: (a) negative inotropic effects; (b) direct cardiotoxicity; or (c) increased sodium and/or water retention (Table 16-3). The resulting symptoms are typically those associated with volume overload, but in more severe cases hypoperfusion may also be present.

Noncompliance with prescribed heart failure medications or with dietary recommendations (e.g., sodium intake and fluid restriction) are common causes of heart failure exacerbation.²⁵ For example, 43% of patients admitted with an acute decompensation of chronic heart failure were assessed as having dietary sodium excess, 34% had excess fluid intake (defined as >2.5 L/day), and approximately 24% had drug noncompliance that may have contributed to their decompensation (although not necessarily defined as the primary cause of decompensation).

Cardiac events may also precipitate heart failure exacerbations. Myocardial ischemia and infarction are potentially reversible causes that must be carefully considered because nearly 70% of heart failure patients have coronary artery disease. It should be noted that myocardial ischemia can either be a cause or consequence of heart failure decompensation. Revascularization should be considered in appropriate patients. Atrial fibrillation occurs in up to 30% of patients with heart failure, and is associated with increased morbidity and mortality.^{26,27} Atrial fibrillation can exacerbate heart failure through rapid ventricular response and loss of atrial contribution to ventricular filling. Conversely, heart failure can precipitate atrial fibrillation by worsening atrial distension resulting from ventricular volume overload. Control of ventricular response, maintenance of sinus rhythm in appropriate patients, and prevention of thromboembolism are important elements in the treatment of heart failure patients with atrial fibrillation.

A number of noncardiac events may also be associated with heart failure decompensation. Pulmonary infections frequently cause worsening of heart failure. Many of these events would be preventable with more widespread use of the pneumococcal and influenza vaccines. Recent studies suggest that anemia occurs frequently in patients with heart failure and that it is an independent predictor of death and hospitalization for heart failure, regardless of left ventricular systolic function.²⁸ The exact cause of anemia in heart failure patients is uncertain but likely involves reduced response to erythropoietin, the presence of inhibitors to hematopoiesis, and/or impaired iron supply. Correction of anemia with erythropoietin analogs is associated with improved symptoms and exercise capacity but some have expressed concern that raising hemoglobin concentrations may increase the risk of thromboembolism or other cardiovascular events. Therefore, the results of ongoing clinical trials evaluating survival are needed to determine the role of this therapy in heart failure.

12 What should be evident is that many of the precipitating factors are preventable, particularly through appropriate pharmacist intervention. Specifically, patient education and counseling by a pharmacist should help to decrease the most common reason for heart failure exacerbation: noncompliance with dietary sodium and water restrictions, drug therapy, or both. Pharmacists also should be able to identify and address inadequate heart failure therapy, poorly controlled hypertension, and administration of drugs that may worsen heart failure (see Table 16–3). Use of medications such as antiarrhythmic agents and selected calcium channel blockers are important precipitants of exacerbations. It should be noted that the cyclooxygenase-2 (COX-2) inhibitor celecoxib and nonsteroidal antiinflammatory drugs (NSAIDs) have similar effects on renal function.²⁹ Thus, both NSAIDs and COX-2 inhibitors should be used judiciously in heart failure patients. The thiazolidinedione hypoglycemic drugs, rosiglitazone and pioglitazone, are associated with the development of weight gain and edema that may exacerbate heart failure. Current guidelines indicate these agents should not be used in patients with New York Heart Association (NYHA) class III or IV heart failure and recent evidence suggests rosiglitazone may increase the risk of myocardial infarction.^{1,30,31} It can be argued that heart failure exacerbations caused by noncompliance, inadequate/inappropriate drug therapy, and poorly controlled hypertension are all preventable and amenable to pharmacist intervention. Thus the value of the pharmacist's role in careful and repeated education of patients and in monitoring of the drug regimen should not be underestimated. Attention to these factors may make an important contribution to reducing the risk of hospitalization and improving the patient's quality of life.

CLINICAL PRESENTATION³²

SIGNS AND SYMPTOMS

2 The primary manifestations of heart failure are dyspnea and fatigue, which lead to exercise intolerance, and fluid overload, that can result in pulmonary congestion and peripheral edema. The presence of these signs and symptoms may vary considerably from patient to patient, such that some patients have dyspnea but no signs of fluid retention whereas others may have marked volume overload with few complaints of dyspnea or fatigue. However, many patients may have both dyspnea and volume overload. Clinicians should remember that symptom severity often does not correlate with the degree of left ventricle dysfunction. Patients with a low LVEF (less than 20% to 25%) may be asymptomatic, whereas patients with preserved LVEF may have significant symptoms. It is also important to note that symptoms can vary considerably over time in a given patient. Historically, signs and symptoms are classified as being a result of left ventricular (pulmonary conges-

tion) or right ventricular failure (systemic congestion). Although most patients initially have left ventricular failure, the ventricles share a septal wall, and because left ventricular failure increases the workload of the right ventricle, both ventricles eventually fail and contribute to the heart failure syndrome. Because of the complex nature of this syndrome, it has become exceedingly more difficult to attribute a specific sign or symptom as caused by either right or left ventricular failure. Therefore, the numerous signs and symptoms associated with this disorder are collectively attributed to heart failure, rather than due to dysfunction of a specific ventricle.

CLINICAL PRESENTATION OF HEART FAILURE

General

- Patient presentation may range from asymptomatic to cardiogenic shock

Symptoms

- Dyspnea, particularly on exertion
- Orthopnea
- Paroxysmal nocturnal dyspnea
- Exercise intolerance
- Tachypnea
- Cough
- Fatigue
- Nocturia
- Hemoptysis
- Abdominal pain
- Anorexia
- Nausea
- Bloating
- Poor appetite, early satiety
- Ascites
- Mental status changes

Signs

- Pulmonary rales
- Pulmonary edema
- S₃ gallop
- Cool extremities
- Pleural effusion
- Cheyne-Stokes respiration
- Tachycardia
- Narrow pulse pressure
- Cardiomegaly
- Peripheral edema
- Jugular venous distension
- Hepatojugular reflux
- Hepatomegaly

Laboratory Tests

- BNP >100 pg/mL
- Electrocardiogram may be normal or it could show numerous abnormalities including acute ST-T-wave changes from myocardial ischemia, atrial fibrillation, bradycardia, left ventricular hypertrophy
- Serum creatinine may be increased because of hypoperfusion. Preexisting renal dysfunction can contribute to volume overload.

- Complete blood count useful to determine if heart failure is a result of reduced oxygen-carrying capacity
- Chest radiography is useful for detection of cardiac enlargement, pulmonary edema, and pleural effusions
- Echocardiogram assesses left ventricle size, valve function, pericardial effusion, wall motion abnormalities, and ejection fraction
- Hyponatremia, serum sodium <130 mEq/L, is associated with reduced survival and may indicate worsening volume overload and/or disease progression

Pulmonary congestion arises as the left ventricle fails and is unable to accept and eject the increased blood volume that is delivered to it. Consequently, pulmonary venous and capillary pressures rise, leading to interstitial and bronchial edema, increased airway resistance, and dyspnea. The associated signs and symptoms may include (a) dyspnea (with or without exertion), (b) orthopnea, (c) paroxysmal nocturnal dyspnea, and (d) pulmonary edema. Exertional dyspnea occurs when there is a reduction in the level of exertion that causes breathlessness. This is typically described as more breathlessness than was associated previously with a specific activity (e.g., vacuuming, stair climbing). As heart failure progresses, many patients eventually have dyspnea at rest.

Orthopnea is dyspnea that occurs with assumption of the supine position. It occurs within minutes of recumbency and is a result of reduced pooling of blood in the lower extremities and abdomen. Orthopnea is relieved almost immediately by sitting upright and typically is prevented by elevating the head with pillows. An increase in the number of pillows required to prevent orthopnea (e.g., a change from “two-pillow” to “three-pillow” orthopnea) suggests worsening heart failure. Attacks of paroxysmal nocturnal dyspnea typically occur after 2 to 4 hours of sleep; the patient awakens from sleep with a sense of suffocation. The attacks are caused by severe pulmonary and bronchial congestion, leading to shortness of breath and wheezing. The reasons these attacks occur at night are unclear but may include (a) reduced pooling of blood in the lower extremities and abdomen (as with orthopnea), (b) slow resorption of interstitial fluid from sites of dependent edema, (c) normal reduction in sympathetic activity that occurs with sleep (e.g., less support for the failing ventricle), and (d) normal depression in respiratory drive that occurs with sleep.

Rales (crackling sounds heard on auscultation) are present in the lung bases as a result of transudation of fluid into alveoli. The rales typically are bibasilar, but if heard unilaterally, they are usually right-sided. Rales are not present in most patients with chronic heart failure even though there is volume overload. This is thought to be a consequence of a compensatory increase in lymphatic drainage. Detection of rales is usually indicative of a rapid onset of worsening heart failure rather than the amount of excess fluid volume. A third heart sound, or S_3 gallop, is heard frequently in patients with left ventricular failure and may be caused by elevated atrial pressure and altered distensibility of the ventricle.

Pulmonary edema is the most severe form of pulmonary congestion, and is caused by accumulation of fluid in the interstitial spaces and alveoli. In heart failure patients, it is the result of increased pulmonary venous pressure. The patient experiences extreme breathlessness and anxiety and may cough pink, frothy sputum. Pulmonary edema can be terrifying for the patient, causing a feeling of suffocation or drowning. Patients with pulmonary edema may also report any of the above mentioned signs or symptoms of pulmonary congestion.

Systemic congestion is associated with a number of signs and symptoms. Jugular venous distension (JVD) is the simplest and most reliable sign of fluid overload. Examination of the right

internal jugular vein with the patient at a 45° angle is the preferred method for assessing JVD. The presence of JVD more than 4 cm above the sternal angle suggests systemic venous congestion. In patients with mild systemic congestion, JVD may be absent at rest, but application of pressure to the abdomen will cause an elevation of JVD (hepatojugular reflux).

Peripheral edema is a cardinal finding in heart failure. Edema usually occurs in dependent parts of the body, and thus is seen as ankle or pedal edema in ambulatory patients, although it may be manifested as sacral edema in bedridden patients. Adults typically have a 10-lb fluid weight gain before trace peripheral edema is evident; therefore, patients with acute decompensated heart failure may have no clinical evidence of systemic congestion except weight gain. Consequently, body weight is the best short-term end point for evaluating fluid status. Nonfluid weight gain or loss of muscle mass as a result of cardiac cachexia are potential confounders for long-term use of weight as a marker for fluid status. Ascites is another common sign of systemic congestion.

Heart failure patients may exhibit signs and symptoms of low cardiac output alone or in addition to volume overload. The primary complaint associated with such poor perfusion is fatigue. Patients may also complain of poor appetite or early satiety because of limited perfusion of the gastrointestinal tract. Conversely, patients with such gastrointestinal complaints may simply be experiencing gut edema. More subjective measures of low cardiac output include worsening renal function, cool extremities, and narrow pulse pressure.

DIAGNOSIS¹

No single test is available to confirm the diagnosis of heart failure. Because the syndrome of heart failure can be caused or worsened by multiple cardiac and noncardiac disorders, accurate diagnosis is essential for development of therapeutic strategies. Heart failure is often initially suspected in a patient based on their symptoms. These will often include dyspnea, exercise intolerance, fatigue, and/or fluid retention. However, it must be emphasized that signs and symptoms lack sensitivity for diagnosing heart failure since these symptoms are frequently found with many other disorders. Even in patients with known heart failure, there is poor correlation between the presence or severity of symptoms and hemodynamic abnormality.

A complete history and physical examination targeted at identifying cardiac or noncardiac disorders or behaviors that may cause or hasten heart failure development or progression are essential in the initial evaluation of a symptomatic patient. A careful medication history should also be obtained with a focus on use of ethanol, tobacco, illicit drugs (e.g., cocaine or methamphetamine), vitamins and supplements (including herbal or “natural” supplements), NSAIDs, and antineoplastic agents (anthracyclines, cyclophosphamide, trastuzumab, imatinib). Particular attention should be paid to cardiovascular risk factors and to other disorders that can cause or exacerbate heart failure. Because coronary artery disease is the cause of heart failure in nearly 70% of patients, careful attention and evaluation of the possibility of coronary disease is essential, especially in men. If coronary artery disease is detected, appropriate revascularization procedures may then be considered. The patient’s volume status should be documented by assessing the body weight, JVD, and presence or absence of pulmonary congestion and peripheral edema. Laboratory testing may assist in identification of disorders that cause or worsen heart failure. The initial evaluation should include a complete blood count, serum electrolytes (including calcium and magnesium), tests of renal and hepatic function, urinalysis, lipid profile, hemoglobin A_{1c} , thyroid function tests, chest radiography, and 12-lead electrocardiogram (ECG). There are no specific ECG findings associated with heart failure, but findings may help detect coronary artery disease or conduction abnormali-

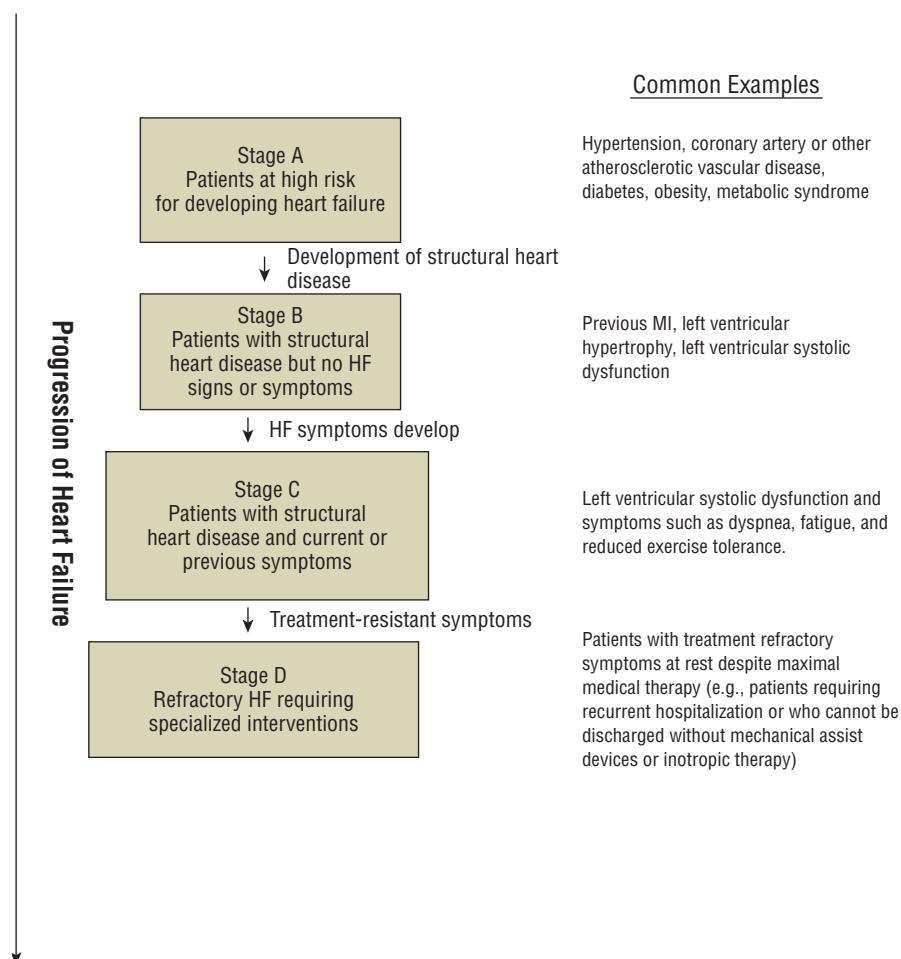

FIGURE 16-5. ACC/AHA heart failure staging system. (HF, heart failure; MI, myocardial infarction.) (Adapted with permission from *Circulation* 2005;112:154–234.)

ties that could affect prognosis and guide treatment decisions. Measurement of BNP may also assist in differentiating dyspnea caused by heart failure from other causes.¹⁸

Although the history, physical examination, and laboratory tests can provide important clues to the underlying cause of heart failure, the echocardiogram is the single most useful test in the evaluation of a patient with heart failure. The echocardiogram is used to evaluate abnormalities in the pericardium, myocardium, or heart valves and to quantify the LVEF to determine if systolic or diastolic dysfunction is present.

TREATMENT

Chronic Heart Failure

■ DESIRED OUTCOMES

The goals of therapy in management of chronic heart failure are to improve the patient's quality of life; relieve or reduce symptoms; prevent or minimize hospitalizations for exacerbations of heart failure; slow progression of the disease process; and prolong survival. Although these goals are still important, identification of risk factors for heart failure development and recognition of its progressive nature have led to increased emphasis on preventing the development of this disorder. With this in mind, the American College of Cardiology/American Heart Association (ACC/AHA) guidelines for the evaluation and management of chronic heart failure use a staging system that recognizes not only the evolution and progression of the disorder, but also emphasizes risk factor modification and preventive

treatment strategies.¹ The system is comprised of four stages (Fig. 16–5). This staging system differs from the NYHA functional classification (Table 16–4) with which most clinicians are familiar. The NYHA system is primarily intended to classify *symptomatic* heart failure according to the clinician's subjective evaluation and does not recognize preventive measures or the progression of the disorder. A patient's symptoms can change frequently over a short period of time as a result of changes in, medications, diet, or intercurrent illnesses. For example, a patient with NYHA class IV symptoms with marked volume overload could rapidly improve to class II or III with aggressive diuretic therapy. In spite of these limitations, this system can be useful for monitoring patients and is widely used in heart failure studies. In contrast, and consistent with the progressive nature of heart failure, a patient's ACC/AHA heart failure stage could not improve (e.g., go from stage C to stage B) even though the

TABLE 16-4 New York Heart Association Functional Classification

Functional class

- I Patients with cardiac disease but without limitations of physical activity. Ordinary physical activity does not cause undue fatigue, dyspnea, or palpitation.
- II Patients with cardiac disease that results in slight limitations of physical activity. Ordinary physical activity results in fatigue, palpitation, dyspnea, or angina.
- III Patients with cardiac disease that results in marked limitation of physical activity. Although patients are comfortable at rest, less-than-ordinary activity will lead to symptoms.
- IV Patients with cardiac disease that results in an inability to carry on physical activity without discomfort. Symptoms of congestive heart failure are present even at rest. With any physical activity, increased discomfort is experienced.

patient's symptoms could fluctuate from NYHA class IV to class I. In addition, the ACC/AHA staging system provides a more comprehensive framework for evaluation, prevention, and treatment of heart failure.

■ GENERAL MEASURES

The complexity of the heart failure syndrome necessitates a comprehensive approach to management that includes accurate diagnosis, identification and treatment of risk factors (e.g., diabetes, hypertension, coronary artery disease), elimination or minimization of precipitating factors, appropriate pharmacologic and nonpharmacologic therapy, and close monitoring and followup.

The first step in management of chronic heart failure is to determine the etiology (see Table 16–1) and/or any precipitating factors. Treatment of underlying disorders, such as hyperthyroidism, may obviate the need for treatment of heart failure. Patients with valvular diseases may derive significant benefit from valve replacement or repair. Revascularization or antiischemic therapy in patients with coronary disease may reduce heart failure symptoms. Drugs that aggravate heart failure (see Table 16–3) should be discontinued if possible.

Restriction of physical activity reduces cardiac workload and is recommended for virtually all patients with acute congestive symptoms. However, once the patient's symptoms have stabilized and excess fluid is removed, restrictions on physical activity are discouraged. In fact, current guidelines indicate that exercise training programs in stable heart failure patients improve exercise tolerance, functional capacity, and may slow heart failure progression.¹

Because a major compensatory response in heart failure is sodium and water retention, restriction of dietary sodium and fluid intake are important nonpharmacologic interventions. Mild (<3 g per day) to moderate (<2 g per day) sodium restriction, in conjunction with daily measurement of weight, should be implemented to minimize volume retention and allow use of lower and safer diuretic doses. The typical American diet contains 3 to 6 g of sodium per day so most patients would need to reduce their intake by approximately 50%. This can often be accomplished by not adding salt to prepared foods and eliminating foods high in sodium (e.g., salt-cured meats, salted snack foods, pickles, soups, delicatessen meats, and processed foods). In patients with hyponatremia (serum Na <130 mEq/L) or those with persistent volume retention despite high diuretic doses and sodium restriction, daily fluid intake should be limited to 2 L per day from all sources.

Other important general measures include patient and family counseling on the signs and symptoms of heart failure, detailed instructions on the importance of appropriate medication use and compliance, and the need for close monitoring and followup to reinforce compliance and minimize the risk of heart failure exacerbations and subsequent hospitalization.

■ GENERAL APPROACH TO TREATMENT

4 Current ACC/AHA treatment guidelines are organized around the four identified stages of heart failure and the treatment recommendations are summarized below (Figs. 16–6 and 16–7).¹ This staging system emphasizes the progressive nature of the disorder and targets treatment to prevent and/or slow the progression of heart failure. Clinicians are reminded that, in addition to the ACC/AHA, other cardiology professional societies have developed guidelines for evaluation and treatment of heart failure. The Heart Failure Society of America (HFSA) issued practice guidelines in 2006.³³ The HFSA and ACC/AHA guidelines are very similar with regard to care and treatment of patients with chronic heart failure. In addition, the HFSA guidelines provide a thorough discussion of other areas including acute decompensated heart failure, heart failure with

preserved LVEF, and management of patients with heart failure and a number of comorbid diseases. The HFSA guidelines will be periodically updated on the HFSA website (www.hfsa.org). Finally, the European Society of Cardiology published guidelines for the management of both acute³⁴ and chronic heart failure.³⁵ Although minor differences exist between the recommendations in the American and European guidelines, they are in general agreement in their overall approach. Clinicians caring for patients with heart failure should be familiar with these guidelines but should also remember that these are only *guidelines* and that management and treatment must be individualized for each patient.

Treatment of Stage A Heart Failure (See Fig. 16–6)

Patients in stage A do not have structural heart disease or heart failure symptoms but are at high risk for developing heart failure because of the presence of risk factors. The emphasis here is on identification and modification of these risk factors to prevent the development of structural heart disease and subsequent heart failure. Commonly encountered risk factors include hypertension, diabetes, obesity, metabolic syndrome, smoking, and coronary artery disease. Although each of these disorders individually increases risk, they frequently coexist in many patients and act synergistically to foster the development of heart failure. Effective control of blood pressure reduces the risk of developing heart failure by approximately 50%, thus current hypertension treatment guidelines should be followed.³⁶ Control of hyperglycemia reduces the risk of end-organ damage and the risk of developing heart failure. Appropriate management of coronary disease and its associated risk factors is also important, including treatment of hyperlipidemia according to published guidelines and smoking cessation.³⁷ Although treatment must be individualized, ACE inhibitors or ARBs should be strongly considered for antihypertensive therapy in patients with multiple vascular risk factors.¹ Diuretics and β -blockers may also be useful in this setting.

Treatment of Stage B Heart Failure (See Fig. 16–6)

Patients in stage B have structural heart disease, but do not have heart failure symptoms. This group includes patients with left ventricular hypertrophy, recent or remote MI, valvular disease, or reduced LVEF (less than 40%). These individuals are at risk for developing heart failure and treatment is targeted at minimizing additional injury and preventing or slowing the remodeling process. In addition to the treatment measures outlined in stage A, ACE inhibitors and β -blockers are important components of therapy. Patients with a previous MI should receive both ACE inhibitors and β -blockers, regardless of the LVEF.¹ Similarly, patients with a reduced LVEF should also receive both these agents, whether or not they have had a MI.¹ ARBs are an effective alternative in patients intolerant to ACE inhibitors.¹

Treatment of Stage C Heart Failure (See Fig. 16–7)

4 5 6 7 Patients with structural heart disease and previous or current heart failure symptoms are classified in stage C. In addition to treatments in stages A and B, most patients in stage C should be routinely treated with three medications: a diuretic, an ACE inhibitor, and a β -blocker (see Drug Therapies for Routine Use below). The benefits of these medications on slowing heart failure progression, reducing morbidity and mortality, and improving symptoms are clearly established. Aldosterone receptor antagonists, ARBs, digoxin, and hydralazine-isosorbide dinitrate are also useful in selected patients. Nonpharmacologic therapy with devices such as an implantable cardiac-defibrillator (ICD) or cardiac resynchroni-

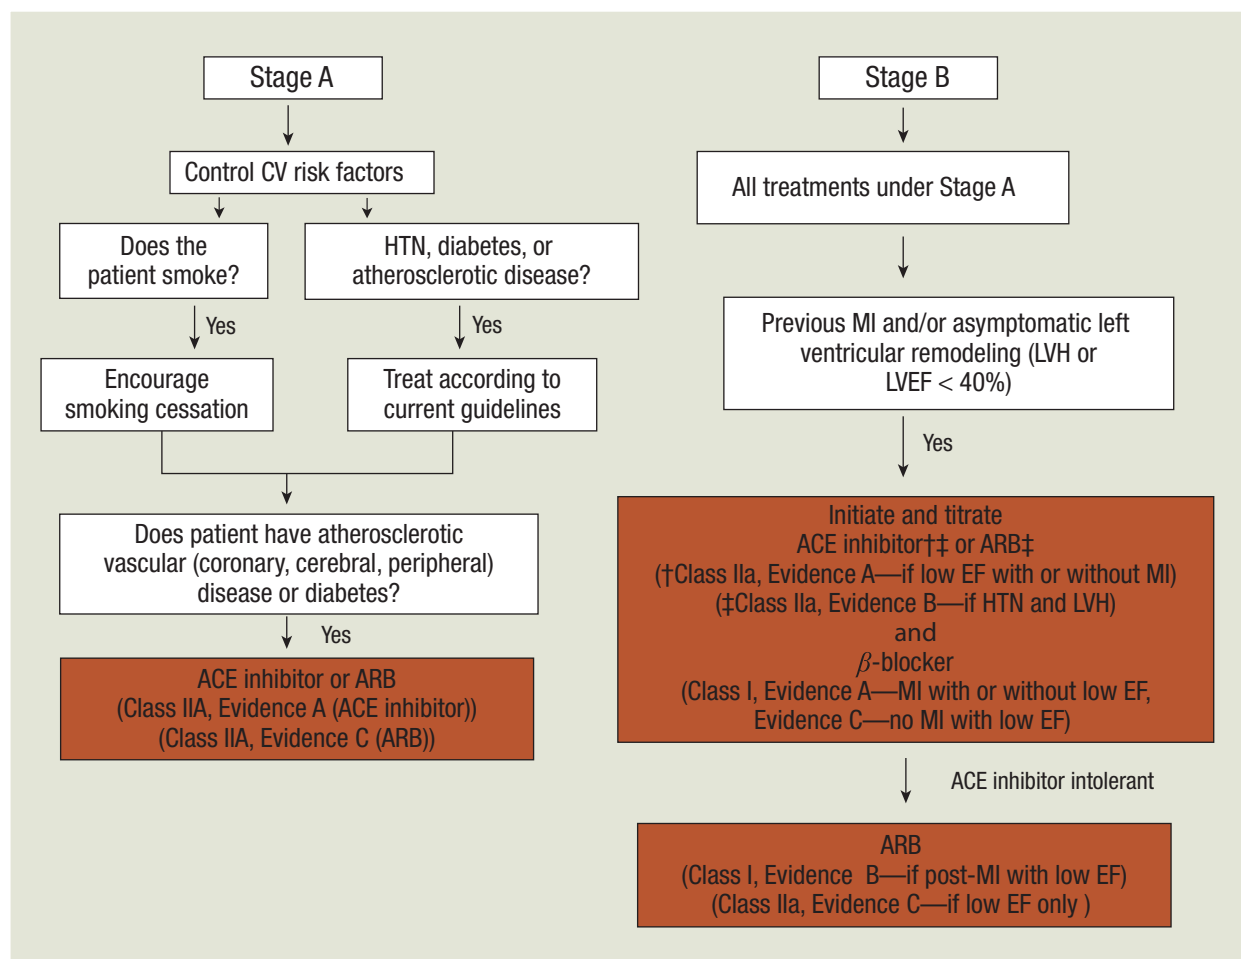

FIGURE 16-6. Treatment algorithm for patients with ACC/AHA stages A and B heart failure. (ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; CV, cardiovascular; EF, ejection fraction; HTN, hypertension; LVEF, left ventricular ejection fraction; LVH, left ventricular hypertrophy; MI, myocardial infarction.) (Adapted with permission from *Circulation* 2005;112:154–234.)

zation therapy (CRT) with a biventricular pacemaker is also indicated in certain patients in stage C (see Nonpharmacologic Therapy below). Other general measures are also important, including moderate sodium restriction, daily weight measurement, immunization against influenza and pneumococcus, modest physical activity, and avoidance of medications that can exacerbate heart failure. Recent evidence suggests that careful followup and patient education that reinforces dietary and medication compliance can prevent clinical deterioration and reduce hospitalization.¹

Treatment of Stage D Heart Failure

Stage D heart failure includes patients with symptoms at rest that are refractory despite maximal medical therapy. This includes patients who undergo recurrent hospitalizations or who cannot be discharged from the hospital without special interventions. These individuals have the most advanced form of heart failure and should be considered for specialized therapies including mechanical circulatory support, continuous intravenous positive inotropic therapy, cardiac transplantation, or hospice care. The approach to treatment of patients with stage D heart failure is discussed in more detail in Acute Decompensated Heart Failure below.

■ NONPHARMACOLOGIC THERAPY

Sudden cardiac death, primarily as a consequence of ventricular tachycardia and fibrillation, is responsible for 40% to 50% of the mortality in heart failure patients. In general, patients in the earlier stages of heart failure with milder symptoms are more likely to die

from sudden death, whereas death from pump failure is more frequent in those with advanced heart failure. Many of these patients have complex and frequent ventricular ectopic beats, although it remains unknown whether these ectopic beats contribute to the risk of malignant arrhythmias or merely serve as markers for individuals at higher risk for sudden death. Drugs that attenuate disease progression such as β -blockers and aldosterone antagonists reduce the risk of sudden death. However, empiric treatment with class I antiarrhythmic agents, although they can suppress ventricular ectopic beats, adversely affect survival.³⁸ The role of the ICD compared to amiodarone for primary prevention of sudden death was evaluated in Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT). Placement of an ICD was superior to amiodarone or placebo for reducing mortality in patients with NYHA class II or III heart failure and LVEF $\leq 35\%$, regardless of the etiology of heart failure.³⁹ Importantly, this study also found that amiodarone had no benefit compared to placebo and thus this drug, because of its multiple adverse effects, drug interactions, and lack of effect on mortality, should not be used for primary prevention of sudden death. However, because of the neutral effects of amiodarone on survival, it is often used in heart failure patients with atrial fibrillation to maintain sinus rhythm and/or to prevent ICD discharges. In cardiac arrest survivors with a reduced LVEF, the ICD is superior to antiarrhythmic drug therapy for improving survival.⁴⁰ Thus, the ACC/AHA guidelines recommend the ICD for both primary and secondary prevention to improve survival in patients with current or previous heart failure symptoms and reduced LVEF. Chapter 19 thoroughly reviews ICD therapy.

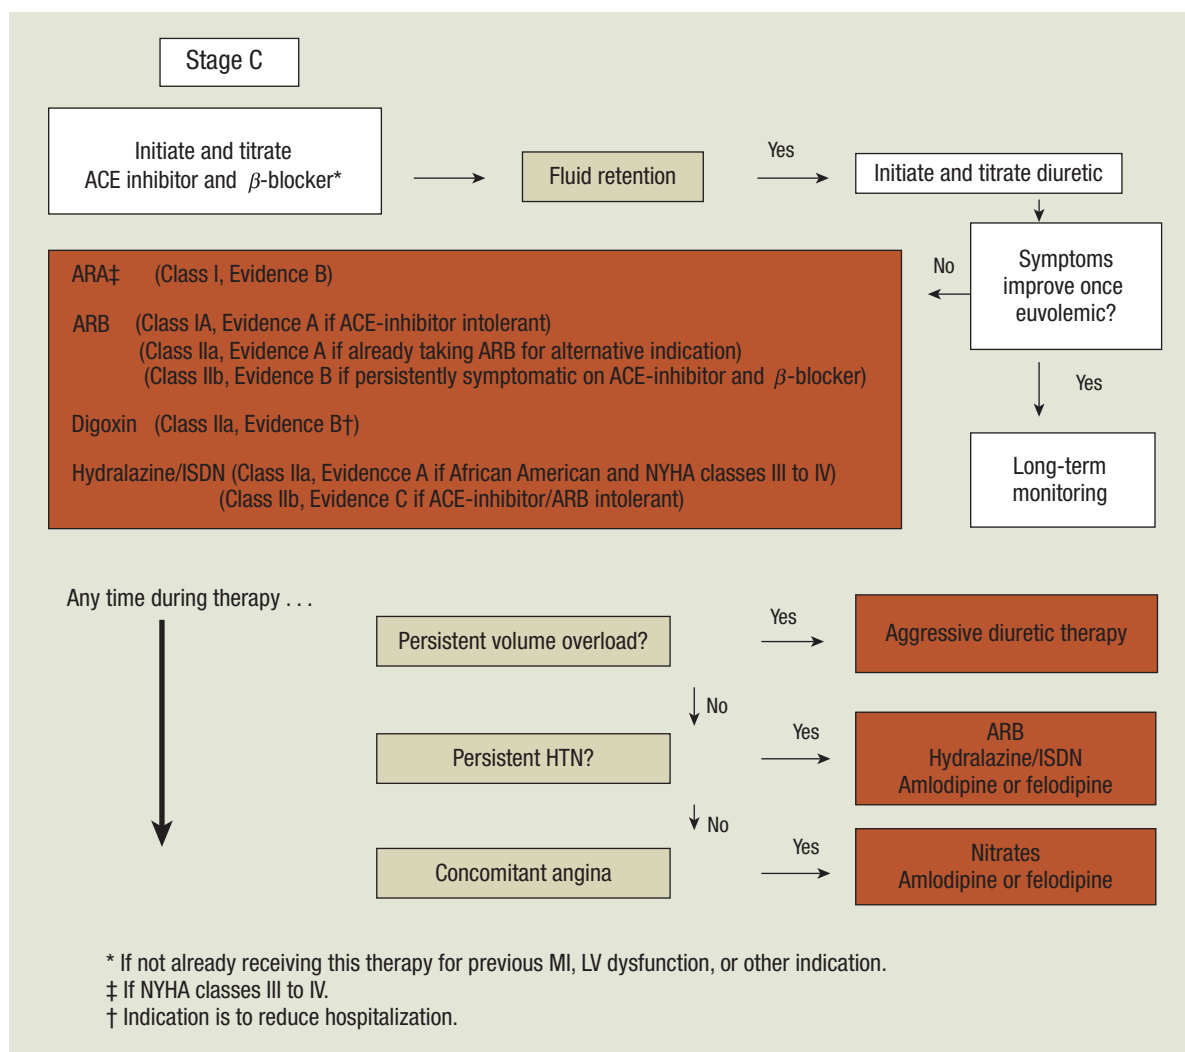

FIGURE 16-7. Treatment algorithm for patients with ACC/AHA stage C heart failure. (ACE, angiotensin-converting enzyme; ARA, aldosterone receptor antagonist; ARB, angiotensin receptor blocker; HTN, hypertension; ISDN, isosorbide dinitrate; LV, left ventricle; MI, myocardial infarction.) (Adapted with permission from *Circulation* 2005;112:154–234.)

Recent studies demonstrate that CRT offers a promising approach to selected patients with chronic heart failure.^{41,42} Delayed electrical activation of the left ventricle, characterized on the ECG by a QRS duration that exceeds 120 msec, occurs in approximately one-third of patients with moderate to severe systolic heart failure. Because the left and right ventricles normally activate simultaneously, this delay results in asynchronous contraction of the ventricles, which contributes to the hemodynamic abnormalities of heart failure. Implantation of a specialized biventricular pacemaker to restore synchronous activation of the ventricles can improve ventricular contraction and hemodynamics. Recent trials show improvements in exercise capacity, NYHA classification, quality of life, hemodynamic function, hospitalizations, and mortality with CRT.^{41,42} A CRT is currently indicated only in NYHA classes III to IV patients receiving optimal medical therapy and with a QRS duration ≥ 120 msec and LVEF $\leq 35\%$. Combined CRT and ICD devices are available and can be used if the patient meets the indications for both devices.

■ PHARMACOLOGIC THERAPY

Drug Therapies for Routine Use

4 5 6 7 8 9 Figure 16–7 is a treatment algorithm for management of patients with reduced LVEF and current or prior

heart failure symptoms (i.e., stage C). In general, these patients should receive combined therapy with an ACE inhibitor or ARB and a β -blocker, plus a diuretic if there is evidence of fluid retention. Initiation of digoxin therapy can be considered at any time for symptom reduction, to decrease hospitalizations, or slow ventricular response in patients with concomitant atrial fibrillation. An aldosterone receptor antagonist should also be considered in selected patients.¹

7 Diuretics^{43,44} The compensatory mechanisms in heart failure stimulate excessive sodium and water retention, often leading to pulmonary and systemic congestion. Diuretic therapy, in addition to sodium restriction, is recommended in all patients with clinical evidence of fluid retention. Once fluid overload has been resolved, many patients require chronic diuretic therapy to maintain euvolemia. Among the drugs used to manage heart failure, diuretics are the most rapid in producing symptomatic benefits. Because diuretics do not alter disease progression or prolong survival, they are not considered mandatory therapy. Thus patients who do not have fluid retention would not require diuretic therapy.

The primary goal of diuretic therapy is to reduce symptoms associated with fluid retention, improve exercise tolerance and quality of life, and reduce hospitalizations from heart failure. They accomplish this by decreasing pulmonary and peripheral edema through reduction of preload. Although preload is a determinant of

cardiac output, the Frank-Starling curve (see Fig. 16–3) shows that patients with congestive symptoms have reached the flat portion of the curve. A reduction in preload improves symptoms but has little effect on the patient's stroke volume or cardiac output until the steep portion of the curve is reached. However, diuretic therapy must be used judiciously because overdiuresis can lead to a reduction in cardiac output and symptoms of dehydration.

Diuretic therapy is usually initiated in low doses in the outpatient setting, with dosage adjustments based on symptom assessment and daily body weight. Change in body weight is a sensitive marker of fluid retention or loss, and it is recommended that patients monitor their status by taking daily morning body weights. Patients who gain a pound per day for several consecutive days, or 3 to 5 lb in a week, should contact their healthcare provider for instructions (which often will be to increase the diuretic dose temporarily). Such action often will allow patients to prevent a decompensation that requires hospitalization. One study demonstrated a significant reduction in emergency department visits with a protocol that directed patients to self-adjust their diuretic dose based on changes in heart failure symptoms and daily body weight.⁴⁵ Hypotension or worsening renal function (e.g., increases in serum creatinine) may be indicative of volume depletion and necessitate a reduction in the diuretic dose. Assessing for volume depletion is particularly important before ACE inhibitor or β -blocker initiation or dose up-titration as overdiuresis may predispose patients to hypotension and other adverse effects with increases in ACE inhibitor or β -blocker doses.

Thiazide Diuretics. Thiazide diuretics such as hydrochlorothiazide block sodium and chloride reabsorption in the distal convoluted tubule (approximately 5% to 8% of filtered sodium). Consequently, the thiazides are relatively weak diuretics and infrequently are used alone in heart failure. However, as reviewed in Treatment: Acute Decompensated Heart Failure below, under Diuretic Resistance, thiazides or the thiazide-like diuretic metolazone can be used in combination with loop diuretics to promote a very effective diuresis. In addition, thiazide diuretics may be preferred in patients with only mild fluid retention and elevated blood pressure because of their more persistent antihypertensive effects compared to loop diuretics.

Loop Diuretics. Loop diuretics are usually necessary to restore and maintain euolemia in heart failure. They act by inhibiting a Na-K-2Cl transporter in the thick ascending limb of the loop of Henle, where 20% to 25% of filtered sodium normally is reabsorbed. Because loop diuretics are highly bound to plasma proteins, they are not highly filtered at the glomerulus. They reach the tubular lumen by active transport via the organic acid transport pathway. Competitors for this pathway (probenecid or organic by-products of uremia) can inhibit delivery of loop diuretics to their site of action and decrease effectiveness. Loop diuretics also induce a prostaglandin-mediated increase in renal blood flow, which contributes to their natriuretic effect. Coadministration of NSAIDs blocks this prostaglandin-mediated effect and can diminish diuretic efficacy. Excessive dietary sodium intake may also reduce the efficacy of loop diuretics. Unlike thiazides, loop diuretics maintain their effectiveness in the presence of impaired renal function, although higher doses may be necessary to obtain adequate delivery of the drug to the site of action.

Heart failure is one of the disease states in which the maximal response to loop diuretics is reduced. This is believed to result from a decrease in the rate of diuretic absorption and/or increased proximal or distal tubule reabsorption of sodium, possibly due to increased activity of the Na-K-2Cl transporter.⁴³ As a consequence, doses above the recommended ceiling doses produce no additional diuresis. Thus, once the ceiling dose is reached, it is recommended to give the diuretic more frequently for additional effect rather than

TABLE 16-5 Loop Diuretics—Use in Heart Failure

	Furosemide	Bumetanide	Torsemide
Usual daily dose (oral)	20–160 mg/day	0.5–4 mg/day	10–80 mg/day
Ceiling dose ^a

to give progressively higher doses. The appropriate chronic dose is that which maintains the patient at a stable dry weight without symptoms of dyspnea. Table 16–5 lists ranges of doses of loop diuretics and recommended ceiling doses.

5 ACE Inhibitors ACE inhibitors are the cornerstone of pharmacotherapy for patients with heart failure. By blocking the conversion of angiotensin I to angiotensin II by ACE, the production of angiotensin II and, in turn, aldosterone is decreased, but not completely eliminated.¹³ This decrease in angiotensin II and aldosterone attenuates many of the deleterious effects of these neurohormones, including ventricular remodeling, myocardial fibrosis, myocyte apoptosis, cardiac hypertrophy, norepinephrine release, vasoconstriction, and sodium and water retention.¹³ Thus, ACE inhibitor therapy plays an important role in preventing RAAS-mediated progressive worsening of myocardial function. The endogenous vasodilator bradykinin, which is inactivated by ACE, is also increased by ACE inhibitors, along with the release of vasodilatory prostaglandins and histamine.¹³ The precise contribution of the effects of ACE inhibitors on bradykinin and vasodilatory prostaglandins is unclear. However, the persistence of clinical benefits with ACE inhibitors despite angiotensin II and aldosterone levels returning to pretreatment levels suggests this is a potentially important effect.¹³

Numerous placebo-controlled clinical trials involving more than 7,000 patients with reduced LVEF have documented the favorable effects of ACE inhibitor therapy on symptoms, NYHA functional classification, clinical status, exercise tolerance, and quality of life.¹³ When compared with placebo, patients treated with ACE inhibitors have fewer treatment failures, hospitalizations, and increases in diuretic dosages.¹³

More importantly, these trials show that ACE inhibitors improve survival by 20% to 30% compared to placebo.¹³ In addition, the Studies of Left Ventricular Dysfunction (SOLVD) Prevention and Treatment trials indicate the survival benefit is maintained long-term (12 years) in patients who were treated with enalapril.⁴⁶ In addition to improving survival, ACE inhibitors also reduce the combined risk of death or hospitalization, slow the progression of heart failure, and reduce the rates of reinfarction.¹³ The benefits of ACE inhibitor therapy are independent of the etiology of heart failure (ischemic versus nonischemic) and are observed in patients with mild, moderate, or severe symptoms.

The most common cause of heart failure is ischemic heart disease, where MI results in loss of myocytes, followed by ventricular dilation and remodeling. Captopril, ramipril, and trandolapril all benefit post-MI patients, whether they are initiated early (within 36 hours) and continued for 4 to 6 weeks or started later and administered for several years.¹³ Collectively, these studies indicate that ACE inhibitors after MI improve overall survival, decrease development of severe heart failure, and reduce reinfarction and heart failure hospitalization rates.¹³ The benefit occurs within the first few days

of therapy and persists during long-term treatment. The effects are most pronounced in higher-risk patients, such as those with symptomatic heart failure or reduced LVEF, with 20% to 30% reductions in mortality reported in these patients.¹³ Post-MI patients without heart failure symptoms or decreases in LVEF (stage B) should also receive ACE inhibitors to prevent the development of heart failure and to reduce mortality.^{1,13,47}

In addition to their benefits in patients with established heart failure, ACE inhibitors also are effective for preventing the development of heart failure and reducing cardiovascular risk. Enalapril decreases the risk of hospitalization for worsening heart failure and reduces the composite end point of death and heart failure hospitalization in patients with asymptomatic left ventricular dysfunction.⁴⁸ The development of diabetes mellitus, an important risk factor for cardiovascular disease that also increases morbidity and mortality in heart failure patients, is reduced by enalapril in patients with chronic heart failure.⁴⁹ In patients with established atherosclerotic vascular disease (e.g., coronary, cerebral, or peripheral circulations) and normal LVEF, ACE inhibitors reduce the development of new-onset heart failure and diabetes, cardiovascular death, overall mortality, MI, and stroke.⁵⁰

The clear benefit of ACE inhibitors is evident in the Joint Commission for Accreditation of Healthcare Organizations (JCAHO) and Centers for Medicare and Medicaid Services (CMS) selection of ACE inhibitor use in patients with heart failure and decreased LVEF as a key quality measure. Despite the overwhelming benefit demonstrated with these agents, there is substantial evidence that they are underused and underdosed.^{51,52} These data indicate that significant numbers of heart failure patients do not receive ACE inhibitors, and of those who are receiving these agents, many are taking lower-than-recommended doses.⁵² Also, for patients receiving an ACE inhibitor at hospital discharge, use significantly decreases over time and patients who were not prescribed ACE inhibitors at discharge were unlikely to have therapy initiated in the outpatient setting.⁵¹ The most common reasons cited for underuse or underdosing are concerns about safety and adverse reactions to ACE inhibitors, especially in patients with underlying renal dysfunction or hypotension. The use of ACE inhibitors in patients with renal insufficiency is particularly relevant because it is present in 25% to 50% of heart failure patients and is associated with an increased risk of mortality.⁵³ Several recent studies in different patient populations, including post-MI patients with decreased left ventricular function and patients with stable coronary artery disease and preserved left ventricular function, indicate that ACE inhibitors may be more effective in those patients with renal insufficiency.^{54–56} Because many heart failure patients have concomitant disorders (e.g., diabetes, hypertension, previous MI) that also may be favorably affected by ACE inhibitors, renal dysfunction should not be an absolute contraindication to ACE inhibitor use in patients with left ventricular dysfunction. However, these patients should be monitored carefully for the development of worsening renal function and/or hyperkalemia with special attention to risk factors associated with this complication of ACE inhibitor therapy.¹

An important practical consideration is determining the proper dose of an ACE inhibitor. The ability to achieve target doses shown to be effective in clinical trials is often limited by hypotension and/or a decline in renal function. Clinical trials establishing the efficacy of these agents titrated drug doses to a predetermined target rather than according to therapeutic response. Although data on the dose-dependent effects of ACE inhibitors in patients with heart failure are limited, higher doses may reduce the risk of hospitalization compared to lower doses, but there do not appear to be significant differences in mortality.⁵⁷ In many positive trials of other heart failure therapies (e.g., β -blockers, aldosterone antagonists), intermediate ACE inhibitor doses were generally used as background therapy. These results emphasize that clinicians should attempt to use

ACE inhibitor doses proven beneficial in clinical trials, but if these doses are not tolerated, lower doses can be used with the knowledge that there are likely only small differences in mortality outcomes between the high and low doses. Also, initiation of β -blocker therapy should not be delayed until target ACE inhibitor doses are achieved as the addition of a β -blocker is proven to reduce mortality, whereas that is not the case with increasing ACE inhibitor doses.

In summary, the evidence that ACE inhibitors improve symptoms, slow disease progression, and decrease mortality in patients with heart failure and reduced LVEF (stage C) is unequivocal. Current guidelines indicate these patients should receive ACE inhibitors, unless contraindications are present.¹ Moreover, ACE inhibitors should also be used to prevent the development of heart failure in at-risk patients (i.e., stages A and B).¹

6 β -Blockers There is overwhelming evidence from multiple randomized, placebo-controlled clinical trials that β -blockers reduce morbidity and mortality in patients with heart failure. As such, the ACC/AHA guidelines on the management of heart failure recommend that β -blockers should be used in all stable patients with heart failure and a reduced left ventricular ejection fraction in the absence of contraindications or a clear history of β -blocker intolerance.¹ Patients should receive a β -blocker even if their symptoms are mild or well controlled with diuretic and ACE inhibitor therapy. Importantly, it is not essential that ACE inhibitor doses be optimized before a β -blocker is started because the addition of a β -blocker is likely to be of greater benefit than an increase in ACE inhibitor dose.¹ β -Blockers are also recommended for asymptomatic patients with a reduced left ventricular ejection fraction (stage B) to decrease the risk of progression to heart failure.

β -Blockers have been studied in more than 20,000 patients with heart failure in placebo-controlled trials. Three β -blockers have been shown to significantly reduce mortality compared to placebo: carvedilol, metoprolol controlled-release/extended-release (CR/XL), and bisoprolol. Each was studied in a large population with the primary end point of mortality. Carvedilol was the first β -blocker shown to improve survival in heart failure. In the U.S. Carvedilol Heart Failure Study, 1,094 patients were randomized to carvedilol or placebo in addition to standard therapy, including an ACE inhibitor, digoxin, and diuretic. The study was stopped early because of a 65% reduction in the risk of death with carvedilol.⁵⁸ Nearly 4,000 patients were randomized to metoprolol CR/XL (Toprol-XL) or placebo in the Metoprolol CR/XL Randomized Intervention Trial in Congestive Heart Failure (MERIT-HF), the largest β -blocker mortality trial to date.⁵⁹ This trial was also stopped early because of a significant survival benefit with β -blockade. Specifically, metoprolol was associated with a 34% reduction in total mortality, a 41% reduction in sudden death, and a 49% reduction in death from worsening heart failure. Bisoprolol was studied in more than 2,600 patients enrolled in the Cardiac Insufficiency Bisoprolol Study (CIBIS) II.⁶⁰ The study was also stopped prematurely because of a 34% reduction in total mortality with bisoprolol compared to placebo. Bisoprolol was also associated with a 44% reduction in sudden death and a 26% reduction in death because of worsening heart failure. Multiple post-hoc subgroup analyses of data from the MERIT-HF and CIBIS II trials suggest that the benefits of β -blockade occur regardless of heart failure etiology or disease severity.

The majority of participants in MERIT-HF and CIBIS II had either class II or class III heart failure, and β -blockers became standard therapy in patients with class II or III disease after these trials were published. However, the efficacy and safety of β -blockers in patients with class IV heart failure were unclear until publication of the Carvedilol, Prospective, Randomized, Cumulative Survival (COPERNICUS) trial.⁶¹ This trial randomized nearly 2,300 clinically stable patients who had symptoms at rest or with minimal exertion

to carvedilol or placebo. Like the other studies, COPERNICUS was stopped prematurely after carvedilol produced a 35% relative reduction in mortality. Carvedilol was well tolerated in this population, with fewer participants receiving carvedilol compared to placebo requiring permanent discontinuation of study medication.

Data supporting the use of β -blockers in asymptomatic patients with left ventricular systolic dysfunction (stage B) come from a study of carvedilol in post-MI patients with a decreased LVEF.⁶² While the primary end point of all-cause mortality or hospital admission for cardiovascular problems was similar in the carvedilol and placebo groups, carvedilol significantly reduced all-cause mortality alone compared to placebo. Cardiovascular mortality and nonfatal MI were also lower among carvedilol-treated patients.

In addition to improving survival, β -blockers improve multiple other end points. All the large clinical trials demonstrated 15% to 20% reductions in all-cause hospitalization and 25% to 35% reductions in hospitalizations for worsening heart failure with β -blocker therapy.^{60,63,64} Studies also show consistent improvements in left ventricular systolic function with β -blockers, with increases in LVEF of 5 to 10 units (e.g., from an ejection fraction of 20% to 25% or 30%) after several weeks to months of therapy. β -Blockers have also been shown to decrease ventricular mass, improve the sphericity of the ventricle, and reduce systolic and diastolic volumes (left ventricular end-systolic volume and left ventricular end-diastolic volume).^{65,66} These effects are often collectively called *reverse remodeling*, referring to the fact that they return the heart toward more normal size, shape, and function.

The effects of β -blockers on symptoms and exercise tolerance varies among studies. Many studies show improvements in NYHA functional class, patient symptom scores, or quality-of-life assessments (such as the Minnesota Living with Heart Failure Questionnaire), and exercise performance, as assessed by the 6-minute walk test.^{63–65} Other investigators find significant reductions in mortality with β -blockers but no significant improvement in symptoms.⁶⁷ As such, it is important to educate patients that β -blocker therapy is expected to positively influence disease progression and survival even if there is little to no symptomatic improvement.

The majority of participants in β -blocker trials were on ACE inhibitors at baseline as the benefits of ACE inhibitors were proven prior to β -blocker trials. Whether the strategy of starting a β -blocker prior to an ACE inhibitor is safe and effective has been debated. This issue was addressed in CIBIS III, in which patients with mild to moderate symptoms were randomized to initial therapy with either bisoprolol or enalapril.⁶⁸ The two strategies produced similar rates of death or hospitalization. However, the trial failed to satisfy the prespecified statistical criterion for noninferiority of initial therapy with a β -blocker compared to an ACE inhibitor. In the absence of more compelling evidence, ACE inhibitors should be started first in most patients. Initiating a β -blocker first may be advantageous for patients with evidence of excessive SNS activity (e.g., tachycardia) and may also be appropriate for patients whose renal function or potassium concentrations preclude starting an ACE inhibitor at that time. However, the risk for decompensation during β -blocker initiation may be greater in the absence of preexisting ACE inhibitor therapy, and careful monitoring is essential.

The mechanism by which β -blockers exert their therapeutic benefit is unclear. β -Blockers antagonize the detrimental effects of the SNS described earlier in the chapter. To this end, potential mechanisms to explain the favorable effects of β -blockers in heart failure include antiarrhythmic effects, attenuating or reversing ventricular remodeling, decreasing myocyte death from catecholamine-induced necrosis or apoptosis, preventing fetal gene expression, improving left ventricular systolic function, decreasing heart rate and ventricular wall stress thereby reducing myocardial oxygen demand, and inhibiting plasma renin release.¹

Components that are critical for successful β -blocker therapy include appropriate patient selection, drug initiation and titration, and patient education. β -Blockers should be initiated in stable patients who have no or minimal evidence of fluid overload.¹ Although β -blockers are typically started in the outpatient setting, there are data indicating that initiation of a β -blocker prior to discharge in patients who are hospitalized for decompensated heart failure increases β -blocker usage compared with outpatient initiation without increasing the risk of serious adverse effects.⁶⁹ However, β -blockers should not be started in patients who are hospitalized in the intensive care unit or recently required intravenous inotropic support. In unstable patients, other heart failure therapy should be optimized and then β -blocker therapy reevaluated once stability is achieved.

Initiation of a β -blocker at normal doses in patients with heart failure may lead to symptomatic worsening or acute decompensation owing to the drug's negative inotropic effect. For this reason, β -blockers are listed as drugs that may exacerbate or worsen heart failure (see Table 16–3). To minimize the likelihood for acute decompensation, β -blockers should be started in very low doses with slow upward dose titration. Table 16–6 describes the starting and target doses. Of note, the smallest commercially available tablet of bisoprolol is a scored 5-mg tablet. Because the recommended starting dose of 1.25 mg/day is not readily available, bisoprolol is the least commonly used of the three agents and, in fact, is not approved by the Food and Drug Administration (FDA) for use in heart failure. Thus, therapy is generally limited to either carvedilol or metoprolol CR/XL, and there is no compelling evidence that one drug is superior to the other. A controlled-release formulation of carvedilol (carvedilol CR) that allows once-daily dosing was recently FDA-approved, and pharmacokinetic studies demonstrate similar degrees of drug exposure with the controlled- and immediate-release formulations of the drug.⁷⁰ Carvedilol CR should be considered in patients with difficulty maintaining adherence to the immediate-release formulation.

β -Blocker doses should be doubled no more often than every 2 weeks, as tolerated, until the target or maximally tolerated dose is reached. Target doses are those associated with reductions in mortality in placebo-controlled clinical trials. It is important to make every effort to titrate doses up to target whenever possible in order to provide maximal survival benefits. In addition, there is evidence that response to β -blockers is dose dependent, with greater reductions in hospitalization rates and improvements in LVEF at higher doses. However, even low doses appear to prolong survival compared to placebo, and thus, any dose of β -blocker is likely to provide some benefit.⁷¹ Data with metoprolol suggest that heart rate may serve as a guide to the degree of β -blockade and that lower β -blocker doses might be considered reasonable if the reduction in heart rate indicates a good response to β -blocker therapy.⁷¹

Good communication between the patient and healthcare provider(s) is particularly important for successful therapy. Patients

TABLE 16-6 Initial and Target Doses for β -Blockers Used in Treatment of Heart Failure

Drug	Initial Dose ^a	Target Dose
Bisoprolol ^b	1.25 mg daily	10 mg daily
Carvedilol ^b	3.125 mg bid	25 mg bid ^c
Metoprolol succinate CR/XL ^b	12.5–25 mg daily ^d	200 mg daily

^aDoses should be doubled approximately every 2 weeks, or as tolerated by the patient, until the highest tolerated or target dose is reached.

^bRegimens proven in large trials to reduce mortality.

^cTarget dose for patients who weigh >85 kg is 50 mg bid.

^dIn Metoprolol CR/XL Randomized Intervention Trial in Congestive Heart Failure (MERIT-HF), the majority of class II patients were given 25 mg daily, whereas the majority of class III patients were given 12.5 mg daily as their starting dose.

should understand that dose up-titration is a long, gradual process and that achieving the target dose is important to maximize the benefits of therapy. Patients should also be aware that response to therapy may be delayed and that heart failure symptoms may actually worsen during the initiation period. In the event of worsening symptoms, patients who understand the potential benefits of long-term β -blocker therapy may be more likely to continue treatment.

In summary, the data provide clear evidence that β -blockers slow disease progression, decrease hospitalizations, and improve survival in heart failure. β -Blockers have also been shown to improve quality of life in many patients with heart failure, although this is not a universal finding. Based on these data, β -blockers are recommended as standard therapy for all patients with systolic dysfunction, regardless of the severity of their symptoms. Clinical trial experience shows that target β -blocker doses can be achieved in the majority of patients provided that appropriate initiation, titration, and education are implemented.

Drug Therapies to Consider for Selected Patients

5 Angiotensin II Receptor Blockers The use of ARBs in heart failure has generated great interest and controversy.⁷² The crucial role of the RAAS in heart failure development and progression is well established, as are the benefits of inhibiting this system with ACE inhibitors. Although ACE inhibitors decrease angiotensin II production in the short-term, these agents do not completely suppress generation of this hormone. With chronic administration of ACE inhibitors, *ACE escape*, characterized by increases in circulating angiotensin II and aldosterone, often occurs.^{12,73} In addition, angiotensin II can be formed in a number of tissues, including the heart, through non-ACE-dependent pathways (e.g., chymase, cathepsin, and kallikrein).¹² Therefore, blockade of the detrimental effects of angiotensin II by ACE inhibition is incomplete. In addition, troublesome adverse effects of ACE inhibitors such as cough are linked to accumulation of bradykinin.¹³ The ARBs block the angiotensin II receptor subtype 1 (AT₁), preventing the deleterious effects of angiotensin II, regardless of its origin. Because ARBs do not inhibit the ACE enzyme, these agents do not appear to affect bradykinin.^{12,73} By inhibiting both the formation of angiotensin II and its effects on the AT₁ receptor, combination therapy with an ACE inhibitor plus an ARB offers a theoretical advantage over either agent used alone through more complete blockade of the deleterious effects of angiotensin II. Also, by directly blocking AT₁ receptors, ARBs would allow unopposed stimulation of AT₂ receptors, causing vasodilation and inhibition of ventricular remodeling.¹² Because bradykinin-related adverse effects of ACE inhibitors such as angioedema and cough lead to drug discontinuation in some patients, the potential for an ARB to produce similar clinical benefits with fewer side effects is of great interest. Whether ARBs add incremental benefit to current established therapies or are superior (or equivalent) to ACE inhibitors is the focus of several clinical trials.⁷²

Although a number of ARBs are currently available, the primary clinical trials supporting the use of these agents in heart failure used either valsartan or candesartan.⁷² The Valsartan Heart Failure Trial (Val-HeFT) evaluated whether the addition of valsartan to standard background heart failure therapy (which included an ACE inhibitor in 93% and a β -blocker in 35% of patients) improved survival.⁷⁴ The addition of valsartan had no effect on all-cause mortality but produced a 13% reduction in morbidity and mortality (principally as a result of reductions in heart failure hospitalizations). Subgroup analysis showed that the benefits were greatest in those patients not receiving background ACE inhibitor therapy. Based on these results, valsartan is now approved for use in patients with NYHA classes II to IV heart failure. The Valsartan in Acute Myocardial Infarction (VALIANT) trial compared the effect of valsartan, captopril, and the combination of the two agents in post-MI patients with symptomatic heart failure, reduced left ventricular systolic function, or both, in a noninferiority trial design.⁴⁷ The primary end point of total mortality occurred in 19.3% of patients receiving valsartan and captopril, 19.5% of captopril-treated patients, and 19.9% of the valsartan group. Thus, in this high-risk post-MI population, valsartan was as effective as captopril in reducing the risk of death, but combination therapy only increased the risk of adverse effects and did not improve survival compared to monotherapy with either agent. Based on these findings, valsartan is now approved for use in post-MI patients with left ventricular failure or left ventricular dysfunction.

The Candesartan in Heart Failure: Assessment of Reduction in Mortality and Morbidity (CHARM) trials were designed as three studies to compare candesartan with placebo in patients with symptomatic heart failure (Table 16-7).⁷⁵ Both the CHARM-Added (patients receiving background ACE-inhibitor therapy)⁷⁶ and CHARM-Alternative (patients intolerant of ACE-inhibitor therapy)⁷⁷ trials found significant reductions in the primary end point of cardiovascular death or hospitalization for heart failure in patients receiving candesartan, although the benefit was modest in CHARM-Added. No significant benefit of candesartan was observed in CHARM-Preserved (patients with LVEF >40%).⁷⁸ Overall, candesartan was well tolerated but its use was associated with an increased risk of hypotension, hyperkalemia, and renal dysfunction. On the basis of these results, candesartan is now approved for use in heart failure.

Although ACE inhibitors remain first-line therapy in patients with stage C heart failure and reduced LVEF, the current ACC/AHA guidelines recommend the use of ARBs in patients who are unable to tolerate ACE inhibitors.¹ Similarly, ARBs are alternatives to ACE inhibitors in patients with stages A and B heart failure.¹ Cough and angioedema are the most common causes of ACE inhibitor intolerance. Caution should be exercised when ARBs are used in patients with angioedema from ACE inhibitors as some cross-reactivity has been reported.^{77,79} ARBs are not an alternative in patients with hypotension, hyperkalemia, or renal insufficiency secondary to ACE inhibitors because they are as likely to cause these adverse effects. Also, the combined use of ACE inhibitors, ARBs, and aldosterone

TABLE 16-7 Clinical Trials of Candesartan in Heart Failure

Trial	Drug	Patient Population	Primary End Point	Results (%)		Adjusted Hazard Ratio	P Value
				Drug	Placebo		
CHARM-Added	Candesartan vs. placebo	Symptomatic HF and EF \leq 40% on ACE inhibitors	CV death or hospital admission for HF	37.9	42.3	0.85	0.01
CHARM-Alternative	Candesartan vs. placebo	Symptomatic HF and EF \leq 40%, ACE-inhibitor intolerant	CV death or hospital admission for HF	33.0	40.0	0.70	<0.0001
CHARM-Preserved	Candesartan vs. placebo	Symptomatic HF and EF \leq 40%	CV death or hospital admission for HF	22.0	24.3	0.86	0.051
CHARM-Overall	Candesartan vs. placebo	Combined from above 3 trials	All-cause mortality	23.0	25	0.90	0.032

antagonists is not recommended because of the increased risk of renal dysfunction and hyperkalemia.¹ The specific drugs and doses proven to be effective in clinical trials should be used.

The role of ARBs as an adjunct to ACE inhibitors remains controversial. The CHARM-Added trial found the addition of candesartan to ACE inhibitor and β -blocker therapy produced incremental reductions in cardiovascular death and hospitalizations for heart failure, but did not improve overall survival.⁷⁶ In contrast, neither the VALIANT nor the Val-HeFT trials found additional benefit from the addition of valsartan to ACE-inhibitor treatment.^{47,74} These results suggest the addition of an ARB to optimal heart failure therapy (ACE inhibitors, β -blockers, diuretics, etc.) offers, at best, marginal benefits with increased risk of adverse effects. The current guidelines indicate that the addition of an ARB can be considered in patients who remain symptomatic despite receiving conventional heart failure pharmacotherapy. Some clinicians suggest that the addition of an aldosterone antagonist to ACE inhibitor and β -blocker therapy is preferred over that of an ARB. The proven survival benefit of aldosterone antagonists in patients with NYHA classes III to IV heart failure (Randomized Aldactone Evaluation Study [RALES] trial) and in post-MI patients with left ventricular systolic dysfunction (Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study [EPHESUS] trial), as discussed in the following section, supports this approach.^{16,17}

9 Aldosterone Antagonists Spironolactone and eplerenone are aldosterone antagonists that work by blocking the mineralocorticoid receptor, the target site for aldosterone. In the kidney, aldosterone antagonists inhibit sodium reabsorption and potassium excretion. Although the diuretic effects with low doses of aldosterone antagonists are minimal, the potassium-sparing effects can have significant consequences as discussed below. In the heart, aldosterone antagonists inhibit cardiac extracellular matrix and collagen deposition, thereby attenuating cardiac fibrosis and ventricular remodeling.⁸⁰ Spironolactone also interacts with androgen and progesterone receptors, which may lead to gynecomastia and other sexual side effects in some patients. Such adverse effects are less frequent with eplerenone owing to its low affinity for the progesterone and androgen receptors.

Evidence that ACE inhibitors incompletely suppress aldosterone provided the impetus for examining the benefits of adding an aldosterone antagonist to ACE inhibitor therapy.⁸¹ RALES randomized more than 1,600 patients with current or recent class IV heart failure to aldosterone blockade with spironolactone 25 mg/day or placebo.¹⁶ Patients were also treated with standard therapy, usually including an ACE inhibitor, loop diuretic, and digoxin. Those with a serum creatinine concentration above 2.5 mg/dL or a serum potassium concentration above 5 mEq/L were excluded. The study was stopped prematurely after an average followup of 24 months because of a significant 30% reduction in the primary end point of total mortality with spironolactone. Spironolactone reduced mortality as a consequence of both progressive heart failure and sudden cardiac death. Spironolactone also produced a 35% reduction in hospitalizations for worsening heart failure and significant symptomatic improvement, as assessed by changes in NYHA functional class. The low dose of spironolactone was well tolerated in RALES. The most common adverse effect was gynecomastia, which occurred in 10% of men on spironolactone, compared to 1% of men on placebo, and led to treatment discontinuation in 2% of patients. There were statistically (but not clinically) significant increases in serum creatinine (by 0.05 to 0.10 mg/dL) and potassium concentrations (by 0.30 mEq/L) with spironolactone. The incidence of serious hyperkalemia (>6 mEq/L) was minimal and did not differ between spironolactone- and placebo-treated groups.

More recently, the EPHESUS trial evaluated the effect of selective antagonism of the mineralocorticoid receptor with eplerenone in

patients with left ventricular dysfunction after MI.¹⁷ To be eligible for study participation, patients had to have either evidence of heart failure or diabetes. More than 6,600 patients were randomized within 3 to 14 days of MI to eplerenone, titrated to 50 mg/day, or placebo in addition to standard therapy, which usually included an ACE inhibitor, β -blocker, aspirin, and diuretics. As occurred in RALES, patients with serum creatinine concentrations greater than 2.5 mg/dL or serum potassium concentrations greater than 5 mEq/L were excluded. Treatment with eplerenone was associated with a significant 15% relative reduction in the risk for death from any cause and a 15% reduction in the risk of hospitalization from heart failure. Serious hyperkalemia occurred in 5.5% of eplerenone-treated patients and 3.9% of placebo-treated patients. Eplerenone was not associated with gynecomastia.

The benefits of aldosterone antagonists in heart failure are not just a result of the inhibition of aldosterone's actions in the heart resulting in inhibition of aldosterone-mediated cardiac fibrosis and ventricular remodeling. Recent evidence points to an important role of aldosterone antagonists in attenuating the systemic proinflammatory state and oxidative stress caused by aldosterone.^{14,80} And while spironolactone historically has been viewed as a diuretic, this is believed to contribute little to its benefits in heart failure, in part, because the doses used have minimal diuretic effect.¹⁶ Thus, as with ACE inhibitors and β -blockers, the data on aldosterone antagonists also support the neurohormonal model of heart failure.

The clinical trial data suggest that the use of aldosterone antagonists in heart failure is associated with minimal risk. However, data from clinical practice suggest otherwise. In particular, an observational study of approximately 1.3 million elderly patients in the Ontario Drug Benefit Program found that the spironolactone prescription rate increased approximately fourfold immediately after the publication of RALES.⁸² The increase in the prescription rate was accompanied by nearly threefold increases in the rate of hospital admissions and the rate of death related to hyperkalemia. Further evidence of spironolactone-induced hyperkalemia comes from small case series showing that 25% to 35% of patients treated outside the controlled clinical trial setting develop hyperkalemia (>5 mEq/L) and that 10% to 12% develop serious hyperkalemia.^{83,84}

Potential factors contributing to the high incidence of hyperkalemia in clinical practice include the initiation of aldosterone antagonists in patients with impaired renal function or high potassium concentrations and the failure to decrease or stop potassium supplements when starting aldosterone antagonists. Other risk factors for hyperkalemia include diabetes, older age, inadequate laboratory monitoring, and concomitant use of high-dose ACE inhibitors, β -blockers, NSAIDs, or cyclooxygenase-2 inhibitors. The ACC/AHA recently recommended strategies to minimize the risk for hyperkalemia with aldosterone antagonists in heart failure.¹ Table 16-8 summarizes these strategies. Chief among these recommendations is to avoid aldosterone antagonists in patients with renal dysfunction. It is important to emphasize here that serum creatinine may overestimate renal function in the elderly and in patients with decreased muscle mass, in whom creatinine clearance should serve as a guide for the appropriateness of aldosterone antagonist therapy. The risk for hyperkalemia is dose dependent, and the morbidity and mortality reductions with aldosterone antagonists in clinical trials occurred at low doses (i.e., spironolactone 25 mg/day and eplerenone 50 mg/day). Therefore, the doses of aldosterone antagonists should be limited to those associated with beneficial effects so as to decrease the risk for hyperkalemia.

Only 10% of RALES participants were taking β -blockers at baseline because the benefits of β -blockers in heart failure were not appreciated fully at the time the trial began.¹⁶ β -Blockers inhibit plasma renin release and may provide additional suppression of the renin-angiotensin-aldosterone system when used with ACE inhib-

TABLE 16-8 Recommended Strategies for Reducing the Risk for Hyperkalemia with Aldosterone Antagonists

- Avoid starting aldosterone antagonists in patients with any of the following:
 - Serum creatinine concentration >2.0 in women or >2.5 mg/dL in men or a creatinine clearance <30 mL/min
 - Recent worsening of renal function
 - Serum potassium concentration ≥ 5.0 mEq/L
 - History of severe hyperkalemia
- Start with low doses (12.5 mg/day for spironolactone and 25 mg/day for eplerenone), especially in the elderly and in those with diabetes or a creatinine clearance <50 mL/min
- Decrease or discontinue potassium supplements when starting an aldosterone antagonist
- Avoid concomitant use of NSAIDs or COX-2 inhibitors
- Avoid concomitant use of high-dose ACE inhibitors or ARBs
- Avoid triple therapy with an ACE inhibitor, ARB, and aldosterone antagonist
- Monitor serum potassium concentrations and renal function within 3 days and 1 week after the initiation or dose titration of an aldosterone antagonist or any other medication that could affect potassium homeostasis; thereafter, potassium concentrations and renal function should be monitored monthly for the first 3 months, and then every 3 months
- If potassium exceeds 5.5 mg/dL at any point during therapy, discontinue any potassium supplementation or, in the absence of potassium supplements, reduce or stop aldosterone antagonist therapy
- Counsel patients to
 - Limit intake of high-potassium-containing foods and salt substitutes
 - Avoid the use of over-the-counter nonsteroidal antiinflammatory drugs
 - Temporarily discontinue aldosterone antagonist therapy if diarrhea develops or diuretic therapy is interrupted

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; COX, cyclooxygenase; NSAIDs, nonsteroidal antiinflammatory drugs.

itors. Thus, there has been some speculation about whether spironolactone will provide further benefit in patients receiving both ACE inhibitors and β -blockers. However, data from EPHESUS provide some clarity to this issue, as the majority of EPHESUS participants were on β -blockers at baseline and the trial still demonstrated significant reductions in mortality with the addition of eplerenone.¹⁷

Current guidelines state that it is reasonable to add an aldosterone antagonist to standard therapy in select patients provided that potassium and renal function can be carefully monitored.¹ Based on data from RALES and EPHESUS, low-dose aldosterone antagonists may be appropriate for two groups of patients: those with moderately severe to severe heart failure who are receiving standard therapy and those with left ventricular dysfunction early after MI.¹ For patients who fall outside the populations studied in these clinical trials, there are no clear guidelines on aldosterone antagonist use. Trials to address the efficacy of aldosterone antagonism in patients with mild to moderate heart failure symptoms or in patients with preserved left ventricular systolic function are ongoing. Although there are currently no data on the use of aldosterone antagonists in patients with class I, class II, or stable class III heart failure, it might be reasonable to consider their use in these patients who require potassium supplementation. The premise for use in this setting would be that it might be possible to reduce or eliminate potassium supplementation while potentially providing additional benefit with respect to altering the disease course.

9 Digoxin In 1785, William Withering was the first to report extensively on the use of foxglove (*Digitalis purpurea*) for the treatment of dropsy (i.e., edema). Although digitalis glycosides have been in clinical use for more than 200 years, not until the 1920s were they clearly demonstrated to have a positive inotropic effect on the heart. Furthermore, it was not until the late 1980s that clinical trials were conducted to critically evaluate the role of digoxin in the therapy of

chronic heart failure. The results of the Digitalis Investigational Group (DIG) trial helped clarify the role of digoxin in this setting.⁸⁵ The view of digoxin has also shifted over the past decade. Although it was historically considered useful in heart failure because of its positive inotropic effects, it now seems clear that its real benefits in heart failure are related to its neurohormonal modulating effects.

The efficacy of digoxin in patients with heart failure and supraventricular tachyarrhythmias such as atrial fibrillation is well established and widely accepted. Its role in heart failure patients with normal sinus rhythm has been considerably more controversial. Until the 1980s, most data supporting efficacy of digoxin in these patients came from anecdotal evidence and seriously flawed or uncontrolled studies. Since then, a number of clinical trials have shown that digoxin improves LVEF, quality of life, exercise tolerance, and heart failure symptoms.^{86,87} However, these studies involved small numbers of patients followed for short time periods with many of the patients being withdrawn from preexisting digoxin treatment upon entering the trial. Although these trials demonstrated hemodynamic and symptomatic improvement in heart failure patients receiving digoxin, an unresolved issue was the unknown effect of digoxin on mortality. This was of particular concern given the increased mortality seen with other positive inotropic drugs, and finally led to organization and performance of the DIG trial to determine the effects of digoxin on survival in patients with heart failure in sinus rhythm.⁸⁵

The DIG trial was a double-blind, randomized, placebo-controlled trial with the primary end point of all-cause mortality.⁸⁵ Patients ($n = 6,800$) with heart failure symptoms and an ejection fraction of 45% or less were eligible and were followed for a mean of 37 months. Most patients received background therapy with diuretics and ACE inhibitors. The mean serum digoxin concentration achieved was 0.8 ng/mL after 12 months of therapy. No significant difference in all-cause mortality was found between patients receiving digoxin and placebo (34.8% and 35.1%, respectively). A trend toward lower mortality as a consequence of worsening heart failure was observed in the digoxin group, although this was offset by a trend toward an increased mortality from other cardiovascular causes (presumably arrhythmias) in patients receiving digoxin. Hospitalizations for worsening heart failure were reduced 28% by digoxin compared to placebo ($P < 0.001$), whereas hospitalizations for other cardiovascular causes were increased in the digoxin group. In all, 64.3% of digoxin-treated patients were hospitalized compared to 67.1% of patients receiving placebo ($P = 0.006$). Therefore, DIG is the first trial to show that a positive inotropic agent does not increase mortality and actually decreases morbidity in patients with heart failure.

Although digoxin does not improve survival in heart failure patients, multiple post-hoc analyses of data from studies evaluating the effect of digoxin withdrawal have helped clarify the role of digoxin use for patients in sinus rhythm.⁸⁶ Collectively, these studies suggested the drug produces important symptomatic benefits and that digoxin withdrawal increased the risk of treatment failure and deterioration of exercise capacity and ejection fraction. Furthermore, the risk of symptomatic exacerbation of heart failure after digoxin discontinuation was highest in patients with the most severe symptoms.⁸⁶ Based on this evidence, digoxin can be beneficial in patients with symptomatic or stage C heart failure and reduced LVEF in addition to standard therapy to reduce heart failure hospitalizations. Furthermore, digoxin should not be used in patients with a normal LVEF, sinus rhythm, and no history of heart failure symptoms, because the risk is not balanced by any known benefit.¹

Two retrospective analyses of the combined PROVED/RADIANCE database⁸⁸ and the DIG Trial database⁸⁹ offer additional insights into the clinical benefit of low serum digoxin concentrations. While all patients in the Prospective Randomized Study of Ventricular Failure and Efficacy of Digoxin (PROVED) and Randomized Assessment of Digoxin on Inhibitors of the Angiotensin

Converting Enzyme (RADIANCE) trials who continued to take digoxin did significantly better than those who were withdrawn, those who had plasma digoxin concentrations between 0.5 and 0.9 ng/mL were just as likely to be free of worsening heart failure as those with higher plasma concentrations. Retrospective analysis of the DIG trial database suggests that a serum digoxin concentration of 0.5 to 0.8 ng/mL may be associated with a reduction in mortality, whereas higher concentrations may increase mortality.⁸⁹ In another post-hoc analysis of the DIG trial, digoxin therapy was associated with an increased risk of death in women, but not in men.⁹⁰ This finding was refuted in another analysis of the same data which demonstrated that a beneficial effect of digoxin was evident at serum concentrations from 0.5 to 0.9 ng/mL, whereas serum concentrations greater than or equal to 1.2 ng/mL were harmful.⁹¹ More recently, the most comprehensive reanalysis of the DIG trial database found that serum concentrations of 0.5 to 0.9 ng/mL were associated with lower mortality, all-cause hospitalizations, and heart failure hospitalizations, whereas serum concentrations greater than or equal to 1 ng/mL were associated with lower heart failure hospitalizations with no effect on mortality. Serum concentrations of 0.5 to 0.9 ng/mL had no interaction with LVEF greater than 45% or gender.⁹² Of the 7,788 patients randomized in the DIG trial, 988 patients had a LVEF greater than 45%; digoxin had no effect on mortality or hospitalization in these patients.⁹³

These results suggest that most of the benefit from digoxin is achieved at low plasma concentrations and little additional effect is achieved with higher doses. Thus, for most patients, the target digoxin plasma concentration should be 0.5 to 1.0 ng/mL. This more conservative target would also be expected to decrease the risk of adverse effects from digoxin toxicity; in fact, more recent assessment of the rate of digoxin toxicity suggests a significant decline in the overall incidence.⁹⁴ In most patients with normal renal function, this plasma concentration range can be achieved with a daily dose of 0.125 mg. Patients with decreased renal function, the elderly, and those who are receiving interacting drugs (e.g., amiodarone) should receive 0.125 mg every other day. In patients with atrial fibrillation and a rapid ventricular response, the historic practice of increasing digoxin doses (and concentrations) until rate control is achieved is no longer recommended. Digoxin alone is often ineffective to control ventricular response in patients with atrial fibrillation and increasing the dose only increases the risk of toxicity. Digoxin combined with a β -blocker or amiodarone is superior to either agent alone for controlling ventricular response in patients with atrial fibrillation and heart failure.⁹⁵ Consequently, target digoxin plasma concentrations are the same regardless of whether the patient is in sinus rhythm or atrial fibrillation. Several equations and nomograms have been proposed to estimate digoxin maintenance doses based on estimated renal function for a particular patient and population pharmacokinetic parameters. These methods are extensively reviewed elsewhere.⁹⁶ Recently, investigators developed a digoxin dosing nomogram that targets a lower digoxin plasma concentration.⁹⁷ In the absence of supraventricular tachyarrhythmias, a loading dose is not indicated because digoxin is a mild inotropic agent that will produce gradual effects over several hours, even after loading.

Digoxin's place in the pharmacotherapy of chronic heart failure can be summarized for two patient groups. In patients with heart failure and supraventricular tachyarrhythmias such as atrial fibrillation, it should be considered early in therapy to help control ventricular response rate. For patients in normal sinus rhythm, although digoxin does not improve survival, its effects on symptom reduction and clinical outcomes are evident in patients with mild to severe heart failure. Consequently, it should be used in conjunction with other standard heart failure therapies, including diuretics, ACE inhibitors, and β -blockers, in patients with symptomatic heart failure to reduce hospitalizations.

10 Nitrates and Hydralazine Nitrates and hydralazine were combined originally in the treatment of heart failure because of their complementary hemodynamic actions. Nitrates, by serving as nitric oxide donors, activate guanylate cyclase to increase cyclic guanosine monophosphate in vascular smooth muscle. This results in venodilation and reductions in preload. Hydralazine is a direct-acting vasodilator that acts predominantly on arterial smooth muscle to reduce SVR and increase stroke volume and cardiac output (see Fig. 16–1). Hydralazine also has antioxidant properties and appears to prevent nitrate tolerance.⁹⁸ Evidence also suggests that the combination of hydralazine and nitrates may exert beneficial effects beyond their hemodynamic actions by interfering with the biochemical processes associated with heart failure progression.^{1,99}

The efficacy of the combination of hydralazine and isosorbide dinitrate (ISDN) was evaluated in three large, randomized heart failure trials. The first trial predated the use of ACE inhibitors and β -blockers in heart failure and found that the combination of hydralazine 75 mg and ISDN 40 mg, each given four times daily, reduced mortality in patients receiving diuretics and digoxin compared to placebo.¹⁰⁰ However, a subsequent trial comparing the combination with an ACE inhibitor demonstrated greater mortality reduction with the ACE inhibitor.¹⁰¹ Post-hoc analysis of these trials suggested that the combination of hydralazine and ISDN was particularly effective in African Americans, and led to examining the efficacy of adding the combination to standard therapy in this racial group.

The African American Heart Failure Trial (A-HeFT) randomized 1,050 self-identified African Americans with class III or IV heart failure to hydralazine plus ISDN or placebo, each in addition to standard therapy, usually including an ACE inhibitor (or ARB), β -blocker, and diuretic, with or without digoxin and spironolactone.⁹⁹ The trial used a fixed dose combination product, BiDil®, that contains hydralazine 37.5 mg and ISDN 20 mg. Therapy was initiated as a single tablet given three times daily, then titrated to two tablets (hydralazine 75 mg/ISDN 40 mg) three times daily if tolerated. The trial was terminated early after a mean followup of 10 months because of a significant (43%) reduction in all-cause mortality in patients receiving hydralazine/ISDN compared to placebo. The primary composite end point of mortality, hospitalizations for heart failure, and quality of life was also significantly improved with the combination product. Based on these results, BiDil® was approved by the FDA to treat heart failure exclusively in African Americans.

The mechanism for the beneficial effects of hydralazine/ISDN is believed to relate to an increase in nitric oxide bioavailability secondary to nitric oxide donation from ISDN and a hydralazine-mediated reduction in oxidative stress.⁹⁸ Nitric oxide attenuates myocardial remodeling and may play a protective role in heart failure.¹⁰² It is suggested that African Americans have less nitric oxide than do non-African Americans, and thus, may derive particular benefit from therapy that enhances nitric oxide bioavailability. Whether the benefits of adding hydralazine/ISDN to standard therapy extend to non-African Americans remains to be determined.

Guidelines from the Heart Failure Society of America recommend the addition of hydralazine and ISDN as part of standard therapy, including ACE inhibitors, in African Americans with moderately severe to severe heart failure.³³ The addition of hydralazine and ISDN is also reasonable in patients of other ethnicities who continue to have symptoms despite optimized therapy with an ACE inhibitor (or ARB) and β -blocker.¹ For patients who are unable to tolerate an ACE inhibitor because of cough or angioedema, an ARB is recommended as the first-line alternative.¹ Hydralazine and ISDN is appropriate as first-line therapy in patients unable to tolerate either an ACE inhibitor or ARB because of renal insufficiency, hyperkalemia, or possibly hypotension.

There are several potential obstacles to successful therapy with hydralazine and ISDN in heart failure. First is the need for frequent

dosing, with the fixed-dose combination dosed three times daily and the individual drugs dosed four times daily in clinical trials. Second, adverse effects are common with hydralazine/ISDN, with headache, dizziness, and gastrointestinal distress occurring more frequently with hydralazine/ISDN than with placebo in clinical trials.^{99,100} A third potential obstacle is the increased cost of the fixed-dose combination product compared to the individual drugs purchased separately, which may preclude the use of the combination product in some patients. Treatment with the two separate drugs rather than the combination product may compromise adherence to therapy. Thus, if therapy with hydralazine and ISDN is deemed appropriate, patients may need continual reinforcement to maintain good medication adherence, especially if the individual drugs are used. It is important to recognize that none of the above trials incorporated a nitrate-free interval in the dosing regimen.

Treatment of Concomitant Disorders

Heart failure is often accompanied by other disorders whose natural history or therapy may affect morbidity and mortality. In selected patients, optimal management of these concomitant disorders may have a profound impact on heart failure symptoms and outcomes.

Hypertension Although ischemic heart disease has replaced hypertension as the most common cause of heart failure, still nearly two-thirds of heart failure patients have current hypertension or a previous history of hypertension.¹ Hypertension can contribute directly to the development of heart failure and also contributes indirectly by increasing the risk of coronary artery disease. Pharmacotherapy of hypertension in patients with heart failure should initially involve agents that can treat both disorders such as ACE inhibitors, β -blockers, and diuretics. If control of hypertension is not achieved after optimizing treatment with these agents, the addition of an ARB, aldosterone antagonist, isosorbide dinitrate/hydralazine, or a second-generation calcium channel blocker such as amlodipine (or possibly felodipine) should be considered. Medications that should be avoided include the calcium channel blockers with negative inotropic effects (e.g., verapamil, diltiazem, and most dihydropyridines) and direct-acting vasodilators (e.g., minoxidil) that cause sodium retention.

Angina Coronary artery disease is the most common heart failure etiology. Consequently, appropriate management of coronary disease and its risk factors is an important strategy for the prevention and treatment of heart failure. Coronary revascularization should be strongly considered in patients with both heart failure and angina.¹ Pharmacotherapy of angina in patients with heart failure should use drugs that can successfully treat both disorders. Nitrates and β -blockers are effective antianginal agents and are the preferred agents for patients with both disorders as they may improve hemodynamics and clinical outcomes.¹ It should be noted that the antianginal effectiveness of these agents may be significantly limited if fluid retention is not controlled with diuretics. Similar to their use in hypertension, both amlodipine and felodipine appear to be safe to use in this setting. Optimization of other treatments for secondary prevention of coronary and other atherosclerotic vascular disease should also be considered.³⁷ Although their precise role in the treatment of heart failure awaits the results of additional studies, initial evidence suggests statins might decrease the risk of heart failure hospitalizations and death, regardless of heart failure etiology.²⁴

Atrial Fibrillation Atrial fibrillation is the most frequently encountered arrhythmia and it is commonly found in patients with heart failure, affecting 10% to 30% of patients.¹ The high incidence of atrial fibrillation in the heart failure population is not surprising as each of these two disorders predisposes to the other and they share many risk factors, including coronary artery disease and

hypertension. The presence of atrial fibrillation in patients with heart failure is associated with a worse long-term prognosis.¹ The combination of atrial fibrillation and heart failure may exert a number of detrimental effects, including increased risk of thromboembolism secondary to stasis of blood in the atria, a reduction in cardiac output because of loss of the atrial contribution to ventricular filling, and hemodynamic compromise from the rapid ventricular response. Moreover, heart failure exacerbations and atrial fibrillation are closely linked and it is often difficult to determine which disorder caused the other. For example, worsening heart failure results in volume overload which, in turn, causes atrial distension and increases the risk of atrial fibrillation. Similarly, atrial fibrillation with a rapid ventricular response can reduce cardiac output and lead to heart failure exacerbation. Thus, optimal management of both conditions is required with careful attention paid to control of ventricular response and anticoagulation for stroke prevention (see Chap. 19).⁹⁵

Recent studies suggest that ACE inhibitors, ARBs, and β -blockers decrease the incidence of atrial fibrillation in patients with heart failure, providing further support for their use in these patients.^{103,104} Digoxin is frequently used to slow ventricular response in patients with heart failure and atrial fibrillation. However, it is more effective at rest than with exercise and it does not affect the progression of heart failure. β -Blockers are more effective than digoxin and have the added benefits of improving morbidity and mortality. Combination therapy with digoxin and a β -blocker may be more effective for rate control than either agent used alone. Calcium channel blockers with negative inotropic effects, such as verapamil or diltiazem, should be avoided. Amiodarone is a reasonable alternative for rate control in those patients who are not responding to digoxin and/or β -blockers or who have contraindications to these agents.⁹⁵ Appropriate selection of antithrombotic therapy that considers the presence of risk factors for thromboembolism in an individual patient is also required.⁹⁵

Because of the close association between atrial fibrillation, heart failure exacerbations, and hospitalizations, many clinicians prefer maintenance of sinus rhythm with antiarrhythmic drugs to the rate-control approach in the treatment of patients with both disorders. However, it must be noted that the benefits of restoring and maintaining sinus rhythm remain unclear in this population and is not without risk. Although the Atrial Fibrillation Follow-up Investigation of Rhythm Management (AFFIRM) study showed no difference in outcomes between the rhythm control and rate control approaches, less than 10% of the patients in this study had significant left ventricular dysfunction.¹⁰⁵ Several ongoing clinical trials should help clarify the best approach to these difficult-to-manage patients. In general, amiodarone is the preferred agent if the rhythm control approach is taken. Although it has many noncardiac toxicities, amiodarone does not have cardiodepressant or significant proarrhythmic effects and appears to be safe in heart failure. Dofetilide also appears to be safe and effective in this population. Class I antiarrhythmics should be avoided.⁹⁵

Diabetes Diabetes is highly prevalent in the heart failure population, with current estimates indicating it is present in approximately one-third of heart failure patients.^{30,106} As an important risk factor for coronary artery disease, diabetes directly contributes to the development of heart failure. Importantly though, diabetes is a risk factor for heart failure independent of coronary artery disease or hypertension, is associated with hastened heart failure progression, and is a significant predictor of mortality in patients with heart failure.¹⁰⁶

Pharmacotherapy of diabetes in heart failure patients is complicated by concerns about adverse effects associated with metformin and the thiazolidinedione (TZD) drugs (rosiglitazone and pioglitazone). The beneficial effects of these agents on glucose control and

cardiovascular risk factors lead to their widespread use in patients with heart failure in spite of the warnings in the product labeling against their use.¹⁰⁶ The metformin product labeling states that it is contraindicated for use in patients with heart failure requiring pharmacologic treatment because of the purported risk of lactic acidosis. However, data from retrospective analyses involving more than 3,000 patients suggest that metformin is safe (no reports of lactic acidosis) in patients with heart failure.¹⁰⁷ In addition, these reports show that metformin treatment is associated with decreased mortality and hospitalizations compared to conventional antihyperglycemic therapy.¹⁰⁷ Consequently, some clinicians suggest that the contraindication to metformin use in heart failure should be reexamined. However, the lack of prospective data about the safety and efficacy of metformin in patients with heart failure indicates that if the drug is used, it should be used cautiously with careful monitoring of volume status and renal function. Although the mechanism(s) are presently unclear, the TZDs are associated with weight gain, peripheral edema, and heart failure. The TZD package insert indicates these agents should not be used in patients with class III or IV heart failure because they may cause intravascular volume expansion and heart failure exacerbation. Most clinical trials with these drugs excluded patients with moderate to severe heart failure, thus the evidence supporting this precaution comes mainly from retrospective analyses and case reports. Because of the potential risk, a recent consensus statement indicates TZDs should not be used in patients with NYHA class III or class IV heart failure.³⁰ TZDs should be used cautiously in patients with class I or II symptoms, with close observation needed to detect weight gain, edema formation, or heart failure exacerbation.³⁰

Drug Class Information

7 Diuretics⁴⁴ Loop diuretics, as described earlier, represent the typical diuretic therapy for patients with heart failure because of their potency and, as such, are the only diuretics discussed here. There are currently three loop diuretics available that are used routinely: furosemide, bumetanide, and torsemide. They share many similarities in their pharmacodynamics, with their differences being largely pharmacokinetic in nature. Table 16–5 shows the relevant information on the loop diuretics. Following oral administration, the peak effect with all the agents occurs in 30 to 90 minutes, with duration of 2 to 3 hours (slightly longer for torsemide). Following intravenous administration, the diuretic effect begins within minutes. All three drugs are highly (>95%) bound to serum albumin and enter the nephron by active secretion in the proximal tubule. The magnitude of effect is determined by the peak concentration achieved in the nephron, and there is a threshold concentration that must be achieved before any diuresis is seen.

The biggest difference between the agents is bioavailability. Bioavailability of bumetanide and torsemide is essentially complete (80% to 100%), whereas furosemide bioavailability exhibits marked intra- and interpatient variability. Furosemide bioavailability ranges from 10% to 100%, with an average of 50%. Thus, if bioequivalent intravenous and oral doses are desired, oral furosemide doses should be approximately double that of the intravenous dose, whereas intravenous and oral doses are the same for torsemide and bumetanide. Coadministration of furosemide and bumetanide with food can decrease bioavailability significantly, whereas food has no effect on bioavailability of torsemide. The intraabdominal congestion that can occur in heart failure also may slow the rate (and thus decrease the peak concentration) of furosemide, which can reduce the diuretic's efficacy. Thus furosemide is most problematic with respect to rate and extent of absorption and the factors that influence it, whereas torsemide has the least-variable bioavailability.

Recent data suggest that these differences in bioavailability and variability may have clinical implications. For example, several stud-

ies suggest that torsemide is absorbed reliably and is associated with better outcomes than the more variably absorbed furosemide.^{108,109} Torsemide is preferred in patients with persistent fluid retention despite high doses of other loop diuretics. And while the costs of torsemide exceed those of furosemide, pharmacoeconomic analyses suggest that the costs of care are similar or less with torsemide.¹⁰⁹ These data require confirmation in controlled, double-blinded clinical trials but provide preliminary evidence that the more reliably absorbed loop diuretics may be superior to furosemide.

The loop diuretics exhibit a ceiling effect in heart failure, meaning that once the ceiling dose is reached, no additional response is achieved by increasing the dose. Thus, when this dose is reached, additional diuresis is achieved by giving the drug more often (twice daily or occasionally three times daily) or by giving combination diuretic therapy. Table 16–5 lists the ceiling doses. Multiple daily dosing achieves a more sustained diuresis throughout the day. When dosed two or three times daily, the first dose is usually given first thing in the morning and the final dose in late afternoon/early evening.

Diuretics cause a variety of metabolic abnormalities, with severity related to the potency of the diuretic. Chapter 15 has a detailed discussion on the adverse effects of diuretic therapy. Hypokalemia is the most common metabolic disturbance with thiazide and loop diuretics, which in heart failure patients may be exacerbated by hyperaldosteronism. Hypokalemia increases the risk for ventricular arrhythmias in heart failure and is especially worrisome in patients receiving digoxin. Hypokalemia is often accompanied by hypomagnesemia. Because adequate magnesium is necessary for entry of potassium into the cell, cosupplementation with both magnesium and potassium may be necessary to correct the hypokalemia. Concomitant ACE inhibitor (or ARB) and/or aldosterone antagonist therapy may help to minimize diuretic-induced hypokalemia because these drugs tend to increase serum potassium concentration through their inhibitory effect on aldosterone secretion. Nonetheless, the serum potassium concentration should be monitored closely in heart failure patients and supplemented appropriately when needed. In addition to metabolic abnormalities, a recent post-hoc analysis of the DIG trial suggested that chronic diuretic use was associated with increased risk of mortality and hospitalization.¹¹⁰ These findings must be interpreted with caution because this trial was not designed to evaluate outcomes associated with diuretic therapy. However, they do serve to remind clinicians of the importance of appropriate patient selection and monitoring when using diuretic therapy.

5 Angiotensin-Converting Enzyme Inhibitors A number of ACE inhibitors are available currently in the United States; Table 16–9 summarizes those commonly used in the treatment of patients with heart failure. Although ACE inhibitors vary in their chemical structure (e.g., sulfhydryl- vs. non-sulfhydryl-containing agents) and tissue affinity, the major differences in the ACE inhibitors are not in these pharmacologic properties but in their pharmacokinetic properties.¹³ Although it appears that mortality reduction with ACE inhibitors is probably a drug class effect, not all ACE inhibitors that are FDA approved for treatment of heart failure have been evaluated for their effects on mortality in heart failure. Thus it seems most prudent to use those agents that have been documented to reduce morbidity and mortality because the dose required for this effect has been documented.¹ Table 16–9 also summarizes the target doses for survival benefit.

To minimize the risk of hypotension and renal insufficiency, ACE inhibitor therapy should be started with low doses followed by gradual titration to the target doses as tolerated.¹ Asymptomatic hypotension should not be considered a contraindication to initiation of an ACE inhibitor although initiation or dose increases in patients with systolic blood pressures less than 90 to 100 mm Hg should be done cautiously. Renal function and serum potassium

TABLE 16-9 Angiotensin-Converting Enzyme Inhibitors Routinely Used for the Treatment of Heart Failure

Generic Name	Brand Name	Initial Dose	Target Dosing—Survival Benefit ^a	Prodrug	Elimination ^b
Captopril	Capoten	6.25 mg tid	50 mg tid	No	Renal
Enalapril	Vasotec	2.5–5 mg bid	10 mg bid	Yes	Renal
Lisinopril	Zestril, Prinivil	2.5–5 mg daily	20–40 mg daily ^c	No	Renal
Quinapril	Accupril	10 mg bid	20–40 mg bid ^d	Yes	Renal
Ramipril	Altace	1.25–2.5 mg bid	5 mg bid	Yes	Renal
Fosinopril	Monopril	5–10 mg daily	40 mg daily ^d	Yes	Renal/hepatic
Trandolapril	Mavik	0.5–1 mg daily	4 mg daily	Yes	Renal/hepatic
Perindopril	Aceon	2 mg daily	8–16 mg daily ^d	Yes	Renal/hepatic

^aTarget doses associated with survival benefits in clinical trials.

^bPrimary route of elimination.

^cNote that in the Assessment of Treatment with Lisinopril and Survival (ATLAS) trial (Circulation 1999;100:2312–2318), no significant difference in mortality was found between low dose (~5 mg/day) and high dose (~35 mg/day) lisinopril therapy.

^dEffects on mortality have not been evaluated.

should be evaluated within 1 to 2 weeks after therapy is started with subsequent periodic assessments, especially after dose increases. Careful attention to appropriate doses of diuretics is important as fluid overload may blunt the beneficial effects of ACE inhibitors and overdiuresis increases the risk of hypotension and renal insufficiency. After titration of the drug to the target dose, most patients tolerate chronic therapy with few complications. Although symptoms may improve within a few days of initiating therapy, it may take weeks to months before the full benefits are apparent. Even if symptoms do not improve, long-term ACE inhibitor therapy should be continued to reduce the risk of mortality and hospitalization.

Because ACE inhibitors were the first agents to show improvements in heart failure survival and were frequently used as background therapy in clinical trials of other medications, they are often used as the initial therapy in patients with left ventricular systolic function. Traditionally, after titration of the ACE inhibitor dose, the addition of β -blockers was considered. The expected ACE inhibitor-mediated decrease in blood pressure made some clinicians reluctant to initiate β -blocker therapy. Because of the impressive benefits of β -blockers, initiation of β -blocker therapy should not be delayed in patients who fail to reach target ACE inhibitor doses.¹ Because activation of the SNS occurs before that of the RAAS and is an important stimulus for RAAS activation, there is debate over whether ACE inhibitors or β -blockers should be used as initial therapy. The results of the previously discussed CIBIS III trial did not provide compelling evidence to support initiation of β -blockers prior to ACE inhibitors.⁶⁸ Consequently, in most patients, ACE inhibitors should be the initial therapy, but it is important to remember that the greatest benefit is seen when both an ACE inhibitor and β -blocker are used.

Because of the high prevalence of coronary artery disease in patients with heart failure, aspirin is frequently coadministered with ACE inhibitors. Several retrospective cohort analyses suggest that aspirin may attenuate the hemodynamic and mortality benefits of ACE inhibitors.¹¹¹ The postulated mechanism of this interaction involves opposing effects on synthesis of vasodilatory prostaglandins. The ACE inhibitor-mediated increase in bradykinin increases the synthesis of vasodilatory prostaglandins that have favorable hemodynamic benefits in heart failure. Because of aspirin's effect on prostaglandin synthesis, this potentially beneficial action of ACE inhibitors may be negated. However, in contrast with studies that showed an ACE inhibitor-aspirin interaction, other investigators have found no interaction, even in patients without coronary artery disease or with impaired renal function.^{111,112} Because there is no prospective evidence confirming an interaction between these agents, it is currently recommended that the decision to use each of these medications be made based on whether an individual patient has indications for each drug. Use of aspirin doses of 160 mg per day or less should be considered.

Adverse Effects. The primary adverse effects of ACE inhibitor therapy are secondary to their major pharmacologic effects of suppressing angiotensin II and increasing bradykinin. The reductions in angiotensin II are associated with hypotension and functional renal insufficiency which are the most common adverse effects observed with ACE inhibitors. Hypotension may be asymptomatic or manifested as dizziness, lightheadedness, presyncope, or syncope. It occurs most commonly early in therapy or after an increase in dose, although it may occur at any time during treatment. Risk factors for hypotension include hyponatremia (serum sodium <130 mEq/L), hypovolemia, and overdiuresis.¹ The occurrence of hypotension may be minimized by initiating therapy with lower ACE inhibitor doses and/or temporarily withholding or reducing the dose of diuretic, and liberalizing salt and fluid intake.¹ An often overlooked solution to hypotension is to space the administration times of vasoactive medications (e.g., diuretics and β -blockers) throughout the day so that these medications are not all administered at or near the same time. Many patients who experience symptomatic hypotension early in therapy are still good candidates for long-term treatment if risk factors for low blood pressure are addressed.

Functional renal insufficiency is manifested as increases in serum creatinine and blood urea nitrogen. As cardiac output and renal blood flow decline, renal perfusion is maintained by the vasoconstrictor effect of angiotensin II on the efferent arteriole. Patients most dependent on this system for maintenance of renal perfusion (and therefore most likely to develop functional renal insufficiency with ACE inhibitors) are those with severe heart failure, hypotension, hyponatremia, volume depletion, bilateral renal artery stenosis, and concomitant use of NSAIDs.¹¹³ Sodium depletion, usually secondary to diuretic therapy, is the most important factor in the development of functional renal insufficiency with ACE inhibitor therapy. Renal insufficiency therefore can be minimized in many cases by reduction in diuretic dosage or liberalization of sodium intake. Increases in serum creatinine of 10% to 20% from baseline are commonly observed after initiation of ACE inhibitor therapy. In some patients, the serum creatinine will return to baseline levels without a reduction in ACE inhibitor dose.¹¹³ Increases in serum creatinine of >0.5 mg/dL if the baseline creatinine is <2.0 mg/dL or >1.0 mg/dL if the creatinine is >2.0 mg/dL, should prompt clinicians to reconsider ACE therapy and evaluate potential causes for the abrupt decline in renal function.¹¹³ Because renal dysfunction with ACE inhibitors is secondary to alterations in renal hemodynamics, it is almost always reversible upon discontinuation of the drug.¹¹³

Careful dose titration can minimize the risks of hypotension and transient worsening of renal function. Thus usual initial doses should be about one-fourth the final target dose with slow upward dose titration over several days based on blood pressure and serum

creatinine. In certain patients, especially those hospitalized patients who seem to be at high risk for hypotension or worsening of renal function, it also may be advisable to initiate therapy with a short-acting agent such as captopril. This will help minimize the duration of adverse effects should they occur. Once stabilized on ACE inhibitor therapy with captopril, the patient can then be switched to a longer-half-life drug.

Retention of potassium with ACE inhibitor therapy can occur and is caused by the reduced feedback of angiotensin II to stimulate aldosterone release. Hyperkalemia is most likely to occur in patients with renal insufficiency and in those taking concomitant potassium supplements, potassium-containing salt substitutes, or potassium-sparing diuretic therapy (including an aldosterone antagonist), especially if they have diabetes.¹¹³ The more widespread use of aldosterone antagonists (e.g., spironolactone) in patients with heart failure may increase the risk of hyperkalemia.⁸²

ACE inhibitors are also associated with other important adverse effects. A dry, hacking cough occurs with a similar frequency (5% to 15% of patients) with all the agents and is related to bradykinin accumulation. The cough is usually nonproductive, occurs within the first few months of therapy, resolves within 1 to 2 weeks of drug discontinuation, and reappears with rechallenge. Because cough occurs in up to 40% of patients with heart failure, independent of ACE inhibitor use, it is important to rule out other potential causes of cough, such as pulmonary congestion. Because cough is a bradykinin-mediated effect, replacement of ACE inhibitor therapy with an ARB would be reasonable in those patients who cannot tolerate the cough. Angioedema is a rare, but potentially life-threatening complication that is also believed to be related to bradykinin accumulation. It may occur more frequently in African Americans than in other populations.¹ Use of ACE inhibitors is contraindicated in patients with a history of angioedema. ARBs may be an alternative therapy in patients with ACE inhibitor-induced angioedema, although caution is advised as rare cross-reactivity is reported.^{1,77,79} ACE inhibitors are contraindicated during the second and third trimesters of pregnancy because of the increased risk of fetal renal failure, intrauterine growth retardation, and other congenital defects. A recent analysis using a Medicaid database of nearly 30,000 patients suggests that first trimester use of ACE inhibitors should also be avoided as the risk of major congenital defects was increased 2.7-fold in infants exposed to these agents during the first trimester.¹¹⁴

5 Angiotensin II Receptor Blockers Although ACE inhibitors remain the agents of first choice to treat stage C heart failure with reduced LVEF, ARBs approved for the treatment of heart failure are now the recommended alternatives in patients who are unable to tolerate an ACE inhibitor.¹ Although seven ARBs are currently on the market, only two, candesartan and valsartan, are approved for the treatment of heart failure. The use of these two agents is supported by clinical trial data that document a target dose associated with improved survival and other important outcomes in patients with decreased LVEF.^{47,74,75} Thus, candesartan or valsartan are the preferred agents in patients with heart failure, whether used alone or in combination with ACE inhibitors. ARBs are also alternative to ACE inhibitors in patients with stages A or B heart failure.¹

The clinical use of ARBs is also similar to that of ACE inhibitors. Therapy should be initiated at low doses (candesartan 4 to 8 mg once daily; valsartan 20 to 40 mg twice daily) and then titrated to target doses (candesartan 32 mg once daily; valsartan 160 mg twice daily).¹ Blood pressure, renal function, and serum potassium should be evaluated within 1 to 2 weeks after initiation of therapy and after increases in dose and these end points used to guide subsequent dose changes. It is not necessary to reach target ARB doses before adding a β -blocker.

Adverse Effects. The ARBs have a low incidence of adverse effects. Because they do not affect bradykinin, they are not associated with cough and have a lower risk of angioedema than ACE inhibitors. However, because of reports of recurrences of ACE inhibitor-related angioedema after ARB administration, ARBs should be used cautiously in any patient with a history of angioedema.^{77,79} The major adverse effects are related to suppression of the RAAS. The incidence and risk factors for developing hypotension, decreases in renal function, and hyperkalemia with the ARBs is similar to that of ACE inhibitors.¹² Thus, ARBs are not alternatives in patients who develop these complications from ACE inhibitors. Careful monitoring is required when an ARB is used with another inhibitor of the RAAS (e.g., ACE inhibitor or aldosterone antagonist) as this combination increases the risk of these adverse effects. Similar to the ACE inhibitors, the ARBs are contraindicated in the second and third trimesters of pregnancy and should be avoided in the first trimester because of increased risk of fetal/neonatal morbidity and mortality. Neither candesartan nor valsartan are metabolized by the cytochrome P450 (CYP) system, so no pharmacokinetic drug-drug interactions with these agents are expected.

6 β -Blockers Metoprolol CR/XL, carvedilol, and bisoprolol are the only β -blockers shown to reduce mortality in large heart failure trials. Metoprolol and bisoprolol selectively block the β_1 -receptor, whereas carvedilol blocks the β_1 , β_2 , and α_1 -receptors and also possesses antioxidant effects. Although there is no clear evidence that these pharmacologic differences result in differences in efficacy among agents, they may aid in selection of a specific agent. For example, carvedilol is expected to have greater antihypertensive effects than the other agents because of its α -receptor blocking properties and may be preferred in patients with poorly controlled blood pressure. Conversely, metoprolol or bisoprolol may be preferred in patients with low blood pressure or dizziness and in patients with significant airway disease.

Bisoprolol is eliminated approximately 50% by renal elimination, whereas metoprolol and carvedilol are essentially completely metabolized and undergo extensive hepatic first-pass metabolism. Both metoprolol and carvedilol are also substrates for the CYP2D6, which is known to be polymorphic. The 7% of the white population and 1% to 2% of the Asian American and African American populations who are CYP2D6-poor metabolizers would be expected to have higher plasma concentrations than anticipated at the usual doses of carvedilol and metoprolol. However, given that β -blockers have a wide therapeutic index, it is unclear whether the poor metabolizer phenotype would result in more pronounced hemodynamic effects.

There is fairly strong evidence that benefits of β -blockers in heart failure are not a class effect. Specifically, in a study powered for mortality reduction, there was no difference in survival between the nonselective β -blocker bucindolol and placebo.¹¹⁵ Although there has been considerable debate over why bucindolol failed to provide a survival benefit, it may be related to the drug's ancillary properties or differences among β -blocker trials in the characteristics of study participants. These data emphasize the importance of confining β -blocker use to one of the agents with proven survival benefits, especially given the diversity among β -blockers in their receptor sensitivities and ancillary properties.

There has been much debate over whether one β -blocker is superior to another. Specifically, it has been hypothesized that nonselective blockade with carvedilol might produce greater benefits than β_1 -selective blockade. This hypothesis is based on observations that the β_1 -receptor is downregulated, and the β_2 - and α_1 -receptors account for a larger proportion of total cardiac adrenergic receptors in the failing heart. Only one trial with a mortality end point has provided a head-to-head comparison of carvedilol and a β_1 -selective blocker. The Carvedilol or Metoprolol European Trial

(COMET) compared carvedilol 25 mg twice daily and immediate-release metoprolol 50 mg twice daily and found a significant 17% lower mortality rate in patients treated with carvedilol.¹¹⁶ However, concerns regarding the formulation and dose of metoprolol used in COMET limit the conclusions that can be drawn from these findings. Specifically, the study used the immediate-release formulation of metoprolol (metoprolol tartrate) not the sustained-release formulation (metoprolol succinate) shown to reduce mortality compared to placebo.⁵⁹ The efficacy of the immediate-release formulation in reducing mortality in heart failure has not been proven. Metoprolol CR/XL provides more consistent plasma concentrations over a 24-hour period and appears to provide more favorable effects on heart rate variability, autonomic balance, and blood pressure, suggesting that this formulation might be superior to immediate-release metoprolol.¹¹⁷ The target dose of metoprolol also differed between COMET and MERIT-HF. The target dose in COMET was 100 mg/day (50 mg twice daily), whereas the target dose of metoprolol in MERIT-HF was 200 mg/day. Many question whether the degree of β -blockade achieved in COMET with immediate-release metoprolol 50 mg twice daily is comparable to that achieved with metoprolol CR/XL 200 mg/day in MERIT-HF or carvedilol 25 mg twice daily in COMET. Thus, the debate over β -blocker superiority continues, and although some clinicians would argue superiority of carvedilol, it seems clear that what is most important is that one of the three β -blockers proven to reduce mortality is used.

Adverse Effects. Possible adverse effects with β -blocker use in heart failure include bradycardia or heart block, hypotension, fatigue, impaired glycemic control in diabetic patients, bronchospasm in patients with asthma, and worsening heart failure. Clinicians should monitor vital signs and carefully assess for signs and symptoms of worsening heart failure during β -blocker initiation and up-titration. Hypotension is more common with carvedilol because of its α_1 -receptor-blocking properties. Bradycardia and hypotension generally are asymptomatic and require no intervention; however, β -blocker dose reduction is warranted in symptomatic patients. Fatigue usually resolves after several weeks of therapy, but sometimes requires dose reduction. In diabetic patients, β -blockers may worsen glucose tolerance and can mask the tachycardia and tremor (but not sweating) that accompany hypoglycemia. In addition, nonselective agents such as carvedilol may prolong insulin-induced hypoglycemia and slow recovery from a hypoglycemic episode. Despite this, there is evidence that carvedilol produces better glycemic control in diabetic patients compared to immediate-release metoprolol and may improve insulin sensitivity.¹¹⁸ Diabetic patients should be warned of these potential adverse effects, and blood glucose should be monitored with initiation, adjustment, and discontinuation of β -blocker therapy. Adjustment of hypoglycemic therapy may be necessary with concomitant β -blocker use in diabetics.

Up-titration should be avoided if the patient experiences signs of worsening heart failure, including volume overload and poor perfusion. Fluid overload may be asymptomatic and manifest solely as an increase in body weight. Mild fluid overload may be managed by intensifying diuretic therapy. The treatment of moderate to severe congestion is discussed in the section on acute decompensated heart failure. Once the patient has been stabilized, dose titration may continue as tolerated until the target or highest tolerated dose is reached.

Absolute contraindications to β -blocker use include uncontrolled bronchospastic disease, symptomatic bradycardia, advanced heart block without a pacemaker, and acute decompensated heart failure. However, β -blockers may be tried with caution in patients with asymptomatic bradycardia or well-controlled asthma. Particular caution is warranted in patients with marked bradycardia (<55 beats/min) or hypotension (systolic blood pressure <80 mm Hg).

Importantly, concerns of masking symptoms of hypoglycemia or worsening glycemic control should not preclude β -blockers use in patients with diabetes. Indeed, post-hoc analysis of heart failure trials shows that β -blockers are well tolerated and significantly reduce morbidity and mortality in patients with diabetes and heart failure.¹¹⁹ β -Blockers should be used cautiously in patients with diabetes and recurrent hypoglycemia.

Digoxin Digoxin exerts its positive inotropic effect by binding to sodium- and potassium-activated adenosine triphosphatase (Na-K-ATPase or sodium pump). Inhibition of Na-K-ATPase decreases outward transport of sodium and leads to increased intracellular sodium concentrations. Higher intracellular sodium concentrations favor calcium entry and reduce calcium extrusion from the cell through effects on the sodium-calcium exchanger. The result is increased storage of intracellular calcium in the sarcoplasmic reticulum, and with each action potential, a greater release of calcium to activate contractile elements. Digoxin also has beneficial neurohormonal actions. These effects occur at low plasma concentrations, where little inotropic effect is seen, and are independent of inotropic activity. Unlike other positive inotropes that increase intracellular cyclic adenosine monophosphate (cAMP), digoxin attenuates the excessive SNS activation present in heart failure patients. Although the precise mechanism is unknown, a digoxin-mediated reduction in central sympathetic outflow and improvement in impaired baroreceptor function appear to play an important role. Because mortality and progression of heart failure are linked to the extent of SNS activation, these sympathoinhibitory effects may be an important component of the clinical response to the drug. Chronic heart failure is also marked by autonomic dysfunction, most notably suppression of the parasympathetic (vagal) system. Digoxin increases parasympathetic activity in heart failure patients and leads to a decrease in heart rate, thus enhancing diastolic filling. The vagal effects also result in slowed conduction and prolongation of atrioventricular node refractoriness, thus slowing the ventricular response in patients with atrial fibrillation. Because atrial fibrillation is a common complication of heart failure, the combined positive inotropic, neurohormonal, and negative chronotropic effects of digoxin can be particularly beneficial for such patients. The overall response to digoxin is usually an increase in cardiac index and a decrease in PAOP with relatively little change in arterial blood pressure.^{86,87,96}

Pharmacokinetics. Numerous studies of digoxin pharmacokinetics have been published; Table 16–10 summarizes them. Digoxin

TABLE 16-10 Clinical Pharmacokinetics of Digoxin

Oral bioavailability	
Tablets	0.5–0.9 (0.65) ^a
Elixir	0.75–0.85 (0.80)
Capsules	0.9–1.0 (0.95)
Onset of action	
Oral	1.5–6 h
Intravenous	15–30 min
Peak effect	
Oral	4–6 h
Intravenous	1.5–4 h
Terminal half-life	
Normal renal function	36 h
Anuric patients	5 days
Volume of distribution at steady state	7.3 L/kg
Fraction unbound in plasma	0.75–0.80
Fraction excreted unchanged in urine	0.65–0.70

Drugs	Mechanism/Effect	Suggested Clinical Management
Amiodarone	Inhibits P-glycoprotein resulting in decrease in renal and nonrenal clearance; can increase SDC by 70%–100%	Monitor SDC and adverse effects; anticipate the need to reduce the dose by 50%
Antacids	Concurrent administration may decrease digoxin bioavailability by 20%–35%	Space doses at least 2 h apart or avoid concurrent use if possible
Cholestyramine, colestipol	Bind digoxin in gut and decrease bioavailability 20%–35%; may also decrease enterohepatic recycling	Space doses at least 2 h apart or avoid concurrent colestipol use if possible
Diuretics	Thiazides or loop diuretics may cause hypokalemia and hypomagnesemia, thereby increasing the risk of digitalis toxicity	Monitor and replace electrolytes if necessary
Erythromycin, clarithromycin, tetracycline	Alter gut bacterial flora; bioavailability and SDC increase 40%–100% in approximately 10% of patients who extensively metabolize digoxin in the gut; may also be caused by inhibition of P-glycoprotein by macrolides	Monitor SDC and anticipate the need to reduce the dose; avoid concurrent use if possible
Ketoconazole, itraconazole	Decrease in renal and nonrenal clearance by inhibition of P-glycoprotein; SDC may increase by 50%–100%	Monitor SDC and anticipate the need to reduce the dose by 50%
Kaolin-pectin	Large dose (30–60 mL) may decrease digoxin bioavailability by approximately 60%	Space doses at least 2 h apart or avoid concurrent use if possible
Metoclopramide	Increase in gut mobility may decrease bioavailability of slow dissolving tablets; unknown significance	Effect is minimized by administration of digoxin capsules
Neomycin, sulfasalazine	Decrease in bioavailability by 20%–25% sulfasalazine	Space doses at least 2 h apart or avoid concurrent use if possible
Propafenone	Decrease in renal clearance; SDC may increase 30%–40%	Monitor SDC and anticipate the need to reduce the dose
Quinidine	Inhibits P-glycoprotein resulting in decrease in renal and nonrenal clearance; also displacement of digoxin from tissue-binding sites with decrease in the volume of distribution; SDC generally increases about twofold	Monitor SDC and adverse effects; anticipate the need to reduce dose by 50%
Spironolactone	Decrease in renal and nonrenal clearance; also interference with some digoxin assays thus increasing apparent SDC	Monitor SDC and anticipate the need to reduce dose; check assay for interference
Verapamil	Inhibits P-glycoprotein resulting in decrease in renal and nonrenal clearance, SDC may increase 70%–100%	Monitor SDC and anticipate the need to reduce the dose by 50%; consider using another calcium channel blocker

SDC, serum digoxin concentration.

has a large volume of distribution and is extensively bound to various tissues, most notably to Na-K-ATPase in skeletal and cardiac muscles. Because it does not distribute appreciably to body fat, loading doses of digoxin (when necessary) should be calculated based on estimates of lean body weight. There is a long “distribution phase” after administration of oral or intravenous digoxin, resulting in a lag time before maximum pharmacologic response is observed (Table 16–10). Transiently elevated serum digoxin concentrations during the distribution phase are not associated with increased therapeutic or adverse effects, although they can mislead the clinician who is unaware of the timing of blood sampling relative to the previous digoxin dose. Consequently, blood samples for measurement of serum digoxin concentrations should be collected at least 6 hours, and preferably 12 hours or more, after the last dose.

In patients with normal renal function, 60% to 80% of a dose of digoxin is eliminated unchanged in urine via glomerular filtration and tubular secretion. The terminal half-life of digoxin is approximately 1.5 days in subjects with normal renal function but approximately 5 days in anuric patients (see Table 16–10). Recent evidence indicates that the drug efflux transporter P-glycoprotein plays an important role in the bioavailability, renal and nonrenal clearance, and drug interactions with digoxin. Table 16–11 summarizes clinically important pharmacokinetic/pharmacodynamic drug interactions. An extensive review of the pharmacokinetics and pharmacodynamics of digoxin is available.⁹⁶

Adverse Effects. Although digoxin can produce a variety of cardiac and noncardiac adverse effects, it is usually well tolerated by most patients (Table 16–12).^{86,87} Noncardiac adverse effects frequently involve the CNS or gastrointestinal systems but also may be nonspecific (e.g., fatigue or weakness). Cardiac manifestations include numerous different arrhythmias that are believed to be caused by multiple electrophysiologic effects (Table 16–12). Cardiac arrhythmias may be the first evidence of toxicity in a patient (before any noncardiac symptoms occur). Rhythm disturbances are of particular concern because patients with chronic heart failure are already at increased risk

for sudden cardiac death, presumably as a consequence of ventricular arrhythmias. Patients who are at increased risk of toxicity include those with impaired renal function, decreased lean body mass, the elderly, and those taking interacting drugs. Hypokalemia, hypomagnesemia, and hypercalcemia will predispose patients to cardiac manifestations of digoxin toxicity. Thus, concomitant therapy with diuretics may lead to electrolyte abnormalities and increase the likelihood of cardiac arrhythmias. Similarly, hypothyroidism, myocardial ischemia, and acidosis will also increase the risk of cardiac adverse effects. Although digoxin toxicity is commonly associated with plasma concentrations greater than 2 ng/mL, clinicians should remember that digoxin toxicity is based on the presence of symptoms rather than a specific plasma concentration.⁹⁶ Usual treatment of digoxin toxicity

TABLE 16-12 Signs and Symptoms of Digoxin Toxicity**Noncardiac (mostly CNS) adverse effects**

Anorexia, nausea, vomiting, abdominal pain

Visual disturbances

Halos, photophobia, problems with color perception (i.e., red-green or yellow-green vision), scotomata

Fatigue, weakness, dizziness, headache, neuralgia, confusion, delirium, psychosis

Cardiac adverse effects^{a,b}

Ventricular arrhythmias

Premature ventricular depolarizations, bigeminy, trigeminy, ventricular tachycardia, ventricular fibrillation

Atrioventricular (AV) block

First degree, second degree (Mobitz type I), third degree

AV junctional escape rhythms, junctional tachycardia

Atrial arrhythmias with slowed AV conduction or AV block

Particularly paroxysmal atrial tachycardia with AV block

Sinus bradycardia

^aSome adverse effects may be difficult to distinguish from the signs/symptoms of heart failure.

^bDigoxin toxicity has been associated with almost every known rhythm abnormality (only the more common manifestations are listed).

includes drug withdrawal or dose reduction and treatment of cardiac arrhythmias and electrolyte abnormalities. In patients with life-threatening digoxin toxicity, purified digoxin-specific Fab antibody fragments should be administered. Serum digoxin concentrations will not be reliable until the antidote has been eliminated from the body.⁸⁷

TREATMENT

Acute Decompensated Heart Failure

As discussed previously, the number of patients with heart failure is substantial and continues to increase. Although mortality from heart failure has improved, the growing number of patients with the disorder and the progressive nature of the syndrome have led to substantial increases in hospitalizations for heart failure.⁴ Recent data indicate approximately 1 million patients are hospitalized annually for heart failure, resulting in significant morbidity, mortality, and consumption of large quantities of healthcare resources.⁴ Inpatient admission for heart failure exacerbations is associated with an increased risk of subsequent hospitalization and decreased survival.¹²⁰ The economic impact of heart failure is considerable with cost driven primarily by hospitalization and inpatient care.⁴

A number of descriptive terms have been used to characterize patients with worsening heart failure requiring hospitalization. Patients with persistent symptoms or *refractory* heart failure requiring specialized interventions despite optimal standard therapy such as ACE inhibitors and β -blockers are classified as stage D in the ACC/AHA classification scheme. These patients typically fall into the category of NYHA class III or IV heart failure, with symptoms upon minimal exertion or at rest.¹ The terms *decompensated heart failure* or *exacerbation of heart failure* refer to those patients with new or worsening signs or symptoms, which are usually caused by volume overload and/or hypoperfusion and lead to additional medical care, such as emergency room visits and hospitalizations. The term *acute* heart failure may be misleading as it more often refers to the patient with a sudden onset of signs or symptoms of heart failure in the setting of previously normal cardiac function. This section of the chapter focuses on the management of patients with acute decompensated heart failure. Clinical syndromes within decompensated heart failure include systemic volume overload, low output, and acute pulmonary edema. It is important to recognize that such patients may present with impaired or preserved left ventricular function and a variety of etiologies may be responsible for the primary disease process. The clinical course of heart failure manifests as periods of relative stability with an increasing frequency in episodes of decompensation as the underlying disease progresses.¹²¹

Despite the considerable morbidity and mortality associated with decompensated heart failure, the first randomized placebo-controlled trials in this patient population were published in 2002.^{122,123} In addition, it was not until recently that guidelines were generated focusing specifically on managing decompensated heart failure. Currently, the ACC/AHA guidelines focus a portion of their recommendations for chronic heart failure on the decompensated patient, but the HFSA and the European Society of Cardiology have published separate guidelines for evaluating and treating decompensated heart failure.^{1,34,124} Because available drug therapies differ between Europe and the United States, the HFSA guidelines are the focus of the remainder of this chapter.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Patients requiring intensive therapy for decompensated heart failure may have a variety of underlying etiologies and clinical presentations.

Patients with worsening chronic heart failure associated with reduced or preserved left ventricular function comprise approximately 70% of heart failure hospital admissions. These patients can become refractory to available oral therapy and decompensate following a relatively mild insult (e.g., dietary indiscretion), medical noncompliance, or a noncardiac concurrent illness (e.g., infection). A new cardiac event, such as recurrent MI, atrial fibrillation, myocarditis, or acute valvular insufficiency also can cause a stable patient to decompensate. Secondly, *de novo* heart failure may occur following a large myocardial infarction or sudden increase in blood pressure in the setting of left ventricular dysfunction and represents approximately 25% of admissions. A third group of patients with severe left ventricular systolic dysfunction associated with progressive worsening of cardiac output and refractoriness to therapy represents approximately 5% of heart failure admissions.¹²⁵ Additional insight into the clinical characteristics of decompensated heart failure patients unexpectedly indicates that a high percentage of patients present with hypertension and preserved systolic function.¹²⁶

Several studies provide a better understanding of the prognostic factors associated with decompensated heart failure. Data from the Acute Decompensated Heart Failure Registry (ADHERE), a registry of hospitalized patients with a primary diagnosis of decompensated heart failure, found blood urea nitrogen greater than or equal to 43 mg/dL to be the best individual predictor of in-hospital mortality, followed by systolic blood pressure less than 115 mm Hg and then by serum creatinine greater than or equal to 2.75 mg/dL. Using these three parameters, patients were identified as low, intermediate, high, and very high risk with an in-hospital mortality of 2%, 6%, 13%, and 20%, respectively.¹²⁷ Additional studies confirm an increase in in-hospital mortality in patients with low systolic blood pressure and worsening renal function on admission.^{128,129} Hyponatremia, elevations in troponin I, ischemic etiology, and poor functional capacity are additional negative prognostic factors.¹²⁵

GENERAL APPROACH TO TREATMENT

The overall goals of therapy in the patient with decompensated heart failure are to relieve congestive symptoms or optimize volume status, as well as treat symptoms of low cardiac output, so that the patient can be discharged in a compensated state on oral drug therapy. Although diuretic, vasodilator, and positive inotrope therapy can be very effective at achieving these goals, their efficacy must be balanced against the potential for serious toxicity. Thus, another important goal is to minimize the risks of pharmacologic therapy. Maintenance of vital organ perfusion to preserve renal function and prevention of additional myocardial injury, diuretic-induced electrolyte depletion, hypotension from vasodilators, and myocardial ischemia and arrhythmias from positive inotropes are all important goals.

In addition, all patients should be evaluated for potential etiologies and precipitating factors, including atrial fibrillation and other arrhythmias, worsening hypertension, myocardial ischemia or infarction, anemia, hypothyroidism or hyperthyroidism, and other causes. Medications, including noncardiac medications, which may worsen cardiac function, should also be considered as precipitating or contributing factors. Patients who may benefit from revascularization should also be identified. Prior to discharge, optimization of chronic oral therapy and patient education are critical to preventing future hospitalizations. When available and appropriate, patients should be referred to a heart failure disease management program.¹²⁴ A careful history and physical examination are key components in the diagnosis of decompensated heart failure. The history should focus on the potential etiologies of heart failure, the presence of any precipitating factors, onset, duration, and severity of symptoms, and a careful medication history. Current guidelines recommend making the diagnosis of decompensated heart failure based primarily on signs and symptoms.¹²⁴ With congestion representing

the more common presentation of heart failure, orthopnea is the main symptom of fluid overload that best correlates with elevated pulmonary pressures.¹²⁹ Important elements of the physical examination include assessment of vital signs and weight, cardiac auscultation for heart sounds and murmurs, pulmonary exam for the presence of rales, and evaluation for the presence of peripheral edema. The jugular venous pressure is the most reliable indicator of the patient's volume status and should be carefully evaluated on admission and closely followed during hospitalization as an indicator of the efficacy of diuretic therapy.¹²⁹ An S₃ gallop also represents ventricular filling and has high diagnostic specificity for heart failure decompensation. Other physical findings, such as pulmonary crackles and lower-extremity edema, have low specificity and sensitivity for the diagnosis of decompensated heart failure.¹²⁴ The development of a bedside assay for plasma BNP has focused considerable attention on the use of BNP as an aid in the diagnosis of suspected heart failure. Plasma BNP is positively correlated with the degree of left ventricular dysfunction and heart failure and this assay is now frequently used in acute care settings to assist in the differential diagnosis of dyspnea (heart failure vs. asthma, chronic obstructive pulmonary disease, or infection). A low BNP concentration has a 96% predictive value for excluding heart failure as an etiology when evaluating patients presenting with dyspnea. In addition, an elevated prehospital discharge BNP concentration is associated with an increased risk of worse long-term outcome. It is important to note that any disease process that increases right heart pressures will elevate BNP, including pulmonary emboli, chronic obstructive lung disease, and primary pulmonary hypertension. Also, BNP levels may be mildly increased with increasing age, female gender, and renal dysfunction, whereas concentrations may be lower with obesity.¹²⁹ Additional research will better characterize the role of BNP measurement in the diagnosis and treatment of heart failure. When the diagnosis of decompensated heart failure is uncertain, current guidelines recommend obtaining a BNP concentration in conjunction with assessing signs and symptoms.

Hospitalization *should occur* or *should be considered* depending on each patient's presenting symptoms and physical examination. Table 16–13 describes the clinical presentation of patients in whom hospitalization should occur or should be considered. Most patients do not require admission to an intensive care unit and are admitted to a monitored unit or general medical floor. Admission to an intensive care unit may be required if the patient experiences hemodynamic instability requiring frequent monitoring of vital signs, invasive hemodynamic monitoring, or rapid titration of intravenous medications with concurrent monitoring to assure safe and effective outcomes.

The first step in the management of decompensated heart failure is to ascertain that optimal treatment with oral medications has been achieved. If fluid retention is evident on physical examination, aggressive diuresis should be accomplished. Although increasing the dose of oral diuretic may be effective in some cases, the use of intravenous diuretics frequently is necessary. Every effort should be made to optimally treat the patient with an ACE inhibitor. β -Blocker therapy should generally be continued during the hospital admission unless recent dose initiation or up-titration was responsible for the decompensated state. In such cases, β -blocker therapy may need to be temporarily held or dose reduced. Appropriateness of initiating this therapy prior to hospital discharge will be discussed later in this chapter. Discontinuation of ACE inhibitor or β -blocker therapy occasionally may be necessary in the setting of cardiogenic shock or symptomatic hypotension. Certain therapies may also need to be temporarily held in the setting of renal dysfunction, especially in the setting of oliguria or hyperkalemia (e.g., ACE inhibitor, ARB, and/or aldosterone antagonist) or elevated serum digoxin concentrations. Most patients should be receiving digoxin

at a low dose prescribed to achieve a trough serum concentration of 0.5 to 1.0 ng/mL.¹

There are two general approaches to maximize therapy in the decompensated heart failure patient. One is to use simple clinical parameters (signs and symptoms, blood pressure, renal function) and the second is to use invasive hemodynamic monitoring in addition to these clinical parameters. In all decompensated heart failure patients, close monitoring is essential for assuring optimal response to therapy while avoiding adverse effects. Daily monitoring should include weight, strict fluid intake and output, and heart failure signs and symptoms to assess clinical efficacy of drug therapy. Foley catheter placement is not recommended unless close monitoring of urine output is needed. As safety end points, monitoring for electrolyte depletion, symptomatic hypotension, and renal dysfunction should be assessed frequently. Although many of the above parameters may be monitored daily, some will need to be monitored more frequently as dictated by the patient's clinical status. Vital signs should be assessed multiple times throughout the day at a frequency that is appropriate for a given patients' level of stability. Orthostatic blood pressure should be assessed at least once daily.¹²⁴ Table 16–14 summarizes the recommendations for monitoring.

■ PRINCIPLES OF THERAPY BASED ON CLINICAL PRESENTATION

Appropriate medical management of the patient presenting with decompensated heart failure is aided by determination of whether the patient has signs and symptoms of fluid overload ("wet" heart failure) or low cardiac output ("dry" heart failure).^{129,130} As previously discussed, most patients present with *fluid overload* (or the "wet" profile). Symptoms consistent with pulmonary congestion include orthopnea and dyspnea with minimal exertion and those of systemic congestion include gastrointestinal discomfort, ascites, and peripheral edema. Patients with no or minimal fluid overload (or the "dry" category of decompensated heart failure) may have symptoms that

TABLE 16-14 Monitoring Recommendations for Patients Hospitalized with Acute Decompensated Heart Failure

Value	Frequency	Specifics
Weight	At least daily	Determine after voiding in the morning Account for possible increased food intake as a result of improved appetite Strict documentation necessary
Fluid intake/output	At least daily	
Vital signs	More than daily	Including orthostatic blood pressure
Signs	At least daily	Edema, acites, pulmonary rales, hepatomegaly, increased jugular venous pressure, hepatojugular reflux, liver tenderness
Symptoms	At least daily	Orthopnea, paroxysmal nocturnal dyspnea, nocturnal cough, dyspnea, fatigue
Electrolytes	At least daily	Potassium, magnesium, sodium
Renal function	At least daily	blood urea nitrogen, serum creatinine

are more difficult to distinguish. This is a syndrome of *low cardiac output* and is characterized principally by extreme fatigue and tiredness as well as other symptoms not commonly attributed to cardiac causes such as poor appetite, nausea, and early satiety. It is important to recognize that gastrointestinal symptoms may be associated with congestion rather than low cardiac output to the gastrointestinal tract. Moreover, these patients frequently exhibit worsening renal function and a decline in serum sodium level. Many patients will present with signs and symptoms of both types of advanced heart failure. In these patients, low-output symptoms may not be obvious until congestion is optimally treated. Figure 16–8 outlines a suggested treatment approach based on whether the patient has signs and symptoms of fluid overload and/or low cardiac output.

■ **PRINCIPLES OF THERAPY BASED ON HEMODYNAMIC SUBSETS**

Patients with decompensated heart failure may have critically reduced cardiac output, usually with low arterial blood pressure and systemic hypoperfusion resulting in organ system dysfunction (i.e., cardiogenic shock). They also may have pulmonary edema with hypoxemia, respiratory acidosis, and markedly increased work of breathing. With cardiopulmonary support, response to interventions should be assessed promptly to allow for timely adjustments in treatment. Because cardiopulmonary support must be instituted and adjusted rapidly, immediate assessment of the results of an intervention limits risks and makes adjustments in therapy more prompt. ECG monitoring, continuous pulse oximetry, urine flow monitoring, and automated blood pressure recording are now the minimal noninvasive standard of care for critically ill patients with cardiopulmonary decompensation. Peripheral or femoral arterial catheters may be used for continuous and accurate assessment of arterial pressure.

Hemodynamic Monitoring

The role of invasive hemodynamic monitoring for improving outcomes in patients with decompensated heart failure remains controversial. The Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE) trial assessed the role of invasive hemodynamic monitoring in the management of patients hospitalized for heart failure. The use of a pulmonary artery catheter had no impact on survival after hospital discharge.¹³¹ It is important to note that patients with a clear indication for pulmonary artery catheter were excluded from this trial. Thus, the routine use of invasive monitoring is not recom-

mended. However, invasive hemodynamic monitoring often provides essential information necessary to achieve optimal drug therapy in patients with a confusing or complicated clinical picture and during dose titration of rapidly acting medications. And thus, such monitoring should be considered in patients who are refractory to initial therapy, whose volume status is unclear, or who has clinically significant hypotension such as a systolic blood pressure less than 80 mm Hg, or worsening renal function despite therapy. Such monitoring is required to document adequate hemodynamic response to inotropic therapy prior to committing to chronic outpatient inotropic therapy.¹²⁴ Finally, assessment of hemodynamic parameters is required to document adequate reversal of pulmonary hypertension prior to cardiac transplantation.¹²⁹

Invasive hemodynamic monitoring is usually performed with a flow-directed pulmonary artery or Swan-Ganz catheter placed percutaneously through a central vein and advanced through the right side of the heart and into the pulmonary artery. Inflation of a balloon proximal to the end port allows the catheter to “wedge,” yielding the PAOP, which estimates the pulmonary venous (left atrial) pressure and, in the absence of intracardiac shunt, mitral valve disease or pulmonary disease, the left ventricular diastolic pressure. Additionally, cardiac output may be measured and systemic vascular resistance (SVR) calculated. Table 16–15 lists the normal values for hemodynamic parameters.

In addition to the clinical presentation, invasive hemodynamic monitoring helps in the selection of appropriate medical therapy as well as in the classification of patients into specific subsets. These *hemodynamic subsets* were first proposed for patients with left ventricular dysfunction following an acute MI but also are applicable to patients with acute or severe heart failure from other causes (Fig. 16–9).¹³² This hemodynamic classification has four subsets and is based on a cardiac index above or below 2.2 L/min/m² and a PAOP above or below 18 mm Hg. Figure 16–10 is a treatment algorithm based on hemodynamic subsets. In addition to using the above profiles or categories to stratify patients with decompensated heart failure, these four hemodynamic profiles are predictive for outcome with patients in the wet-warm profile having a twofold greater risk of death and those in the wet-cold profile having a 2.5-fold increased risk of death at 1 year compared to dry-warm patients.¹²⁹

Subset I Patients in hemodynamic subset I have a cardiac index and PAOP within generally acceptable ranges and have the lowest mortality of any subset. These patients do not need immediate specific interventions other than maximizing oral therapy and monitoring. It should be emphasized that patients with significant left ventricular dysfunction may still present in subset I because normal compensatory mechanisms and/or appropriate drug therapy may at least partially correct an otherwise abnormal hemodynamic profile.

Subset II As shown in Fig. 16–9, patients in subset II have an adequate cardiac index but a PAOP greater than 18 mm Hg. These patients are likely to have pulmonary congestion (i.e., “wet” heart failure) secondary to increased hydrostatic pressure in the pulmonary capillaries but no evidence of peripheral hypoperfusion. The primary goal of therapy in these patients is to reduce pulmonary congestion by lowering PAOP which is associated with improved outcomes. Accordingly, the therapeutic goal in this setting is to reduce filling pressures without reducing cardiac output, increasing heart rate, or further activating neurohormones. And thus, it is critically important that PAOP not be decreased excessively so as to cause a significant decrease in cardiac index. Although the normal range of PAOP is 5 to 12 mm Hg for individuals without cardiac dysfunction, higher pressures of 15 to 18 mm Hg frequently are necessary for heart failure patients to optimize cardiac index while avoiding pulmonary congestion. Generally, the PAOP can be low-

FIGURE 16-8. General treatment algorithm for acute decompensated heart failure (ADHF) based on clinical presentation. IV vasodilators that may be used include nitroglycerin, nesiritide, or nitroprusside. Metolazone or spironolactone may be added if the patient fails to respond to loop diuretics and a second diuretic is required. IV inotropes that may be used include dobutamine or milrinone. (D/C, discontinue; HF, heart failure; SBP, systolic blood pressure.) (Reprinted and adapted from *J Cardiac Fail*, Vol. 12, Pages e1–e122, Copyright 2006, with permission from Elsevier.)

TABLE 16-15 Hemodynamic Monitoring: Normal Values

Central venous (right atrial) pressure, mean	<5 mm Hg
Right ventricular pressure	25/0 mm Hg
Pulmonary artery pressure	25/10 mm Hg
Pulmonary artery pressure, mean	<18 mm Hg
Pulmonary artery occlusion pressure, mean	<12 mm Hg
Systemic arterial pressure	120/80 mm Hg
Mean arterial pressure	90–110 mm Hg
Cardiac index	2.8–4.2 L/min/m ²
Stroke volume index	30–65 mL/b/m ²
Systemic vascular resistance	900–1,400 dyne.sec.cm ⁻⁵
Pulmonary vascular resistance	150–250 dyne.sec.cm ⁻⁵
Arterial oxygen content	20 mL/dL
Mixed venous oxygen content	15 mL/dL
Arteriovenous oxygen content difference	3–5 mL/dL

ered to the range of 15 to 18 mm Hg with relatively little decrease in cardiac index because the Frank-Starling curve is flatter at higher PAOP values, particularly in patients with heart failure. Intravenous administration of agents that reduce preload (i.e., loop diuretics, nitroglycerin, or nesiritide) is the most appropriate acute therapy to achieve the therapeutic goal for patients in subset II. These agents will produce a very rapid decrease in preload, although signs and symptoms of pulmonary congestion may take longer to resolve.

Current guidelines recommend loop diuretics as first-line therapy for management of heart failure patients admitted with fluid overload and that such agents should typically be administered intravenously. The rate of diuresis should achieve a desirable volume status without causing a rapid reduction in intravascular volume resulting in symptomatic hypotension or renal dysfunction. Electrolyte depletion should be monitored for closely, especially

FIGURE 16-9. Hemodynamic subsets of heart failure based on cardiac index and pulmonary artery occlusion pressure. (Adapted with permission from *N Engl J Med* 1976;295:1356–1362.)

when a high dose or diuretic combination therapy is used. In addition to sodium restriction (less than 2 g daily), supplemental oxygen should be administered as needed for hypoxemia. In patients with moderate hyponatremia (less than 130 mEq/L), fluid restriction (less than 2 L daily) should be considered, and in patients with worsening or severe hyponatremia (less than 125 mEq/L), stricter fluid restriction may be necessary.¹²⁴

Intravenous vasodilators may be considered in addition to diuretics for rapid symptom resolution and may be especially useful in patients with acute pulmonary edema or severe hypertension, as well as in patients who fail to respond to aggressive treatment with diuretics. It is essential to avoid use of vasodilators in patients with symptomatic hypotension, and frequent blood pressure monitoring is essential for the safe use of these agents. In addition, these agents should not be used in patients with low left-heart filling pressures. If symptomatic hypotension occurs with vasodilator therapy, the dose should be reduced or the agent discontinued. If patients fail to respond to the above therapies or experience worsening renal function, intravenous inotropic therapy should be considered.¹²⁴

Subset III Patients in hemodynamic subset III have a cardiac index of less than 2.2 L/min/m² but without an abnormally elevated PAOP (see Fig. 16–9). These patients usually present without evidence of pulmonary congestion, but the low cardiac index results in signs and symptoms of peripheral hypoperfusion (i.e., decreased urine output, weakness, peripheral vasoconstriction, weak pulses). The mortality rate of subset III patients is reported to be four times higher than that of patients without hypoperfusion.¹³² Although the treatment goal is to alleviate signs and symptoms of hypoperfusion by increasing cardiac index and perfusion to essential organs, therapy will differ among patients. If the PAOP is significantly below 15 mm Hg, initial therapy will be to administer intravenous fluids to provide a more optimal left ventricular filling pressure of 15 to 18 mm Hg and consequently improve cardiac index. When there is only mild left ventricular dysfunction, intravenous fluid administration may be all that is necessary to achieve a cardiac index above 2.2 L/min/m². However, many patients will have significant left ventricular dysfunction and a depressed Frank-Starling relationship despite adequate preload (i.e., PAOP of 15 to 18 mm Hg). In these patients, intravenously administered positive inotropic agents (e.g., dobutamine, milrinone) and/or arterial vasodilators (e.g., nitroprusside or nitroglycerin) are often necessary to achieve an adequate cardiac index. It is noteworthy that some positive inotropic medications also will have arterial vasodilating activity (see specific drug classes that follow).

Current guidelines recommend intravenous inotropes for symptom relief or end-organ dysfunction in patients with left ventricular dysfunction and low cardiac output syndrome. Such therapy may be especially useful in patients with low systolic blood pressure (less than 90 mm Hg) or symptomatic hypotension in the setting of adequate filling pressures. As previously discussed (see Subset II above), inotropic therapy may be considered in patients who do not tolerate or respond to intravenous vasodilators or patients with worsening renal function. As with vasodilators, inotrope administration requires frequent blood pressure monitoring as well as continuous monitoring for arrhythmias. If arrhythmias arise, dose reduction or discontinuation of inotropic therapy should occur. Also, these agents should be avoided in patients with low left-heart filling pressures. Given the potential risks associated with inotropic therapy, vasodilators should be considered prior to using inotropes.¹²⁴

In general, inotropic therapy should not be used in the broad decompensated heart failure population. They are useful to increase cardiac output in the patients described above. These agents may be used to “bridge” patients with cardiogenic shock to heart transplantation or left ventricular assist device. Inotropes may also be used as palliative therapy to improve functional status and quality of life in patients who are not considered optimal candidates for these definitive therapies.¹²⁴

Subset IV Patients with a cardiac index of less than 2.2 L/min/m² and a PAOP higher than 18 mm Hg are in hemodynamic subset IV. These patients have the worst prognosis of any subset and illustrate the typical hemodynamic profile for the patient hospitalized for severe heart failure.

Because of severe pump failure, these patients cannot maintain an adequate cardiac index despite the elevated left ventricular filling pressure and increased myocardial fiber stretch. These patients will present with signs and symptoms of both “wet” and low-output heart failure. The treatment goals are to alleviate these signs and symptoms by increasing cardiac index above 2.2 L/min/m² and reducing PAOP to 15 to 18 mm Hg while maintaining an adequate mean arterial pressure. Thus therapy will involve a combination of agents used for subset II and subset III patients to achieve these goals (i.e., combination of diuretic plus positive inotrope). These targets may be difficult to achieve and will necessitate careful monitoring and individualization of drug therapy. Nitroprusside is a particularly useful agent in this setting because of its mixed arterial–venous vasodilating effects. In the presence of significant hypotension, inotropic agents with vasopressor activity may be required initially to achieve an adequate perfusion pressure to essential organs and can then be combined, if necessary, with diuretics and/or vasodilators to obtain the desired hemodynamic effects and clinical response.

■ PHARMACOLOGIC THERAPY OF ACUTE DECOMPENSATED HEART FAILURE

❶ Unfortunately, the treatment of decompensated heart failure has not improved substantially in the past decade in large part because of the lack of clinical trial data in this population. The pharmacotherapeutic agents used to treat patients with decompensated heart failure rarely, if ever, produce a single cardiovascular action. Even when intended for a single purpose (e.g., a positive inotrope), other drug effects (tachycardia, vasodilation, or vasoconstriction) may either add to the therapeutic effect or cause adverse events that negate or even outweigh the intended therapeutic benefit. It often can be difficult to anticipate how an individual patient will respond to a given intervention. For this reason, hemodynamic monitoring can be useful, and many drugs are considered first-line therapy due in part to their short half-lives and ease of titration. The description of expected drug actions outlined below should be viewed as a general guide to the clinician, who must continuously reassess the

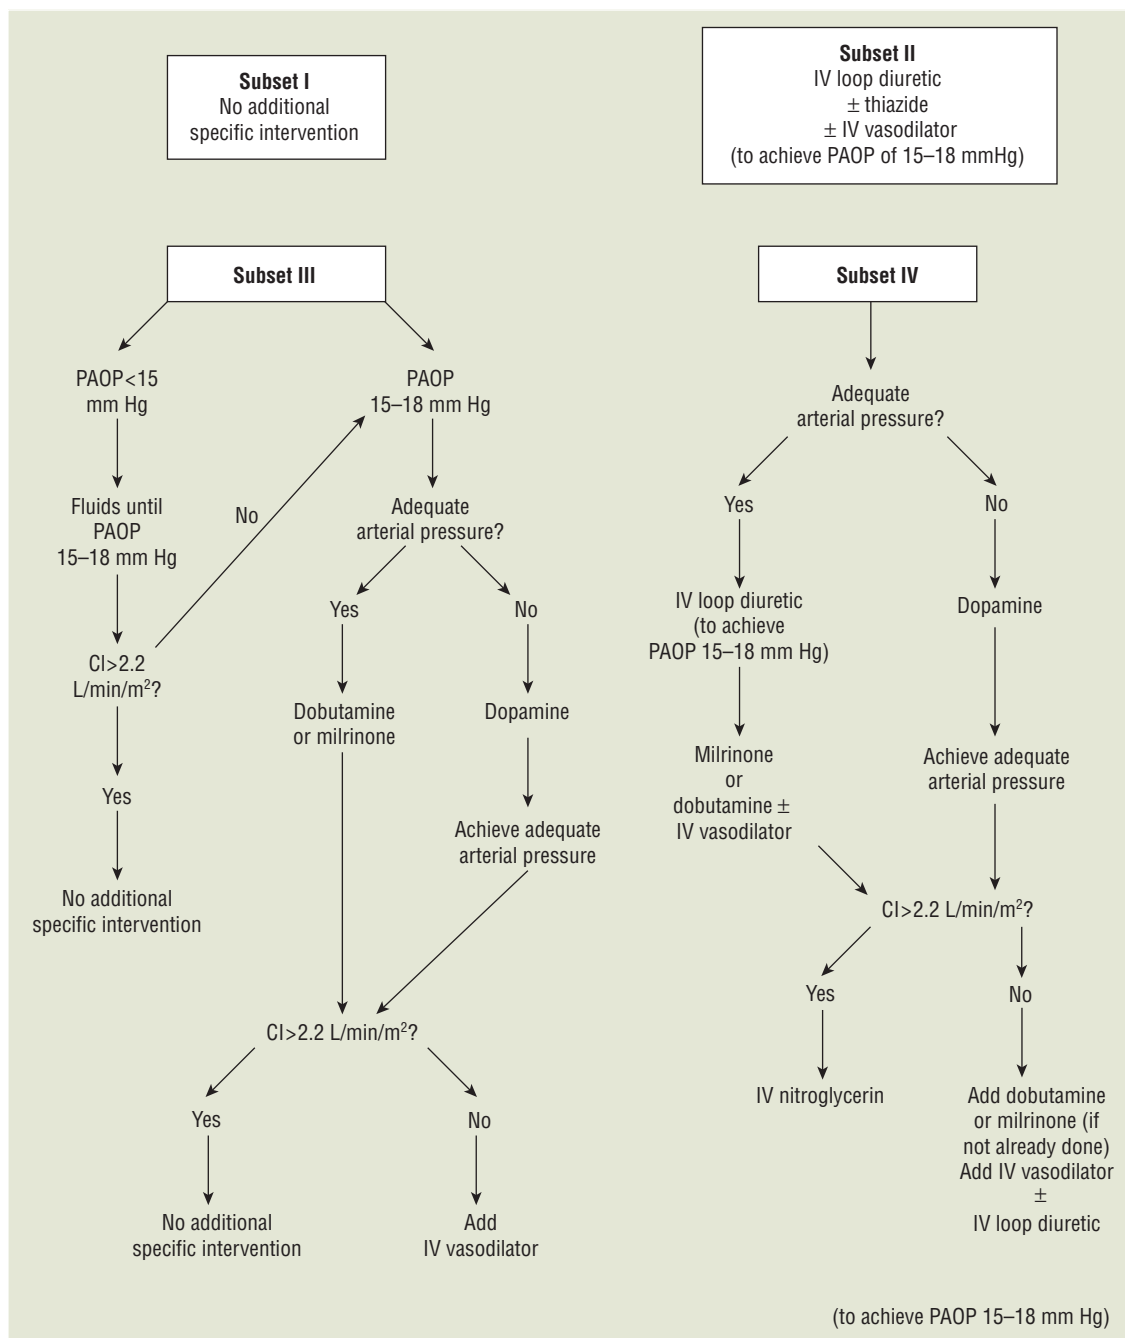

FIGURE 16-10. General treatment algorithm for patients with advanced/decompensated heart failure based on hemodynamic monitoring and hemodynamic subsets. IV vasodilators that may be used include nitroglycerin, nesiritide, or nitroprusside. See text for details. (CI, cardiac index; PAOP, pulmonary artery occlusive pressure.)

patient for desired outcomes. Table 16–16 contains a summary of the expected hemodynamic effects of the various drugs discussed below (see also Chap. 25).

Diuretics^{44,133,134}

Intravenous loop diuretics, including furosemide, bumetanide, and torsemide, are used in the management of decompensated heart failure, with furosemide being the most widely studied and used agent in this setting. Bolus administration of diuretics decreases preload within 5 to 15 minutes by functional venodilation and later (>20 minutes) via sodium and water excretion, thereby improving pulmonary congestion. However, the acute reduction in venous return may severely compromise effective preload in patients with significant diastolic dysfunction or intravascular depletion. This results in a reflex increase in sympathetic activation, renin release,

NE, and AVP elevations and the expected consequences of arteriolar and coronary constriction, tachycardia, and increased PAOP and myocardial oxygen consumption. Unlike arterial dilators and positive inotropic agents, diuretics do not cause an upward shift in the Frank-Starling curve or increase cardiac index significantly in most patients (see Table 16–16). Excessive preload reduction with diuretics can lead to a decline in cardiac output (see Fig. 16–3). Consequently, diuretics must be used judiciously to obtain the desired improvement in symptoms of congestion while avoiding a reduction in cardiac output, symptomatic hypotension, or worsening renal function. Although counterintuitive, renal function may also improve in the setting of diuresis.

Diuretic Resistance Occasionally, patients respond poorly to large doses of loop diuretics, and heart failure is the most common clinical setting in which diuretic resistance is observed. Data from

TABLE 16-16 Usual Hemodynamic Effects of Intravenous Agents Commonly Used for Treatment of Advanced or Decompensated Heart Failure^a

^aSee text for a more detailed description of the interpatient variability in response.

retrospective analyses suggest that diuretics, especially aggressive diuretic administration, may be harmful. The use of diuretics is associated with a dose-dependent increase in mortality.¹³⁵ Recent evidence also suggests that high diuretic doses are associated with a decline in renal function in decompensated heart failure.^{134,136} Thus, the need for increased exposure to diuretics in the setting of diuretic resistance is concerning.

The mechanisms responsible for diuretic resistance in heart failure patients appear to be both pharmacokinetic and pharmacodynamic. The bioavailability of furosemide is relatively normal in heart failure patients, but the rate of absorption is prolonged approximately twofold, and peak concentrations are about half of normal. Because loop diuretics have a sigmoidal-shaped urine concentration–response curve, prolonged absorption may result in concentrations that fail to reach the steep portion of this curve, resulting in diminished responsiveness. Despite normal pharmacokinetics following intravenous administration, diuretic resistance is also observed with this route, suggesting an important pharmacodynamic component to diuretic resistance. The decreased responsiveness in heart failure patients is explained in part by the high concentrations of sodium reaching the distal tubule as a result of the blockade of sodium reabsorption in the loop of Henle. As a consequence, the distal tubule hypertrophies, increasing its ability to reabsorb sodium. In addition, low cardiac output, reduced renal perfusion, and subsequent decreased delivery of drug to the kidney may also contribute to resistance.

Several maneuvers can be attempted to overcome diuretic resistance. Treatment of heart failure with other agents (e.g., positive inotropes or afterload reducers) may improve diuresis by increasing cardiac output and renal perfusion. Administration of low doses of dopamine with the hope of enhancing diuresis is also a common practice. However, data suggest that addition of dopamine to furosemide provides no additional diuresis.¹²⁴ Larger intravenous bolus doses of diuretics may achieve concentrations closer to the top of the concentration–response curve, or a continuous intravenous infusion may be used to maintain more constant concentrations in the steep portion of the concentration–response curve. Studies of continuous-infusion furosemide suggest a greater natriuretic effect and no difference in metabolic adverse effects when compared with the same total daily dose given by intravenous bolus.¹²⁴ Continuous infusions also may limit adverse hemodynamic events.

Another approach to improving diuresis is addition of a second diuretic with a different mechanism of action. Combining a loop

diuretic with a distal tubule blocker such as metolazone or hydrochlorothiazide can produce a synergistic diuretic effect. The synergism is not a pharmacokinetic interaction but is related to the increased delivery of sodium to the distal convoluted tubule. Enhanced sodium delivery to (and reabsorption in) the distal tubule can then be blocked by the thiazide-type diuretic. Thus, when thiazide-type diuretics are added to a loop diuretic, they block more than their normal 5% to 8% of filtered sodium, and the combination results in synergistic natriuresis.

The loop diuretic–thiazide combination generally should be reserved for the inpatient setting, where the patient can be monitored closely, because it can induce a profound diuresis with severe electrolyte and volume depletion. When used in the outpatient setting, very low doses or only occasional doses of the thiazide-type diuretic should be used along with close followup (weight, vital signs, dizziness) to avoid serious adverse events.

Current guidelines support each of the above mentioned options for managing patients who do not initially respond to diuretic therapy. Further restricting sodium and fluid (e.g., less than 1 g and less than 1 L per day, respectively) beyond that which is routine may also prove useful in managing diuretic refractory patients. Such severe fluid restrictions also will be helpful in managing moderate to severe hyponatremia. Ultrafiltration is an additional therapeutic option in the diuretic refractory patient. This topic is discussed within Mechanical Circulatory Support below.

Positive Inotropic Agents^{137,138}

Drugs that increase intracellular cAMP are the only positive inotropic agents currently approved for the treatment of acute heart failure. β -Agonists activate adenylate cyclase through stimulation of β -adrenergic receptors, with the enzyme then catalyzing the conversion of adenosine triphosphate to cAMP. Phosphodiesterase inhibitors raise cAMP concentrations by reducing its degradation. Consequently, both drug classes increase intracellular cAMP, which enhances phospholipase (and, subsequently, phosphorylase) activity, increasing the rate and extent of calcium influx during systole and enhancing contractility. Additionally, cAMP enhances reuptake of calcium by the sarcoplasmic reticulum during diastole, improving active relaxation. Table 16–17 summarizes the receptor activities of the β -agonists. Although rarely used in management of heart failure, the receptor effects of epinephrine, NE, and isoproterenol are provided for reference.

Digoxin has little, if any, place in the acute treatment of patients with decompensated heart failure who are hemodynamically unstable. The delay in peak inotropic effect, limited inotropic effect, long duration of action, and potential toxicity (arrhythmic, vasoconstrictive, neurologic) are disadvantages in the acute setting. However, in patients with acute decompensation who are taking digoxin as part of their chronic therapy, it is generally unnecessary to adjust the dose or discontinue its use unless changes in renal function increase the risk of toxicity.

Although a number of parenteral agents have been used for the treatment of patients with decompensated heart failure, dobutamine and milrinone have emerged as the two drugs most commonly

administered. These drugs differ in their mechanism of action and resulting pharmacologic effects and provide advantages and disadvantages in any given patient.

Dobutamine Dobutamine, a synthetic catecholamine, is a β_1 - and β_2 -receptor agonist with some α_1 -agonist effects (see Table 16–17). Unlike dopamine, dobutamine does not cause release of NE from nerve terminals. The overall hemodynamic effects of dobutamine are the result of its effects on adrenergic receptors and reflex-mediated actions. Its β_2 -receptor-mediated effects are greater than those of dopamine, and β_2 -receptor-mediated vasodilation will tend to offset some of the α_1 -receptor-mediated vasoconstriction. Thus the net vascular effect is usually vasodilation. The positive inotropy is primarily a β_1 -receptor mediated effect. Cardiac β_1 -receptor stimulation by dobutamine causes an increase in contractility but generally no significant change in heart rate and may provide an explanation for the apparently more modest chronotropic actions of dobutamine compared with dopamine.

The overall hemodynamic effects of dobutamine are those of a potent inotropic agent with vasodilating action. Initial doses of 2.5 to 5 mcg/kg per minute can be increased progressively to 20 mcg/kg/min based on clinical and hemodynamic responses. The onset of action is within minutes; however, peak effects may take 10 minutes to become evident. Dobutamine has a half-life of 2 minutes. Cardiac index is increased because of inotropic stimulation, arterial vasodilation, and a variable increase in heart rate. Because of the offsetting changes in arteriolar resistance and cardiac index, dobutamine usually will cause relatively little change in mean arterial pressure although these effects may be variable. This is compared with the more consistent increase observed with dopamine. Dobutamine's vasodilating action usually can decrease PAOP, making it particularly useful in the presence of low cardiac index and an elevated left ventricular filling pressure, or detrimental in the presence of a reduced filling pressure. Unfortunately, an increase in oxygen consumption with dobutamine has been demonstrated in patients with both ischemic and nonischemic cardiomyopathy. The major adverse effect of dobutamine is tachycardia. Although concern over attenuation of dobutamine's hemodynamic effects has been raised with prolonged administration, some effect is likely still retained. And thus, dobutamine dose should be tapered rather than abruptly discontinued.

In some patients, dobutamine (or milrinone) dose reduction or discontinuation results in acute decompensation and these patients may then require placement of an indwelling intravenous catheter for continuous therapy. This approach may be used to “bridge” patients awaiting cardiac transplantation, and may also be used to facilitate the discharge of patients who are not transplant candidates, but who cannot be weaned from inotrope therapy. In this latter group, the use of continuous outpatient dobutamine therapy is for palliative use only and should only be considered after multiple unsuccessful attempts to maximize oral therapy and discontinue inotrope therapy. Although effective for symptom palliation, it should be realized that the risk of mortality is likely increased. In contrast, the use of regularly scheduled intermittent dobutamine infusions at home or in an outpatient clinic is not recommended in the current guidelines.¹²⁴

Milrinone Milrinone is a bipyridine derivative that inhibits phosphodiesterase III, an enzyme responsible for the breakdown of cAMP to adenosine monophosphate. Milrinone has supplanted the use of amrinone, the prototype drug for milrinone, because of the more frequent occurrence of thrombocytopenia with amrinone. Both positive inotropic and arterial and venous vasodilating effects contribute to the therapeutic response in heart failure patients; hence milrinone has been referred to as an *inodilator*. The relative balance of these pharmacologic effects may vary with dose and underlying cardiovascular pathology.

During intravenous administration, there is an increase in stroke volume (and, therefore, cardiac output) with little change in heart rate (see Table 16–16). Despite the increase in cardiac index, mean arterial pressure may remain constant as a result of a concomitant decrease in arteriolar resistance. In contrast, the vasodilating effects may predominate and lead to a decrease in blood pressure and a reflex tachycardia. Like dobutamine, milrinone lowers PAOP by venodilation and thus is particularly useful in patients with a low cardiac index and an elevated left ventricular filling pressure. Such a reduction in preload, however, can be hazardous for patients without excessive filling pressure (especially those with symptoms of “dry” heart failure), leading to a decrease in cardiac index. Such an effect would blunt the improvement in cardiac output that would otherwise be produced by the positive inotropic and arterial dilating actions. Milrinone should be used cautiously as a single agent in severely hypotensive heart failure patients because it will not increase, and may even decrease, arterial blood pressure. The results of controlled studies comparing dobutamine with milrinone indicate that these agents produce generally similar hemodynamic effects. A clinically insignificant but greater increase in heart rate with dobutamine is the most consistent difference in these studies.

Milrinone has a longer terminal elimination half-life than adrenergic agonists. The average milrinone half-life in healthy subjects is about 1 hour and approximately 3 hours in patients with heart failure. This long elimination half-life may be a disadvantage in this patient population because a loading dose may be necessary to obtain a prompt initial response, minute-to-minute titrations in dose cannot be made based on response, and adverse effects (arrhythmias or hypotension) will persist longer after drug discontinuation. The usual loading dose for milrinone is 50 mcg/kg administered over 10 minutes. However, if rapid hemodynamic changes are unnecessary, the loading dose should be eliminated because of the risk of hypotension. Thus, most patients are simply started on the maintenance infusion without a preceding bolus dose. The maintenance infusion for milrinone is 0.25 mcg/kg/min (up to 0.75 mcg/kg/min). Milrinone is excreted unchanged in urine, and thus, its infusion rate should be decreased by 50% to 70% in patients with significant renal impairment.

The most notable adverse events associated with milrinone are arrhythmia, hypotension, and thrombocytopenia. Although the incidence of thrombocytopenia associated with milrinone therapy is rare, patients should still have platelet counts determined before and during therapy.

The combination of dobutamine and milrinone is expected to produce additive effects on cardiac index and PAOP reduction, suggesting this regimen as an option in patients who have dose-limiting adverse effects with either class of drugs. It is unclear, however, if this combination provides a therapeutic advantage over the combination of a positive inotrope and a traditional pure vasodilator such as nitroprusside.

One study with milrinone points out the risk associated with routine administration of inotropic therapy to a broad population of patients admitted to the hospital with an acute exacerbation of heart failure. Although this approach is not supported by clinical trial data, many patients without signs or symptoms of hypoperfusion receive milrinone or other inotropic therapy with the belief that the hemodynamic effects may shorten hospitalization and improve clinical outcomes. Designed to evaluate this strategy, the Outcomes of a Prospective Trial of Intravenous Milrinone for Exacerbations of Chronic Heart Failure (OPTIME-CHF) trial was a randomized, double-blind trial comparing the effects of milrinone and placebo in patients hospitalized with an acute exacerbation of chronic heart failure who, in the investigator's opinion, did not require inotropic therapy.¹²² The 949 patients received a 48-hour infusion of milrinone 0.5 mcg/kg/min with no loading dose or placebo. No difference

between milrinone and placebo was found in the primary end point of the number of days patients were hospitalized for cardiovascular causes within 60 days of randomization. However, adverse events were more common in the milrinone group. Sustained hypotension requiring intervention (10.7% vs. 3.2%; $P < 0.001$) and new onset of atrial fibrillation or flutter (4.6% vs. 1.5%; $P = 0.004$) occurred more frequently in patients receiving milrinone.

Recently, data from the ADHERE Registry ($n = 15,230$) was used to compare in-hospital mortality with intravenous nitroglycerin, nesiritide, milrinone, and dobutamine. After adjusting for baseline parameters that predict in-hospital mortality, both dobutamine- and milrinone-treated patients had a higher in-hospital mortality when compared to patients receiving either nitroglycerin or nesiritide ($P < 0.005$). There was no difference in in-hospital mortality between nitroglycerin- and nesiritide-treated patients ($P = 0.58$). In-hospital mortality was higher in patients receiving dobutamine compared to milrinone ($P = 0.027$).¹³⁹

These results add to the growing concern about the use of inotropic drugs in patients with decompensated heart failure and strongly suggest that milrinone, and probably other inotropes, should not be routinely used for the treatment of acute heart failure exacerbations. Although the routine use of milrinone should be discouraged, clinicians should be aware that inotropic therapy may be needed in selected patients such as those with low cardiac output states with organ hypoperfusion or with cardiogenic shock. Generally, milrinone should be considered for patients who are receiving chronic β -blocker therapy because its positive inotropic effect does not involve stimulation of β -receptors. In contrast to dobutamine, milrinone's positive hemodynamic effects persist despite concomitant β -blocker therapy.

Dopamine Although dopamine generally should be avoided in the treatment of decompensated heart failure, the only clinical scenario where its pharmacologic actions may be preferable to dobutamine or milrinone is in the patient with marked systemic hypotension or cardiogenic shock in the face of elevated ventricular filling pressures, where dopamine in doses greater than 5 mcg/kg per minute may be necessary to raise central aortic pressure. However, there are no data to support this commonly employed practice.

Dopamine, the endogenous precursor of NE, exerts its effects by directly stimulating adrenergic receptors, as well as causing release of NE from adrenergic nerve terminals. Dopamine produces dose-dependent hemodynamic effects because of its relative affinity for α_1 -, β_1 -, β_2 -, and D_1 - (vascular dopaminergic) receptors (see Table 16–17). The following dose-dependent actions are intended as a general guide to the clinician.

Positive inotropic effects mediated primarily by β_1 -receptors become more prominent with dopamine doses of 2 to 5 mcg/kg/min. Cardiac index is increased because of an increase in stroke volume and a variable increase in heart rate, which is partially dose dependent. There is usually little change in SVR, presumably because neither vasodilation (D_1 - and β_2 -receptor mediated) nor vasoconstriction (α_1 -receptor mediated) predominates. At doses between 5 and 10 mcg/kg/min, chronotropic and α_1 -receptor-mediated vasoconstricting effects become more prominent. Mean arterial pressure usually increases because of an increase in both cardiac index and SVR (see Table 16–16). The vasoconstricting effects of higher doses could indirectly limit the increase in cardiac index by increasing afterload and PAOP, thus complicating the management of patients with preexisting high afterload. In such patients, alternative agents (dobutamine, milrinone) or the addition of diuretics and/or vasodilators may be necessary.

Dopamine, particularly at higher doses, may alter several parameters that increase myocardial oxygen demand (increased heart rate, contractility, and systolic pressure) and potentially decrease myocardial blood flow (coronary vasoconstriction and increased wall

tension), worsening ischemia in some patients with coronary disease. As with dobutamine and milrinone, arrhythmogenesis is also more common at higher doses.

Vasodilators^{134,140}

Activation of the SNS, the RAAS, AVP, and other mediators all cause vasoconstriction and increased SVR. In patients with heart failure, stroke volume varies inversely with SVR such that an increase in peripheral resistance leads to a severe decline in stroke volume and cardiac output (see Fig. 16–1).

Vasodilators typically are described by their prominent site of action (arterial or venous). Arterial vasodilators act as impedance-reducing agents, reducing afterload and a reflexive increase in cardiac output. Venodilators act as preload reducers by increasing venous capacitance, reducing symptoms of pulmonary congestion in patients with high cardiac filling pressures. Mixed vasodilators act on both resistance and capacitance vessels, reducing congestive symptoms while increasing cardiac output. Nitroprusside, nitroglycerin, and nesiritide are the most commonly used intravenous vasodilating agents in decompensated heart failure.

Nitroprusside Sodium nitroprusside, a mixed arterial–venous vasodilator, acts on vascular smooth muscle, increasing synthesis of nitric oxide to produce its balanced vasodilating action. As such, it both increases cardiac index and decreases venous pressure. Nitroprusside's effects on these parameters are qualitatively similar to those produced by dobutamine and phosphodiesterase inhibitors, despite the fact that it has no direct inotropic activity (see Table 16–16). However, nitroprusside generally causes a greater decrease in PAOP, SVR, and blood pressure than these agents. Mean arterial pressure may remain fairly constant but often decreases depending on the relative increase in cardiac output and reduction in arteriolar tone. Hypotension is an important dose-limiting adverse effect of nitroprusside and other vasodilators. Consequently, this drug is used primarily in patients who have a significantly elevated SVR and often requires invasive hemodynamic monitoring.

Patients with normal left ventricular function will not have an increase in stroke volume when SVR falls because the normal ventricle is fairly insensitive to small changes in afterload. Consequently, these patients experience a significant decrease in blood pressure after administration of arterial vasodilators. This explains why nitroprusside is a potent antihypertensive agent in patients without heart failure but causes less hypotension and reflex tachycardia in patients with left ventricular dysfunction. Nonetheless, even a modest increase in heart rate could have adverse consequences in patients with underlying ischemic heart disease and/or resting tachycardia, and close monitoring is necessary during therapy.

Nitroprusside has been studied extensively and shown to be effective in the short-term management of patients with severe heart failure in a variety of settings (i.e., acute MI, valvular regurgitation, after coronary bypass surgery, decompensated chronic heart failure). Generally, nitroprusside will not worsen, and may improve, the balance between myocardial oxygen demand and supply. This is mainly a result of a decrease in oxygen demand caused by the lowering of left ventricular wall tension and a possible increase in subendocardial blood flow resulting from decreased left ventricular end-diastolic pressure. However, an excessive decrease in systemic arterial pressure can reduce coronary perfusion and worsen ischemia, leading to increased risk of coronary steal.

Nitroprusside has a rapid onset of action and a duration of action of less than 10 minutes, necessitating its administration by continuous intravenous infusion. This allows for precise dose titration based on measured clinical and hemodynamic parameters. It, like other vasodilators used in heart failure, should be initiated at a low dose (0.1 to 0.2 mcg/kg/min) to avoid excessive hypotension and then

increased by small increments (0.1 to 0.2 mcg/kg/min) every 5 to 10 minutes as needed and tolerated. Effective doses usually range from 0.5 to 3.0 mcg/kg/min. A rebound phenomenon has been reported after abrupt withdrawal of nitroprusside in patients with heart failure and is apparently caused by reflex neurohormonal activation during therapy. If renal perfusion pressure is compromised by the drug, salt and water retention can contribute to volume expansion and tachyphylaxis; this is seen typically only in patients with chronic hypertension, baseline azotemia, or when therapeutic augmentation of cardiac output during therapy is minimal. When stopping nitroprusside and switching to oral drugs, it is usually advisable to taper doses slowly. Nitroprusside can cause cyanide and thiocyanate toxicity, but these are very unlikely when doses less than 3 mcg/kg/min are administered for less than 3 days, except in patients with a serum creatinine level greater than 3 mg/dL.

Given the potent pulmonary vasodilatory effects of nitroprusside as well as its short half-life, this agent is frequently used to determine reversibility of pulmonary hypertension in patients being assessed for heart transplantation. This is the most common use of nitroprusside for the management of decompensated heart failure.

Nitroglycerin Intravenous nitroglycerin is often considered the preferred agent for preload reduction in patients with severe heart failure. Because of its short half-life, intravenous nitroglycerin is administered by continuous infusion. Its major hemodynamic actions are reductions in preload and PAOP via functional venodilation and mild arterial vasodilation that is particularly evident in patients with heart failure and elevated SVR or when given in doses approaching 200 mcg/min (see Table 16–16). Intravenous nitroglycerin is used primarily as a preload reducer for patients with pulmonary congestion. In higher doses, nitroglycerin displays potent coronary vasodilating properties and beneficial effects on myocardial oxygen demand and supply, making it the vasodilator of choice for patients with severe heart failure and ischemic heart disease.

Nitroglycerin should be initiated at a dose of 5 to 10 mcg/min (0.1 mcg/kg/min) and increased every 5 to 10 minutes as necessary and tolerated. Hypotension and an excessive decrease in PAOP are important dose-limiting side effects. Maintenance doses usually vary from 35 to 200 mcg/min (0.5 to 3.0 mcg/kg/min). Tolerance to the hemodynamic effects of nitroglycerin may develop over 12 to 72 hours of continuous administration, but some patients have a sustained response. Neither nitroglycerin nor nitroprusside should be used in the presence of elevated intracranial pressure because either may worsen cerebral edema in this setting.

Nesiritide Nesiritide is the first new drug approved for the treatment of decompensated heart failure since milrinone. Manufactured by recombinant techniques, it is identical to the endogenous human BNP secreted by the ventricular myocardium in response to volume overload. Exogenous administration of nesiritide mimics the vasodilatory and natriuretic actions of the endogenous peptide by stimulating the natriuretic peptide receptor A which leads to increased levels of cyclic guanosine monophosphate in target tissues. Nesiritide produces dose-dependent venous and arterial vasodilation, increases in cardiac output, natriuresis, and diuresis, and decreases cardiac filling pressures, SNS and RAAS activity. Unlike nitroglycerin or dobutamine, tolerance does not develop to nesiritide's pharmacologic actions. It does not affect cAMP or stimulate β -receptors, mechanisms that are thought to contribute to the myocardial toxicity associated with the positive inotropic drugs. Thus, nesiritide does not have the proarrhythmic effects associated with dobutamine. Nesiritide is eliminated by several pathways including the natriuretic peptide receptor C on target tissues, proteolytic cleavage by neutral endopeptidase, and renal filtration. Its elimination half-life of 18 minutes is considerably longer than that of other vasodilators or β -agonists.

The Vasodilation in the Management of Acute CHF (VMAC) trial was a randomized, double-blind trial that compared the effects of nesiritide, IV nitroglycerin, and placebo in patients with decompensated heart failure and dyspnea who were receiving standard background therapy.¹²³ Patients received pulmonary artery catheterization at the discretion of the investigators. The primary end points were the patient's self-assessment of dyspnea (all patients) and the change in PAOP at 3 hours after the start of the study drug infusion (only in patients with a pulmonary artery catheter) compared to placebo. Although nesiritide reduced dyspnea at 3 hours compared to placebo, no difference between nesiritide and nitroglycerin was found.

The precise role of nesiritide in the pharmacotherapy of decompensated heart failure remains controversial. Some of this controversy centers on the marginal lack of improvement in mortality or other clinical outcomes with nesiritide compared to nitroglycerin (or nitroprusside) balanced against nesiritide's significantly greater costs (~\$450 for a 24-hour nesiritide infusion compared to \$10 to \$15 for nitroglycerin). In addition, two recent meta-analyses suggest an increased risk of worsening renal function, as well as an increase in mortality with nesiritide.^{141,142} The authors of these studies concluded that these findings are hypothesis generating and should be further investigated. More recently, the safety of nesiritide in 303 patients with a low LVEF (<40%) who were undergoing coronary artery bypass surgery was evaluated in the multicenter, randomized, placebo-controlled Nesiritide Administered Peri-Anesthesia in Patients Undergoing Cardiac Surgery (NAPA) study.¹⁴³ Patients received intravenous nesiritide 0.01 mcg/kg/min or placebo in the preanesthesia period and the infusion continued for 24 to 96 hours at the investigator's discretion. Serum creatinine increased and glomerular filtration rate decreased after surgery compared with preoperative values in both treatment groups. However, the changes in creatinine and glomerular filtration rate were significantly greater in placebo-treated patients. In contrast, the mean hospital length of stay was significantly shorter and the 180-day mortality rate was significantly lower in the nesiritide group. To clarify these issues about the safety and efficacy of nesiritide, its manufacturer is conducting an additional prospective randomized controlled trial.

■ MECHANICAL CIRCULATORY SUPPORT¹⁴⁴

Intraaortic Balloon Pump

The intraaortic balloon pump (IABP) is a frequently used form of mechanical circulatory assistance and typically is employed in patients with advanced heart failure who do not respond adequately to drug therapy, such as those with intractable myocardial ischemia or patients in cardiogenic shock. The IABP consists of a polyethylene balloon mounted on a catheter that is usually inserted percutaneously into the femoral artery and the balloon is then advanced into the descending thoracic aorta. During counterpulsation, the balloon is synchronized with the ECG so that it inflates during diastole and displaces aortic blood thus increasing aortic diastolic pressure and coronary perfusion. The balloon deflates just prior to the opening of the aortic valve during systole and causes a sudden decrease in aortic pressure, allowing the left ventricle to pump against reduced arterial impedance. IABP support results in increased cardiac index, coronary artery perfusion, and myocardial oxygen supply accompanied by decreased myocardial oxygen demand. Thus, it is particularly useful for short-term use in patients with decompensated heart failure in the setting of myocardial ischemia (evolving infarction, patients awaiting emergency coronary bypass surgery). It is also used in hemodynamically unstable patients who are unresponsive to inotropic therapy to stabilize them prior to insertion of a left ventricular assist device that will serve as a bridge to transplantation. Generally, intravenous vasodilators and

inotropic agents are used in conjunction with the IABP to maximize hemodynamic and clinical benefits.

Ventricular Assist Devices

A number of ventricular assist devices are available or under investigation. These pumps are surgically implanted and assist, or in some cases replace, the pumping functions of the right and/or left ventricles. A left ventricular assist device (LVAD) removes blood directly from the left ventricle or the left atrium and pumps it to the aorta. The right ventricular assist device works similar to the LVAD and may be used alone or in conjunction with the LVAD.

LVADs can be used in the short-term (days to a couple of weeks) for temporary stabilization of a patient awaiting an intervention to correct the underlying cardiac dysfunction. Alternatively, these devices can be used in the long-term (several months to a couple of years) as a bridge to heart transplantation. More recently, permanent device implantation has become an option for patients who are not heart transplantation candidates.

The REMATCH (Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure) trial randomized 129 patients with decompensated heart failure to LVAD or optimal medical therapy. LVAD patients experienced improved 2-year survival; however, only 23% of these patients were alive at 2 years, compared to only 8% in the medically managed group.¹⁴⁵ The REMATCH trial was responsible for the approval of the use of these devices as “destination” therapy, destination being the last therapeutic option for a given patient. It also raised awareness regarding some of the limitations of these devices. Complications with LVADs include bleeding, air embolism, and right ventricular failure, as well as those complications associated with a major surgical procedure, including infection. In addition, these pumps can cause hemolysis, thrombosis, renal and hepatic dysfunction, and arrhythmias. Finally, device malfunction may occur. Controversy exists regarding the cost of such procedures given the already significant economic impact of this disease state on the healthcare system. Although only a small number of patients were studied, recent research suggests that prolonged unloading of the left ventricle with an LVAD in combination with drug therapy to induce reverse remodeling can produce sustained recovery in left ventricle function and amelioration of symptoms.¹⁴⁶

For complete heart replacement therapy, the total artificial heart systems continue to be investigated; however, embolic complications, as well as the large size of the currently available systems, are limiting their use. Inserted percutaneously, catheter-based LVADs are a more recent advancement. Although these small pumps may offer an advantage as they avoid the need for open-heart surgery, the technology is still in developmental stages.

Ultrafiltration

Renal dysfunction often occurs in the setting of decompensated heart failure, and thus, renal replacement therapy may be necessary. Ultrafiltration provides an additional modality for fluid removal by rapidly removing salt and water (up to 500 mL/h) in a predictable manner. It reduces PAOP and increases cardiac output and diuresis without adversely affecting blood pressure, heart rate, or renal function. Also, ultrafiltration is proposed to be safer than diuretics because removal of sodium and water is isotonic. Potential candidates for ultrafiltration include patients with diuretic resistance, renal impairment with diuretic administration, and renal impairment despite inotropic therapy. Complications of ultrafiltration include those associated with central venous access, such as infection, as well as those associated with rapid volume removal and intravascular depletion. Electrolyte depletion is not significant, but still requires close monitoring.

Small studies suggest that ultrafiltration is an effective method to remove fluid in heart failure patients and that early initiation prior to intravenous diuretics is effective and safe in reducing hospital length of stay and readmission in diuretic resistant patients. Recently, the Ultrafiltration versus IV Diuretics for Patients Hospitalized for Acute Decompensated Congestive Heart Failure (UNLOAD) trial investigated the effects of early ultrafiltration alone compared to intravenous diuretics alone in 200 patients hospitalized for decompensated heart failure and evidence of fluid overload. The primary end point of weight loss after 48 hours was significantly greater in the ultrafiltration group (5.0 kg) than in the diuretic group (3.1 kg). There was no significant difference between the two treatment groups in the dyspnea score at 48 hours, another primary end point. Compared with the diuretic group, the net fluid loss was significantly greater in the ultrafiltration group (4.6 L vs. 3.3 L) after 48 hours. After 90 days, the incidence and duration of rehospitalization and the incidence of unscheduled office or emergency department visits were significantly lower in patients who were treated using ultrafiltration than in patients who were treated with intravenous diuretics.¹⁴⁷

■ SURGICAL THERAPY

Orthotopic cardiac transplantation remains the best therapeutic option for patients with chronic, irreversible NYHA class IV heart failure, with a 10-year survival of approximately 50% in well-selected patients.¹⁴⁸ Unfortunately, the shortage of acceptable donor hearts has resulted in long waiting times for transplantation, with many patients succumbing to their disease prior to transplantation. Another large percentage of patients are rejected from consideration for transplantation because of age, concurrent illnesses, psychosocial factors, and other reasons. See Chap. 92 for additional details on cardiac transplantation. The shortage of donor hearts has prompted development of new surgical techniques, including ventricular aneurysm resection, mitral valve repair, and myocardial cell transplantation, which have resulted in variable degrees of symptomatic improvement. Further development of these and other techniques may offer additional options in patients who are not transplantation candidates.

■ PREPARATION FOR HOSPITAL DISCHARGE

For patients who are hospitalized with decompensated heart failure, all factors contributing to decompensation should be addressed. Patients should be near if not at optimal fluid status, transitioned from intravenous to oral diuretic therapy. Both the patient and family should receive appropriate education (see details below). Chronic drug therapy should be optimized and appropriate followup clinic appointments scheduled. Typically, patients should be seen in the clinic in 7 to 10 days following hospital discharge. For patients with recurrent hospital admissions, additional discharge criteria should be considered (Table 16–18).¹²⁴

Patient education is essential in the discharge process and should be multidisciplinary involving input from dietitians, pharmacists, and other healthcare providers. Teaching should promote self-care by incorporating identification of specific positive and negative behaviors. By having a better understanding of the key concepts of the disease and its management, patient self-care should improve and future hospitalizations may be avoided.¹²⁴

Although all patients should benefit from education, those with more severe symptoms (NYHA class III or IV) require the most intensive counseling. During a hospitalization, only essential education is recommended, which should be supplemented within a couple of weeks after discharge in the clinic setting. Patients recently hospitalized for heart failure should be considered for referral to a disease-management program.

TABLE 16-18 Discharge Criteria for Patients with Heart Failure

Recommended for all heart failure patients	<ul style="list-style-type: none"> • Exacerbating factors addressed • At least near-optimal volume status achieved • Transition from intravenous to oral diuretic successfully completed • Patient and family education completed • At least near-optimal pharmacologic therapy achieved • Followup clinic visit scheduled, usually for 7–10 days after discharge
Should be considered for patients with advanced heart failure or recurrent admissions for heart failure	<ul style="list-style-type: none"> • Oral medication regimen stable for 24 hours • No intravenous vasodilator or inotropic agent for 24 hours • Ambulation before discharge to assess functional capacity after therapy • Plans for postdischarge management (scale present in home, visiting nurse or telephone followup generally no longer than 3 days after discharge) • Referral for disease management

Adapted from Adams KF, Lindenfield J, Arnold JMO, et al. HFSA 2006 comprehensive heart failure practice guidelines. *J Card Fail* 2006;12:e1–e122.

For patients with end-stage disease, quality of life and prognosis should be discussed with the patient and caregivers. The patient's clinical status should be optimally managed prior to discussing end-of-life care. If possible, this discussion should occur while the patient is still able to participate in the decision-making process. End-of-life care should be considered in patients with persistent symptoms at rest despite multiple attempts to optimize therapy as evidenced by frequent hospitalizations (three or more per year), ongoing limited quality of life, requiring intermittent or continuous intravenous therapy, or consideration of assist devices as destination therapy. In such cases, inactivation of an ICD should be discussed and patients may be considered for hospice services.¹²⁴ Integration of a palliative care approach may be necessary. As clinical status deteriorates and medical therapies become ineffective, healthcare providers should transition from focusing on mortality reduction to palliative care.¹⁴⁹

■ PHARMACOECONOMIC CONSIDERATIONS

Heart failure imposes a tremendous economic burden on the healthcare system. In patients older than age 65 years, it is the most common reason for hospitalization, with hospital admission rates for this disorder continuing to increase. Heart failure is also associated with unacceptably high readmission rates during the 3 to 6 months after initial discharge. Current estimates of costs of heart failure treatment in the United States approach \$30 billion with most of the costs associated with hospitalization.^{1,4} The prevalence of heart failure and the costs associated with patient care are expected to increase as the population ages and as survival from ischemic heart disease is improved. Thus approaches to improve the quality and cost-effectiveness of care for these patients may have a significant impact on healthcare costs.

Studies to assess the cost-effectiveness of drug therapy for heart failure were recently reviewed.¹⁵⁰ Many studies provide direct cost estimates, demonstrating an economic value when employing standard heart failure therapies, specifically ACE inhibitors, β -blockers, and digoxin. Much of the economic benefit of these therapies is a result of a reduction in hospitalization. While the clinical and economic benefits of these therapies are well-recognized, standard heart failure therapies are often underprescribed. A recent study found that more optimal use of evidence-based therapies with a 10% increase in the use of ACE inhibitors, β -blockers, digoxin, and spironolactone would result in cost savings as a consequence of a reduction in hospitalization.¹⁵¹ In addition, prescribing optimal doses that approach target doses shown in clinical trials to affect outcomes would have a similar impact. For example, patients receiv-

ing high doses versus low doses of ACE inhibitors experienced cost saving as a consequence of fewer heart failure hospitalizations.¹⁵²

More recent pharmacoeconomic studies have focused on the impact of newer heart failure therapies or those used as alternatives to standard therapy. ARBs have been shown to be cost effective in patients not receiving ACE inhibitors.¹⁵³ Eplerenone is a cost-effective therapy in patients with post-MI heart failure.¹⁵⁴ Fixed-dose combination hydralazine and isosorbide dinitrate is cost-effective in black patients with severe heart failure.¹⁵⁵ Other cost-effective studies have focused on device therapy. Prophylactic ICD implantation in heart failure patients with systolic dysfunction is cost-effective.¹⁵⁶ Although cost-effectiveness of CRT has been suggested, it was found to be sensitive to changes in several key variables. Thus investigators cautioned that such therapy should not be considered in patients with any comorbid illnesses that may shorten life expectancy.¹⁵⁷ Finally, LVADs as a bridge to heart transplantation were found to be cost-ineffective unless costs associated with their implantation decrease or their clinical benefits increase.¹⁵⁸

As the management of heart failure has become increasingly complex, the development of disease-management programs approaches that use multidisciplinary teams has been studied extensively. These programs use several broad approaches, including heart failure specialty clinics and/or home-based interventions. Most are multidisciplinary and may include physicians, advanced practice nurses, dietitians, and pharmacists. In general, the programs focus on optimization of drug and nondrug therapy, patient and family education and counseling, exercise and dietary advice, intense followup by telephone or home visits, and monitoring and management of signs and symptoms of decompensation. In general, multidisciplinary disease management programs reduce heart failure and all-cause hospitalizations, mortality, and costs.¹⁵⁹

¹² Pharmacists can play an important role in the multidisciplinary team management of heart failure.^{160,161} Compared to conventional treatment, pharmacist interventions, that included medication evaluation and therapeutic recommendations, patient education, and followup telephone monitoring, reduced hospitalizations for heart failure. Adherence to guideline-recommended therapy was also improved by pharmacist intervention. A recent study found that pharmacist intervention improved medication adherence and reduced emergency department visits and hospitalizations in low-income patients with heart failure.¹⁶² Thus, the role and cost benefits of pharmacist involvement in the multidisciplinary care of heart failure patients are now apparent and should include optimizing doses of heart failure drug therapy, screening for drugs that exacerbate heart failure, monitoring for adverse drug effects and drug interactions, educating patients, and patient followup.

■ CURRENT CONTROVERSIES

1. For patients with chronic heart failure who remain symptomatic despite standard therapy (ACE inhibitor, β -blocker, diuretic, digoxin), which additive therapy should be used is uncertain. Agents that can be considered are aldosterone antagonists, ARBs, or hydralazine/nitrates. Drug selection should be based on patient-specific criteria (e.g., renal function, ethnicity) that will influence the benefits and risks of each agent.
2. The African American Heart Failure Trial confirmed that the addition of a fixed-dose combination of isosorbide dinitrate and hydralazine to standard background therapy improved survival in African American patients with heart failure. Whether isosorbide/hydralazine is beneficial in non-African American patients is unknown.
3. The optimal pharmacotherapy for patients with acute decompensated heart failure who are refractory to diuretic therapy is controversial. Recent meta-analyses suggest that nesiritide use

is associated with worsening renal function and increased mortality. However, the safety of other vasodilators, such as nitroglycerin or nitroprusside, is not well established and the use of positive inotropes is associated with poor outcomes.

EVALUATION OF THERAPEUTIC OUTCOMES

CHRONIC HEART FAILURE

Although mortality is an important end point, it does not give a complete measure of the overall effects of the disease on patient outcomes because many patients are hospitalized repeatedly for heart failure exacerbations and continue to survive. Thus some of the more important therapeutic outcomes in heart failure management, such as prolonged survival or prevention or slowing of the progression of heart failure, cannot be quantified in an individual patient. However, after appropriate diagnostic evaluation to determine the etiology of heart failure, ongoing clinical assessment of patients typically focuses on three general areas: (a) evaluation of functional capacity, (b) evaluation of volume status, and (c) laboratory evaluation.

The evaluation of functional capacity should focus on the presence and severity of symptoms the patient experiences during activities of daily living and how their symptoms affect these activities. Questions directed toward the patient's ability to perform specific activities may be more informative than general questions about what symptoms the patient may be experiencing. For example, ask patients if they can participate in exercise, climb stairs, get dressed without stopping, check the mail, or clean the house. Another important component of assessment of functional capacity is to ask patients what activities they would like to do but are now unable to perform.

Assessment of volume status is a vital component of the ongoing care of patients with heart failure. This evaluation provides the clinician important information about the adequacy of diuretic therapy. Because the cardinal signs and symptoms of heart failure are caused by excess fluid retention, the efficacy of diuretic treatment is readily evaluated by the disappearance of these signs and symptoms. The physical examination is the primary method for the evaluation of fluid retention and specific attention should be focused on the patient's body weight, extent of jugular venous distension, presence of hepatojugular reflux, presence and severity of pulmonary congestion, and peripheral edema. Specifically, in a patient with pulmonary congestion, monitoring is indicated for resolution of rales and pulmonary edema and improvement or resolution of dyspnea on exertion, orthopnea, and paroxysmal nocturnal dyspnea. For patients with systemic congestion, a decrease or disappearance of peripheral edema, jugular venous distension, and hepatojugular reflux is sought. Other therapeutic outcomes include an improvement in exercise tolerance and fatigue, decreased nocturia, and a decrease in heart rate. Clinicians also will want to monitor blood pressure and ensure that the patient does not develop symptomatic hypotension as a result of drug therapy. Body weight is a sensitive marker of fluid loss or retention, and patients should be counseled to weigh themselves daily, reporting changes to their healthcare provider so that adjustments can be made in diuretic doses. It should be noted, particularly with β -blocker therapy, that symptoms may worsen initially and that it may take weeks to months of treatment before patients notice improvement in symptoms. Also, patients and healthcare providers should be aware that heart failure progression may be slowed even though symptoms have not resolved.

Routine monitoring of serum electrolytes and renal function is required in patients with heart failure. Assessment of serum potassium is especially important because hypokalemia is a common adverse effect of diuretic therapy and is associated with an increased

risk of arrhythmias and digoxin toxicity. Serum potassium monitoring is also required because of the risk of hyperkalemia associated with ACE inhibitors, ARBs, and aldosterone antagonists. A serum potassium ≥ 4.0 mEq/L should be maintained with some evidence suggesting it should be ≥ 4.5 mEq/L.¹⁶³ Assessment of renal function (blood urea nitrogen and serum creatinine) is also an important end point for monitoring diuretic and ACE inhibitor therapy. Common causes of worsening renal function in patients with heart failure include overdiuresis, adverse effects of ACE inhibitor or ARB therapy, and hypoperfusion.

ACUTE DECOMPENSATED HEART FAILURE

Assessment of adequacy of therapy in the acute decompensated heart failure patient can be separated into two general categories: initial improvement of physiologic parameters and safe discharge from the intensive care unit following conversion to a chronic oral therapeutic regimen. Both goals must be achieved because hemodynamic improvement has not correlated with prolonged symptom improvement or enhanced survival.

Initial stabilization requires achievement of adequate arterial oxygen saturation and content. Cardiac index and blood pressure must be sufficient to ensure adequate organ perfusion, as assessed by alert mental status, creatinine clearance sufficient to prevent metabolic azotemic complications, hepatic function adequate to maintain synthetic and excretory functions, a stable heart rate and rhythm (predominately sinus rhythm, rate-stabilized atrial fibrillation or flutter, or paced rhythm), absence of ongoing myocardial ischemia or infarction, skeletal muscle and skin blood flow sufficient to prevent ischemic injury, and normal arterial pH (7.34 to 7.47) with a normal serum lactate concentration. Although these goals are achieved most often with a cardiac index greater than 2.2 L/min/m², a mean arterial blood pressure greater than 60 mm Hg, and a PAOP of 15 mm Hg or greater, the absolute values are highly variable and depend on chronicity of illness, efficacy of chronic compensatory mechanisms, previous chronic therapy, and concurrent illness.

Discharge from the intensive care unit requires maintenance of the preceding parameters in the absence of ongoing intravenous infusion therapy, mechanical circulatory support, or positive-pressure ventilation. Some patients may achieve this goal with markedly lower blood pressure or higher filling pressure than suggested earlier; hence numerical goals cannot always be substituted for clinical status. Nonpharmacologic treatments aimed at the precipitants of a patient's heart failure exacerbation include permanent pacing, CRT with or without ICD, coronary angioplasty or valvuloplasty, pericardial drainage, cardiac surgery (coronary bypass, valve replacement or reconstruction, closure of intracardiac shunts), or even cardiac transplantation, to achieve initial stabilization, definitive therapy, or both.

ABBREVIATIONS

ACE: angiotensin-converting enzyme

ARB: angiotensin receptor blocker

AVP: arginine vasopressin

BNP: B-type natriuretic peptide

cAMP: cyclic adenosine monophosphate

COX-2: cyclooxygenase-2

CRT: cardiac resynchronization therapy

HFSA: Heart Failure Society of America

IABP: intraaortic balloon pump

ICD: implantable cardioverter-defibrillator

JVD: jugular venous distension
 LVAD: left ventricular assist device
 LVEF: left ventricular ejection fraction
 MI: myocardial infarction
 NE: norepinephrine
 NSAID: nonsteroidal antiinflammatory drug
 NYHA: New York Heart Association
 PAOP: pulmonary artery occlusion pressure
 RAAS: renin–angiotensin–aldosterone system
 SNS: sympathetic nervous system
 SVR: systemic vascular resistance
 TNF- α : tumor necrosis factor- α
 TZD: thiazolidinedione

ROBERT L. TALBERT

KEY CONCEPTS

- 1 Ischemic heart disease (IHD) is primarily caused by coronary atherosclerotic plaque formation that leads to an imbalance between oxygen supply and demand resulting in myocardial ischemia.
- 2 Chest pain is the cardinal symptom of myocardial ischemia caused by coronary artery disease (CAD).
- 3 Risk factor identification and modification are important interventions for individual patients with known or suspected IHD and as a population-based policy to reduce the impact of this disease.
- 4 Major risk factors that can be altered include dyslipidemia (high total and low-density lipoprotein cholesterol, low high-density lipoprotein cholesterol, and high triglycerides), smoking, glycemic control in diabetes mellitus, hypertension, and adoption of therapeutic lifestyle changes (exercise, weight reduction and reduced cholesterol and fat in the diet). Reduction in inflammation may also play an important role.
- 5 Most patients with CAD should be receiving antiplatelet therapy. Chronic stable angina should be managed initially with β -blockers because they provide better symptomatic control, at least as well as nitrates or calcium channel blockers, and decrease the risk of recurrent myocardial infarction and CAD mortality.
- 6 Nitroglycerin and other nitrate products are useful for prophylaxis of angina when patients are undertaking activities known to provoke angina; however, when angina is occurring on a regular, routine basis, chronic prophylactic therapy should be instituted.
- 7 Although calcium channel blockers are effective as monotherapy, they are generally used in combination with β -blockers or as monotherapy if patients are intolerant of β -blockers; most patients with moderate to severe angina will require two drugs to control their symptoms. Ranolazine is a second-line drug to be used with β -blockers and certain calcium channel blockers.
- 8 Pharmacologic management is as effective as revascularization (percutaneous transluminal coronary angioplasty, coronary artery bypass graft, etc.) if one or two vessels are involved and there are no differences in survival, recurrent myocardial infarction, or other measures of effectiveness.
- 9 Multivessel involvement, especially if the patient has left main coronary artery disease or left main equivalent disease, or two-

to three-vessel involvement with significant left ventricular dysfunction is best managed with revascularization.

- 10 Percutaneous transluminal coronary angioplasty and coronary artery bypass graft produce similar results overall but certain patient subsets (e.g., diabetics) should have coronary artery bypass grafting done.
- 11 The clinical performance measures for chronic stable CAD recommended by the American College of Cardiology and the American Heart Association include blood pressure measurement, lipid profile, symptom and activity assessment, smoking cessation, antiplatelet therapy, drug therapy for lowering low-density lipoprotein cholesterol, β -blocker therapy for prior myocardial infarction, angiotensin-converting enzyme inhibitor therapy, and screening for diabetes.

Ischemic heart disease (IHD) caused by atherosclerosis of the epicardial vessels leading to coronary heart disease (CHD) is the main etiology of IHD. This process begins early in life, often not being clinically manifest until the middle-aged years and beyond. IHD may present as an acute coronary syndrome (acute coronary syndrome includes unstable angina, non-ST-segment elevation myocardial infarction or ST-segment elevation myocardial infarction; see Chap. 18), chronic stable exertional angina pectoris, and ischemia without clinical symptoms. Coronary artery vasospasm (variant or Prinzmetal angina) produces similar symptoms but is not caused by atherosclerosis. Other manifestations of atherosclerosis include heart failure, arrhythmias, cerebrovascular disease (stroke), and peripheral vascular disease. The American Heart Association, the American College of Cardiology, and the European Society of Cardiology have published management guidelines for stable and unstable angina.¹⁻³

EPIDEMIOLOGY

The American Heart Association (AHA) estimates that 79,400,000 American adults have one or more types of cardiovascular disease (CVD) based on data from 1999 through 2004.⁴ Nearly 2,400 Americans die of CVD each day, or an average of 1 death every 33 seconds. In 2004, the death rates from CVD were 448.9 (per 100,000) for black males, 335.7 for white males, 331.6 for black females, and 239.3 for white females.⁴ CHD was responsible for 52% of deaths from CVD. Men die earlier from IHD and acute myocardial infarction than women, and aging of both sexes is associated with a higher incidence of these afflictions. The disparity in mortality from IHD between men and women decreases with aging, being about four to five times more common in men from the age of the mid-30s to a preponderance of female deaths in the very elderly.

The syndrome of angina pectoris is reported to occur with an average annual incidence rate (number of new cases per time period/

Learning objectives, review questions, and other resources can be found at
www.pharmacotherapyonline.com.

total number of persons in the population for the same time period) of approximately 1.5% (range: 0.1 to 5/1,000) depending on the patient's age, gender, and risk-factor profile.⁵ The presenting manifestation in women is more commonly angina, whereas men more frequently have myocardial infarction as the initial event. Estimates of the incidence and prevalence of angina are not entirely accurate because of waxing and waning of symptoms; angina may disappear in up to 30% of patients with angina that is less severe and of recent onset.

Data from the Framingham study show that the prevalence in a 1970 cohort followed for 10 years was approximately 1.5% for women and 4.3% for men ages 50 to 59 years at inception.⁵ The annual rate of new episodes of angina range from 28.3 to 33 per 1,000 population for nonblack men, 22.4 to 39.5 for black men, 14.1 to 22.9 for nonblack women, and 15.3 to 35.9 for black women in the age range of 65 to 84 years or older.⁴ AHA estimates that the prevalence of angina was 8.9 million in 2004.⁴ Other interesting trends noted included a 21% decline in the incidence of cardiovascular disease in women, but only a 6% decline in men over two cohorts from 1950 and 1970. Cardiovascular mortality was reduced by 59% in women and 53% in men from the same cohorts. The risk of developing ischemic heart disease is not the same worldwide. Countries such as Japan and France are on the low end of the spectrum, whereas Finland, Northern Ireland, Scotland, and South Africa have very high rates of IHD.^{6,7}

Angina may be classified according to symptom severity, disability induced, or a specific activity scale (Tables 17-1 and 17-2). The specific activity scale developed by Goldman and coworkers⁸ may be preferable because it has been shown to be equal to or better than the New York Heart Association or Canadian Cardiovascular Society functional classifications for reproducibility and provides better agreement with exercise treadmill testing.

TABLE 17-1 Criteria for Determination of the Specific Activity Scale Functional Class

	Any Yes	No
1. Can you walk down a flight of steps without stopping (4.5–5.2 MET)?	Go to 2	Go to 4
2. Can you carry anything up a flight of 8 steps without stopping (5–5.5 MET)? Or can you:	Go to 3	Class III
a. Have sexual intercourse without stopping (5–5.2 MET)		
b. Garden, rake, weed (5.6 MET)		
c. Roller skate, dance foxtrot (5–6 MET)		
d. Walk at a 4-miles/h rate on level ground (5–6 MET)		
3. Can you carry at least 24 lb up 8 steps (10 MET)? Or can you:	Class I	Class II
a. Carry objects that weigh at least 80 lb (18 MET)		
b. Do outdoor work, shovel snow, spade soil (7 MET)		
c. Do recreational activities such as skiing, basketball, touch football, squash, handball (7–10 MET)		
d. Jog/walk 5 miles/h (9 MET)		
4. Can you shower without stopping (3.6–4.2 MET)? Or can you:	Class III	Go to 5
a. Strip and make bed (3.9–5 MET)		
b. Mop floors (4.2 MET)		
c. Hang washed clothes (4.4 MET)		
d. Clean windows (3.7 MET)		
e. Walk 2.5 miles/h (3–3.5 MET)		
f. Bowl (3–4.4 MET)		
g. Play golf, walk and carry clubs (4.5 MET)		
h. Push a power lawnmower (4 MET)		
5. Can you dress without stopping because of symptoms (2–2.3 MET)?	Class III	Class IV

MET, metabolic equivalents of activity.

TABLE 17-2 Grading of Angina Pectoris by the Canadian Cardiovascular Society Classification System

Class	Description of Stage
Class I	Ordinary physical activity does not cause angina, such as walking, climbing stairs. Angina occurs with strenuous, rapid, or prolonged exertion at work or recreation.
Class II	Slight limitation of ordinary activity. Angina occurs on walking or climbing stairs rapidly, walking uphill, walking or stair climbing after meals, or in cold, or in wind, or under emotional stress, or only during the few hours after waking. Walking more than 2 blocks on the level and climbing more than 1 flight of ordinary stairs at a normal pace and in normal condition.
Class III	Marked limitations of ordinary physical activity. Angina occurs on walking 1 to 2 blocks on the level and climbing 1 flight of stairs in normal conditions and at a normal pace.
Class IV	Inability to carry on any physical activity without discomfort—anginal symptoms may be present at rest.

From Campeau L. Grading of angina [letter]. *Circulation* 1976;54:522–523, with permission.

An important determinate of outcome for the angina patient is the number of vessels obstructed. Twelve-year survival from the Coronary Artery Surgery Study (CASS) for patients with zero-, one-, two-, and three-vessel disease was 88%, 74%, 59%, and 40%, respectively.⁹ Other factors that increase the risk of death in medically managed patients include the presence of heart failure (or markers such as poor ventricular wall motion and low ejection fraction), smoking, left main or left main equivalent coronary artery disease, diabetes, and prior myocardial infarction. Twelve-year survival for patients with at least one diseased vessel and ejection fractions in the ranges of $\geq 50\%$, 35% to 49%, and 0% to 34% is 73%, 54%, and 21%, respectively. Of particular note, patients with left main coronary artery disease (or left main equivalent) are at extremely high risk and constitute a unique group for therapeutic consideration.¹⁰ In the CASS, at 15 years of followup, 37% of the surgery group and 27% of the medical group are surviving; median survival is 13.3 years versus 6.7 years, respectively ($P < 0.0001$). If systolic function was normal, then median survival and percent surviving were not different between the surgery and medical groups (median survival of about 15 years). Patients screened but not randomized to CASS had similar survival rates, suggesting that results from randomized patients may be applicable to more generalized populations as a measure of external reliability.

ETIOLOGY AND PATHOPHYSIOLOGY

The pathophysiology that underlies this disease process is dynamic, evolutionary, and complex. An understanding of the determinants of myocardial oxygen demand (MVO_2), regulation of coronary blood flow, the effects of ischemia on the mechanical and metabolic function of the myocardium, and how ischemia is recognized are important to understanding the rationale for the selection and use of pharmacotherapy for IHD.

1 Ischemia may be defined as lack of oxygen and decreased or no blood flow in the myocardium. In contrast, anoxia, defined as the absence of oxygen to the myocardium, results in continued perfusion with washout of acid by-products of glycolysis, thereby preserving the mechanical and metabolic status of the heart to a greater extent than does ischemia for short periods of time.

DETERMINANTS OF OXYGEN DEMAND

The major determinants of MVO_2 are (a) heart rate, (b) contractility, and (c) intramyocardial wall tension during systole. Overall, intramyocardial wall tension is thought to be the most important among these three factors. As the consequences of IHD are a result

of increased demand in the face of a fixed supply of oxygen in most situations, alterations in MVO_2 are critically important in producing ischemia and for interventions intended to alleviate ischemia. MVO_2 cannot be directly measured in patients; however, an indirect assessment that correlates reasonably well with MVO_2 as determined in experimental animal models is the tension–time index. This is a measure of the area under the curve of the left ventricular (LV) pressure curve. Tension in the ventricle wall is a function of the radius of the LV and intraventricular pressure. These factors are related through the Laplace law, which states that wall stress is related directly to the product of intraventricular pressure and internal radius and inversely to wall thickness multiplied by a factor of two. Increasing systemic blood pressure or ventricular dilation would increase wall tension and oxygen demand whereas ventricular hypertrophy would tend to minimize increasing MVO_2 . Clinical application of these principles has led to the use of the double product (DP), which is heart rate (HR) multiplied by systolic blood pressure (SBP) ($DP = HR \times SBP$). Although this is a clinically useful indirect estimate of MVO_2 , it does not consider changes in contractility (an independent variable), and because only changes in pressure are considered with the double product, volume loading of the LV and increased MVO_2 related to ventricular dilation are underestimated.

REGULATION OF CORONARY BLOOD FLOW

Although coronary blood flow is influenced by multiple factors, the caliber of the resistance vessels delivering blood to the myocardium and MVO_2 are the prime determinants in the occurrence of ischemia. The anatomy of the vascular bed will affect oxygen supply and, subsequently, myocardial metabolism and mechanical function.

Anatomic Factors

The normal coronary system (Fig. 17–1 illustrates normal anatomy) consists of large epicardial or surface vessels (R1) that normally offer little intrinsic resistance to myocardial flow and intramyocardial arteries and arterioles (R2), which branch into a dense capillary network (about 4,000 capillaries per mm^2) to supply basal blood flow of 60 to 90 mL/min per 100 g of myocardium. R1 and R2 are in series and total resistance is the algebraic sum; however, under normal circumstances, the resistance in R2 is much greater. Myocardial blood flow is inversely related to arteriolar resistance and directly related to the coronary driving pressure. The arterioles dynamically alter their intrinsic tone in response to demands for oxygen and other factors, and as a result, myocardial oxygen delivery

and myocardial oxygen demand are tightly coupled in a rapidly responsive system.

Atherosclerotic lesions encroaching on the luminal cross-sectional area of the larger epicardial vessels (R1) transform the relationships among R1, R2, and blood flow. As resistance increases in R1 owing to occlusion, R2 can vasodilate to maintain coronary blood flow. This response is inadequate with greater degrees of obstruction, and the coronary flow reserve afforded by R2 vasodilation is insufficient to meet oxygen demand (also referred to as autoregulation). The extent of functional obstruction is important in the limitation of coronary blood flow, and the presence of relatively severe stenosis (>70%) may provoke ischemia and symptoms at rest, whereas less-severe stenosis may allow a reserve of coronary blood flow for exertion.¹¹

The diameter of the lesion impeding blood flow through a vessel is important, but other factors such as length of the lesion and the influence of pressure drop across an area of stenosis also affect coronary blood flow and function of the collateral circulation. Resistance to flow in a vessel is directly related to length of the obstructing lesion, but resistance is inversely related to the diameter of the vessel to the fourth power. Consequently, diameter is much more important. As blood flows across a stenotic lesion the pressure drops (energy losses) as a result of friction between blood and the lesion and to the abrupt turbulent expansion as blood emerges from the stenosis. This pressure drop is dynamic and directly related to flow giving rise to a resistance that is not fixed, but rather fluctuates, as flow is changed. This relationship can dramatically affect collateral blood flow and its response to exercise, resulting in what has been called “coronary steal.” A similar situation may also occur when the epicardial or subepicardial vessels “steal” blood flow from the endocardium in the presence of a stenotic lesion.

Large and small coronary arteries may undergo dynamic changes in coronary vascular resistance and coronary blood flow. Dynamic coronary obstruction can occur in normal vessels and vessels with stenosis in which vasomotion or spasm may be superimposed on a fixed stenosis. Although it is possible that these changes may be “active” in small coronary arteries, it is also possible that the observed changes may reflect collapse owing to poststenotic intraluminal pressure drop or increased intramyocardial compressive forces associated with inadequate ventricular relaxation.

Collateral blood flow exists to a certain extent from birth as native collaterals, but persisting ischemia may promote collateral growth as developed collaterals. These two types of collaterals differ in anatomy and in their ability to regulate coronary blood flow. Collateral development is dependent on the severity of obstruction, the presence of various growth factors (basic fibroblast growth factor [β -FGF] and vascular endothelial growth factor), endogenous vasodilators (e.g., nitrous oxide, prostacyclin), hormones such as estrogen, and, potentially, exercise. Collateral development is highly species dependent and this should be considered when reading experimental literature.

Metabolic Regulation

Coronary blood flow is closely tied to the oxygen needs of the heart. Changes in oxygen balance lead to very rapid changes in coronary blood flow. Although a number of mediators may contribute to these changes, the most important ones are likely to be adenosine, other nucleotides, nitric oxide, prostaglandins, CO_2 , and H^+ . Adenosine, which is formed from adenosine triphosphate and adenosine monophosphate under conditions of ischemia and stress, is a potent vasodilator that links decreased perfusion to metabolically induced vasodilation or “reactive hyperemia.” The synthesis and release of adenosine into coronary sinus venous effluent occurs within seconds after coronary artery occlusion, and approximately 30% of the hyperemic response can be blocked by metabolic blockers of adenosine.¹²

FIGURE 17-1. Coronary anatomy. (From Tintinalli JE, Kelen GD, Stapczynski JR, eds. *Tintinalli's Emergency Medicine: A Comprehensive Study Guide*, 6th ed. New York: McGraw-Hill, 2004:344.)

Endothelial Control of Coronary Vascular Tone

The vascular endothelium, a single-cell tissue with an enormous surface area separating the blood from vascular smooth muscle of the artery wall, is capable of a broad range of metabolic functions. The endothelium functions as a protective surface for the artery wall, and as long as it remains intact and functional, it promotes vascular smooth muscle relaxation and inhibits thrombogenesis and atherosclerotic plaque formation; damaged endothelium reacts to numerous stimuli with vasoconstriction, thrombosis, and plaque formation. The vascular endothelium of the coronary arteries synthesizes large molecules such as fibronectin, interleukin-1, tissue plasminogen activator, and various growth factors. Small molecules that are also produced include prostacyclin, platelet-activating factor, endothelin-1, and endothelium-derived relaxing factor (EDRF) that is now characterized as nitric oxide. EDRF is synthesized from L-arginine via nitric oxide synthase and released by shear force on the endothelium, as well as through interaction with many biochemical stimuli such as acetylcholine, histamine, arginine, catecholamines, arachidonic acid, adenosine diphosphate, endothelin-1, bradykinin, serotonin, and thrombin.¹² EDRF or nitric oxide then causes relaxation of the underlying smooth muscle and may be thought of as a paracrine homeopathic defense mechanism against noxious stimuli. Denudation or loss of the vascular endothelium results in loss of EDRF and this protective mechanism. Loss of the endothelial cell layer and function may occur secondary to physical disruption (percutaneous transluminal angioplasty [PTCA]), factors impinging from the vascular side (cyanide from smoke), or disruption of the intimal-medial layers (oxidized low-density lipoprotein). Impaired endothelial function may be related to the development of premature atherosclerosis based on recent family studies.¹³

Factors Extrinsic to the Vascular Bed

Blood flow to the coronary arteries arises from orifices located immediately distal to the aorta valve. Perfusion pressure is equal to the difference between the aortic pressure at an instantaneous point in time minus the intramyocardial pressure. Coronary vascular resistance is influenced by phasic systolic compression of the vascular bed. Consequently, the driving force for perfusion is not constant throughout the cardiac cycle. Opening of the aortic valve may also lead to a Venturi effect, which can slightly decrease perfusion pressure. If perfusion pressure is elevated for a period of time, coronary vascular resistance declines and blood flow increases; however, continued perfusion pressure increases lead, within limits, to a return of coronary blood flow back toward baseline levels through autoregulation.

Alterations in intramyocardial wall tension throughout the cardiac cycle will also impose significant changes in coronary blood flow. Diastole is the period during which coronary artery filling can occur as a result of these pressure differences and little or no coronary blood flow occurs to the left ventricle during systole. The extent of pressure development in the ventricle and heart rate have a major effect on the development of wall tension, time for diastolic coronary artery filling, and myocardial oxygen demand.

Under normal conditions, the average global distribution of blood flow between the epicardial and endocardial layer is about 1:1 at rest and remains approximately even during exercise secondary to autoregulatory changes. Regional disparity of blood flow distribution does exist normally, and these disparities are magnified in the presence of diseased coronary arteries and with increased cardiac work as the vasodilator reserve in the resistance vessels of the subendocardium layers is exhausted. Factors that favor a reduction in subendocardial blood flow include decreased perfusion pressure because of decreased diastolic blood pressure or coronary artery obstruction by atherosclerotic plaques with or without vasomotion,

abbreviation of diastole (increased heart rate), and increased intraventricular diastolic pressure (e.g., valvular obstruction to flow).

Extravascular resistance may decrease coronary blood flow, primarily during systole. This effect is much more pronounced in the left ventricle compared with the right ventricle. When the effect of increased contractility is separated from the effect of ventricular pressure, approximately 75% of extravascular resistance is accounted for by passive stretch in equilibrium with ventricular pressure whereas only 25% results from active myocardial contraction.

Factors Intrinsic to the Vascular Bed

Metabolic factors, myogenic responses, neural reflexes, and humoral substances within the vascular bed of the coronary circulation function in an orchestrated fashion to maintain relative consistency in blood flow to the myocardium in the face of imposed changes in perfusion pressures. Autoregulation, mediated primarily through the effects of myogenic responses and metabolic factors, is thought to be responsible for maintaining regional blood flow in a narrow range while systemic pressure varies over a range of approximately 50 to 150 mm Hg.

Myogenic control (also known as the Bayliss effect) of coronary artery tone occurs when the vessel is stretched secondary to an increase in pressure and contracts to return blood flow to normal. It is thought that the myogenic response to stretching in coronary arteries is a modest one and that metabolic factors such as nitric oxide play a much larger role in autoregulation.

There are three well-studied metabolic factors that have the ability to modify coronary artery resistance and blood flow at the local level. Basal coronary blood flow meets oxygen demands of 8 to 10 mL/min per 100 g of myocardium with essentially complete extraction of oxygen from the blood. As cardiac output or mean arterial blood pressure increases, the increased demand for oxygen is met by increasing blood flow because little additional oxygen is available from hemoglobin. Decreased oxygen availability causes vasodilation of vascular smooth muscle and relaxation of precapillary sphincters, which increase tissue oxygen and help maintain blood flow on a regional basis.

At perfusion pressures below 60 mm Hg, as the coronary arteries are maximally dilated and the buffering effect of autoregulation has reached its capacity, further reduction in coronary blood flow will decrease perfusion pressure and tissue oxygenation. It is thought that autoregulation works more efficiently in the epicardial layers than in subendocardial layers, and this may contribute to coronary steal.

Neural components that participate in the regulation of coronary blood flow include the sympathetic nervous system, the parasympathetic nervous system, coronary reflexes, and possibly, central control of coronary blood flow. Within the sympathetic system, stimulation of the stellate ganglion elicits coronary vasodilation, which is associated with tachycardia and enhanced contractility. This indirect coronary vasodilation is secondary to increased MVO_2 related to increased heart rate, contractility, and aortic pressure and occurs following stellate stimulation. The direct effect of the sympathetic system is α_1 -mediated vasoconstriction at rest and during exercise. Other receptor types, α_2 and β_1 , have little influence on tone, whereas β_2 stimulation produces a modest vasodilatory effect. Although coronary atherosclerosis may decrease blood flow secondary to obstruction, severe coronary atherosclerosis and obstruction may also increase the sensitivity of coronary arteries to the effects of α_1 stimulation and vasoconstriction.

Vagal stimulation within the parasympathetic system produces a small to moderate increase in coronary blood flow, which involves the coronary efferent and afferent parasympathetic components (Bezold-Jarisch reflex). Indirectly, vasoconstriction may result, with vagal stimulation as the result of bradycardia and decreased contractility reducing myocardial oxygen demand.

Coronary reflexes have an undetermined role in the regulation of coronary blood flow. Based on experimental data, coronary reflexes that may be important include the baroreceptor, the chemoreceptor, Bezold-Jarisch reflex, and the pulmonary inhalation reflex.

Factors Limiting Coronary Perfusion

During exercise and pacing, as MVO_2 increases, coronary vascular resistance can be reduced to approximately 25% of basal values, which results in a four- to fivefold increase in coronary blood flow. The cross-sectional area can be reduced by approximately 80% prior to any mechanical or biochemical changes in the myocardium, reflecting a margin of safety for coronary blood flow. The extent of cross-sectional obstruction, the length of the lesion, lesion composition, and the geometry of the obstructing lesion can each affect flow across coronary arteries with atherosclerosis. The Bernoulli theorem states that the pressure drop across a lesion is directly related to the length of the lesion and inversely related to the radius of the lesion to the fourth power; critical stenosis occurs when the obstructing lesion encroaches on the luminal diameter and exceeds 70%. Lesions creating an obstruction of 50% to 70% may reduce blood flow; however, these obstructions are not consistent and vasospasm and thrombosis superimposed on a “noncritical” lesion may lead to clinical events such as myocardial infarction.¹⁴ If the lesion enlarges from 80% to 90%, resistance in that vessel is tripled. Coronary reserve is diminished at approximately 85% obstruction owing to vasoconstriction. Exaggerated responsiveness can be seen when coronary stenosis reaches this critical level and the role of vasoactive substances such as prostaglandins, thromboxanes, and serotonin may play more of a role in the regulation of coronary vascular tone and thrombosis.

Little reserve exists for coronary blood flow and a relatively small reduction of 10% to 20% results in decreased myocardial fiber shortening as the first evidence for abnormal function. The subendocardial layers are affected to a greater extent than the epicardium by ischemia, considering changes in fiber shortening, arteriovenous (AV) difference in oxygen saturation, and lactate production. A reduction of 80% gives rise to akinesis and a 95% reduction of coronary blood flow produces dyskinesis during contraction of the ventricles. Although these abnormalities of contraction are associated with transient impaired function, depletion of high-energy phosphate compounds and ultrastructural changes may last for days, even after transient ischemia; this is referred to as “stunned myocardium.” Chronic hypoperfusion may lead to “hibernation,” in which ventricular function is impaired over longer time intervals. Hibernating myocardium can be differentiated from necrosis with various techniques (see Chap. 13) and revascularization of hibernating myocardium is useful in improving ventricular function. Regional loss of contractility may impose a burden on the remaining myocardial tissue, resulting in heart failure, increased MVO_2 , and rapid depletion of blood flow reserve. Consequently, zones of tissue with marginal blood flow may develop in a lateral or transmural fashion; such development puts this tissue at risk for more severe damage if the ischemic episode persists or becomes more severe. Nonischemic areas of myocardium may compensate for the severely ischemic and border zones of ischemia by developing more tension than usual in an attempt to maintain cardiac output. At the cellular level, ischemia and the attendant acidosis are thought to alter calcium release from storage sites such as the sarcolemma and the sarcoplasmic reticulum, as well as inhibiting the binding of calcium to troponin, thereby impairing the association of actin and myosin. The clinical correlates of these cellular biochemical events leading to the development of left ventricle or right ventricle dysfunction include an S_3 , dyspnea, orthopnea, tachycardia, fluctuating blood pressure, transient murmurs, and mitral or tricuspid regurgitation.

Calcium accumulation and overload secondary to ischemia impairs ventricular relaxation as well as contraction. This is apparently a result of impaired calcium uptake after systole from the myofilaments, leading to a less negative decline of the pressure in the ventricle over time. Impaired relaxation is associated with enhanced diastolic stiffness, decreased rate of wall thinning, and slowed pressure decay, producing an upward shift in the ventricular pressure–volume relationship; put more simply, MVO_2 is likely to be increased secondary to increased wall tension. Impairment of both diastolic and systolic function leads to elevation of the filling pressure of the left ventricle.

CLINICAL PRESENTATION AND DIAGNOSIS OF ANGINA

General

- Many episodes of ischemia do not cause symptoms of angina (silent ischemia)
- Patients often have a reproducible pattern of pain or other symptoms which appear after specific amount of exertion
- Increased frequency, severity, duration, or symptoms at rest suggest an unstable angina pattern and the patient should seek help immediately

Symptoms

- 2 Sensation of pressure or burning over the sternum or near it, often but not always radiating to the left jaw, shoulder and arm; also chest tightness, shortness of breath
- Pain usually lasts from 0.5 to 30 minutes, often with a visceral quality (deep location)
- Precipitating factors include exercise, cold environment, walking after a meal, emotional upset, fright, anger, and coitus
- Relief occurs with rest and nitroglycerin

Signs

- Abnormal precordial (over the heart) systolic bulge
- Abnormal heart sounds

Laboratory Tests

- Typically, no laboratory tests are abnormal; however, if the patient has intermediate to high-risk features for unstable angina, electrocardiographic changes and serum troponin, or creatine kinase may become abnormal (Table 17–3)
- Patients are likely to have laboratory test abnormalities for the risk factors for IHD such as elevated total and low-density lipoprotein cholesterol, low high-density lipoprotein cholesterol, impaired fasting glucose or elevated glucose, high blood pressure, elevated C-reactive protein, and abnormal renal function. Hemoglobin should be checked to make sure the patient is not anemic.

Other Diagnostic Tests (See Chap. 13)

- A resting electrocardiogram followed by an exercise tolerance test are usually the first tests done in stable patients. A chest radiograph should be done if the patient has heart failure symptoms. Cardiac imaging using radioisotopes to detect ischemic myocardium and measure ventricular function are commonly done when revascularization is being considered. Echocardiography may also be used to assess ventricular wall motion at rest or during stress. Cardiac catheterization and coronary arteriography are used to determine coronary artery anatomy and if the patient would benefit from angioplasty, coronary artery bypass surgery or other revascularization procedures. Coronary artery calcium may be useful in detecting early disease.

TABLE 17-3 Short-Term Risk of Death or Nonfatal Myocardial Infarction in Patients with Unstable Angina

Feature	High Risk (At least 1 of the following features must be present)	Intermediate Risk (No high-risk feature but must have 1 of the following)	Low Risk (No high- or intermediate-risk feature but may have any of the following)
History	Accelerating tempo of ischemic symptoms in preceding 48 h	Prior MI, peripheral or cerebrovascular disease, or CABG, prior aspirin use	
Character of pain	Prolonged ongoing (>20 min), rest pain	Prolonged (>20 min), rest angina, now resolved, with moderate or high likelihood of CAD	New-onset CCS class III or IV angina in the past 2 weeks without prolonged (>20 min) rest pain but with moderate or high likelihood of CAD
Clinical findings	Pulmonary edema, most likely caused by ischemia New or worsening MR murmur S ₃ or new/worsening rales Hypotension, bradycardia, tachycardia Age >75 y		
ECG	Angina at rest with transient ST-segment changes >0.05 mV	T-wave inversions >0.2 mV	Normal or unchanged ECG during an episode of chest discomfort
Cardiac markers	Bundle-branch block, new or presumed new Markedly elevated (e.g., TnT or TnI >0.1 ng/mL)	Pathologic Q waves Slightly elevated (e.g., TnT >0.01 but <0.1 ng/mL)	Normal

CABG, coronary artery bypass grafting; CAD, coronary artery disease; CCS, Canadian Cardiovascular Society; ECG, electrocardiogram; MI, myocardial infarction; MR, mitral regurgitation; TnI, troponin; TnT, troponin T.

CLINICAL PRESENTATION AND DIAGNOSIS

Important aspects of the clinical history for chest pain for patients with angina include the nature or quality of the pain, precipitating factors, duration, pain radiation, and the response to nitroglycerin or rest. Because there can be considerable variation in the manifestations of angina, it is more accurate to refer to these symptoms as an anginal syndrome. For some patients with significant coronary disease, their presenting symptoms may differ from the classical symptoms, yet the symptoms are a result of ischemic pain, and these are often referred to as anginal equivalents. Obtaining an accurate and detailed family history is useful in placing symptoms in perspective. Significant positive information includes premature coronary heart disease (<55 years of age in men and <65 years of age in women) as manifested as fatal and nonfatal myocardial infarction (MI), stroke, and peripheral vascular disease, as well as other risk factors such as hypertension, smoking, familial lipid disorders, and diabetes mellitus. Typical pain radiation patterns include anterior chest pain (96%), left upper arm pain (83.7%), left lower arm pain (29.3%), and neck pain at some time (22%). Pain from other areas is less common. Ischemia detected by electrocardiogram (ECG) monitoring is more likely to be detected in the morning hours (6 AM to 12 noon) than other periods throughout the day. Patients suffering from variant or Prinzmetal angina secondary to coronary spasm are more likely to experience pain at rest and in the early morning hours. Prinzmetal anginal pain is not usually brought on by exertion or emotional stress, nor is it relieved by rest, and the ECG pattern is that of current injury with ST elevation rather than depression.

It is also important to differentiate the pattern of pain for stable angina from that of unstable angina. Unstable angina may be stratified into categories of risk ranging from high to low (see Table 17-3).¹⁵ Ischemia may also be painless or “silent” in 60% to 100% of patients, depending on the series cited and the patient population.¹⁶ In patients with myocardial ischemia, approximately 70% of the episodes of documented ischemia are painless as determined by ambulatory ECG monitoring, and the ST segment changes associated with these episodes can be ST elevation or depression. The mechanism of silent ischemia is unclear, but studies show that patients not experiencing pain have altered pain perception, with the threshold and tolerance for pain being higher than that of patients who have pain more frequently. Although patients with diabetes tend to have more extensive coronary disease than those without diabetes and may suffer from autonomic neuropathy,

asymptomatic ischemia is not more prevalent based on the Asymptomatic Cardiac Ischemia Pilot (ACIP) study.¹⁷ Altered endorphin release is a plausible explanation, but investigations with naloxone to block endorphins do not consistently show altered pain thresholds to various stimuli compared with patients with symptomatic ischemia and patients with asymptomatic ischemia do not necessarily have impaired somatic pain sensitivity.¹⁸ Alternatively, adenosine and substance P release during ischemia and mechanical stretch on coronary arteries may play a role in the perception of pain.

Lastly, it should be recognized that the threshold for pain caused by exertion is fixed in some patients and variable in others and that the amount of exercise or stress necessary to provoke symptoms can change over time. A fixed threshold for the induction of pain or ECG evidence of ischemia means these indicators of ischemia occur at the same, or nearly so, double rate–pressure product (systolic blood pressure × heart rate). This is apparently a consequence of at least two factors. Over long periods of time, atherosclerosis may progress, leading to more severe stenosis, reduced oxygen supply, and less of an increase in demand to precipitate ischemic symptoms. Once stenotic lesions reach a critical level of approximately 80% or greater, vasomotion, vasospasm, and thrombotic occlusion become significant factors impairing blood flow to the myocardium. Consequently, anatomic considerations and vasoactive substances may interact to provide an environment amenable to changing thresholds for the production of angina.

There appears to be little relationship between the historical features of angina and the severity or extent of coronary artery vessel involvement. Therefore, one may speculate that severe symptoms might be associated with multivessel disease, but no predictive markers exist on a routine basis.

Chest pain may resemble pain arising from a variety of noncardiac sources and the differential diagnosis of anginal pain from other etiologies may be quite difficult based on history alone. Table 17-4 outlines other common problems that may present with episodic chest pain. Although much less common, nonatherosclerotic etiologies of coronary artery disease do exist and should be excluded with appropriate tests. The clinical classification of chest pain encompasses typical angina including (a) substernal chest pain with a characteristic quality and duration that is (b) provoked by exertion or emotional stress and (c) relieved by rest or nitroglycerin; atypical angina (meets two of the characteristics for typical angina); and noncardiac chest pain (meets ≤1 of the typical angina characteristics).^{2,3}

There are few signs apparent on physical examination to indicate the presence of coronary artery disease and usually only the cardio-

TABLE 17-4 Differential Diagnosis of Episodic Chest Pain Resembling Angina Pectoris

	Duration	Quality	Provocation	Relief	Location	Comment
Effort angina	5–15 min	Visceral (pressure)	During effort or emotion	Rest, NTG	Substernal, radiates	First episode vivid
Rest angina	5–15 min	Visceral (pressure)	Spontaneous (? with exercise)	NTG	Substernal, radiates	Often nocturnal
Mitral prolapse	Min–hours	Superficial (rarely visceral)	Spontaneous (no pattern)	Time	Left anterior	No pattern, variable
Esophageal reflux	10 min–1 h	Visceral	Spontaneous, cold liquids, exercise, lying down	Foods, antacids, H ₂ blockers, proton pump inhibitors, NTG	Substernal, radiates	Mimics angina
Peptic ulcer	Hours	Visceral, burning	Lack of food, “acid” foods	Foods, antacids, H ₂ blockers, proton pump inhibitors	Epigastric, substernal	
Biliary disease	Hours	Visceral (wax and wane)	Spontaneous, food	Time, analgesia	Epigastric, radiates	Colic
Cervical disk	Variable (gradually subsides)	Superficial	Head and neck, movement and palpation	Time, analgesia	Arm, neck	Not relieved by rest
Hyperventilation	2–3 min	Visceral	Emotion, tachypnea	Stimulus removed	Substernal	Facial paraesthesia
Musculoskeletal	Variable	Superficial	Movement, palpation	Time, analgesia	Multiple	Tenderness
Pulmonary	30 min	Visceral (pressure)	Often spontaneous	Rest, time bronchodilator	Substernal	Dyspneic

NTG, nitroglycerin.

vascular system reveals any useful information. Elevated heart rate or blood pressure can yield an increased double product and may be associated with angina, and it would be important to correct extreme tachycardia or hypertension if present. Other noncardiac physical findings that suggest that significant cardiovascular disease may be associated with angina include abdominal aortic aneurysms or peripheral vascular disease. Table 17-5 lists the cardiac examination findings in coronary artery disease. During an angina attack these findings may appear or become more prominent, making them more valuable if present.

TABLE 17-5 Cardiac Findings in Patients with Coronary Artery Disease

Sign	Clinical Significance	Frequency
Abnormal precordial systolic bulge	Left ventricular wall motion abnormality	Not usually present unless patient has sustained a prior MI (especially anterior wall) or is experiencing angina at time of examination
Decreased intensity of S ₁	Decrease in left ventricular contractility	Difficult to evaluate in resting state, but can be commonly demonstrated during angina
Paradoxical splitting of S ₂	Left ventricular wall motion abnormality	Very uncommon but occasionally noted during angina
S ₃ (ventricular gallop)	Increased left ventricular diastolic pressure, with or without clinical CHF	Not usually present unless patient sustained extensive MI; may occasionally be present during angina
S ₄ (atrial gallop)	Reduced ventricular compliance (“stiff heart”)	Common; very common in patients who have sustained a prior MI as well as during angina
Apical systolic murmur (in absence of rheumatic mitral regurgitation or Barlow syndrome)	Papillary muscle dysfunction	Not usually present unless patient has sustained prior MI
Diastolic murmur (in absence of aortic regurgitation)	Coronary artery stenosis	Rare

CHF, congestive heart failure; MI, myocardial infarction; S₁, first heart sound; S₂, second heart sound; S₃, third heart sound; S₄, fourth heart sound.

From Cohn PF, ed. *Diagnosis and Therapy of Coronary Artery Disease*, 2d ed. Boston: Martinus Nijhoff, 1985:101, with permission.

In addition to screening for CVD risk factors (see Table 23-7), other recommended tests include hemoglobin, fasting glucose, fasting lipoprotein panel, resting ECG, and chest radiograph in patients with signs or symptoms of heart failure, valvular heart disease, pericardial disease, or aortic dissection/aneurysm.² Hemoglobin is assessed to insure adequate oxygen carrying capacity. Fasting glucose determinations to exclude diabetes and glucose monitoring for concurrent diabetes should be performed routinely. Lipids are assessed total-, low-density lipoprotein (LDL)- and high-density lipoprotein (HDL)-cholesterol and triglycerides (see Chap. 23).¹⁹ Other risk factors that may be important for some patients include C-reactive protein, homocysteine level, evidence of chlamydia infection, and elevations in lipoprotein(a), fibrinogen, and plasminogen activator inhibitor.^{20,21} Cardiac enzymes should all be normal in stable angina. Troponin T or I, myoglobin, or creatinine phosphokinase-MB (myocardial band) isoform may be elevated in patients with unstable angina, and interventions such as anticoagulation or antiplatelet therapy reduce cardiac end points when these markers for injury are elevated (see Table 17-3).²²

Patients presenting with chest pain are stratified into chronic stable angina or having features of intermediate or high-risk unstable angina (Fig. 17-2 and see Table 17-3). These features include rest pain lasting longer than 20 minutes, age older than 65 years, ST- and T-wave changes and pulmonary edema. Patients with acute coronary syndrome (unstable angina, non-ST-segment elevation acute myocardial infarction and ST-segment elevation acute myocardial infarction) are managed differently than chronic stable angina.

DIAGNOSTIC TESTS

See also Chap. 13.

Electrocardiogram

The ECG is normal in about one-half of patients with angina who are not experiencing an acute attack. Typical ST-T-wave changes include depression, T-wave inversion, and ST-segment elevation. Forms of ischemia other than exertional angina may have ECG manifestations that are different; variant angina is associated with ST-segment elevation, whereas silent ischemia may produce elevation or depression. Significant ischemia is associated with ST-segment depression of greater than 2 mm, exertional hypotension, and reduced exercise tolerance.

FIGURE 17-2. Clinical assessment. (ACC/AHA, American College of Cardiologists/American Heart Association; AHCPR, Agency for Health Care Policy and Research; CABG, coronary artery bypass graft; ECG, electrocardiogram; LV, left ventricular; MI, myocardial infarction; PTCA, percutaneous transluminal coronary angioplasty.)

Exercise Tolerance Testing²³

Exercise tolerance (stress) testing (ETT) is recommended for patients with intermediate pretest probability of coronary artery disease (CAD) based on age, gender, and symptoms, including those with complete right bundle-branch block or <1 mm of rest ST depression (Fig. 17-3). Although ETT is insensitive for predicting coronary artery anatomy, it does correlate well with outcome, such as the likelihood of progressing to angina, the occurrence of acute MI, and cardiovascular death. Ischemic ST depression that occurs during ETT is an independent risk factor for cardiac events and cardiovascular mortality. Thallium (^{201}Tl) myocardial perfusion scintigraphy may be used in conjunction with ETT to detect revers-

ible and irreversible defects in blood flow to the myocardium because it is more sensitive than ETT.

Cardiac Imaging

Radionuclide angiocardigraphy (performed with technetium-99m, a radioisotope) is used to measure ejection fraction, regional ventricular performance, cardiac output, ventricular volumes, valvular regurgitation, asynchrony or wall motion abnormalities, and intracardiac shunts.²⁴ Technetium pyrophosphate scans are used routinely for detection and quantification of acute myocardial infarction. Positron emission tomography is useful for quantifying ischemia with metabolically important substrates such as oxygen,

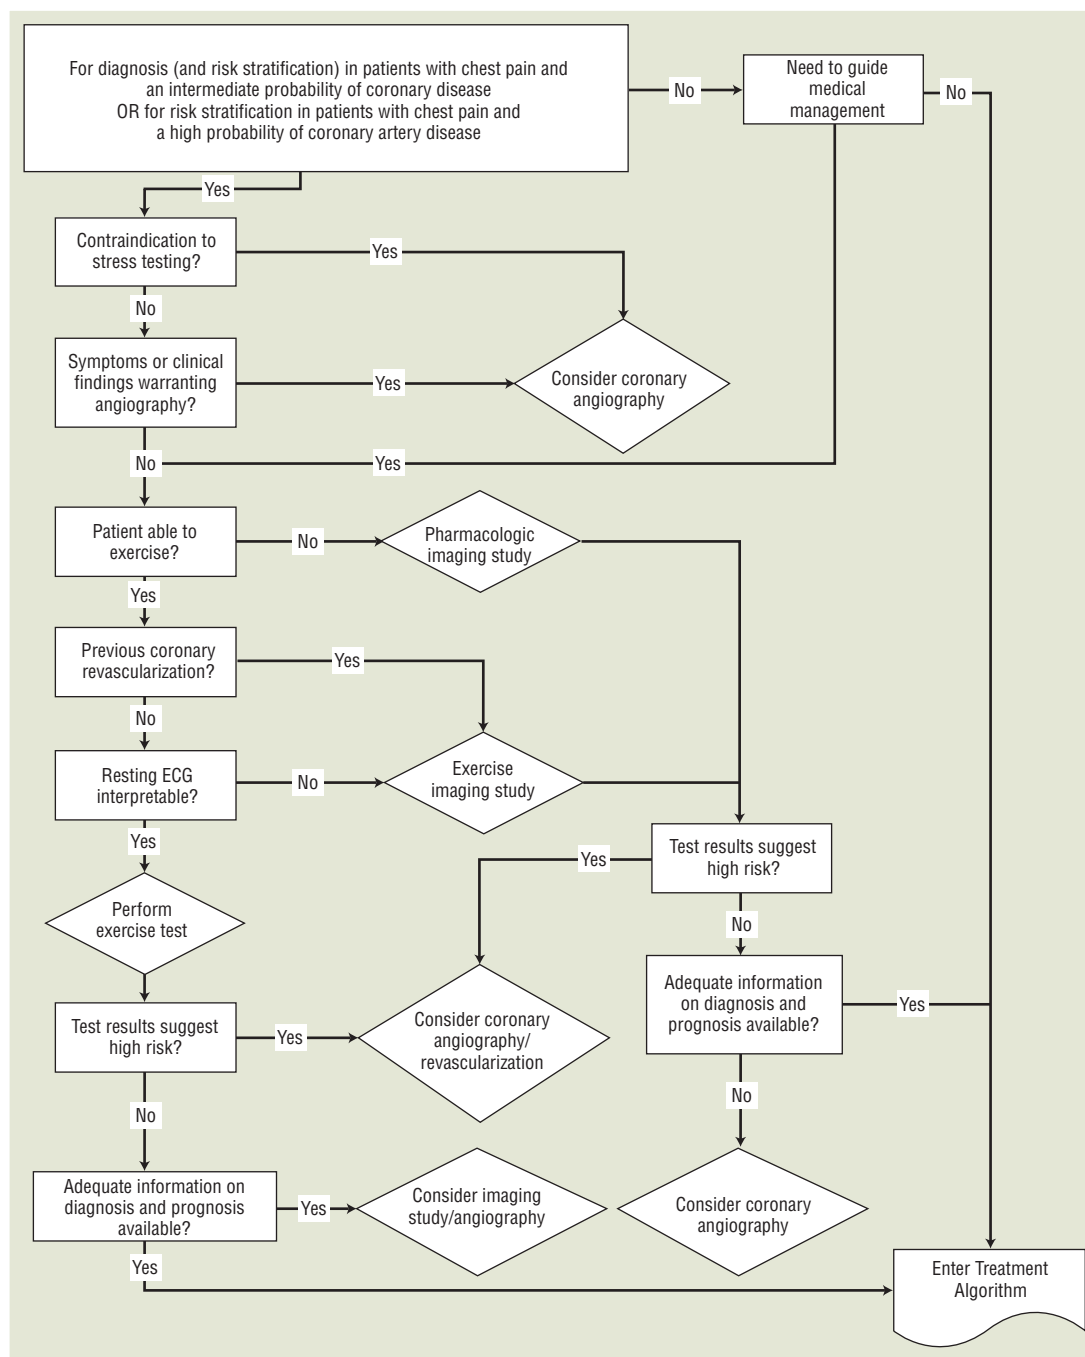

FIGURE 17-3. Stress testing/angiography algorithm. (ECG, electrocardiogram.)

carbon, and nitrogen. Other metabolic probes use radiolabeled fatty acids and glucose to study metabolic processes that may be deranged during ischemia in animals and for investigative purposes in man.

A new method using ultrarapid computerized tomography (spiral CT, ultrafast CT, electron-beam CT) minimizes artifact caused by motion of the heart during contraction and relaxation and provides a semiquantitative assessment of calcium content in coronary arteries.²⁵ Calcium scores >150 provide a sensitivity of 74% and specificity of 89%; consequently, this method may be cost-effective compared with ETT.

Echocardiography

Echocardiography is useful if patients have history or physical examination suggestive of valvular, pericardial disease or ventricular dysfunction. For patients unable to exercise, pharmacologic

stress echocardiography (dobutamine, dipyridamole, or adenosine) or pacing may be done to identify abnormalities during stress.

Cardiac Catheterization and Coronary Arteriography

Cardiac catheterization and angiography in patients with suspected coronary artery disease are used diagnostically to document the presence and severity of disease, as well as for prognostic purposes. High-risk features during ETT suggesting the need for coronary angiography include early and significant (≥ 2 mm) changes on the ECG during ETT as well as multiple lead involvement, prolonged recovery from ischemia, low workload performance, abnormal blood pressure response (reduction in blood pressure), or ventricular arrhythmias. Multiple defects with thallium scans as well as lung uptake during exercise or postexercise ventricular cavity dilation are also high-risk indications for catheterization. Interventional catheterization is used for thrombolytic therapy in patients with acute myo-

cardial infarction and for the management of patients with significant coronary artery disease to relieve obstruction through PTCA, atherectomy, laser treatment, or stent placement. Catheterization and angiography may be done after coronary artery bypass grafting (CABG) to determine if the graft has closed or if coronary artery disease has progressed. Coronary artery intravascular ultrasound is useful for directly imaging anatomy, calcified and fatty plaques, and thrombosis superimposed on plaque as well as determining patency following revascularization procedures. Intravascular ultrasound guidance of stent implantation may result in more effective stent expansion compared with angiographic guidance alone.²⁶

TREATMENT

Ischemic Heart Disease

■ DESIRED OUTCOME

The short-term goals of therapy for ischemic heart disease are to reduce or prevent the symptoms of angina that limit exercise capability and impair quality of life. Long-term goals of therapy are to prevent CHD events such as myocardial infarction, arrhythmias, and heart failure and to extend the patient's life. Because there is little evidence that revascularization procedures such as angioplasty and coronary artery bypass surgery extend life, the primary focus should be on altering the underlying and ongoing process of atherosclerosis through risk factor modification while providing symptomatic relief through the use of nitrates, β -blockers, calcium channel blockers, and ranolazine for anginal symptoms.

Risk Factor Modification

③ Primary prevention of ischemic heart disease through the identification and modification of risk factors prior to the initial morbid event would be the optimal management approach and should result in a significant impact on the prevalence of IHD. However, early recognition of some risk factors may not be possible in all cases, and in others, the patient may not be willing to undertake intervention until overt evidence of coronary disease is apparent. Secondary intervention continues to be more commonly pursued by both healthcare professionals and patients, and it is important to recognize this type of intervention as effective in reducing subsequent morbidity and mortality. The presence of risk factors in individual patients plays a major role in determining the occurrence and severity of IHD.^{19,27} Risk factors are additive in nature and can be classified as alterable or unalterable (see Table 23-7). Unalterable risk factors include gender; age; family history or genetic composition; environmental influences such as climate, air pollution, trace metal composition of drinking water; and to some extent, diabetes mellitus. Improved glycemic control reduces the microvascular complications of diabetes mellitus (see Chap. 77) and reduces coronary end points; however, based on the Diabetes Control and Complications study, the reduction was impressive (40 vs. 23 major events) but not significant because the trial was underpowered to detect these changes.²⁸ ④ Risk factors that can be altered include smoking, hypertension, hyperlipidemia, obesity, sedentary lifestyle, hyperuricemia, psychosocial factors such as stress and type A behavior patterns, and the use of certain drugs that may be detrimental, including progestins, corticosteroids, and cyclosporine.

Cigarette smoking is common. The Centers for Disease Control and Prevention estimates that 45.1 million people are current smokers (23.9% men; 18.1% women) in this country, and the risk for CHD is increased by about 1.8 in active smokers and by about 1.3 for passive or environmental smoke exposure.²⁹ From 1997 to 2001 437,902 Americans died from smoking-related illnesses and 34.7% of

the deaths were attributable to CVD.⁴ Risk because of smoking is related to the number of cigarettes smoked per day and the duration of smoking. Passive smoking in angina pectoris patients decreases exercise time.⁶ Pipe and cigar smokers are at increased risk compared with nonsmokers, but their risk is somewhat less than that of cigarette smokers.³⁰ The direct effects of cigarette smoke that are detrimental to patients with angina include (a) elevated heart rate and blood pressure from nicotine, which increases MVO₂, and impaired myocardial oxygen delivery due to carboxyhemoglobin generation from carbon monoxide inhalation in smoke; (b) the negative inotropic effect of carboxyhemoglobin; (c) increased platelet adhesiveness and promotion of aggregation resulting in thrombotic tendencies because of nicotine and carboxyhemoglobin; (d) lowered threshold for ventricular fibrillation during ischemia as a consequence of carboxyhemoglobin; and (e) impaired endothelial function owing to smoking.³¹ Similar changes have been noted for marijuana smoking as well. Smoking also accelerates the risk for myocardial infarction, sudden death, cerebrovascular disease, peripheral vascular disease, and hypertension, and it reduces high-density lipoprotein concentrations. Clearly, primary prevention is needed for this risk factor and much of the education effort to discourage initiation of smoking should be targeted for teenagers. Techniques for cessation of smoking that may be useful include aversive conditioning, group programs, self-help programs, hypnosis, "cold turkey," and the use of nicotine substitutes (loberline) or other sources of nicotine replacement products for short-term substitution during withdrawal syndrome. The antidepressant sustained-release bupropion is more effective than placebo and best used with smoking cessation counseling. Recently, varenicline, a partial agonist selective for the $\alpha_4\beta_2$ nicotinic acetylcholine receptor subtype also was shown to improve cessation rates.^{32,33} Cessation of smoking reduces the incidence of coronary events to approximately 15% to 25% of that associated with continued smoking and these benefits are noted within 2 years of cessation.³⁴

Hypertension, whether labile or fixed, borderline or definite, casual or basal, systolic or diastolic, at any age regardless of gender, is the most common and a powerful contributor to atherosclerotic coronary vascular disease.³⁵ Morbidity and mortality increase progressively with the degree of blood pressure elevation of either systolic or diastolic pressure and pulse pressure, and no discernible critical value exists (see Chap. 15). Numerous trials have documented the reduction in risk associated with blood pressure lowering; however, most of these studies show that mortality and morbidity reduction is a result of fewer strokes and less renal failure and heart failure. The reduction in coronary heart disease end points is significant but not as dramatic. The reasons for this are unclear but perhaps relate to the multifactorial etiology of IHD. Recent guideline changes from the AHA recommend goal blood pressure of <130/80 mm Hg for patients with stable angina, unstable angina, non-ST-segment myocardial infarction, ST-segment myocardial infarction and <120/80 mm Hg in patients with left ventricular dysfunction.³⁶

Hypercholesterolemia is a significant cardiovascular risk factor, and risk is directly related to the degree of cholesterol elevation.^{19,27} As with hypertension, there is no critical value that defines risk, but rather, risk is incrementally related to the degree of elevation and the presence of other risk factors (see Chap. 23 for a detailed discussion). A fasting lipoprotein panel should be obtained in all patients with known CAD. Chapter 23 discusses the goals for total-, LDL-, and HDL-cholesterol and triglycerides. All patients should undertake therapeutic lifestyle changes. Reductions in LDL-cholesterol for primary prevention and secondary intervention have been shown to reduce total and CAD mortality and stroke as well as the need for interventions such as PTCA and CABG. Supplemental vitamin E or other antioxidants reduce the susceptibility of LDL-cholesterol to oxidation, but clinical trial data fail to show any benefit with supplementation.³⁷

The prevalence of overweight and obesity, defined as a body mass index (weight in kilograms divided by height in meters squared) of $\geq 25 \text{ kg/m}^2$ and $\geq 30 \text{ kg/m}^2$, respectively, are estimated to occur in 66.3% and 32.2% of the U.S. population. Body mass index is associated with an increased mortality ratio compared with individuals of normal body weight, and the objective for patients with IHD is to maintain or reduce to a normal body weight.⁴ This may be accomplished through dietary modification, exercise, pharmacologic therapy, or surgical therapy. Frequently associated with obesity is a sedentary lifestyle, and inactivity may contribute to higher blood pressure, elevated blood lipid levels, and insulin resistance associated with glucose intolerance in diabetics (insulin resistance or metabolic syndrome). Exercise to the level of about 300 kcal three times a week is useful in improving maximal oxygen uptake, improving cardiorespiratory efficiency, promoting collateral artery formation, and promoting potential alterations in the risk of ventricular fibrillation, coronary thrombosis, and improved tolerance to stress. Epidemiologic studies have found that mortality is directly related to resting heart rate and a low heart rate difference between resting and maximal exercise heart rate, and inversely related to exercise heart rate. A regular exercise program has been shown to reduce all-cause and cardiac mortality.³⁸

Competitiveness, intense striving for achievement, easily provoked hostility, a sense of urgency about doing things quickly and being punctual, impatience, abrupt and rapid speech and gestures, and concentration on self-selected goals to the point of not perceiving and attending to other aspects of the environment are traits that characterize the behavioral pattern known as the type A or coronary prone personality. Although the issue is somewhat controversial, type A individuals may have increased cardiovascular risk with risk ratios ranging from insignificant to three times that of a matched population. Psychological stress and type D personality have been associated with adverse cardiac prognosis, but little is known about their relative effect on the pathogenesis of CHD. "Type D" refers to the tendency to experience negative emotions and to inhibit the expression of these emotions in social interactions. The mechanism by which personality affects the cardiovascular system is not understood, but may reflect the activity of the sympathetic system and enhanced responsiveness of other stress hormones when compared with non-type A personalities.

Alcohol ingestion in small to moderate amounts ($<40 \text{ g/day}$ of pure ethanol) reduces the risk of coronary heart disease; however, consumption of large amounts ($>50 \text{ g/day}$) or binge drinking of alcohol is associated with increased mortality from stroke, cancer, vehicular accidents, and cirrhosis.^{39,40} There appears to be a differential effect depending on race with an inverse relationship between ethanol consumption in whites but a direct relationship in Blacks between consumption and CAD risk. The mechanisms for the presumed protective effects of alcohol are not known but the effects may be related to increased high-density lipoprotein levels, impaired platelet function, or associations between the amount of alcohol ingested and personality type. Whatever the relationship, it is well to remember that alcohol drinking is implicated in more than

40% of all fatal automobile accidents and consumption of alcohol predisposes to hepatic cirrhosis, the sixth to seventh most common cause of death in middle age adults in the United States. With this in mind, it seems illogical to suggest alcohol ingestion as a prophylactic measure for coronary disease but rather to advise moderation of alcohol consumption, if it is the preference of the individual.

Thiazide diuretics elevate serum cholesterol and triglyceride levels whereas β -blockers tend to lower HDL and raise LDL slightly; however, a direct association between these drugs and cardiovascular risk is tenuous and based on aggregating results rather than randomized clinical trials. Conjugated equine estrogen alone or in combination with progestin lowers LDL and raises HDL based on the Postmenopausal Estrogen/Progestin Interventions (PEPI) study.⁴¹ Unfortunately, the Heart and Estrogen/Progestin Replacement Study (HERS) trial showed no benefit of hormone replacement therapy for secondary intervention and an increased risk for thromboembolism.⁴² In secondary intervention, hormone replacement therapy or estrogen alone in women after hysterectomy, HERS found that hormonal therapy health risks exceeded benefits as well.⁴³ Unopposed estrogen is the optimal regimen for elevation of HDL, but the high rate of endometrial hyperplasia restricts use to women without a uterus. In women with a uterus, estrogen with cyclic medroxyprogesterone has the most favorable effect on HDL and no excess risk of endometrial hyperplasia. Use of oral contraceptives in women who smoke and are older than age 35 years increases the risk of MI, stroke, and venous thromboembolism by threefold or greater. Alternative forms of contraception and cessation of smoking should be promoted in these patients. The risk for nonsmoking oral contraceptive users younger than age 35 years is very small. The relative risk of breast cancer is increased, but in the absence of risk factors for breast cancer, the relative risk is approximately 1.3 (30% increase). Coffee consumption is also linked to coronary heart disease and caffeine does transiently elevate blood pressure; however, the overall risk, if any, appears to be low and may be related to genetic makeup.⁴⁴ Although thiazide diuretics and β -blockers (nonselective without intrinsic sympathomimetic activity) may elevate both cholesterol and triglycerides by some 10% to 20%, and these effects may be detrimental, no objective evidence exists from prospective well-controlled studies to support avoiding these drugs at this time. This controversy is most pertinent in the treatment of mild hypertension and it is discussed in greater detail in Chap. 15.

TREATMENT

Stable Exertional Angina Pectoris

Table 17-6 lists the American College of Cardiology and American Heart Association's evidence-grading recommendations.

The current national guidelines recommend that all patients be given the following unless contraindications exist: (a) aspirin (Class I, Level A); (b) β -blockers with prior MI (Class I, Level A); (c) angiotensin-converting enzyme inhibitor (ACEI) to patients with CAD and

TABLE 17-6 The American College of Cardiology and American Heart Association Evidence Grading System

Recommendation Class		Level of Evidence	
I	Conditions for which there is evidence or general agreement that a given procedure or treatment is useful and effective	A	Data derived from multiple randomized clinical trials with large numbers of patients
II	Conditions for which there is conflicting evidence or a divergence of opinion about the usefulness/efficacy of a given procedure or treatment is useful and effective	B	Data derived from a limited number of randomized trials with small numbers of patients, careful analyses of nonrandomized studies, or observational registries
IIa	Weight of evidence/opinion is in favor of usefulness/efficacy	C	Expert consensus was the primary basis for the recommendation
IIb	Usefulness/efficacy is less well established by evidence/opinion		
III	Conditions for which there is evidence or general agreement that a given procedure or treatment is not useful/effective and in some cases may be harmful		

diabetes or LV systolic dysfunction (Class I, Level A); (d) LDL-lowering therapy with CAD and LDL >130 mg/dL (Class I, Level A) (target LDL <100 mg/dL; <70 mg/dL in patients with CHD and multiple risk factors is reasonable)²⁷; (e) sublingual nitroglycerin or immediate relief of angina (Class I, Level B); (f) calcium antagonists or long-acting nitrates for reduction of symptoms when β -blockers are contraindicated (Class I, Level B); (g) calcium antagonists or long-acting nitrates in combination with β -blockers when initial treatment with β -blockers is unsuccessful (Class I, Level C); (h) calcium antagonists or long-acting nitrates are recommended as a substitute for β -blockers if initial treatment with β -blockers leads to unacceptable side effects (Class I, Level A). Clopidogrel may be substituted for when aspirin is absolutely contraindicated (Class IIa, Level B) and long-acting nondihydropyridine calcium antagonists used instead of β -blockers as initial therapy (Class IIa, Level B). ACEIs are recommended in patients with CAD or other vascular disease (Class IIa, Level B). Angiotensin receptor antagonists are not mentioned in these guidelines but substitution for ACEI intolerance is reasonable. Low-intensity anticoagulation with warfarin, in addition to aspirin is recommended, but bleeding would be increased (Class IIb, Level B).² Therapies to be avoided include dipyridamole (Class III, Level B) and chelation therapy (Class III, Level B). Ranolazine is not addressed in these guidelines because it was released after their publication. In the European Society of Cardiology guidelines, it has a Class IIb, Level B recommendation.

After assessing and manipulating the alterable risk factors as discussed previously, the next intervention that could be undertaken is the institution of a regular exercise program. Training is possible in many patients with angina and the observed benefits include decreased heart rate and systolic blood pressure, as well as increased ejection fraction and duration of exercise. Although the mechanism of these effects has been debated, improved overall cardiovascular and muscular condition are probably most important. Improved production of nitric oxide and coronary vasomotion may account partially for the beneficial effects of exercise. The intensity of exercise influences training and more vigorous programs provide better overall results.³⁸ Obviously, an exercise program should be undertaken with caution and in a graded fashion with adequate supervision.

⑤ Chronic prophylactic therapy for patients with more than one angina episode per day may also be instituted with β -adrenergic blocking agents, and in many instances β -blockers may be preferable because of less-frequent dosing and other properties inherent in β -blockade (e.g., potential cardioprotective effects, antiarrhythmic effects, lack of tolerance, and antihypertensive effects), as well as their antianginal effects and documented protective effects in post-MI patients.² Patients who continue to smoke have reduced antianginal efficacy of β -blockers. This may be a result of enhanced hepatic metabolism of drugs that are eliminated through this route or related to the effects of smoking on MVO₂ and oxygenation.⁴⁵ The one characteristic that is relevant is the duration of effect on the double product. β -Blockers with longer half-lives (e.g., nadolol) are more likely to affect the double product for a longer period of time and require fewer doses per day. The choice of β -blocker for angina rests on choosing the appropriate dose to achieve the goals outlined for heart rate and double product, and choosing an agent that is well tolerated by individual patients and cost. Selective use may incorporate ancillary properties but these are secondary considerations in overall drug product selection. Patients most likely to respond well to β -blockade are those who have a high resting heart rate and those who have a relatively fixed anginal threshold. In other words, their symptoms appear at the same level of exercise or workload on a consistent basis. Symptoms appearing with variable work loads suggest fluctuations in myocardial oxygen supply, perhaps due to coronary artery vasomotion, and these patients are more likely to respond to calcium channel antagonists.

⑥ Nitrate therapy should be the first step in managing acute attacks for patients with chronic stable angina if the attacks are infrequent (i.e., a few times per month) or for prophylaxis of symptoms when undertaking activities known to precipitate attacks. In general, if angina occurs no more often than once every few days, then sublingual nitroglycerin tablets or spray or buccal products may be sufficient to allow the patient to maintain an adequate lifestyle. For episodes of “first-effort” angina occurring in a predictable fashion, nitroglycerin may be used in a prophylactic manner with the patient taking 0.3 to 0.4 mg sublingually about 5 minutes prior to the anticipated time of activity. Nitroglycerin spray may be useful when inadequate saliva is produced to rapidly dissolve sublingual nitroglycerin or if a patient has difficulty opening the container. Most patients have a response that lasts about 30 minutes or so, but this is subject to interindividual variability. When angina occurs more frequently than once a day, a chronic prophylactic regimen using β -blockers as the first line of therapy should be considered (Fig. 17–4 illustrates the stable angina algorithm). Chronic prophylactic therapy with long-acting forms of nitroglycerin (oral or transdermal), isosorbide dinitrate, 5-mononitrate, and pentaerythritol trinitrate may be effective; however, the development of tolerance is a major limiting step in their continued effectiveness. Because long-acting nitrates are not as effective as β -blockers and do not have beneficial effects, monotherapy with nitrates should not be first-line therapy unless β -blockers and calcium channel blockers are contraindicated or not tolerated. As described previously, providing a nitrate-free interval of 8 hours per day or longer appears to be the most promising approach to maintaining the efficacy of chronic nitrate therapy. Recent investigations into the mechanisms of nitrate tolerance have shown in normal volunteers that treatment with isosorbide mononitrate for 7 days resulted in tolerance as well as endothelial dysfunction, which is thought to be a consequence of reactive oxygen species generated during bioactivation of high-potency nitrates.^{46,47} Oral administration of nitrates is susceptible to a saturable first-pass effect; consequently, larger doses can produce a measurable hemodynamic effect and dose titration should be based on these changes in the double product. There are few well-controlled studies that compare oral or sublingual nitrate efficacy, and the choice among these products should be based on familiarity with the preparation, cost, and patient acceptance.

⑦ Calcium channel antagonists have the potential advantage of improving coronary blood flow through coronary artery vasodilation as well as decreasing MVO₂ and may be used instead of β -blockers for chronic prophylactic therapy; however, in chronic stable angina, comparative trials of long-acting calcium channel blockers with β -blockers do not show significant differences in response.^{48,49} They are as effective as β -blockers and are most useful in patients who have a variable threshold for exertional angina. Calcium antagonists may provide better skeletal muscle oxygenation, resulting in decreased fatigue and better exercise tolerance. Additionally, if contraindications exist to β -blocker therapy, calcium antagonists can be safely used in many patients. The available calcium channel blockers appear to have similar efficacy in the management of chronic stable angina. Differences in their electrophysiology, peripheral and central hemodynamic effects, and adverse-effect profiles are useful in selecting the appropriate agent. Patients with conduction abnormalities and moderate to severe LV dysfunction (ejection fraction <35%) should not be treated with verapamil, whereas amlodipine may be safely used in many of these patients. Diltiazem has significant effects on the AV node and can produce heart block in patients with preexisting conduction disease or when other drugs with effects on conduction, such as digoxin or β -blockers, are used concurrently. Nifedipine may cause excessive heart rate elevation, especially if the patient is not receiving a β -blocker, and this may offset the beneficial effect it has on MVO₂. Gingival hyperplasia has also been reported

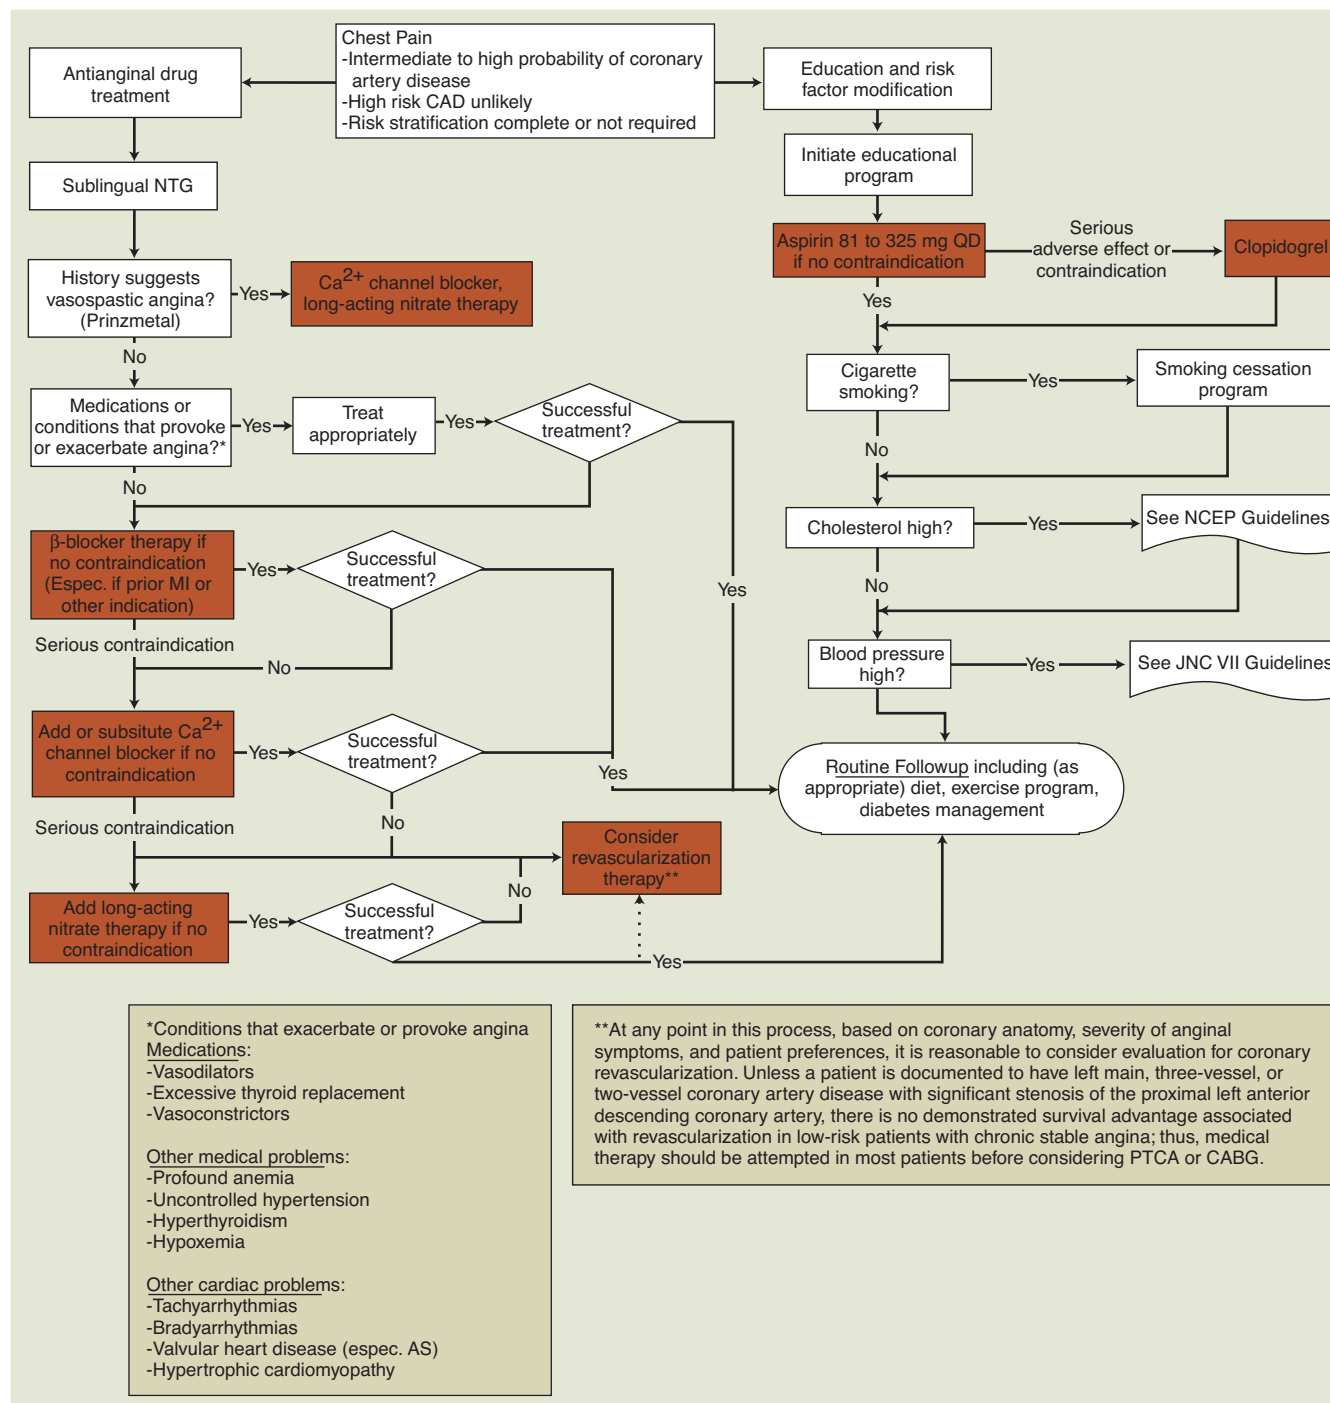

FIGURE 17-4. Treatment algorithm. (AS, aortic stenosis; CABG, coronary artery bypass grafting; CAD, coronary artery disease; JNC VII, Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure; MI, myocardial infarction; NCEP, National Cholesterol Education Program; NTG, nitroglycerin; PTCA, percutaneous transluminal coronary angioplasty; QD, every day.)

with nifedipine, and some dental authorities say this may be seen in as many as 20% of patients on nifedipine. Case control studies with calcium blockers suggest an increased risk for MI and cancer.^{50,51} The relationship to cancer appears to be weak to nonexistent whereas the risk for MI is probably real and related to the type of drug used and relationship to recent MI. Immediate-release formulations of calcium blockers can activate the sympathetic nervous system and in patients with recent MI or significant coronary disease, may induce ischemia. This effect has not been shown for longer-acting products. The hemodynamic effect of calcium antagonists is complementary to β-blockade and, consequently, combination therapy is rational but clinical trial data do not support the notion that combination therapy is always more effective.^{48,52}

Although revascularization (see below) would seem to provide better symptomatic relief and improved survival rates, recent randomized trials have shown no advantage of angioplasty or surgery over medical therapy in patients with stable coronary artery disease.^{53,54} In the Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation (COURAGE) trial, the 4.6-year cumulative primary event rates (death from any cause and nonfatal myocardial infarction) were 19.0% in the percutaneous coronary intervention (PCI) group and 18.5% in the medical therapy group (hazard ratio for the PCI group, 1.05; 95% confidence interval [CI], 0.87 to 1.27; $P = 0.62$).⁵³ The Medicine, Angioplasty, or Surgery Study (MASS II) found medical therapy was associated with an incidence of long-term events and rate of additional revasculariza-

tion similar to those for PCI. CABG was superior to medical therapy in terms of the primary end points, reaching a significant 44% reduction in primary end points at the 5-year followup of patients with stable multivessel coronary artery disease.⁵⁴

■ 8 NONPHARMACOLOGIC THERAPY

Revascularization

The decision to undertake PCI or CABG for revascularization is based on the extent of coronary disease (number of vessels and location/amount of stenosis) and ventricular function. Table 17–7 outlines the recommended mode of coronary revascularization.^{15,55}

The largest randomized trial of PCI versus CABG is the Bypass Angioplasty Revascularization Investigation (BARI) trial conducted in 1,829 patients with two- or three-vessel disease; 64% of these patients had an admitting diagnosis of unstable angina and 19% were diabetic.⁵⁶ The 10-year survival was 71.0% for PTCA and 73.5% for CABG ($P = 0.18$). At 10 years, the PTCA group had substantially higher subsequent revascularization rates than the CABG group (76.8% vs. 20.3%, $P < 0.001$), but angina rates for the two groups were similar. In the subgroup of patients with no treated diabetes, survival rates were nearly identical by randomization (PTCA 77.0% vs. CABG 77.3%, $P = 0.59$).⁵⁷ Insulin-requiring diabetics seem to be at the highest risk and CABG is the revascularization procedure of choice for this population.⁵⁸ In a large observational study by Hannan et al., patients with proximal left anterior descending (LAD) lesions and multivessel disease had higher survival rates with CABG than with PTCA.⁵⁹ High-risk patients who should be considered for CABG over PCI are those with LV systolic dysfunction, patients with diabetes, and those with two-vessel disease with severe proximal LAD involvement or severe three-vessel or left main disease (see Table 17–7).¹⁵ AWESOME (Angina With Extremely Serious Operative Mortality Evaluation) found that either bypass or percutaneous intervention effectively relieves medically refractory ischemia among high-risk unstable angina patients whose age was greater than 70 years.⁶⁰

PCI has been used successfully in the management of unstable angina.^{55,61} PTCA involves the insertion of a guidewire and inflatable

balloon into the affected coronary artery and enlarging the lumen of the artery by stretching the vessel wall. This frequently causes atheroma plaque fracture by stretching inelastic components and denudation of the endothelium resulting in loss of nitric oxide and other vasodilators and exposure of plaque contents to the vascular compartment. Consequently, immediate vascular recoil, platelet adhesion and aggregation, mural thrombus formation, and smooth muscle proliferation, and synthesis of extracellular matrix may give rise to acute occlusion and early or late restenosis.^{62,63} The presence of coronary artery spasm and intraluminal thrombus, common occurrences in unstable angina, increases the hazard of these complications. The advent of combination therapy with acetylsalicylic acid, unfractionated heparin or low-molecular-weight heparin, and glycoprotein IIb/IIIa receptor antagonists and coronary artery stents has dramatically reduced the occurrence of early reocclusion and late restenosis.⁶⁴ Patients best suited for PTCA are those with recent onset of worsening of angina without a long history of symptoms. Angiographic characteristics associated with these clinical findings that allow the greatest probability of success for PTCA are severe, discrete, proximal lesions found in a large epicardial vessel subtending a moderate or large area of viable myocardium and have high-risk features. Patients with focal saphenous vein graft lesions who are poor candidates for reoperation have a class IIa recommendation for PCI. Class IIb indications include patients with one or more lesions to be dilated in vessels subtending a less-than-moderate area of viable myocardium and patients with multivessel disease and proximal LAD lesions, diabetes, or abnormal LV function.⁶⁵ Candidates for PTCA must also be suited for CABG because a small percentage of procedures results in emergency CABG. Success of PCI may be defined as angiographic success (Thrombolysis In Myocardial Infarction [TIMI] 3 flow and $<20\%$ residual stenosis), procedural success (lack of in-hospital clinical complications), and clinical success (anatomic and procedural success with relief of ischemic pain for at least 6 months). In trials of invasive versus conservative strategies (medical management) using PCI, death or MI is less frequent in some, but not all, trials.^{66–69} Numerous studies support the use of glycoprotein IIb/IIIa receptor antagonists in addition to acetylsalicylic acid and unfractionated heparin or low-molecular-weight heparin, and as described previously, abciximab was superior to tirofiban in the only comparative study available.^{15,65} The initial success rate for PTCA in unstable angina is ~80% to 90%, but these patients are at risk for more complications than are those with stable angina because of the underlying pathophysiology.

In the event of prolonged chest pain and ischemic ECG changes unrelieved by nitrate therapy or calcium channel antagonists, one may assume total occlusion of a coronary vessel and steps should be taken to restore blood flow with either PCI or CABG.

Coronary Artery Bypass Grafting⁷⁰

Following the introduction of saphenous vein graft replacement for the severely occluded coronary arteries by Favorolo and Garrett in 1967, CABG became an accepted and commonly used approach for the management of IHD. The objectives in performing CABG are twofold: (a) to reduce the number of symptomatic anginal attacks not controlled with medical management or PCI and improve the lifestyle of the patient, and (b) to reduce the mortality associated with coronary artery disease. Surgery is effective in providing pain relief in large numbers of patients, with approximately 70% to 95% being pain-free at 1 year and 46% to 55% being pain-free at 5 years. This compares favorably with medical management, with which only approximately 30% are free of symptoms at 5 years. Mortality at 10 years from the largest published studies is 26.4% with CABG and 30.5% with medical management ($P = 0.03$) but there are significant differences based on subgroup analysis (e.g., left main disease vs. one-vessel disease without a proximal LAD lesion).⁷¹ The second

	CABG	I/A
Three-vessel disease with EF <0.50	CABG	I/A
Multivessel disease including proximal LAD with EF <0.50 or treated diabetes	CABG	I/A
Multivessel disease with EF >0.50 and without diabetes	PCI	IIb/B
Multivessel disease with EF >0.50 and without diabetes	PCI	I/A
One- or two-vessel disease without proximal LAD but with large areas of myocardial ischemia or high-risk criteria on noninvasive testing (see text)	CABG or PCI	I/B
One-vessel disease with proximal LAD	CABG or PCI	IIa/B
One- or two-vessel disease without proximal LAD with small area of ischemia or no ischemia on noninvasive testing	CABG or PCI	III/C
Insignificant coronary stenosis	CABG or PCI	III/C

CABG, coronary artery bypass grafting; EF, ejection fraction; LAD, left anterior descending coronary artery; PCI, percutaneous coronary intervention.
^a $\geq 50\%$ diameter stenosis.
From Braunwald E, Antman EM, Beasley JW, et al. ACC/AHA guidelines for the management of patients with unstable angina and non-ST-segment elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on the Management of Patients with Unstable Angina). J Am Coll Cardiol 2000;36:970–1062, with permission.

objective is met in certain patients and was addressed in three large, well-controlled trials of bypass surgery. These three studies, the Veterans Administration, European Cooperative Surgery Study, and the CASS, are not directly comparable because the inclusion and exclusion criteria for entry into each study were different and patients were followed for different periods of time. They have also been criticized for not being representative of the population that may be candidates for surgery, lacking women or late-middle aged or elderly patients, and for crossover of medically managed patients to the surgical group. A major change in medical practice that influences the interpretation of these older studies is the common procedure of stent placement at the time of angioplasty.⁷² There are about 20 different types of stents available and their use is associated with greater luminal diameter after angioplasty, fewer acute reocclusions and less restenosis after stent placement. Consequently, the validity of generalizing the results from these studies to routine practice has been questioned, but these studies are useful for providing a basis for decisions concerning surgery. Current class I recommendations for CABG in asymptomatic or mild angina patient includes significant (>50%) left main coronary artery stenosis, left main equivalent ($\geq 70\%$ stenosis of the proximal LAD and proximal left circumflex artery), and three-vessel disease, especially in patients with a LV ejection fraction < 0.50 .⁷¹ Class IIa recommendations for CABG are proximal LAD stenosis with one- or two-vessel disease and class IIb recommendations for one- or two-vessel disease not involving the proximal LAD. In stable angina, class I recommendations are the same as for mild angina with the following additions: one- or two-vessel disease without significant proximal LAD stenosis, but with a large area of viable myocardium and high-risk criteria in noninvasive testing; disabling angina despite maximal medical therapy, when surgery can be performed with acceptable risk. Class IIb recommendations in stable angina include proximal LAD stenosis with one-vessel disease and one- or two-vessel disease without significant proximal LAD stenosis but with a moderate area of viable myocardium and ischemia on noninvasive testing. The indications for CABG in unstable angina/non-ST-segment elevation myocardial infarction were described previously. In ST-segment MI, CABG is indicated for ongoing ischemia/infarction not responsive to maximal medical therapy (class IIb).

In patients with poor LV function CABG is indicated for the same indications as in mild angina for class I. Class IIa recommendations include poor LV function with significant viable, noncontracting, revascularizable myocardium without any of the aforementioned anatomic patterns (e.g., left main disease). CABG is useful in patients with life-threatening ventricular arrhythmia in the presence of left main disease, three-vessel disease (class I) and in bypassable one- or two-vessel disease causing life-threatening ventricular arrhythmias and proximal LAD disease with one- or two-vessel disease (class IIa).

CABG may also be used for patients who have failed PTCA if there is ongoing ischemia or threatened occlusion with significant myocardium at risk and in patients with hemodynamic compromise (class I). Class IIa recommendations for failed PTCA include a foreign body in a crucial anatomic position and hemodynamic compromise in patient with impairment of the coagulation system and without a previous sternotomy. CABG may be repeated in patients with a previous CABG if disabling angina exists despite maximal noninvasive therapy (class I) and if a large area of myocardium is threatened and is subtended by bypassable distal vessels (class IIa).

The need for nitrates and β -blockers is clearly reduced by surgery, with only 30% of CABG patients requiring chronic medication, whereas 70% of their medical counterparts received anginal drugs. CASS showed that employment status after surgery was more dependent on the pretreatment status than an effect induced by the treatment arm, and that approximately 70% of patients are employed before and after surgery. Recent followup analyses of these studies

suggest that patients who have diabetes or peripheral vascular disease, who are African Americans, or who continue to smoke are at high risk for CAD events, and diabetics, in particular, are more likely to have a better outcome with CABG than PTCA.^{56,73,74} The overall benefit noted after CABG is similar in men and women, and elderly patients appear to have outcomes similar to younger patients.

Operative mortality is reported to range from 1% to 3% and is related to the number of vessels involved and preoperative ventricular function. Patients in CASS with one-, two-, or three-vessel disease had operative mortalities of 1.4%, 2.1%, and 2.8%, respectively. The relationship to left ventricular ejection fraction follows a similar trend with ejection fractions of greater than 50%, 20% to 40%, and less than 20% having operative mortality rates of 1.9%, 4.4%, and 6.7%, respectively. Perioperative infarction averages 5% depending on the sensitivity of the method for assessment, and the occurrence of an infarct reduces long-term survival. Neurologic dysfunction is relatively common postoperatively in CABG patients (~6%), but many of the deficits are clinically insignificant and resolve with time. Fatal brain damage occurs in 0.3% to 0.7%, stroke in approximately 5%, and ophthalmologic defects in 25%, but only 3% have clinically apparent field defects. Peripheral nerve lesions (12%) and brachial plexopathy (7%) are also reported to occur. Other complications include constrictive pericarditis (0.2%), cellulitis at the site of vein graft, and mediastinal infections (1% to 4%).

Graft patency influences the success for symptom control, and survival and the mechanism for early graft occlusion is probably different from that associated with late closure. Early occlusion is related to platelet adhesion and aggregation whereas late occlusion may be related to endothelial proliferation and progression of atherosclerosis. Patency of grafts early on after the CABG are reported to range from 88% to 97% in at least one graft and 58% to 81% in all grafts at 1 year. Long-term patency based on the CASS Montreal Heart Institute experience suggests that 60% to 67% of all grafts remain patent at 5 to 11 years. Antiplatelet therapy has been demonstrated to improve early and late patency rates and should probably be used in all patients who do not have any contraindications. Aspirin with or without other antiplatelet agents (clopidogrel) reduces the late development of vein-graft occlusions. Late graft closure is related to elevated lipid levels and the progression of atherosclerosis in the grafted vessels as well as the native circulation. Elevation of very-low-density lipoprotein, LDL, and LDL apolipoprotein B is correlated to disease progression and graft closure. Aggressive lipid lowering can stabilize the progression of CAD and may induce regression in selected coronary artery segments within a patient following CABG. Cessation of smoking is an important preoperative and postoperative objective as well as in the management of other coronary risk factors (e.g., hypertension) and institution of a supervised, daily exercise program is recommended. Internal mammary artery grafts should be used for revascularizing the left anterior descending artery system when possible owing to better graft survival and clinical outcomes.

Valvular heart disease can coexist with coronary heart disease, although this is relatively uncommon with rheumatic valve disease, usually the mitral valve, and more common with aortic stenosis and regurgitation. Angina may occur in 35% to 65% of patients with aortic stenosis or regurgitation, and if severe, may be the cause of angina in the absence of coronary artery disease. Patients being evaluated for possible CABG should also be evaluated for valvular disease to determine if valve replacement needs to be performed along with bypass grafting.

Percutaneous Transluminal Coronary Angioplasty⁵⁵

Since the introduction into clinical cardiology of PTCA by Gruentzig in 1977, this procedure has gained rapid acceptance as a safe and

effective means of managing coronary artery disease. It is estimated that more than 750,000 PCI procedures are done each year in this country and 525,000 of them are PTCA. The proposed mechanisms of reduced stenosis with PTCA include (a) compression and redistribution of the atherosclerotic plaque; (b) embolization of plaque contents; (c) aneurysm formation; and (d) disruption of the plaque and arterial wall with distortion and tearing of the intima and media, which leads to denudation of the endothelium, platelet adhesion and aggregation, thrombus formation, and smooth muscle proliferation. Of these mechanisms, the last one is felt to be the most important, but the others may contribute to opening of the lesions in some situations.

9 The indications for PTCA have been provided by the American College of Cardiology/American Heart Association (ACC/AHA) and now span single or multivessel disease, as well as asymptomatic and symptomatic patients (Table 17–8).⁵⁵ In addition to providing recommendations for which type of patients are appropriate for PTCA, the guidelines also provide recommendations for the volume of procedures, the use of intravascular ultrasound, and surgery backup when PTCA is being considered. 10 PTCA generally is not useful if only a small area of viable myocardium is at risk, or when ischemia cannot be demonstrated, borderline (<50%) stenosis or lesions that are difficult to dilate are present, or the patient were at high risk for morbidity or mortality or both (e.g., left main or equivalent disease or three-vessel disease). PTCA alone or when used in conjunction or sequentially with thrombolysis for acute myocardial infarction is discussed in Chap. 18. Stent placement accompanies balloon angioplasty in approximately 80% of cases in the United States. Table 17–8 lists the current recommendations for PCI based on class of angina.

Assessment of outcome with PCI can be based on several angiographic, procedural, and clinical outcomes, as discussed previously. The success of PCI is dependent on the experience of the operator (high volume, better outcome), on complicating factors for the patient (including the number of vessels to be dilated), and on technical advances in the equipment used (e.g., steerable and low-profile catheters). The acute success rate for opening of uncomplicated stenotic lesions ranges from 96% to 99% with the combined balloon/device/pharmacologic approach in experienced hands, and angina is decreased or eliminated in approximately 80% of cases. The success rate totally occluded lesions is somewhat less (~65%). Mortality at 1 year is 1% for single-vessel disease and 2.5% for multivessel involvement, reflecting the good prognosis associated with this degree of coronary artery disease. At 10 years, survival is 95% for single-vessel disease and 81% for multivessel disease.⁷⁵ Most patients remain event-free (no death, MI, or CABG) for an extended period. Symptomatic status, as measured by the New York Heart Association classification, is improved in many patients. Restenosis is noted in 32% to 40% after balloon angioplasty at 6 months, and half of these patients will have symptoms associated with restenosis.⁷⁵ A few late restenotic events occur, but most restenosis occurs within the first 6 months. Anatomic factors that predict restenosis include lesions >20 mm in length, excessive tortuosity of the proximal segment, extremely angulated segments (>90°), total occlusions >3 months old and and/or bridging collaterals, inability to protect major side branches, and degenerated vein grafts with friable lesions. Clinical factors that predict worse outcome include diabetes, advanced age, female gender, unstable angina, heart failure and multivessel disease. A four-variable scoring system that predicts cardiovascular collapse for failed PTCA includes percentage of myocardium at risk (e.g., >50% viable myocardium at risk and LV ejection fraction <25%), preangioplasty percent diameter stenosis, multivessel CAD, and diffuse disease in the dilated segment or a high myocardial jeopardy score.⁶⁵ Strut thickness of the stent influences restenosis as well and thicker struts are associated with angiographic and clinical restenosis.⁷⁶

The overall complication rate ranges from 2% to 21%, depending on the lesion type.⁷⁷ Coronary occlusion, dissection, or spasm occurs in 4% to 8% of patients, whereas ST-segment elevation MI occurs in 1.6% to 4.8%.⁶⁵ Prolonged angina and ventricular tachycardia or fibrillation occurs in 6.9% and 2.3%, respectively. In-hospital mortality ranges from 0.7% to 2.5% overall, and high-risk events for mortality includes ventricular arrhythmias and myocardial infarction. The frequency of urgent CABG because of complications ranges from 0.4% to 5.8%.⁶⁵

Table 17–9 outlines current AHA/ACC recommendations for anti-thrombotic therapy in PCI.^{55,78} Antiplatelet therapy with acetylsalicylic acid 80 to 325 mg/day given at least 2 hours prior to angioplasty is currently recommended. If patients are sensitive to acetylsalicylic acid, clopidogrel or ticlopidine are acceptable alternatives. Most centers now use clopidogrel because of adverse effects (described in Chap. 18) and prolonged time to onset for ticlopidine. In elective settings, clopidogrel should be started at least 72 hours in advance of the procedure to allow for maximal antiplatelet effects. Alternatively, a loading dose of clopidogrel (300 to 600 mg) or ticlopidine (500 mg) may be given to achieve a more rapid antiplatelet effect.⁷⁹ The combination of acetylsalicylic acid plus clopidogrel is currently recommended for patients undergoing angioplasty and stenting, and this combination is safer and superior to antiplatelet therapy plus anticoagulation with warfarin-like drugs.⁸⁰ Followup for up to 4 years from the ISAR (Intracoronary Stenting and Antithrombotic Regimen) trial shows that the benefit of combined antiplatelet therapy evident after 30 days is maintained after 4 years.⁸¹ Aspirin is an incomplete inhibitor of platelet aggregation; combination therapy of acetylsalicylic acid plus a glycoprotein (GP) IIb/IIIa receptor antagonist for PCI shows a relative risk reduction of 37.5% for death and nonfatal MI at 30 days, favoring GP IIb/IIIa receptor antagonists over placebo (absolute rates of 5.5% vs. 8.9% based on PCI trials. As discussed in Chap. 18, high-risk patients and those having a stent placed are most likely to benefit from GP IIb/IIIa receptor antagonist use. Patients presenting with elevated cardiac biomarkers are also more likely to receive benefit from GP IIb/IIIa receptor antagonists than patients with normal levels of biomarkers.⁸² In the only comparative trial, abciximab was superior to tirofiban.⁸³

During PTCA patients are usually heparinized to prevent immediate thrombus formation at the site of arterial injury and on coronary guidewires and catheters; anticoagulation is continued for up to 24 hours. The intensity of anticoagulation is monitored using the activated clotting time and the targeted range for activated clotting time is 250 to 300 seconds (HemoTec device) in the absence of GP IIb/IIIa receptor antagonist use.⁶⁵ When GP IIb/IIIa receptor antagonists are not used, unfractionated heparin is given as an IV bolus of 70 to 100 international units/kg to achieve a target activated clotting time of 200 seconds. The loading dose is lowered to 50 to 70 international units/kg when GP IIb/IIIa receptor antagonists are given. Target activated clotting time for eptifibatide and tirofiban is <300 seconds during angioplasty; post-procedure unfractionated heparin infusions are not recommended during GP IIb/IIIa receptor antagonist therapy. Mechanisms that result in restenosis include acute lumen loss owing to “recoil,” mural thrombosis formation, and smooth muscle cell proliferation with synthesis of extracellular matrix.⁸⁴ Approaches to prevent restenosis may be aimed at altering the underlying mechanisms. Recoil and loss of luminal diameter may be reduced by the use of stent placement; however, this beneficial effect is offset by an increased number of vascular complications. Cracking of the plaque leads to severe damage to the arterial wall, exposure of collagen, and endothelial dysfunction. These factors promote mural thrombi, and the propensity for thrombus formation is related, in part, to the composition of the plaque as well as the depth of injury. Combination therapy with acetylsalicylic acid, heparin and GP IIb/IIIa receptor antagonists is recommended to minimize acute occlusion and numerous clinical

TABLE 17-8 Percutaneous Coronary Intervention Based on Angina Class

Patients with Asymptomatic Ischemia or Canadian Cardiovascular Society (CCS) Class I or II Angina		
Class I Patients who do not have treated diabetes with asymptomatic ischemia or mild angina with 1 or more significant lesions in 1 or 2 coronary arteries suitable for PCI with a high likelihood of success and low risk of morbidity and mortality. The vessels to be dilated must subtend a large area of viable myocardium. <i>(Level of Evidence: B)</i>	Class Ia 1. PCI is reasonable in patients with asymptomatic ischemia or CCS class I or II angina and with 1 or more significant lesions in 1 or 2 coronary arteries suitable for PCI with a high likelihood of success and a low risk of morbidity and mortality. The vessels to be dilated must subtend a moderate to large area of viable myocardium or be associated with a moderate to severe degree of ischemia on noninvasive testing. <i>(Level of Evidence: B)</i>	Phrasing has been changed to reflect current terminology. The recommendation and all of those that follow in Section 5 have been reworded to be consistent with the CCS classification system of angina. This recommendation has been changed to class Ia to reflect the published data and Writing Committee consensus that not all patients in this clinical category must have PCI performed.
Class IIa 1. The same clinical and anatomic requirements as for Class I, except the myocardial area at risk is of moderate size or the patient has treated diabetes. <i>(Level of Evidence: B)</i>	2. PCI is reasonable for patients with asymptomatic ischemia or CCS class I or II angina, and recurrent stenosis after PCI with a large area of viable myocardium or high-risk criteria on noninvasive testing. <i>(Level of Evidence: C)</i> 3. Use of PCI is reasonable in patients with symptomatic ischemia or CCS class I or II angina with significant left main CAD (greater than 50% diameter stenosis) who are candidates for revascularization but are not eligible for CABG. <i>(Level of Evidence: B)</i>	This recommendation has been merged with other class IIa recommendations of this section, and the phrasing has been changed to reflect current terminology. This is a new recommendation dealing with the management of recurrent stenosis after PCI among patients with asymptomatic ischemia or class I or II angina. This recommendation for PCI among patients who are eligible for CABG who have significant left main disease has been added to reflect the favorable results noted by several trials with PCI.
Class IIb Patients with asymptomatic ischemia or mild angina with greater than or equal to 3 coronary arteries suitable for PCI with a high likelihood of success and a low risk of morbidity and mortality. The vessels to be dilated must subtend at least a moderate area of viable myocardium. In the physician's judgment, there should be evidence of myocardial ischemia by ECG exercise testing, stress nuclear imaging, stress echocardiography or ambulatory ECG monitoring or intracoronary physiologic measurements. <i>(Level of Evidence: B)</i>		This recommendation has been eliminated and replaced by the following 2 recommendations. For each, the phrasing has been constructed to reflect current terminology.
	Class IIb 1. The effectiveness of PCI for patients with asymptomatic ischemia or CCS class I or II angina who have 2- or 3-vessel disease with significant proximal LAD CAD who are otherwise eligible for CABG with 1 arterial conduit and who have treated diabetes or abnormal LV function is not well established. <i>(Level of Evidence: B)</i> 2. PCI might be considered for patients with asymptomatic ischemia or CCS class I or II angina with nonproximal LAD CAD that subtends a moderate area of viable myocardium and demonstrates ischemia on noninvasive testing. <i>(Level of Evidence: C)</i>	Phrasing has been changed to reflect current terminology. Among patients who are eligible, CABG with 1 arterial conduit is generally preferred for treatment of multivessel disease with significant proximal LAD obstruction in patients with treated diabetes and/or abnormal LV function. Phrasing has been changed to reflect current terminology. PCI might be considered in this clinical setting.
Class III Patients with asymptomatic ischemia or mild angina who do not meet the criteria as listed under Class I or Class II and who have: a. Only a small area of viable myocardium at risk b. No objective evidence of ischemia c. Lesions that have a low likelihood of successful dilation d. Mild symptoms that are unlikely to be due to myocardial ischemia e. Factors associated with increased risk of morbidity or mortality f. Left main disease g. Insignificant disease less than 50% <i>(Level of Evidence: C)</i>	Class III PCI is not recommended in patients with asymptomatic ischemia or CCS class I or II angina who do not meet the criteria as listed under the class II recommendations or who have 1 or more of the following: a. Only a small area of viable myocardium at risk <i>(Level of Evidence: C)</i> b. No objective evidence of ischemia <i>(Level of Evidence: C)</i> c. Lesions that have a low likelihood of successful dilation <i>(Level of Evidence: C)</i> d. Mild symptoms that are unlikely to be due to myocardial ischemia <i>(Level of Evidence: C)</i> e. Factors associated with increased risk of morbidity or mortality <i>(Level of Evidence: C)</i> f. Left main disease and eligibility for CABG <i>(Level of Evidence: C)</i> g. Insignificant disease (less than 50% coronary stenosis) <i>(Level of Evidence: C)</i>	Phrasing has been changed to reflect current terminology. Recommendation has been reworded to be consistent with CCS classification system for angina. Level of evidence has been added for each subgroup.

(continued)

TABLE 17-8 Percutaneous Coronary Intervention Based on Angina Class (continued)

Patients with CCS Class III Angina		
Class I Patient with 1 or more significant lesions in 1 or more coronary arteries suitable for PCI with a high likelihood of success and low risk of morbidity or mortality. The vessel(s) to be dilated must subtend a moderate or large area of viable myocardium and high risk. (<i>Level of Evidence: B</i>)	Class Ia 1. It is reasonable that PCI be performed in patients with CCS class III angina and single-vessel or multivessel CAD who are undergoing medical therapy and who have 1 or more significant lesions in 1 or more coronary arteries suitable for PCI with a high likelihood of success and low risk of morbidity or mortality. (<i>Level of Evidence: B</i>)	Phrasing has been changed to reflect current terminology. Recommendation has been reworded to be consistent with CCS classification system for angina. The recommendation class has been changed to Ia to reflect published data and Writing Committee consensus. Criteria regarding viable and high-risk myocardium have been deleted from this commendation.
Class IIa Patients with focal saphenous vein graft lesions or multiple stenoses who are poor candidates for reoperative surgery. (<i>Level of Evidence: C</i>)	2. It is reasonable that PCI be performed in patients with CCS class III angina with single-vessel or multivessel CAD who are undergoing medical therapy with focal saphenous vein graft lesions or multiple stenoses who are poor candidates for reoperative surgery. (<i>Level of Evidence: C</i>) 3. Use of PCI is reasonable in patients with CCS class III angina with significant left main CAD (greater than 50% diameter stenosis) who are candidates for revascularization but are not eligible for CABG. (<i>Level of Evidence: B</i>)	Phrasing has been changed to reflect current terminology. This recommendation for PCI among patients with significant left main disease who are not eligible for CABG has been added to reflect the favorable results noted by several trials with PCI.
Class IIb Patient has 1 or more lesions to be dilated with reduced likelihood of success of the vessel(s) subtend a less than moderate area of viable myocardium. Patients with 2- or 3-vessel disease, with significant proximal LAD CAD and treated diabetes or abnormal LV function. (<i>Level of Evidence: B</i>)	Class IIb 1. PCI may be considered in patients with CCS class III angina with single-vessel or multivessel CAD who are undergoing medical therapy and who have 1 or more lesions to be dilated with a reduced likelihood of success. (<i>Level of Evidence: B</i>) 2. PCI may be considered in patients with CCS class III angina and no evidence of ischemia on noninvasive testing or who are undergoing medical therapy and have 2- or 3-vessel CAD with significant proximal LAD CAD and treated diabetes or abnormal LV function. (<i>Level of Evidence: B</i>)	Phrasing has been changed to reflect current terminology. The 2001 recommendation has been split into 2 separate recommendations. Phrasing has been changed to reflect current terminology. The use of noninvasive testing to evaluate for evidence of ischemia has been added.
Class III Patient has no evidence of myocardial injury or ischemia on objective testing and has not had a trial of medical therapy, or has a. Only a small area of myocardium at risk b. All lesions or the culprit lesion to be dilated with morphology with a low likelihood of success c. A high risk of procedure-related morbidity or mortality. (<i>Level of Evidence: C</i>) 2. Patients with insignificant coronary stenosis (e.g., less than 50% diameter). (<i>Level of Evidence: C</i>) 3. Patients with significant left main CAD who are candidates for CABG. (<i>Level of Evidence: B</i>)	Class III PCI is not recommended for patients with CCS class III angina with single-vessel or multivessel CAD, no evidence of myocardial injury or ischemia on objective testing, and no trial of medical therapy, or who have 1 of the following: a. Only a small area of myocardium at risk (<i>Level of Evidence: C</i>) b. All lesions or the culprit lesion to be dilated with morphology that conveys a low likelihood of success (<i>Level of Evidence: C</i>) c. A high risk of procedure-related morbidity or mortality (<i>Level of Evidence: C</i>) d. Insignificant disease (less than 50% coronary stenosis) (<i>Level of Evidence: C</i>) e. Significant left main CAD and candidacy for CABG (<i>Level of Evidence: C</i>)	Phrasing has been changed to reflect current terminology. Class II recommendations #2 and #3 from the 2001 guidelines have been merged into this recommendation.

CAEBG, coronary artery bypass graft; CAD, coronary artery disease; ECG, electrocardiography; LAD, left anterior descending; LV, left ventricle; OV, outflow volume; PCI, percutaneous coronary intervention. From Smith SC Jr, Feldman TE, Hirshfeld JW Jr, et al. ACC/AHA/SCAI 2005 guideline update for percutaneous coronary intervention—Summary article: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (ACC/AHA/SCAI Writing Committee to Update the 2001 Guidelines for Percutaneous Coronary Intervention). *Circulation* 2006;113:156–175.

trials document the efficacy of this combined approach.^{55,78} Bivalirudin is a specific and reversible direct thrombin inhibitor that is indicated for use as an anticoagulant in patients with unstable angina undergoing PTCA. Bivalirudin is comparable to heparin in preventing thrombosis and may be associated with less bleeding.^{85–87} Chapter 18 has a more complete discussion of antithrombotic therapy.

Alternatives to PTCA include directional coronary atherectomy (DCA), excimer laser, rotational atherectomy (rotablator), and intracoronary stents, or some combination of these interventions.⁸⁸

Based on randomized trials, DCA produces greater initial luminal diameter but results in a higher rate of post-procedure complications, such as non-Q-wave MI and death, and is more expensive. Consequently, PTCA is considered to be superior to DCA for most patients. Tissue debulking with DCA is useful for in-stent restenosis, particularly for diabetic patients.⁸⁹ The use of abciximab may improve these results.⁹⁰ Excimer laser angioplasty followed by balloon angioplasty or rotational atherectomy provides no benefit additional to balloon angioplasty alone.⁹¹

TABLE 17-9 Pharmacologic Management of Percutaneous Coronary Intervention**Antiplatelet and antithrombotic adjunctive therapies for PCI—oral antiplatelet therapy****Class I**

1. Patients already taking daily chronic aspirin therapy should take 75 to 325 mg of aspirin before the PCI procedure is performed. (*Level of Evidence: A*)
2. Patients not already taking daily chronic aspirin therapy should be given 300 to 325 mg of aspirin at least 2 hours and preferably 24 hours before the PCI procedure is performed. (*Level of Evidence: C*)
3. After the PCI procedure, in patients with neither aspirin resistance, allergy, nor increased risk of bleeding, aspirin 325 mg daily should be given for at least 1 month after bare-metal stent implantation, 3 months after sirolimus-eluting stent implantation, and 6 months after paclitaxel-eluting stent implantation, after which daily chronic aspirin use should be continued indefinitely at a dose of 75 to 162 mg. (*Level of Evidence: B*)
4. A loading dose of clopidogrel should be administered before PCI is performed. (*Level of Evidence: A*) An oral loading dose of 300 mg, administered at least 6 hours before the procedure, has the best established evidence of efficacy. (*Level of Evidence: B*)
5. In patients who have undergone PCI, clopidogrel 75 mg daily should be given for at least 1 month after bare-metal stent implantation (unless the patient is at increased risk for bleeding; then it should be given for a minimum of 2 weeks), 3 months after sirolimus stent implantation, and 6 months after paclitaxel stent implantation, and ideally up to 12 months in patients who are not at high risk of bleeding. (*Level of Evidence: B*)

A daily dose of 75 mg of aspirin has been shown to result in improved cardiovascular outcomes similar to daily doses of 325 mg but with fewer bleeding complications. Higher doses of aspirin are recommended for patients not already taking aspirin therapy immediately before PCI procedures.

The doses and duration of aspirin therapy recommended herein and derived from those used for US Food and Drug Administration approval of the specific stent types noted in the recommendation. Daily chronic aspirin therapy is based on recommendations in the ACC/AHA Guidelines for the Management of Patients with ST-Elevation Myocardial Infarction and evidence indicating that aspirin therapy in dosages as low as 75 mg per day yields outcomes similar to those achieved with 325 mg per day but with fewer side effects. Clopidogrel is an important adjunctive therapy for patients undergoing PCI with stent placement. The best evidence of efficacy exists for 300 mg given at least 6 hours before PCI is performed.

Clopidogrel therapy in the dosage of 75 mg daily should be given after stent placement to all patients. The duration of therapy varies for each stent and is based on data from clinical trials used for U.S. Food and Drug Administration approval of that stent.

Class IIa

1. If clopidogrel is given at the time of procedure, supplementation with GP IIb/IIIa receptor antagonists can be beneficial to facilitate earlier platelet inhibition than with clopidogrel alone. (*Level of Evidence: B*)
2. For patients with an absolute contraindication to aspirin, it is reasonable to give a 300-mg loading dose of clopidogrel, administered at least 6 hours before PCI, and/or GP IIb/IIIa antagonists, administered at the time of PCI. (*Level of Evidence: C*)
3. When a loading dose of clopidogrel is administered, a regimen of greater than 300 mg is reasonable to achieve higher levels of antiplatelet activity more rapidly, but the efficacy and safety compared with a 300-mg loading dose are less established. (*Level of Evidence: C*)
4. It is reasonable that patients undergoing brachytherapy be given daily clopidogrel 75 mg indefinitely and daily aspirin 75 to 325 mg indefinitely unless there is significant risk for bleeding. (*Level of Evidence: C*)

When clopidogrel is given at the time of a PCI procedure, supplementation with glycoprotein IIb/IIIa receptor antagonists can be beneficial, especially among high-risk patients.

A significant number of patients will have resistance to aspirin. The strongest evidence for clopidogrel benefit exists for doses of 300 mg given at least 6 hours before the procedure.

Many patients receive clopidogrel therapy at the time of PCI in dosages greater than 600 mg. Although more pronounced inhibition of platelet function has been demonstrated for doses of clopidogrel greater than 300 mg, the safety of these higher doses and their benefits on clinical outcome are not fully established. Subacute or later thrombosis has been observed in patients undergoing brachytherapy, and for this reason long-term antiplatelet therapy is recommended.

Class IIb

In patients in whom subacute thrombosis may be catastrophic or lethal (unprotected left main, bifurcating left main, or last patent coronary vessel), platelet aggregation studies may be considered and the dose of clopidogrel increased to 150 mg per day if less than 50% inhibition of platelet aggregation is demonstrated. (*Level of Evidence: C*)

Clopidogrel resistance is a significant problem, and owing to its contribution to catastrophic clinical outcomes, the Writing Committee recommends studies be performed with increases in clopidogrel dose being recommended for use in those with higher-risk lesions.

Glycoprotein IIb/IIIa inhibitors**Class I**

In patients with UA/NSTEMI undergoing PCI without clopidogrel administration, a GP IIb/IIIa inhibitor (abciximab, eptifibatide, or tirofiban) should be administered. (*Level of Evidence: A*) It is acceptable to administer the GP IIb/IIIa inhibitor before performance of the diagnostic angiogram ("upstream treatment") or just before PCI ("in-lab treatment").

This recommendation and phrasing are compatible with the ACC/AHA 2002 Guideline Update for the Management of Patients With Unstable Angina and Non-ST-Segment Myocardial Infarction and current evidence from randomized clinical trials. The benefits of GP IIb/IIIa inhibition are especially efficacious when clopidogrel is not given.

Class IIa

1. In patients with UA/NSTEMI undergoing PCI with clopidogrel administration, it is reasonable to administer a GP IIb/IIIa inhibitor (abciximab, eptifibatide, or tirofiban). (*Level of Evidence: B*)
- It is acceptable to administer the GP IIb/IIIa inhibitor before performance of the diagnostic angiogram ("upstream treatment") or just before PCI ("in-lab treatment").
2. In patients with STEMI undergoing PCI, it is reasonable to administer abciximab as early as possible. (*Level of Evidence: B*)
 3. In patients undergoing elective PCI with stent placement, it is reasonable to administer a GP IIb/IIIa inhibitor (abciximab, eptifibatide, or tirofiban). (*Level of Evidence: B*)

Recommendation has been added for consistency with the ACC/AHA Guidelines for the Management of Patients With ST-Elevation Myocardial Infarction. Phrasing has been changed to reflect current terminology, especially in a high-risk patient.

Class IIb

In patients with STEMI undergoing PCI, treatment with eptifibatide or tirofiban may be considered. (*Level of Evidence: C*)

Recommendation has been added for consistency with the ACC/AHA Guidelines for the Management of Patients With ST-Elevation Myocardial Infarction.

Antithrombotic therapy**Unfractionated heparin, low-molecular-weight heparin, and bivalirudin****Class I**

1. Unfractionated heparin should be administered to patients undergoing PCI. (*Level of Evidence: C*)
2. For patients with heparin-induced thrombocytopenia, it is recommended that bivalirudin or argatroban be used to replace heparin. (*Level of Evidence: B*)

Phrasing has been changed to reflect current terminology.

Bivalirudin and argatroban are established therapies in place of heparin among patients with heparin-induced thrombocytopenia.

(continued)

TABLE 17-9 Pharmacologic Management of Percutaneous Coronary Intervention (continued)**Class IIa**

1. It is reasonable to use bivalirudin as an alternative to unfractionated heparin and glycoprotein IIb/IIIa antagonists in low-risk patients undergoing elective PCI. (*Level of Evidence: B*)
2. Low-molecular-weight heparin is a reasonable alternative to unfractionated heparin in patients with UA/NSTEMI undergoing PCI. (*Level of Evidence: B*)

New recommendation is based on data from a clinical trial (REPLACE-2) indicating bivalirudin is an acceptable alternative to heparin and GP IIb/IIIa antagonists in low-risk patients undergoing PCI.

Recommendation from the ACC/AHA 2002 Guideline Update for the Management of Patients with Unstable Angina and Non-ST-Segment Myocardial Infarction has been approved by this Writing Committee and included in these guidelines for consistency.

Class IIb

Low-molecular-weight heparin may be considered as an alternative to unfractionated heparin in patients with STEMI undergoing PCI. (*Level of Evidence: B*)

Recommendation from the ACC/AHA Guidelines for the Management of Patients With ST-Elevation Myocardial Infarction has been approved by this Writing Committee and included in these guidelines for consistency.

GP, glycoprotein; NSTEMI, non-ST-segment elevation myocardial infarction; PCI, percutaneous coronary intervention; STEMI, ST-segment elevation myocardial infarction; UA, unstable angina.

From Smith SC Jr, Feldman TE, Hirshfeld JW Jr, et al. ACC/AHA/SCAI 2005 guideline update for percutaneous coronary intervention—Summary article: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (ACC/AHA/SCAI Writing Committee to Update the 2001 Guidelines for Percutaneous Coronary Intervention). *Circulation* 2006;113:156–175.

When medical therapy, PTCA, and CABG have been compared, low-risk patients with single-vessel coronary artery disease and normal left ventricular function had greater alleviation of symptoms with PTCA than with medical treatment; mortality rates and rates of myocardial infarction were unchanged. In high-risk patients (risk was defined by severity of ischemia, number of diseased vessels, and presence of left ventricular dysfunction), improvement of survival was greater with CABG than with medical therapy. In moderate-risk patients with multivessel coronary artery disease (most had two-vessel disease and normal left ventricular function), PTCA and CABG produced equivalent mortality rates and rates of myocardial infarction.

The development of drug-eluting stents has changed the natural course of stent thrombosis when compared to bare-metal stents that have existed for a longer period of time. Currently there are two types of drug-eluting stents available: sirolimus (Cypher) and paclitaxel (Taxus). Soon after the introduction of bare-metal stents, it became apparent that early stent thrombosis (≤ 30 days) was an uncommon but serious complication of therapy.^{92–95} Stent thrombosis is an infrequent but severe complication of both bare-metal stents and drug-eluting stents but there is no apparent difference in overall stent thrombosis frequency at 4 years of followup, but the time course appears to be different. Although there is a relative numeric excess of stent thrombosis late after drug-eluting stents implantation, no differences in death or death and infarction have been observed. Target lesion revascularization is needed less often with drug-eluting stents than with bare-metal stents. Implantation of drug-eluting stents outside of approved indications is probably related to the occurrence of late stent thrombosis. Longer-term followup with larger subsets of patients (i.e., lesion number, type and location, and patient comorbidities) is needed to fully understand this issue and the evolution of newer platforms for drug delivery will likely alter the natural history of drug-eluting stent thrombosis. A very important consideration is the use of combination antiplatelet therapy (aspirin + clopidogrel) for at least 1 year following implantation.⁹⁶ Patients who are hyporesponsive to clopidogrel may be treated with 150 mg/day rather than 75 mg/day.⁹⁴

■ PHARMACOLOGIC THERAPY

Historically, approximately 30% of anginal syndrome symptoms have responded regardless of which therapy was instituted. These observations stem from two problems inherent in clinical trials undertaken to assess the efficacy of any therapy for angina: (a) adequate trial design incorporating appropriate controls and washout periods, and (b) assessment of treatment effects using objective measures of efficacy, including improvement in exercise performance, resting and ambulatory ECG improvement in ischemic changes, or other objective tests to address other aspects of myocardial function or metabolism. The use of pain episode frequency and nitroglycerin consumption is

subjective, and their use as sole measures of efficacy should be avoided. Objective assessment using ETT has shown that placebo does not provide improvement in patients with exertional angina, substantiating this as a valid means to assess efficacy.

β -Adrenergic-Blocking Agents⁹⁷

Decreased heart rate, decreased contractility, and a slight to moderate decrease in blood pressure with β -adrenergic receptor antagonism reduce MVO₂. The predominant receptor type in the heart is the β_1 -receptor, and competitive blockade minimizes the influence of endogenous catecholamines on the chronotropic and inotropic state of the myocardium. These beneficial effects may be countered to some degree with increased ventricular volume and ejection time seen with β -blockade; however, the overall effect of β -blockers in patients with effort-induced angina is a reduction in oxygen demand (Table 17–10). The β -blockers do not improve oxygen supply, and in certain instances, unopposed α -adrenergic stimulation following the use of β -blockers may lead to coronary vasoconstriction. For patients with chronic exertional stable angina, β -blockers improve symptoms approximately 80% of the time and objective measures of efficacy demonstrate improved exercise duration and delay in the time at which ST-segment changes and initial or limiting symptoms occur. β -Blockers do not alter the rate–pressure product (double product) for maximal exercise, therefore substantiating reduced demand rather than improved supply as the major consequence of their actions. Reflex tachycardia from nitrate therapy can be blunted with β -blocker therapy, making this a common and useful combination. Although β -blockade may decrease exercise capacity in healthy individuals or in patients with hypertension, it may allow angina patients previously limited by symptoms to perform more exercise and ultimately improve overall cardiovascular performance through a training effect. Ideal candidates for β -blockers include patients in whom physical

TABLE 17-10 Effect of Drug Therapy on Myocardial Oxygen Demand^a

	Heart Rate	Myocardial Contractility	LV Wall Tension	
			Systolic Pressure	LV Volume

β -Blockers	↓↓	↓	↓	↓
Nifedipine	↓	0 or ↓	↓↓	0 or ↓
Verapamil	↓	↓	↓	0 or ↓
Diltiazem	↓↓	0 or ↓	↓	0 or ↓

LV, left ventricular.

^aCalcium channel antagonists and nitrates also may increase myocardial oxygen supply through coronary vasodilation. Diastolic function also may be improved with verapamil, nifedipine, and perhaps, diltiazem. These effects may vary from those indicated in the table depending on individual patient baseline hemodynamics.

activity figures prominently in their anginal attacks, those who have coexistent hypertension, those with a history of supraventricular arrhythmias or post-MI angina, and those who have a component of anxiety associated with angina.³ β -Blockers may also be safely used in angina and heart failure as described in Chap. 16.

Pertinent pharmacokinetics for the β -blockers include half-life and route of elimination, which are reviewed in Chap. 15. Drugs with longer half-lives need to be dosed less frequently than drugs with shorter half-lives; however, disparity exists between half-life and duration of action for several β -blockers (e.g., metoprolol), which may reflect attenuation of the central nervous system-mediated effects on the sympathetic system, as well as the direct effects of this category on heart rate and contractility. Renal and hepatic dysfunction can affect the disposition of β -blockers, but these agents are dosed to effect, either hemodynamic or symptomatic, and route of elimination is not a major consideration in drug selection.

Guidelines for the use of β -blockers in treating angina include the objective of lowering resting heart rate to 50 to 60 beats per minute and limiting maximal exercise heart rate to about 100 beats per minute or less. It has also been suggested that exercise heart rate should be no more than about 20 beats per minute or a 10% increment over resting heart rate with modest exercise. Because β -blockade is competitive and circulating catecholamine concentrations vary depending on the intensity of exercise and other factors, and cholinergic tone may be important in controlling heart rate in some patients, these guidelines are general in nature. These effects are generally dose and plasma concentration related, and for propranolol, plasma concentrations of 30 ng/mL are needed for a 25% reduction of anginal frequency. Initial doses of β -blockers should be at the lower end of the usual dosing range and titrated to response as indicated above.

Although there is little evidence to suggest superiority of any β -blocker, the duration of β -blockade is dependent partially on the half-life of the agent used, and agents with longer half-lives may be dosed less frequently. Of note, propranolol may be dosed twice a day in most patients with angina and the efficacy is similar to that seen with more frequent dosing. The ancillary property of membrane stabilizing activity is irrelevant in the treatment of angina, and intrinsic sympathomimetic activity appears to be detrimental in rest or severe angina because the reduction in heart rate would be minimized, therefore limiting a reduction in MVO₂. Cardioselective β -blockers may be used in some patients to minimize adverse effects such as bronchospasm in asthma, intermittent claudication, and sexual dysfunction. A common misunderstanding is that β -blockers are not well tolerated in peripheral arterial disease but, in fact, their use is associated with a reduction in death and improved quality of life.⁹⁸ It should be remembered that cardioselectivity is a relative property and the use of larger doses (e.g., metoprolol 200 mg/day) is associated with the loss of selectivity and with adverse effects. Post-acute-MI patients with angina are particularly good candidates for β -blockade, both because anginal symptoms may be treated and the risk of post-MI reinfarction reduced, and because mortality has been demonstrated with timolol, propranolol, and metoprolol (see Chap. 15). Combined β - (nonselective) and α -blockade with labetalol may be useful in some patients with marginal LV reserve, and fewer deleterious effects on coronary blood flow are seen when compared with other β -blockers.

Extension of pharmacologic effect is the underlying reason for many of the adverse effects seen with β -blockade. Hypotension, decompensated heart failure, bradycardia and heart block, bronchospasm, and altered glucose metabolism are directly related to β -adrenoreceptor antagonism. Patients with preexisting left ventricular systolic decompensated and heart failure and the use of other negative inotropic agents are most prone to developing overt heart failure, and in the absence of these, heart failure is uncommon (less

than 5%). Other drugs that depress conduction are additive to β -blockade, and intrinsic conduction system disease predisposes the patient to conduction abnormalities. Altered glucose metabolism is most likely to be seen in insulin-dependent diabetics, and β -blockade obscures the symptoms of hypoglycemia except for sweating. β -Blockers may also aggravate the lipid abnormalities seen in patients with diabetes; however, these changes are dose related, are more common with normal baseline lipids than dyslipidemia, and may be of short-term significance only. One of the more common reasons for discontinuation of β -blocker therapy is related to central nervous system adverse effects of fatigue, malaise, and depression. Cognition changes seen with β -blockers are usually minimal and comparable to other categories of drugs based on studies done in hypertension.^{99,100} Abrupt withdrawal of β -blocker therapy in patients with angina has been associated with increased severity and number of pain episodes and myocardial infarction. The mechanism of this effect is unknown but may be related to increased receptor sensitivity or disease progression during therapy, which becomes apparent following discontinuation of β -blockade. In any event, tapering of β -blocker therapy over about 2 days should minimize the risk of withdrawal reactions for those patients in whom therapy is being discontinued.

β -Adrenoreceptor blockade is effective in chronic exertional angina as monotherapy and in combination with nitrates and/or calcium channel antagonists. β -Blockers should be the first-line drug in chronic angina that requires daily maintenance therapy because β -blockers are more effective in reducing episodes of silent ischemia, reducing early morning peak of ischemic activity, and improving mortality after Q-wave MI than nitrates or calcium channel blockers (see Fig. 17-4).³ If β -blockers are ineffective or not tolerated, then monotherapy with a calcium channel blocker or combination therapy if monotherapy is ineffective may be instituted. Patients with severe angina, rest angina, or variant angina (i.e., a component of coronary artery spasm) may be better treated with calcium channel blockers or long-acting nitrates.

Nitrates^{101,102}

Nitroglycerin has a well-documented role in the alleviation of acute anginal attacks when used as rapidly absorbed and readily available preparations by the oral and intravenous routes (Table 17-11; see also Fig. 17-4). Sublingual, buccal, or spray products are the products of choice for this indication. Prevention of symptoms may be accomplished by the prophylactic use of oral or transdermal products; however, recent concern has been expressed over the long-term efficacy of many of these preparations and the development of tolerance.^{46,47}

Nitrates have multiple potential mechanisms of action, and for a given patient it is not always clear which of these is most important. In general, the major action appears to be indirectly mediated

TABLE 17-11 Nitrate Products

Product	Onset (min)	Duration	Initial Dose
Nitroglycerin			
IV	1-2	3-5 min	5 mcg/min
Sublingual/lingual	1-3	30-60 min	0.3 mg
Oral	40	3-6 h	2.5-9 mg tid
Ointment	20-60	2-8 h	0.5-1 in
Patch	40-60	>8 h	1 patch
Erythritol tetranitrate	5-30	4-6 h	5-10 mg tid
Pentaerythritol tetranitrate	30	4-8 h	10-20 mg tid
Isosorbide dinitrate			
Sublingual/chewable	2-5	1-2 h	2.5-5 mg tid
Oral	20-40	4-6 h	5-20 mg tid
Isosorbide mononitrate	30-60	6-8 h	20 mg daily, bid ^a

^aProduct dependent.

through a reduction of myocardial oxygen demand secondary to venodilation and arterial–arteriolar dilation, leading to a reduction in wall stress from reduced ventricular volume and pressure (see Table 17–10). Systemic venodilation also promotes increased flow to deep myocardial muscle by reducing the gradient between intraventricular pressure and coronary arteriolar (R2) pressure. Direct actions on the coronary circulation include dilation of large and small intramural coronary arteries, collateral dilation, coronary artery stenosis dilation, abolition of normal tone in narrowed vessels, and relief of spasm; these actions occur even if the endothelium is denuded or dysfunctional. It is likely that depending on the underlying pathophysiology, different mechanisms become operative. For example, in the presence of a 60% to 70% stenosis, venodilation with MVO_2 reduction is most important; however, with higher grade lesions, direct effects on the coronary circulation and vessel tone are the predominant effects. Nitroglycerin and pentaerythritol tetranitrate in low doses are bioactivated by mitochondrial aldehyde dehydrogenase to nitrite or denitrated metabolites, which require further activation by cytochrome oxidase or acidic disproportionation in the inner membrane space, finally yielding nitric oxide. Nitric oxide activates soluble guanylate cyclase to increase intracellular concentrations of cyclic guanosine monophosphate (GMP) resulting in vasorelaxation.⁴⁷ In contrast, isosorbide dinitrate (ISDN) and isosorbide mononitrate (ISMN) are bioactivated via P450 enzymes to nitric oxide. At higher concentrations, nitroglycerin and pentaerythritol tetranitrate may also be bioactivated to nitric oxide via P450 enzymes. Increased cyclic GMP induces a sequence of protein phosphorylation associated with reduced intracellular calcium release from the sarcoplasmic reticulum or reduced permeability to extracellular calcium and, consequently, smooth muscle relaxation. Oxidative stress within the mitochondria causes inactivation of mitochondrial aldehyde dehydrogenase, leading to impaired bioactivation of nitroglycerin during prolonged treatment.^{103,104} Thomas et al. performed a study in normal volunteers to evaluate the effect of ISMN 120 mg/day given for 7 days on endothelial function. They found that ISMN impaired endothelial function suggesting a role for oxygen free radicals and nitrate induced abnormalities in endothelial-dependent vasomotor responses that were reversed with a vitamin C infusion of 24 mg/min given for 15 minutes.⁴⁶ Furthermore, ISDN impairs flow-mediated dilation and carotid intimal-media thickness after 3 months of treatment.¹⁰⁵ These deleterious changes in endothelial function, intima-media thickness and the occurrence of tolerance suggest that the role of nitrates in IHD may be changing.

Pharmacokinetic characteristics common to the organic nitrates used for angina include a large first-pass effect of hepatic metabolism, short to very short half-lives (except for isosorbide mononitrate), large volumes of distribution, high clearance rates, and large interindividual variations in plasma or blood concentrations. Pharmacodynamic–pharmacokinetic relationships for the entire class remain poorly defined, presumably because of methodologic difficulty in characterizing the parent drug and metabolite concentrations at or within vascular smooth muscle and secondary to counterregulatory or adaptive mechanisms from the drug's effects, as well as the occurrence of tolerance. Nitroglycerin is extracted by a variety of tissues and metabolized locally; differential extraction and metabolite generation occur depending on the tissue site. There are also numerous technical problems limiting the generation of reliable pharmacokinetic parameter estimates including the following: assay sensitivity; arterial–venous extraction gradients and therefore extrahepatic metabolism; in vitro degradation; drug adsorption to polyvinyl chloride tubing and syringes; potentially saturable metabolism; accumulation of metabolites (some of which are active) with multiple doses; postural and exercise-induced changes in pharmacokinetics; a variety of variables associated with transdermal delivery including the delivery system (matrix, membrane-limited, oint-

ment), vehicle used, the surface area and thickness of application, the site application, and other skin variables (temperature, moisture content).

Nitroglycerin concentrations are affected by the route of administration, with the highest concentrations usually obtained with intravenous administration, the lowest seen with lower oral doses. Peak concentrations with sublingual nitroglycerin appear within 2 to 4 minutes, with the oral route producing peaks at about 15 to 30 minutes and by the transdermal route at 1 to 2 hours. The half-life of nitroglycerin is 1 to 5 minutes regardless of route; hence the potential advantage of sustained-release and transdermal products. Transdermal nitroglycerin does produce sufficient concentrations for acute hemodynamic effects to occur and these concentrations are maintained for long intervals; however, the hemodynamic and antianginal effects are minimal after 1 week or less with chronic, continuous (24 h/day) therapy.

ISDN is metabolized to isosorbide 2-mono- and 5-mononitrate (ISMN). ISMN is well absorbed and has a half-life of about 5 hours and may be given once or twice daily depending on the product chosen. Multiple, larger doses of ISDN lead to disproportionate increases in the area under the plasma time profile, suggesting that metabolic pathways are being saturated or that metabolite accumulation may influence the disposition of ISDN. Little pharmacokinetic information is available for other nitrate compounds.

Nitrate therapy may be used to terminate an acute anginal attack, to prevent effort or stress-induced attacks, or for long-term prophylaxis, usually in combination with β -blockers or calcium channel blockers. Sublingual nitroglycerin 0.3 to 0.4 mg will relieve pain in approximately 75% of patients within 3 minutes, with another 15% becoming pain free in 5 to 15 minutes. Pain persisting beyond about 20 to 30 minutes following the use of two or three nitroglycerin tablets is suggestive of acute coronary syndrome and the patient should be instructed to seek emergency aid. Patients should be instructed to keep nitroglycerin in the original, tightly closed glass container and to avoid mixing with other medication, because mixing may reduce nitroglycerin adsorption and vaporization. Additional counseling should include the facts that nitroglycerin is not an analgesic but rather it partially corrects the underlying problem and that repeated use is not harmful or addicting. Patients should also be aware that enhanced venous pooling in the sitting or standing positions may improve the effect, as well as the symptoms of postural hypotension, and that inadequate saliva may slow or prevent tablet disintegration and dissolution. An acceptable, albeit expensive, alternative is lingual spray, which may be more convenient and has a shelf-life of 3 years, compared with 6 months or so for some forms of nitroglycerin tablets.

Chewable, oral, and transdermal products are acceptable for the long-term prophylaxis of angina; however, considerable controversy surrounds their use and it appears that the development of tolerance or adaptive mechanisms limits the efficacy of all chronic nitrate therapies regardless of route. Dosing of the longer-acting preparations should be adjusted to provide a hemodynamic response and, as an example, may require doses of oral ISDN ranging from 10 to 60 mg as often as every 3 to 4 hours owing to tolerance or first-pass metabolism, and similar large doses are required for other products. Nitroglycerin ointment has a duration of up to 6 hours, but it is difficult to apply in a cosmetically acceptable fashion over a consistent surface area, and response varies depending on the epidermal thickness, vascularity, and amount of hair. Percutaneous adsorption of nitroglycerin ointment may occur unintentionally if someone other than the patient applies the ointment, and limiting exposure through the use of gloves or some other means is advisable. Peripheral edema may also impair the response to nitroglycerin because venodilation cannot increase capacitance to a maximum and pooling may be reduced. Transdermal patch delivery systems were approved

on the basis of sustained and equivalent plasma concentrations to other forms of therapy. Trials required by the Food and Drug Administration using transdermal patches as a continuous 24-hour delivery system revealed a lack of efficacy for improved exercise tolerance. Subsequently, large, randomized, double-blind, placebo-controlled trials of intermittent (10 to 12 hours on; 12 to 14 hours off) transdermal nitroglycerin therapy in chronic stable angina demonstrated modest but significant improvement in exercise time after 4 weeks for the highest doses at 8 to 12 hours after patch placement.¹⁰⁶ Subjective assessment methods for nitrate effects include reduction in the number of painful episodes and the amount of nitroglycerin consumed. Objective assessment includes the resolution of ECG changes at rest, during exercise, or with ambulatory ECG monitoring. Because nitrates work primarily through a reduction in MVO_2 , the double product can be used to optimize the dose of sublingual and oral nitrate products. It is important to realize that reflex tachycardia may offset the beneficial reduction in systolic blood pressure and calculation of the observed changes is necessary. The double product is best assessed in the sitting position and at intervals of 5 to 10 minutes and 30 to 60 minutes following sublingual and oral therapy, respectively. Owing to the placebo effect, unpredictable and variable course of angina, numerous pharmacologic effects of nitroglycerin, diurnal variation in pain patterns, stringent investigative protocols, and interindividual sensitivity to nitroglycerin, assessment with transdermal and sustained-release products is difficult. ETT provides valuable information concerning efficacy and mechanism of action for nitrates but its use is usually reserved for clinical investigation rather than routine patient care. Most ETT studies have shown nitrates to delay the onset of ischemia (ST-segment changes or initial chest discomfort) at submaximal exercise but that the threshold for maximal exercise is unaltered, suggesting a reduction in oxygen demand rather than an improved oxygen supply. More sophisticated studies of myocardial function, such as wall motion abnormalities and myocardial metabolism, could be used to document efficacy; however, these studies are generally only for investigative purposes.

Adverse effects of nitrates are related most commonly to an extension of their pharmacologic effects and include postural hypotension with associated central nervous system symptoms, headaches and flushing secondary to vasodilation, and occasional nausea from smooth muscle relaxation. If hypotension is excessive, coronary and cerebral filling may be compromised, leading to myocardial infarction and stroke. Although reflex tachycardia is most common, bradycardia with nitroglycerin has been reported. Other noncardiovascular adverse effects include rash with all products, but particularly with transdermal nitroglycerin, the production of methemoglobinemia with high doses given for extended periods, and measurable concentrations of ethanol (intoxication has been reported) and propylene glycol (found in the diluent) with intravenous nitroglycerin.

Tolerance with nitrate therapy was first described in 1867 with the initial experience using amyl nitrate for angina and later widely recognized in munitions workers who underwent withdrawal reactions during periods of absence from exposure. Tolerance to nitrates is associated with a reduction in tissue cyclic GMP, which results from decreased production (guanylate cyclase) and increased breakdown via cyclic GMP-phosphodiesterase and increased superoxide levels. One proposed mechanism for the lack of cyclic GMP is lack of conversion of organic nitrates to nitric oxide as described previously.^{47,97}

Most of the published information from controlled trials examining nitrate tolerance have been done with either ISDN or transdermal nitroglycerin, and these studies demonstrate the development of tolerance within as little as 24 hours of therapy. Although the onset of tolerance is rapid, the offset may be just as rapid, and one alternative-dosing strategy to circumvent or minimize tolerance is to provide a daily nitrate-free interval of 6 to 8 hours. Studies with a variety of

nitrate preparations and dosing schedules demonstrate that this approach is useful and the nitrate-free interval should be a minimum of 8 hours, and perhaps 12 hours for even better effects.⁹⁷ Another concern for intermittent transdermal nitrate therapy is the occurrence of rebound ischemia during the nitrate-free interval. Freedman et al.¹⁰⁷ found more silent ischemia during the patch-free interval during a randomized, double-blind, placebo-controlled trial than during the placebo patch phase, although others have not noted this effect. ISDN, for example, should not be used more often than three times per day if tolerance is to be avoided. Interestingly, hemodynamic tolerance does not always coincide with antianginal efficacy, but this is not well studied.

Nitrates may be combined with other drugs for anginal therapy including β -adrenergic-blocking agents and calcium channel antagonists. These combinations are usually instituted for chronic prophylactic therapy based on complementary or offsetting mechanisms of action (see Table 17–10). Combination therapy is generally used in patients with more frequent symptoms or with symptoms that are not responding to β -blockers alone (nitrates plus β -blockers or calcium blockers), in patients intolerant of β -blockers or calcium channel blockers, and in patients having an element of vasospasm leading to decreased supply (nitrates plus calcium blockers).¹⁰⁸ Modulation of calcium entry into vascular smooth muscle and myocardium as well as a variety of other tissues is the principal action of the calcium antagonists. The cellular mechanism of these drugs is incompletely understood and it differs among the available classes of the phenylalkylamines (verapamil-like), dihydropyridines (nifedipine-like), benzothiazepines (diltiazem-like), bepridil, and a recent class referred to as T-channel blockers. Receptor-operated channels stimulated by norepinephrine and other neurotransmitters, and potential-dependent channels activated by membrane depolarization, control the entry of calcium, and, consequently, the cytosolic concentration of calcium responsible for activation of actin–myosin complex leading to contraction of vascular smooth muscle and myocardium. In the myocardium, calcium entry triggers the release of intracellular stores of calcium to increase cytosolic calcium, whereas in smooth muscle, calcium derived from the extracellular fluid may do this directly. Binding proteins within the cell, calmodulin and troponin, after binding with calcium, participate in phosphorylation reactions leading to contraction. Decreased calcium availability, through the actions of calcium antagonists, inhibits these reactions.

Direct actions of the calcium antagonists include vasodilation of systemic arterioles and coronary arteries, leading to a reduction of arterial pressure and coronary vascular resistance, as well as depression of the myocardial contractility and conduction velocity of the sinoatrial and atrioventricular nodes (see Chap. 19). Reflex β -adrenergic stimulation overcomes much of the negative inotropic effect, and depression of contractility becomes clinically apparent only in the presence of LV dysfunction and when other negative inotropic drugs are used concurrently. Verapamil and diltiazem cause less peripheral vasodilation than nifedipine, and, consequently, the risk of myocardial depression is greater with these two agents. Conduction through the AV node is predictably depressed with verapamil and diltiazem, and they must be used cautiously in patients with preexisting conduction abnormalities or in the presence of other drugs with negative chronotropic properties. MVO_2 is reduced with all of the calcium channel antagonists because of reduced wall tension secondary to reduced arterial pressure and, to a minor extent, depressed contractility (see Table 17–10). Heart rate changes are dependent on the drug used and the state of the conduction system. Nifedipine generally increases heart rate or causes no change, whereas either no change or decreased heart rate is seen with verapamil and diltiazem because of the interaction of these direct and indirect effects. In contrast to the β -blockers, calcium channel antagonists have the potential to improve coronary blood flow through areas of fixed coronary

obstruction and by inhibiting coronary artery vasomotion and vasospasm. Beneficial redistribution of blood flow from well-perfused myocardium to ischemic areas and from epicardium to endocardium may also contribute to improvement in ischemic symptoms. Overall, the benefit provided by calcium channel antagonists is related to reduced MVO_2 , rather than improved oxygen supply, based on lack of alteration in the rate pressure product at maximal exercise in most studies performed to date. However, as coronary artery disease progresses and vasospasm becomes superimposed on critical stenotic lesions, improved oxygen supply through coronary vasodilation may become more important.

Absorption of the calcium channel antagonists is characterized by excellent absorption and large, variable, first-pass metabolism resulting in oral bioavailability ranging from approximately 20% to 50% or greater for diltiazem, nifedipine, nifedipine, verapamil, felodipine, and isradipine. Amlodipine has a range of bioavailability of approximately 60% to 80%. Saturation of this effect may occur with verapamil and diltiazem, resulting in greater amounts of drug being absorbed with chronic dosing. Nifedipine may have slow or fast absorption patterns, and the ingestion of food delays and impairs its absorption as well as potential enhanced absorption in elderly patients. This variability in absorption produces fluctuation in the hemodynamic response with nifedipine. Sublingual nifedipine is frequently used to provide a more rapid response; however, the rationale for this application is suspect because little nifedipine is absorbed from the buccal mucosa and the swallowed drug is responsible for the observed plasma concentrations. Absorption of verapamil in sustained-release products may be influenced by food, and when used in the fasted state, dose dumping may occur, resulting in high peak concentrations with some products. The approved sustained-release products for nifedipine, verapamil, and diltiazem are approved primarily for the treatment of hypertension (see Chap. 15). The presence of severe liver disease (e.g., alcoholic liver disease with cirrhosis) reduces the first-pass metabolism of verapamil, and this shunting of drug around the liver gives rise to higher plasma concentrations and lower dose requirements in these patients. Interestingly, this effect appears to be stereoselective for the more active isomer of verapamil. Verapamil may also reduce liver blood flow; however, evidence for this reduction is based primarily on animal experiments. Few data are available regarding the influence of liver disease on the kinetics of calcium blockers; however, these drugs undergo extensive hepatic metabolism with little unchanged drug being renally excreted, and liver disease can be expected to alter the pharmacokinetics. Nifedipine has no active metabolites whereas norverapamil possesses 20% or less activity of the parent compound. Desacetyl-diltiazem has not been studied in man, but canine studies suggest its potency ranges from 100% to 40% of the parent compound for various cardiovascular effects; the clinical importance of these observations remains to be determined. With chronic dosing of verapamil and diltiazem, apparent saturation of metabolism occurs, producing higher plasma concentrations of each drug than those seen with single-dose administration. Consequently, the elimination half-life for verapamil is prolonged, and less-frequent dosing intervals may be used in some patients. The elimination half-life for diltiazem is also somewhat prolonged and the half-life of desacetyl-diltiazem is longer than that of the parent drug, but it is not clear if less-frequent dosing may be used. Bepridil also undergoes hepatic elimination and an active metabolite, 4-hydroxyphenyl bepridil, is produced; the parent compound has a long half-life of 30 to 40 hours. Nifedipine does not accumulate with chronic dosing; however, it is eliminated via oxidative pathways that may be polymorphic, and slow and fast metabolizers have been described for nifedipine. Most of the calcium channel blockers are eliminated via cytochrome (CYP) 3A4 and other CYP isoenzymes and many inhibit CYP3A4 activity as well.¹⁰⁹ Renal insufficiency has little or no effect on the pharmacokinetics of these

three drugs. Although disease alterations in kinetics have been described, the most important quantitative alteration is the influence of liver disease on bioavailability and elimination that reduce the clearance of verapamil and diltiazem, and dosing in this population should be done with caution. Altered protein binding because of renal disease, decreased protein concentration, or increased α_1 -acid glycoprotein has been noted, but the clinical import of these changes is unknown.

Good candidates for calcium channel blockers in angina include patients with contraindications or intolerance of β -blockers, coexisting conduction system disease (except for verapamil and diltiazem), patients with Prinzmetal angina (vasospastic or variable threshold angina), the presence of peripheral vascular disease, severe ventricular dysfunction (amlodipine is probably the calcium channel blocker of choice and others need to be used with caution if the ejection fraction is <40%), and concurrent hypertension.

Ranolazine is a new drug for angina that has a unique mechanism of action which is unlike that of any other drug used to alter the relationship between oxygen supply and demand. Ranolazine reduces calcium overload in the ischemic myocyte through inhibition of the late sodium current (I_{Na}). Myocardial ischemia produces a cascade of complex ionic exchanges that can result in intracellular acidosis, excess cytosolic Ca^{2+} , myocardial cellular dysfunction, and, if sustained, cell injury and death. Activation of the adenosine triphosphate-dependent K^+ current during ischemia results in a strong efflux of K^+ ions from myocytes. Sodium channels are activated on depolarization, leading to a rapid influx of sodium into the cells. The inactivation of I_{Na} has a fast component that lasts a few milliseconds and a slowly inactivating component that can last hundreds of milliseconds.¹¹⁰ Ranolazine is a relatively selective inhibitor for late I_{Na} . In isolated ventricular myocytes in which the late I_{Na} was pathologically augmented, ranolazine prevented or reversed the induced mechanical dysfunction, as well as ameliorated abnormalities of ventricular repolarization. Ranolazine does not affect heart rate, inotropic state, or hemodynamic state or increase coronary blood flow.

Ranolazine is extensively metabolized via CYP450 3A and potent inhibitors of 3A increase the plasma concentration by a factor of about three. Ketoconazole, diltiazem and verapamil should not be coadministered with ranolazine. Absorption from the gut is quite variable and the apparent half-life is 7 hours. Steady state is reached after 3 days of twice-daily dosing. Ranolazine is indicated for the treatment of chronic angina and because it prolongs the QT interval, it should be reserved for patients who have not achieved an adequate response with other antianginal agents. Contraindications include preexisting QT interval prolongation, hepatic impairment, concurrent QT interval-prolonging drugs, and moderately potent to potent concurrent 3A inhibitors. QT prolongation occurs in a dose-dependent fashion with ranolazine with an average increase of 6 milliseconds but 5% of the population has QT_c prolongation of 15 milliseconds. Baseline and followup ECGs should be obtained to evaluate effects of the QT interval. In controlled trials, the most common adverse reactions are dizziness, headache, constipation and nausea. Ranolazine should be started at 500 mg twice daily and increased to 1,000 mg twice daily as needed based on symptoms.¹¹¹

Based on randomized, placebo-controlled trials, the improvement in exercise time is a modest increase of 15 to about 45 seconds compared with placebo.^{112,113} In a large acute coronary syndrome trial, ranolazine reduced recurrent ischemia but did not improve the primary efficacy end point of the composite of cardiovascular death, MI, or recurrent ischemia.¹¹⁴

Investigational Agents

Therapeutic angiogenesis aims to deliver an angiogenic growth factor or cytokine to the myocardium to stimulate collateral blood vessel

growth throughout the ischemic tissue. The angiogenic factor may be administered as a recombinant protein or as a transgene within a plasmid or gene-transfer vector. An example of this approach is the intracoronary administration of the adenoviral gene for fibroblast growth factor (Ad5FGF-4) to determine if therapeutic angiogenesis could improve myocardial perfusion compared with placebo.¹¹⁵ In this study of 52 patients with stable angina and reversible ischemia, Ad5FGF-4 decreased ischemic defect by 21% ($P < 0.001$) as determined by single-photon emission computed tomography imaging.¹¹⁵ More trials are needed before angiogenesis becomes a standard therapy.¹¹⁶

TREATMENT

Coronary Artery Spasm and Variant Angina Pectoris (Prinzmetal Angina)¹¹⁷

Prinzmetal, in his original description of variant angina pectoris, noted the waxing and waning course of this syndrome associated with ST-segment elevation and that it most commonly resolves without progression to MI. Patients who develop variant angina are usually younger, have fewer coronary risk factors but more commonly smoke than patients with chronic stable angina. Hyperventilation, exercise, and exposure to cold may precipitate variant angina attacks, or there may be no apparent precipitating cause. The onset of chest discomfort is usually in the early morning hours. The exact cause of variant angina is not well understood, but may be an imbalance between endothelium-produced vasodilator factors (prostacyclin, nitric oxide) and vasoconstrictor factors (e.g., endothelin, angiotensin II) as well as an imbalance of autonomic control characterized by parasympathetic dominance or inflammation may also play a role.^{118,119} More recently there have been a number of potential common adrenoceptor polymorphisms that may predispose patients to developing vasospasm.^{120,121}

The diagnosis of variant angina is based on ST-segment elevation during transient chest discomfort (usually at rest) that resolves when the chest discomfort diminishes in patients who have normal or nonobstructive coronary lesions. In the absence of ST-segment elevation, provocative test using ergonovine, acetylcholine, or methacholine may be used to precipitate coronary artery spasm, ST-segment elevation and typical symptoms. Nitrates and calcium antagonists should be withdrawn prior to provocative testing. Provocative testing should not be used in patients with high-grade lesions. Hyperventilation may also be used to provoke spasm and patients who positive a hyperventilation test are more likely to have higher frequency of attacks, multivessel disease, and a high degree of AV block or ventricular tachycardia.

Optimization of therapy includes dose titration using sufficiently high doses to obtain clinical efficacy without unacceptable adverse effects in individual patients. All patients should be treated for acute attacks and maintained on prophylactic treatment for 6 to 12 months following the initial episode. The occurrence of serious arrhythmias during attacks is associated with a greater risk of sudden death, and these patients should be treated more aggressively and for prolonged periods. Patients without arrhythmias who become asymptomatic and remain so for several months after treatment has been instituted, withdrawal of therapy may be safe after first ascertaining that disease activity is quiescent. Aggravating factors such as alcohol or cocaine use or cigarette smoking should be eliminated when instituting treatment.

Nitrates have been the mainstay of therapy for the acute attacks of variant angina and coronary artery spasm for many years. Most

patients respond rapidly to sublingual nitroglycerin or isosorbide dinitrate; however, intravenous and intracoronary nitroglycerin may be very useful for patients who do not respond to sublingual preparations. In particular, vasospasm provoked by ergonovine may require intracoronary nitroglycerin. Although studies with nitrates generally show them to be efficacious, high doses are often required and it is unclear if they reduce mortality. Because calcium antagonists may be more effective, have few serious adverse effects in effective doses, and can be given less frequently than nitrates, some consider them the agents of choice for variant angina.

Nifedipine, verapamil, and diltiazem are all equally effective as single agents for the initial management of variant angina and coronary artery spasm. Dose titration is important to maximize the response with calcium antagonists. Comparative trials are few in number and do not reveal significant differences among these three drugs for variant angina. Patients unresponsive to calcium antagonists alone, may have nitrates added. Combination therapy with nifedipine–diltiazem or nifedipine–verapamil is reported to be useful for patients who are unresponsive to single-drug regimens. Although this is probably rational as at the cellular level the drugs have different receptors, the combination of verapamil–diltiazem should be used cautiously owing to their potential additive effects on contractility and conduction.

β -Adrenergic blockade has little or no role in the management of variant angina according to most authorities.¹²² Although not all studies report increased painful episodes of variant angina with the addition of β -blockers, they may induce coronary vasoconstriction and prolong ischemia, as documented by continuous ECG monitoring. Other approaches to therapy attempting to modify sympathetic/parasympathetic tone include α -antagonists, anticholinergics, plexectomy, surgical interruption of the sympathetic innervation of the heart, thromboxane receptor antagonism, prostacyclin, lipoxigenase inhibition, and ticlopidine but these drugs or procedures do not occupy a major place in therapy at the present time.

TREATMENT

Silent Ischemia¹⁶

The objective in the treatment of silent myocardial ischemia is to reduce the total number of ischemic episodes, both symptomatic and asymptomatic, regardless of the direction of ST-segment shift. The incidence of silent ischemia in the general, asymptomatic population is unknown. Significant day-to-day variability in the number of episodes, the duration of ischemia, and the amount of ST-segment deviation complicates both the understanding of this process and the utility of various therapeutic interventions. Silent ischemia in patients with known CAD is common (~80% of all ischemic episodes) and associated with the extent of disease as well as a high risk for myocardial infarction and sudden death when compared with symptomatic episodes of ischemia. Although the underlying mechanisms for silent ischemia are continuing to be defined, increased physical activity, activation of the sympathetic nervous system, increased cortisol secretion, increased coronary artery tone, and enhanced platelet aggregation as a result of endothelial dysfunction leading to intermittent coronary obstruction may be additive in lowering the threshold for ischemia. Platelet aggregability is increased in the morning hours (7 AM to 11 AM), corresponding to circadian rhythms noted for the peak frequency of ischemia, acute myocardial infarction, and sudden death. Silent ischemia is associated with ST-segment elevation or depression and frequently occurs without antecedent changes in heart rate or blood pressure, suggesting that this form of ischemia is a result of primary reduction in oxygen supply. Silent ischemia is classified into class I, patients who

do not experience angina at any time, and class II, patients who have both asymptomatic and symptomatic ischemia. Patients with silent ischemia have a defective warning system for angina pain that may encourage excessive myocardial demand. Regardless of the exact mechanism, there is increasing concern that painless ischemia carries considerable risk for myocardial perfusion defects, detrimental hemodynamic changes, arrhythmogenesis, and sudden death. Silent ischemia is associated with reduced survival and increased need for PTCA and CABG, as well as increased risk of acute MI.¹²³ Because it is apparently very common in some settings, major emphasis should be placed on its management. Although a consensus has not been reached for the most appropriate method of detecting and quantifying the magnitude of silent ischemia, ambulatory electrocardiogram monitoring is thought by many to be the most useful tool at the present time.

The initial step in management is to modify the major risk factors for IHD, hypertension, hypercholesterolemia, and smoking, and data from the Multiple Risk Factor Intervention Trial (MRFIT) show these interventions to be useful in patients with silent ischemia. In a subset of the study population who had abnormal baseline exercise ECG responses, the special intervention group had a 57% reduction in coronary heart disease death (22.2/1,000 vs. 51.8/1,000) and a reduction in sudden death resulting from cessation of smoking and lowering of blood pressure and cholesterol when compared with the usual-care group.

ACIP, a randomized trial of medical therapy versus revascularization (PTCA or CABG), at the 2-year followup demonstrated that total mortality was 6.6% in the angina-guided strategy (i.e., therapy based on symptoms), 4.4% in the ischemia-guided strategy (based on ECG changes), and 1.1% in the revascularization strategy ($P < 0.02$). The rate of death or myocardial infarction was 12.1% in the angina-guided strategy, 8.8% in the ischemia-guided strategy, and 4.7% in the revascularization strategy ($P < 0.04$).¹²⁴ The rate of death, myocardial infarction, or recurrent cardiac hospitalization was 41.8% in the angina-guided strategy, 38.5% in the ischemia-guided strategy, and 23.1% in the revascularization strategy ($P < 0.001$). Post-MI patients and those with a high level of sympathetic nervous system activity are perhaps the best candidates for β -blocker therapy.

Calcium channel antagonists alone and in combination are effective in reducing symptomatic and asymptomatic ischemia; however, they do not interrupt the diurnal surge in ischemia observed on ambulatory monitoring and, in general, are somewhat less effective than β -blockers for silent ischemia.^{125,126} Nifedipine in particular seems to provide less protection and provides wide fluctuations in response, with approximate reductions in the number of episodes ranging from 0% to 93% and in duration from 23% to 65% unless combined with β -blockers. Fewer studies are available with other calcium blockers and comparative trials are uncommon. Earlier studies showed that combination therapy with calcium and β -blockers provides a better response than calcium blockers and nitrates or monotherapy.^{127,128}

Swiss Interventional Study on Silent Ischemia Type II (SWISSI II), a randomized, unblinded, controlled trial of PCI in patients with silent ischemia after acute MI, found that PCI, compared with antiischemic drug therapy, reduced the long-term risk of major cardiac events with better preservation of ventricular function than did medical therapy.¹²⁹

PHARMACOECONOMIC CONSIDERATIONS

Pharmacoeconomic studies have been performed primarily in patients with acute coronary syndromes and only with low-molecular-weight heparins, GP IIb/IIIa receptor antagonists, and statins.¹³⁰ Most of the studies on low-molecular-weight heparins have been cost-minimization analyses that focused on enoxaparin sodium,

because this is the only low-molecular-weight heparin proven to be superior to unfractionated heparin. Several analyses show that, compared with unfractionated heparin plus aspirin, enoxaparin sodium provides cost savings both during hospitalization (30 days) and at 1-year followup. These cost savings are mainly attributable to fewer cardiac interventions, shorter hospital stays, and lower administrative costs. Indeed, the clinical and economic advantages of enoxaparin sodium have led to its recommendation in recent guidelines as the antithrombotic agent of choice for coronary artery disease. Most of the economic analyses of GP IIb/IIIa inhibitors have been cost-effectiveness analyses.¹³¹ Such analyses indicate that the high acquisition costs of these drugs may be at least partially offset by reductions in other costs if a noninvasive approach to risk stratification is used. Furthermore, use of GP IIb/IIIa inhibitors appears to give favorable cost-effectiveness ratios compared with other accepted therapies, such as fibrin-specific thrombolytic therapy, in the cardiovascular field, particularly in high-risk patients and those undergoing percutaneous coronary intervention. However, more comprehensive economic data on the GP IIb/IIIa inhibitors are needed. Bivalirudin combined with provisional glycoprotein IIb/IIIa inhibitors appears to be an acceptable alternative to the standard of care and is superior to unfractionated heparin alone in PCI and is considered to be cost-effective.¹³²

Atorvastatin when used in acute coronary syndrome reduces events, which offsets the upfront acquisition costs.¹³¹ The total expected cost was \$1,573.83 per patient in the placebo cohort and \$1,709.39 per patient in the atorvastatin cohort, resulting in an incremental cost of \$135.56 per patient in the atorvastatin group. The cost per event avoided was \$3,536.95. A third of the cost of atorvastatin treatment was offset within 16 weeks by the cost savings resulting from the reduction in the number of events in the atorvastatin cohort compared with the placebo cohort. Other analyses of statins have found this class to be cost-effective, especially in patients who are at higher risk of an ischemic event.¹³³

Aspirin and clopidogrel have been evaluated for secondary prevention of CHD, and although aspirin is very cost-effective, clopidogrel is only cost-effective for patients who cannot take aspirin.¹³⁴

CLINICAL CONTROVERSIES

Once patients with angina develop symptoms sufficient for pharmacologic therapy on a daily basis, the initial prophylactic therapy recommended is a β -blocker. There is a paucity of comparative, long-term clinical trials of β -blockade versus calcium channel blockers to determine which is superior for survival benefit. β -Blockers are recommended first-line therapy because of their efficacy in post-MI patients and favorable adverse effect profile.

Recent developments in the understanding of bioactivation of organic nitrates have given rise to concern over endothelial dysfunction induced by nitrates when administered long-term. Not all nitrate products are activated via the same mechanisms and this may impact how effective individual drugs are in long-term treatment.

In stable CAD, medical management has been reported to produce outcomes similar to revascularization and these findings may have a significant impact on how healthcare resources are used in the future.

EVALUATION OF THERAPEUTIC OUTCOMES

Improved symptoms of angina, improved cardiac performance and improvement in risk factors may all be used to assess the outcome of treatment of IHD and angina. Symptomatic improvement in

exercise capacity (longer duration) or fewer symptoms at the same level of exercise is subjective evidence that therapy is working. Once patients have been optimized on medical therapy, symptoms should improve over 2 to 4 weeks and remain stable until their disease progresses. There are several instruments (e.g., Seattle angina questionnaire, specific activity scale [see Table 17–1], Canadian classification system [see Table 17–2]) that could be used to improve the reproducibility of symptom assessment.² If the patient is doing well, then no other assessment may be necessary. Objective assessment is

obtained through increase exercise duration on ETT and the absence of ischemic changes on ECG or deleterious hemodynamic changes. Echocardiography and cardiac imaging may also be used, however, due to their expense, they are only used if a patient is not doing well to determine if revascularization or other measures should be undertaken. Coronary angiography may be used to assess the extent of stenosis or re-stenosis after angioplasty or CABG. Table 17–12 outlines the performance measurement set recommended by the ACC/AHA.

TABLE 17-12 American College of Cardiology, American Heart Association, and Physician Consortium for Performance Improvement Chronic Stable Coronary Artery Disease Core Physician Performance Measurement Set^a

	Clinical Recommendations
Blood pressure measurement	A blood pressure reading is recommended at every visit. Recommended blood pressure management targets are ≤ 130 mm Hg systolic (<i>Class I Recommendation, Level A Evidence</i>) and ≤ 85 mm Hg diastolic in patient with CAD coexisting condition (e.g., diabetes, heart failure, or renal failure) and $< 140/90$ mm Hg in patient with CAD and no coexisting condition.
Lipid profile	A lipid profile is recommended and should include total cholesterol, high-density lipoprotein cholesterol (HDL-C), low-density lipoprotein cholesterol (LDL-C), and triglycerides. (<i>Class I Recommendation, Level C Evidence</i>)
Symptom and activity assessment	Regular assessment of patients' anginal symptoms and levels of activity is recommended. (Serves as a basis for treatment modification.)
Smoking cessation	Smoking status should be determined and smoking cessation counseling and interventions are recommended. (<i>Class I Recommendation, Level B Evidence</i>)
Antiplatelet therapy Denominator exclusion Documentation of medical reason(s) ^b for not prescribing antiplatelet therapy; documentation of patient reason(s) ^c for not prescribing antiplatelet therapy	Routine use of aspirin is recommended in the absence of contraindications. If contraindications exist, other antiplatelet therapies may be substituted. (<i>Class I Recommendation, Level A Evidence</i>)
Drug therapy for lowering LCL-cholesterol Denominator exclusion Documentation that a statin was not indicated; ^e documentation of medical reason(s) ^b for not prescribing a statin; documentation of patient reason(s) ^c for not prescribing statin	The LCL-C treatment goal is < 100 mg/dL. Persons with established coronary heart disease (CHD) who have a baseline LCL-C ≥ 130 mg/dL should be started on a cholesterol-lowering drug simultaneously with therapeutic lifestyle changes and control of nonlipid risk factors. (<i>Class I Recommendation, Level A Evidence</i>)
β-Blocker therapy—prior myocardial infarction (MI) Denominator inclusion Prior MI Denominator exclusion Documentation that a β -blocker was not indicated; documentation of medical reason(s) ^b for not prescribing a β -blocker; documentation of patient reason(s) ^c for not prescribing a β -blocker	β -Blocker therapy is recommended for all patients with prior MI in the absence of contraindications. (<i>Class I Recommendation, Level A Evidence</i>)
ACE inhibitor therapy Denominator inclusion Patient with CAD who also has diabetes and/or left ventricular systolic dysfunction (LVSD) (left ventricular ejection fraction [LVEF] $< 40\%$ or moderately or severely depressed left ventricular systolic function) Denominator exclusion Documentation that ACE inhibitor was not indicated (e.g., patients on angiotensin receptor blockers [ARB]); documentation of medical reason(s) ^b for not prescribing ACE inhibitor; documentation of patient reason(s) ^c for not prescribing ACE inhibitor	ACE inhibitor use is recommended in all patients with CAD who also have diabetes and/or LVSD (<i>Class I Recommendation, Level A Evidence</i>) ACE inhibitor use is also recommended in patients with CAD or other vascular disease (<i>Class IIa Recommendation, Level B Evidence</i>)
Screening for diabetes^f Denominator exclusion Patients with documented diabetes	Screening for diabetes is recommended in patients who are considered high risk (e.g., CAD) (<i>Class I Recommendation, Level A Evidence</i>)

ACE, angiotensin-converting enzyme; CAD, coronary artery disease; MI, myocardial infarction.

^aRefers to all patients diagnosed with CAD

^bMedical reasons for not prescribing **antiplatelet therapy** (aspirin, clopidogrel, or combination of aspirin and dipyridamole): active bleeding in the previous 6 months with required hospitalization and/or transfusion(s), patient on other antiplatelet therapy, etc.

Medical reasons for not prescribing a **statin**: clinical judgement, documented LCL-C < 130 mg/dL, etc.

Medical reasons for not prescribing a **β -blocker**: bradycardia (defined as heart rate < 50 beats/min without β -blocker therapy), history of class IV (congestive) heart failure, history of second- or third-degree atrioventricular block without permanent pacemaker, etc.

Medical reasons for not prescribing **ACE inhibitor (ACEI)**: allergy, angioedema caused by ACEI, anuric renal failure caused by ACEI, pregnancy, moderate or severe aortic stenosis, etc.

^cPatient reasons for not prescribing antiplatelet therapy, statin, β -blocker, or ACEI: economic, social, and/or religious, etc.

^dAntiplatelet therapy may include aspirin, clopidogrel, or combination of aspirin and dipyridamole.

^eNot indicated for a stat refers to LCL-C < 100 mg/dL.

^fTest measure.

^gScreening for diabetes is usually done by fasting blood glucose or 2-hour glucose tolerance testing. Clinical recommendations indicate screening should be considered at 3-year intervals.

SARAH A. SPINLER AND SIMON DE DENUS

KEY CONCEPTS

- 1 The cause of an acute coronary syndrome (ACS) is erosion or rupture of an atherosclerotic plaque with subsequent platelet adherence, activation, aggregation, and activation of the clotting cascade. Ultimately, a clot composed of fibrin and platelets forms.
- 2 The American Heart Association and the American College of Cardiology recommend strategies or guidelines for the care of patients with ST-segment elevation and non-ST-segment elevation ACS.
- 3 Patients with ischemic chest discomfort and suspected ACS are risk stratified based on a 12-lead electrocardiogram, medical history, signs and symptoms, and results of creatine kinase myocardial band (CK MB) and troponin biochemical marker tests.
- 4 The diagnosis of myocardial infarction is confirmed based on the results of the CK MB and troponin tests.
- 5 Early reperfusion therapy with either primary percutaneous coronary intervention or administration of a fibrinolytic agent is the recommended therapy for patients presenting with ST-segment elevation ACS.
- 6 In addition to reperfusion therapy, all patients with ST-segment elevation ACS and without contraindications should receive pharmacotherapy within the first day of hospitalization and preferably in the emergency department, consisting of intranasal oxygen (if oxygen saturation is low), aspirin, clopidogrel, sublingual nitroglycerin, oral β -blockers, and either unfractionated heparin or enoxaparin. Intravenous β -blockers and nitroglycerin should be given to selected patients.
- 7 High-risk patients with non-ST-segment elevation ACS should undergo early coronary angiography and revascularization with either percutaneous coronary intervention or coronary artery bypass graft surgery.
- 8 In the absence of contraindications, all patients with non-ST-segment elevation ACS should be treated in the emergency department with intranasal oxygen (if oxygen saturation is low), aspirin, sublingual nitroglycerin, oral β -blockers, and an anticoagulant (unfractionated heparin, enoxaparin, fondaparinux, or bivalirudin). Most patients should receive additional therapy with clopidogrel. High-risk patients also should receive a glyco-

protein IIb/IIIa receptor blocker. Intravenous β -blockers and nitroglycerin should be given to selected patients.

- 9 Following myocardial infarction, all patients, in the absence of contraindications, should receive indefinite therapy with aspirin, a β -blocker, and an angiotensin-converting enzyme inhibitor for secondary prevention of death, stroke, and recurrent infarction. Most patients are given a statin to reduce the low-density-lipoprotein cholesterol level to less than 70 to 100 mg/dL. Administration of clopidogrel should be considered for most patients, but the level of the recommendation and duration of therapy depend on the diagnosis, the method of reperfusion used, and the risk of bleeding. Anticoagulation with warfarin should be considered for patients at high risk for death, reinfarction, or stroke.

Since the early 1900s, cardiovascular disease (CVD) has been the leading cause of death in the United States. Acute coronary syndromes (ACSs), including unstable angina and myocardial infarction (MI), are forms of coronary heart disease (CHD) that constitute the most common cause of CVD death.¹ 1 The cause of an ACS is erosion or rupture of an atherosclerotic plaque with subsequent platelet adherence, activation, aggregation, and activation of the clotting cascade. Ultimately, a clot composed of fibrin and platelets forms. Correspondingly, pharmacotherapy of ACS has advanced to include combinations of fibrinolytics, antiplatelets, and anticoagulants, with more traditional therapies such as nitrates and β -adrenergic blockers. Pharmacotherapy is integrated with reperfusion therapy and revascularization of the culprit coronary artery through interventional means such as percutaneous coronary intervention (PCI) and coronary artery bypass graft (CABG) surgery. 2 The American Heart Association (AHA) and the American College of Cardiology (ACC) recommend strategies or guidelines for the care of patients with ST-segment elevation (STE) and non-ST-segment elevation (NSTEMI) ACS. These joint practice guidelines are based on a review of available clinical evidence, have graded recommendations based on the weight and quality of evidence, and are updated periodically. The guidelines form the cornerstone for quality patient care of the ACS patient.^{2,3}

EPIDEMIOLOGY

Each year more than 1.5 million Americans will experience an ACS, and 220,000 will die of an MI.¹ In the United States, more than 7.6 million living persons have survived an MI.¹ Chest discomfort is the second most frequent reason for patient presentation to emergency departments. Up to 5.6 million (~5.1%) emergency department visits are linked to chest discomfort and possible ACS.^{2,4} CHD is the leading cause of premature chronic disability in the United States. The cost of CHD is high, with direct and indirect costs estimated at \$151.6 billion for 2007.¹ The median length of hospital stay for MI in 1999 was 4.3 days¹ but decreased to a median of 3.3 days in 2006.⁵

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

Much of the epidemiologic data regarding ACS treatment and survival come from the National Registry of Myocardial Infarction (NORMI), the Global Registry of Acute Coronary Events (GRACE), and statistical summaries of U.S. hospital discharges prepared by the AHA. In-hospital death rates are approximately 4.6% for patients with STE ACS but are lower (2.2%) for patients with NSTEMI ACS.⁶ Patients with STEMI who are treated with reperfusion therapy, either fibrinolytics or primary PCI, have lower mortality rates than patients treated without reperfusion. Reperfusion rates and mortality rates are higher in the elderly and in women. For example, the mortality rate is 19% in elderly patients who were eligible for reperfusion therapy but did not receive it compared to 10.5% in patients who did.⁷ In women, the mortality rate is 18% for those eligible for reperfusion therapy but did not receive it compared to 9.3% for those who do not.⁷ In the first year after MI, 23% of women and 18% of men will die, most from recurrent infarction.¹ At 1 year, rates of mortality and reinfarction between STE and NSTEMI are similar.

The rate of developing heart failure during hospitalization for ACS is declining rapidly. Compared to data from 1999, the incidence of in-hospital heart failure in patients with STEMI declined from 19.5% to 11% and that for patients with NSTEMI ACS declined from 13% to 6.1%.⁶ In-hospital death rates for patients who present with or develop heart failure are more than threefold higher than for those who do not.⁶

Because reinfarction and death are major outcomes following ACS, therapeutic strategies to reduce morbidity and mortality, particularly use of coronary angiography, revascularization, and pharmacotherapy, will have a significant impact on the social and economic burden of CHD in the United States.

ETIOLOGY

This section discusses the formation of atherosclerotic plaques, the underlying cause of coronary artery disease (CAD), and ACS in most patients. The process of atherosclerosis starts early in life. Although atherosclerosis once was considered only a disease of cholesterol excess, it now is clear that inflammation also plays a central role in the genesis, progression, and complication of the disease.⁸ In the earliest stage of atherosclerosis—endothelial dysfunction—induction and/or repression of several genes occurs in response to sheer stress of the blood flowing over the atherosclerotic plaque on the endothelial lining of the artery. In response to gene induction and repression, the endothelial cells decrease synthesis of nitric oxide, increase oxidation of lipoproteins and facilitate their entry into the arterial wall, promote the adherence of monocytes to the vessel wall and deposition of extracellular matrix, cause smooth muscle cell proliferation, and release local vasoconstrictor and prothrombotic substances into the blood; each action has a subsequent inflammatory response.⁹ Taken together, all these factors contribute to the evolution of endothelial dysfunction to the formation of fatty streaks in the coronary arteries and eventually to atherosclerotic plaques. Therefore, the endothelium serves as an important autocrine and paracrine organ in the development of atherosclerosis.

A number of factors are directly responsible for the development and progression of endothelial dysfunction and atherosclerosis, including hypertension, age, male gender, tobacco use, diabetes mellitus, obesity, and dyslipidemias.¹

PATHOPHYSIOLOGY

SPECTRUM OF ACS

Acute coronary syndromes (ACSs) is a term that includes all clinical syndromes compatible with acute myocardial ischemia resulting from

an imbalance between myocardial oxygen demand and supply.³ In contrast to stable angina, an ACS results primarily from diminished myocardial blood flow secondary to an occlusive or partially occlusive coronary artery thrombus. ACSs are classified according to electrocardiographic (ECG) changes into STE ACS, also called STEMI, and NSTEMI ACS, which includes NSTEMI MI and unstable angina (Fig. 18–1).¹⁰ Approximately 21% of patients presenting with ACS have STEMI.¹ NSTEMI MI differs from unstable angina in that ischemia is severe enough to produce myocardial necrosis, resulting in the release of a detectable amount of biochemical markers, mainly troponin I or T, and creatine kinase myocardial band (CK MB) from the necrotic myocytes into the bloodstream.³ The clinical significance of serum biochemical markers is discussed in greater detail in the Clinical Presentation and Biochemical Markers sections of this chapter. Following an STEMI, pathologic Q waves are seen frequently on the ECG; such an ECG manifestation is seen less commonly in patients with NSTEMI MI.⁷ The presence of Q waves usually indicates transmural MI. Non-Q-wave MI, which is predominantly seen in NSTEMI MI, is limited to the subendocardial myocardium.²

PLAQUE RUPTURE AND CLOT FORMATION

1 The predominant cause of ACS in more than 90% of patients is atheromatous plaque rupture, fissuring, or erosion of an unstable atherosclerotic plaque. Plaques that encompass less than 50% of the coronary lumen are more likely to rupture than those that occlude 70% to 90% of the coronary artery.³ Such stable 70% to 90% stenoses of the coronary artery are characteristic of stable angina and tend to have a small lipid core, a thick fibrous cap, more calcification, and less compensatory enlargement.⁸ Plaques that are more susceptible to rupture are characterized by an eccentric shape, thin fibrous cap (particularly in the shoulder region of the plaque), large fatty core, high content in inflammatory cells such as macrophages and lymphocytes, limited amounts of smooth muscle, and significant compensatory enlargement. Compensatory enlargement is the growth of the lesion pushing the vessel outward rather than inward plaque growth. Therefore, compensatory enlargement may result in underestimation of the atherosclerotic stenosis as measured by coronary angiography. Inflammatory cells promote thinning of the fibrous cap through the release of proteolytic enzymes, particularly matrix metalloproteinases.⁸

Following plaque rupture, a partially occlusive or completely occlusive thrombus—a clot—forms on top of the ruptured plaque. The thrombogenic contents of the plaque are exposed to blood elements. Exposure of collagen and tissue factor induces platelet adhesion and activation, which promote the release of platelet-derived vasoactive substances, including adenosine diphosphate (ADP) and thromboxane A₂.¹¹ These substances produce vasoconstriction and potentiate platelet activation. Furthermore, during platelet activation, the conformation of the glycoprotein (GP) IIb/IIIa surface receptors of platelets changes such that platelets cross-link to each other via fibrinogen bridges. This process is considered the final common pathway of platelet aggregation. Other substances known to promote platelet aggregation include serotonin, thrombin, and epinephrine.⁸ Inclusion of platelets gives the clot a white appearance. Simultaneously, the extrinsic coagulation cascade pathway is activated as a result of exposure of blood components to the thrombogenic lipid core and endothelium, which are rich in tissue factor. This leads to the production of thrombin (factor IIa), which converts fibrinogen to fibrin through enzymatic activity.¹¹ Fibrin stabilizes the clot and traps red blood cells, giving the clot a red appearance. Therefore, the clot is composed of both cross-linked platelets and fibrin strands.¹¹ Although patients with an ACS more commonly present with a single, ruptured atherosclerotic plaque in one major coronary artery, they also may present with more than one ruptured plaque and multiple active lesions in more than one coronary artery, which predispose patients to a worse prognosis.⁸

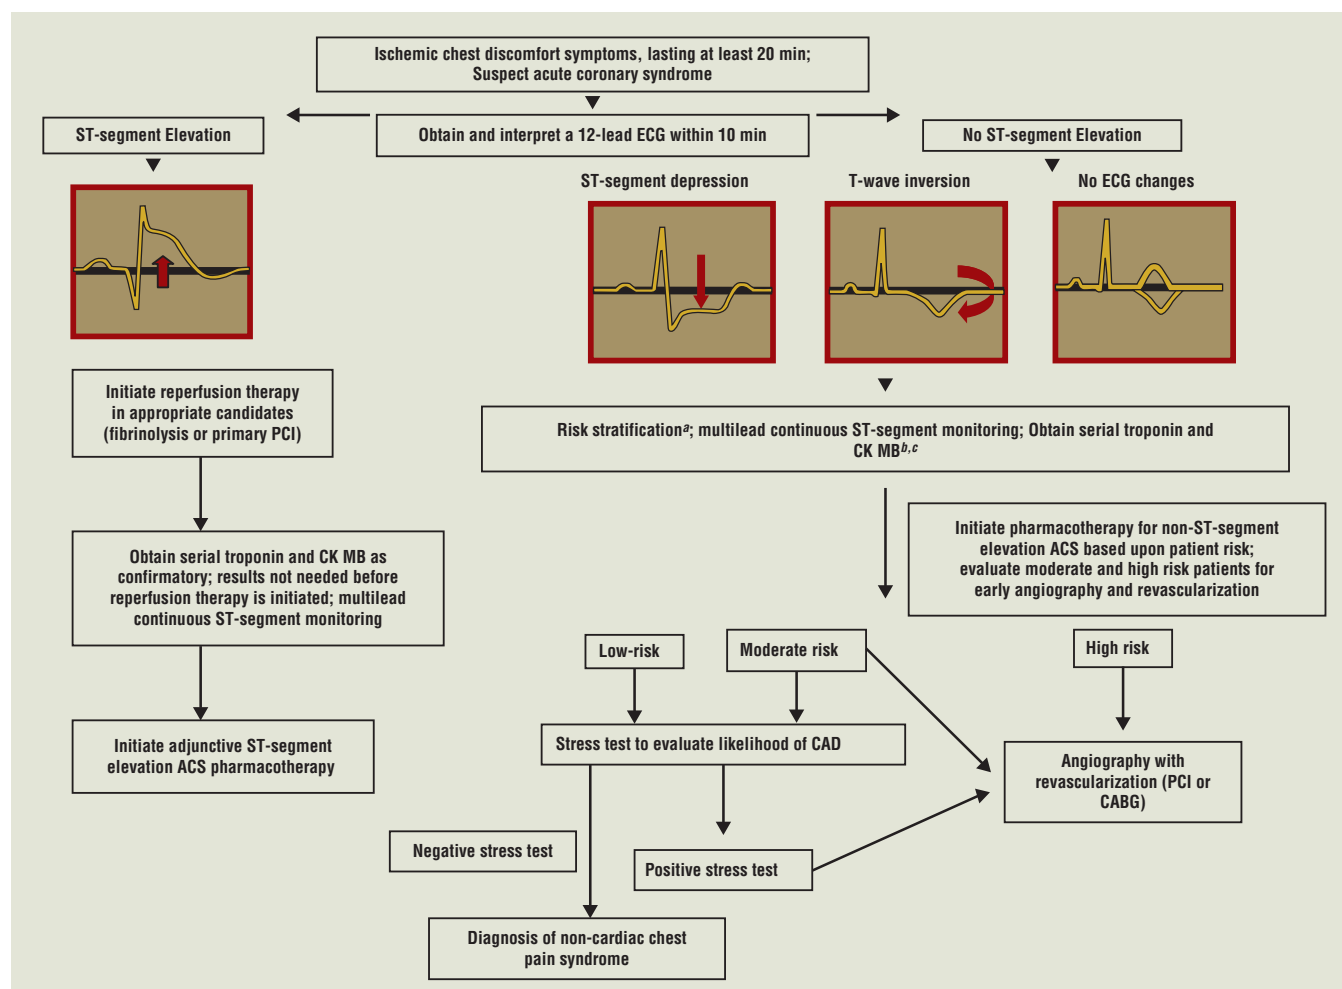

FIGURE 18-1. Evaluation of the acute coronary syndrome patient. (ACS, acute coronary syndrome; CABG, coronary artery bypass graft surgery; CAD, coronary artery disease; CK MB, creatine kinase myocardial band; ECG, electrocardiogram; PCI, percutaneous coronary intervention.) ^aAs described in Table 18–2. ^bPositive, above the myocardial infarction (MI) decision limit. ^cNegative, below the MI decision limit. (Reprinted with permission from the American College of Clinical Pharmacy. Spinler SA. Acute coronary syndromes. In: Dunsworth TS, Richardson MM, Cheng JWM, et al., eds. *Pharmacotherapy Self-Assessment Program*, 6th ed. Cardiology II module. Kansas City: American College of Clinical Pharmacy, 2007:69–70.)

A thrombus containing more platelets than fibrin, or a “white” clot, generally produces an incomplete occlusion of the coronary lumen and is more common in NSTEMI ACS. In patients presenting with STE ACS, the vessel generally is completely occluded by a “red” clot, which contains larger amounts of fibrin and red blood cells but a smaller amount of platelets compared with a “white” clot.² As discussed later in Treatment of Acute Coronary Syndromes, the composition of the clot influences the selection of the combinations of antithrombotic agents used for treatment of STE and NSTEMI ACS. Finally, myocardial ischemia can result from downstream embolization of microthrombi and produce ischemia with eventual necrosis.²

VENTRICULAR REMODELING FOLLOWING AN ACUTE MI

Ventricular remodeling is a process that occurs in several cardiovascular conditions, including heart failure, and following an MI. It is characterized by changes in the size, shape, and function of the left ventricle (LV) of both the infarcted area and the remaining ventricle, ultimately leading to cardiac failure.¹² Because heart failure is one of the principal causes of mortality and morbidity following an MI, preventing ventricular remodeling is an important therapeutic goal.¹²

Many factors contribute to ventricular remodeling, including neurohormonal factors (e.g., activation of the renin-angiotensin-aldosterone and sympathetic nervous systems), hemodynamic factors, mechanical factors, changes in gene expression, and modifications in myocardial

matrix metalloproteinase activity and their inhibitors.^{13,14} This process affects both cardiomyocytes (cardiomyocyte hypertrophy, loss of cardiomyocytes) and the extracellular matrix (increased interstitial fibrosis), thereby promoting both systolic and diastolic dysfunction.¹⁴

Angiotensin-converting enzyme (ACE) inhibitors, β -blockers, and aldosterone antagonists are agents that slow down or reverse ventricular remodeling through neurohormonal blockage and/or through improvement in hemodynamics (decreasing preload or afterload).¹² These agents also improve survival (discussed in more detail in the Secondary Prevention Following MI section of this chapter). This effect underlines the importance of the remodeling process and the urgency of preventing, halting, or reversing the process in patients who have experienced an MI.

COMPLICATIONS

This chapter focuses on management of the uncomplicated ACS patient. However, it is important for clinicians to recognize complications of MI because they are associated with increased mortality. The most serious complication is cardiogenic shock, which occurs in approximately 5% to 6% of patients presenting with STEMI and in less than 2% of those presenting with NSTEMI ACS.^{9,15} Mortality in cardiogenic shock patients with MI is high, approaching 60%.¹⁶ Other complications that may result from MI are heart failure, valvular dysfunction, ventricular and atrial tachyarrhythmias, bradycardia, heart block, pericarditis, stroke secondary to LV thrombus embolization, venous thromboembolism, and LV free-wall rupture.¹⁷ More

than 25% of MI patients die, presumably of ventricular fibrillation, prior to reaching the hospital.¹⁸

CLINICAL PRESENTATION

The key points in the clinical presentation of patients with ACS are given in Table 18–1.

SYMPTOMS AND PHYSICAL EXAMINATION FINDINGS

The classic symptom of an ACS is midline anterior anginal chest discomfort, most often at rest, severe new-onset angina, or increasing angina at least 20 minutes in duration. The chest discomfort may radiate to the shoulder, down the left arm, to the back, or to the jaw. Associated symptoms that may accompany chest discomfort include nausea, vomiting, diaphoresis, and shortness of breath. Typically, patients with STE ACS present with unremitting chest discomfort. Patients with NSTEMI ACS may present with (1) rest angina, (2) new-onset (<2 months) angina, or (3) angina that increases in frequency, duration, or intensity. All healthcare professionals should review these warning symptoms with patients at high risk for CHD. On physical examination, no specific features are indicative of ACS.

TWELVE-LEAD ECG

3 Key features of a 12-lead ECG identify and risk stratify patients with an ACS. Within 10 minutes of a patient presenting to an emergency

department with symptoms of ischemic chest discomfort (or preferably prehospital), a 12-lead ECG should be obtained and interpreted. If available, a previously recorded 12-lead ECG should be reviewed to identify whether the findings on the current ECG are new or old, with new findings more indicative of an ACS. Key findings on review of a 12-lead ECG indicating myocardial ischemia or MI are ST-segment elevation, ST-segment depression, and T-wave inversion (see Fig. 18–1). ST-segment and/or T-wave changes in contiguous leads help to identify the location of the coronary artery that is the cause of the ischemia or infarction. In addition, the appearance of a new left bundle-branch block accompanied by chest discomfort is highly specific for acute MI. Approximately 65% of patients diagnosed with MI present with STE on ECG; the remainder have ST-segment depression, T-wave inversion, or, in some instances, no ECG changes.⁵ Some parts of the heart are more “electrically silent” than others, and myocardial ischemia may not be detected on surface ECG. Therefore, it is important to review findings from the ECG in conjunction with biochemical markers of myocardial necrosis, such as troponin I or T levels, and other risk factors for CHD to determine the patient’s risk for experiencing a new MI or having other complications.

BIOCHEMICAL MARKERS

4 Biochemical markers of myocardial cell death are important for confirming the diagnosis of MI. The ACC defines *evolving MI* as “typical rise and gradual fall (troponin) or more rapid rise and fall (CK MB) of biochemical markers of myocardial necrosis.”¹⁹ Troponin and CK MB levels rise in the blood following the onset of complete coronary artery occlusion subsequent to myocardial cell death. Their time course is depicted in Fig. 18–2. Typically, blood is obtained from the patient at least three times, once in the emergency department and twice more over the next 12 to 24 hours, in order to measure troponin and CK MB levels. A single measurement of a biochemical marker is not adequate to exclude a diagnosis of MI because up to 15% of values that initially were below the level of detection (a negative test) are above the level of detection (a positive test) in the subsequent hours. An MI is identified if at least one troponin value is greater than the MI decision limit (set by the hospital laboratory) or two CK MB results are greater than the MI decision limit (set by the hospital laboratory). These are termed *positive* biochemical markers for MI. Although troponins and CK MB appear in the blood within 6 hours of infarction, troponins stay elevated in the blood for up to 10 days, whereas CK MB returns to normal values within 48 hours. Therefore, if a patient is admitted with elevated troponin and CK MB concentrations and several days later experiences recurrent chest discomfort, the troponin will be less sensitive for detecting new myocardial damage because the level still is elevated from the earlier event. If early reinfarction is suspected, CK MB concentration determination is the preferred diagnostic test.¹⁹ Biochemical markers, such as troponin measurements, that are below the detectable limit of hospital laboratories are termed *negative*, and the diagnosis of MI is excluded.

RISK STRATIFICATION

Patient signs and symptoms, medical history, ECG, and troponin or CK MB determinations are used to stratify patients as having low, medium, or high risk of death or MI or likelihood of not responding to pharmacotherapy and requiring urgent coronary angiography and PCI. Initial treatment according to risk stratification is depicted in Fig. 18–1. Patients with STE ACS are at the highest risk of death. Initial treatment of STE ACS should proceed without evaluation of troponin or CK MB levels because these patients have a greater than 97% chance of having an MI subsequently diagnosed with biochemical markers. The ACC/AHA defines a target time to initiate reperfu-

TABLE 18-1 Presentation of Acute Coronary Syndromes	
General	
• The patient typically is in acute distress and may develop or present with cardiogenic shock.	
Symptoms	
• The classic symptom of ACS is midline anterior chest discomfort. Accompanying symptoms may include arm, back or jaw pain, nausea, vomiting, or shortness of breath.	
• Patients less likely to present with classic symptoms include elderly patients, diabetic patients, and women.	
Signs	
• No signs are classic for ACS.	
• However, patients with ACS may present with signs of acute heart failure, including jugular venous distention, rales, and S ₃ sound on auscultation.	
• Patients may present with arrhythmias and therefore may have tachycardia, bradycardia, or heart block.	
Laboratory tests	
• Troponin I or T and creatine kinase MB are measured.	
• Blood chemistry tests are performed with particular attention to potassium and magnesium, which may affect heart rhythm, and glucose, which when elevated places the patient at higher risk for morbidity and mortality.	
• Serum creatinine level is measured to identify patients who may need dosing adjustments for some pharmacotherapy and patients who are at high risk for morbidity and mortality.	
• Baseline complete blood count and coagulation tests (activated partial thromboplastin time and international normalized ratio) should be obtained because most patients will receive antithrombotic therapy, which increases the risk for bleeding.	
• Fasting lipid panel is obtained.	
Other diagnostic tests	
• The 12-lead electrocardiogram is the first step in management. Patients are risk stratified into two groups: ST-segment elevation ACS and suspected non-ST-segment elevation ACS.	
• During hospitalization, measurement of left ventricular function, such as an echocardiogram, is performed to identify patients with low ejection fractions (<40%) who are at high risk for death following hospital discharge.	
• Selected low-risk patients may undergo early stress testing.	

ACS, acute coronary syndrome.

FIGURE 18-2. Biochemical markers in suspected acute coronary syndrome. (AMI, acute myocardial infarction; CK MB, creatine kinase myocardial band; MI, myocardial infarction.)

sion treatment for STEMI within 30 minutes of hospital presentation for fibrinolytics and within no more than 90 minutes from presentation for primary PCI.³ The sooner the infarct-related coronary artery is opened in these patients, the lower is their mortality and the greater is the amount of preserved myocardium.^{20,21} While all patients should be evaluated for reperfusion therapy, not all patients may be eligible. Indications and contraindications for fibrinolytic therapy as well as eligibility criteria for primary PCI are described in the treatment section of this chapter. In the United States in 2006, approximately 83% of *eligible* patients presenting to the hospital with STEMI underwent reperfusion therapy; 62% of the patients were treated with primary PCI, 17% fibrinolysis alone, 1% fibrinolysis followed by immediate PCI, and 2% immediate CABG surgery.⁵ However, more than 40% of patients with STEMI present too late for reperfusion therapy (>12 hours since onset of symptoms).^{22,23} In addition, fewer than 25% of hospitals in the United States are equipped to perform primary PCI,²⁴ and approximately 5% to 6% of patients present with at least one contraindication to fibrinolysis.^{23,25} Unfortunately, 17% of patients *eligible* for reperfusion therapy consisting of either fibrinolysis or primary PCI do not receive it, suggesting a need for more thorough patient evaluation and treatment triage.⁵

If patients are not eligible for reperfusion therapy, additional pharmacotherapy for STE patients should be initiated in the emergency department, and patients should be transferred to the coronary intensive care unit.

Risk stratification of the patient with NSTEMI ACS is more complex because in-hospital outcomes for this group of patients vary, with reported rates of death of 0% to 12%, reinfarction 0% to 3%, and recurrent severe ischemia 5% to 20%.²⁶ Not all patients who present with suspected NSTEMI ACS have CAD. Some eventually are diagnosed with nonischemic chest discomfort. Additional information regarding risk stratification of NSTEMI ACS is presented in the General Approach to Treatment section.

Newer markers that identify patients at high risk of mortality or reinfarction that are under development but have not yet been

incorporated into routine patient care include C-reactive protein,²⁷ a maker of vascular inflammation; elevated serum creatinine or reduced creatinine clearance,²⁸ and brain (B-type) natriuretic peptide (BNP),²⁹ which is released predominately from ventricular myocytes in response to cell stretch as the infarct remodels. Dialysis patients have a 1-year mortality rate of greater than 40% following a first MI.²⁸

TREATMENT

Acute Coronary Syndromes

■ DESIRED OUTCOMES

The short-term goals of treatment for the ACS patient are as follows:

1. Early restoration of blood flow to the infarct-related artery to prevent infarct expansion (in the case of MI) or prevent complete occlusion and MI (in unstable angina)
2. Prevention of death and other complications
3. Prevention of coronary artery reocclusion
4. Relief of ischemic chest discomfort
5. Maintenance of normoglycemia

■ GENERAL APPROACH TO TREATMENT

Selecting evidence-based therapies described in the ACC/AHA guidelines for patients without contraindications results in lower mortality.^{30,31} General treatment measures for all STE ACSs and high- and intermediate-risk NSTEMI ACS patients include admission to hospital, oxygen administration (if oxygen saturation is low, i.e., <90%), continuous multilead ST-segment monitoring for arrhythmias and ischemia, glycemic control, frequent measurement of vital signs, bedrest for 12 hours in hemodynamically stable patients, avoidance of Valsalva maneuver (prescribe stool softeners routinely), and pain relief.

TABLE 18-2 TIMI Risk Score for Non–ST-Segment Elevation Acute Coronary Syndromes

Past Medical History	Clinical Presentation
Age ≥65 years	ST-segment depression (≥0.5 mm)
≥3 Risk factors for CAD	≥2 episodes of chest discomfort within the past 24 hours
Hypercholesterolemia	Positive biochemical marker for infarction ^a
HTN	
TM	
Smoking	
Family history of premature CHD ^b	
Known CAD (≥50% stenosis of coronary artery)	
Use of aspirin within the past 7 days	

Using the TIMI Risk Score		
One point is assigned for each of the seven medical history and clinical presentation findings. The score (point) total is calculated, and the patient is assigned a risk for experiencing the composite end point of death, myocardial infarction or urgent need for revascularization as follows:		
High Risk	Medium Risk	Low Risk
TIMI risk score 5–7 points	TIMI risk score 3–4 points	TIMI risk score 0–2 points

Other Ways to Identify High-Risk Patients
Other findings that alone, or in combination, may identify high-risk patients:
<ul style="list-style-type: none">• ST-segment depression• Positive biochemical marker for infarction• Deep symmetric T-wave inversions (≥2 mm)• Acute heart failure• DM• Chronic kidney disease• Refractory chest discomfort despite maximal pharmacotherapy for ACS• Recent MI within the past 2 weeks

ACS, acute coronary syndromes; CAD, coronary artery disease; CHD, coronary heart disease; DM, diabetes mellitus; HTN, hypertension; MI, myocardial infarction; TIMI, Thrombolysis in Myocardial Infarction

^aA positive biochemical marker for infarction is a value of troponin I, troponin T, or creatinine kinase MB greater than the MI detection limit.

^bAs defined in Chapter 23.

From Anderson et al.² and Eagle et al.³¹

Because risk varies and resources are limited, triage and treatment of patients according to their risk category are important. Initial approaches to treatment of STE and NSTEMI ACS patients are outlined in Fig. 18–1.^{2,3,10} Patients with STE ACS are at high risk of death, and efforts to reestablish coronary perfusion should be initiated immediately. Reperfusion therapy should be considered immediately and adjunctive pharmacotherapy initiated.³

Features identifying low-, moderate-, and high-risk NSTEMI ACS patients are listed in Table 18–2.^{2,30} Patients at low risk for death, MI, or the need for urgent coronary artery revascularization typically are evaluated in the emergency department, where serial biochemical marker tests are obtained. If these test results are negative, the patient may be admitted to a general medical floor with ECG telemetry monitoring for ischemic changes and arrhythmias, undergo a noninvasive stress test, or be discharged from the emergency department. Moderate- and high-risk patients are admitted to a coronary intensive care unit, an intensive care step-down unit, or a general medical floor in the hospital depending on the patient’s symptoms and perceived level of risk. High-risk patients should undergo early coronary angiography (within 24–48 hours) and revascularization (with PCI or CABG) if a significant coronary artery stenosis is found² (see Fig. 18–1 and Table 18–2). Moderate-risk patients with positive biochemical markers for infarction typically also undergo angiography and revascularization during hospital admission. Moderate-risk patients with negative biochemical markers for infarction also may undergo angiography and revascularization or first undergo a noninvasive stress test; only selected patients with a positive stress test proceed to angiography. Following risk stratification, pharmacotherapy for NSTEMI ACS is initiated.

■ NONPHARMACOLOGIC THERAPY

Primary PCI for STE ACS

5 Either fibrinolysis or immediate primary PCI is the treatment of choice for reestablishing coronary artery blood flow in patients with

STE ACS when the patient presents within 3 hours of symptom onset and both options are available at the institution. For primary PCI, the patient is taken from the emergency department to the cardiac catheterization laboratory and undergoes coronary angiography with either balloon angioplasty or placement of a bare-metal or drug-eluting intracoronary stent. Additional details regarding angioplasty and intracoronary stenting are provided in Chapter 17. Results from a meta-analysis of trials comparing fibrinolysis with primary PCI indicate a lower mortality rate with primary PCI.²⁰ One reason for the superiority of primary PCI compared with fibrinolysis is that more than 90% of occluded infarct-related coronary arteries are opened with primary PCI compared with less than 60% of coronary arteries with currently available fibrinolytics.^{3,32} In addition, the intracranial hemorrhage (ICH) and major bleeding risks from primary PCI are lower than following fibrinolysis. An invasive strategy of primary PCI is generally preferred for patients presenting to institutions where skilled interventional cardiologists and a catheterization laboratory are immediately available, patients with cardiogenic shock, patients with contraindications to fibrinolytics, and patients presenting with symptom onset greater than 3 hours.³ A quality performance measure in the care of patients with STEMI is the time from hospital presentation to the time that the occluded artery is opened with PCI. This “door-to-primary PCI time” should be 90 minutes or less (Table 18–3).^{3,10,33} In 2006, the median time to primary PCI in the United States was 86 minutes, and only 55% of patients met the performance measure target of 90 minutes or less, suggesting that slightly less than half of the primary PCIs occur more than 90 minutes after hospital presentation.⁵ Unfortunately, most hospitals do not have interventional cardiology services capable of performing primary PCI 24 hours per day.

PCI during hospitalization for STEMI also may be appropriate for other patients following STEMI, such as those in whom fibrinolysis is not successful (termed *rescue* PCI), those presenting later in cardiogenic shock, patients with life-threatening ventricular arrhythmias, and those with persistent rest ischemia or signs of ischemia on stress

TABLE 18-3 2006 American College of Cardiology/American Heart Association ST-Segment Elevation and Non-ST-Segment Elevation Myocardial Infarction Performance Measures

Performance Measure	Description
1. Aspirin upon arrival	STEMI and NSTEMI MI patients without aspirin contraindications who received aspirin within 24 hours before or after hospital arrival
2. Aspirin prescribed at hospital discharge	STEMI and NSTEMI MI patients without aspirin contraindications who are prescribed aspirin at hospital discharge
3. β -Blocker upon hospital arrival	β -Blocker STEMI and NSTEMI MI patients without β -blocker contraindications who received a β -blocker within 24 hours after hospital arrival
4. β -Blocker prescribed at hospital discharge	STEMI and NSTEMI MI patients without β -blocker contraindications who are prescribed a β -blocker at hospital discharge
5. LDL cholesterol assessment	STEMI and NSTEMI MI patients with documentation of LDL cholesterol level in the hospital record or documentation that LDL cholesterol testing was done during the hospital stay or is planned for after hospital discharge
6. Lipid-lowering therapy at hospital discharge	STEMI and NSTEMI MI patients with elevated LDL cholesterol (≥ 100 mg/dL or narrative equivalent ^a) who are prescribed lipid-lowering medicine at hospital discharge
7. ACE inhibitor or ARB for LVSD at discharge	STEMI and NSTEMI MI patients with LVSD and without ACE inhibitor and ARB contraindications who are prescribed an ACE inhibitor or ARB at hospital discharge
8. Time to fibrinolytic therapy	Median time from arrival to administration of fibrinolytic therapy in patients with STE or LBBB on the ECG performed closest to hospital arrival time STEMI or LBBB patients receiving fibrinolytic therapy during the hospital stay and having a time from hospital arrival to fibrinolysis of 30 minutes or less
9. Time to PCI	Median time from arrival to PCI in patients with STE or LBBB on the ECG performed closest to hospital arrival time STEMI or LBBB patients receiving PCI during the hospital stay with a time from hospital arrival to PCI of 90 minutes or less
10. Reperfusion therapy	STEMI patients with STE on the ECG performed closest to the arrival who receive fibrinolytic therapy or primary PCI
11. Adult smoking cessation advice counseling	STEMI and NSTEMI MI patients with a history of smoking cigarettes who are given smoking cessation advice or counseling during hospital stay

^aMention in the patient's medical record of elevated LDL cholesterol if not measured.

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; ECG, electrocardiogram; LDL, low-density lipoprotein; LBBB, left bundle-branch block; LVSD, left ventricular systolic dysfunction; cholesterol; MI, myocardial infarction; NSTEMI, non-ST-segment elevation; PCI, percutaneous coronary intervention; STE, ST-segment elevation.

testing following MI.^{3,32} A randomized study established that rescue PCI was superior to repeated fibrinolytic administration or conservative management and resulted in fewer cardiac and cerebrovascular events.³⁴ The strategy of routine angiography and revascularization performed in all STE patients later during hospitalization was controversial for almost more than a decade, but data from the Occluded Artery Trial (OAT)³⁵ demonstrated that routine angiography followed by PCI in stable patients 3 to 28 days post-MI, without recurrent unprovoked ischemia or ischemia induced by stress testing, was not beneficial in reducing mortality or heart failure and may increase the risk of recurrent MI.³⁵ Therefore, routine *late* restoration of antegrade coronary artery blood flow should not be performed.

PCI in NSTEMI ACS

6 The most recent NSTEMI ACS ACC/AHA clinical practice guidelines recommend early coronary angiography with either PCI or CABG revascularization as an early treatment for high-risk NSTEMI ACS patients, and that such an approach be considered in patients at moderate risk.^{2,32} Several clinical trials support an “early invasive strategy” with PCI or CABG versus a “medical stabilization management strategy” whereby coronary angiography with revascularization is reserved for patients with symptoms refractory to pharmacotherapy and patients with signs of ischemia on stress testing. An early invasive approach results in fewer MIs, hospital readmissions for recurrent ACS, and less need for additional revascularization procedures over the next year following hospitalization.³⁶ In addition, an early invasive strategy is less costly than the conservative medical stabilization approach.³⁷

Additional Testing and Risk Stratification

At some point during hospitalization but prior to discharge, patients with MI should undergo evaluation of LV function for the purpose of risk stratification.^{2,3,33} The most common form of LV function measurement is echocardiography to calculate the patient's left ventricular ejection fraction (LVEF). LV function is the single best predictor of mortality following MI. Patients with LVEF less than 40% are at highest risk of death. Patients with ventricular fibrillation or sustained

ventricular tachycardia more than 2 days following MI and those with LVEF <30% measured at least 1 month following STEMI and 3 months after coronary artery revascularization with either PCI or CABG benefit from placement of an implantable cardioverter-defibrillator (ICD).³ The Multicenter Automatic Defibrillator Implantation Trial II (MADIT II) demonstrated a 29% reduction in mortality in patients with a history of MI, low LVEF, and no history of symptomatic ventricular arrhythmias who underwent prophylactic placement of an ICD.³⁸ Additional discussion of the role of ICDs in the management of high-risk patients and those with ventricular arrhythmias can be found in Chapter 19.

Predischarge stress testing (see Fig. 18–1) may be indicated for moderate- or low-risk patients in order to determine which patients would benefit from coronary angiography to establish the diagnosis of CAD and for patients following MI to predict intermediate- and long-term risk of recurrent MI and death.³⁹ In most cases, patients with a positive stress test indicating coronary ischemia then undergo coronary angiography and subsequent revascularization of significantly occluded coronary arteries. Exercise stress testing, most often with the addition of a radionuclide imaging agent, is preferred over nonpharmacologic stress testing because it evaluates the workload achieved with exercise as well as the occurrence of ischemia. If a patient has a negative exercise stress test for ischemia, the patient is at low risk for subsequent CHD events. Therefore, exercise stress testing has high negative predictive value. Additional discussion of the types of stress testing can be found in Chapter 13.

For patients admitted to the hospital for ACS, a fasting lipid panel should be drawn within the first 24 hours of hospitalization because, after that period, values for cholesterol, an acute-phase reactant, may be falsely low.³³ Initiation of pharmacotherapy with a statin is common for all ACS patients.

EARLY PHARMACOTHERAPY FOR STE ACS

Pharmacotherapy for early treatment of STE ACS is outlined in Fig. 18–3.^{2,3,10,40} **7** According to the ACC/AHA STE ACS practice guidelines, early pharmacotherapy of STE ACS should include intranasal oxygen (if oxygen saturation is <90%), sublingual (SL) nitroglycerin

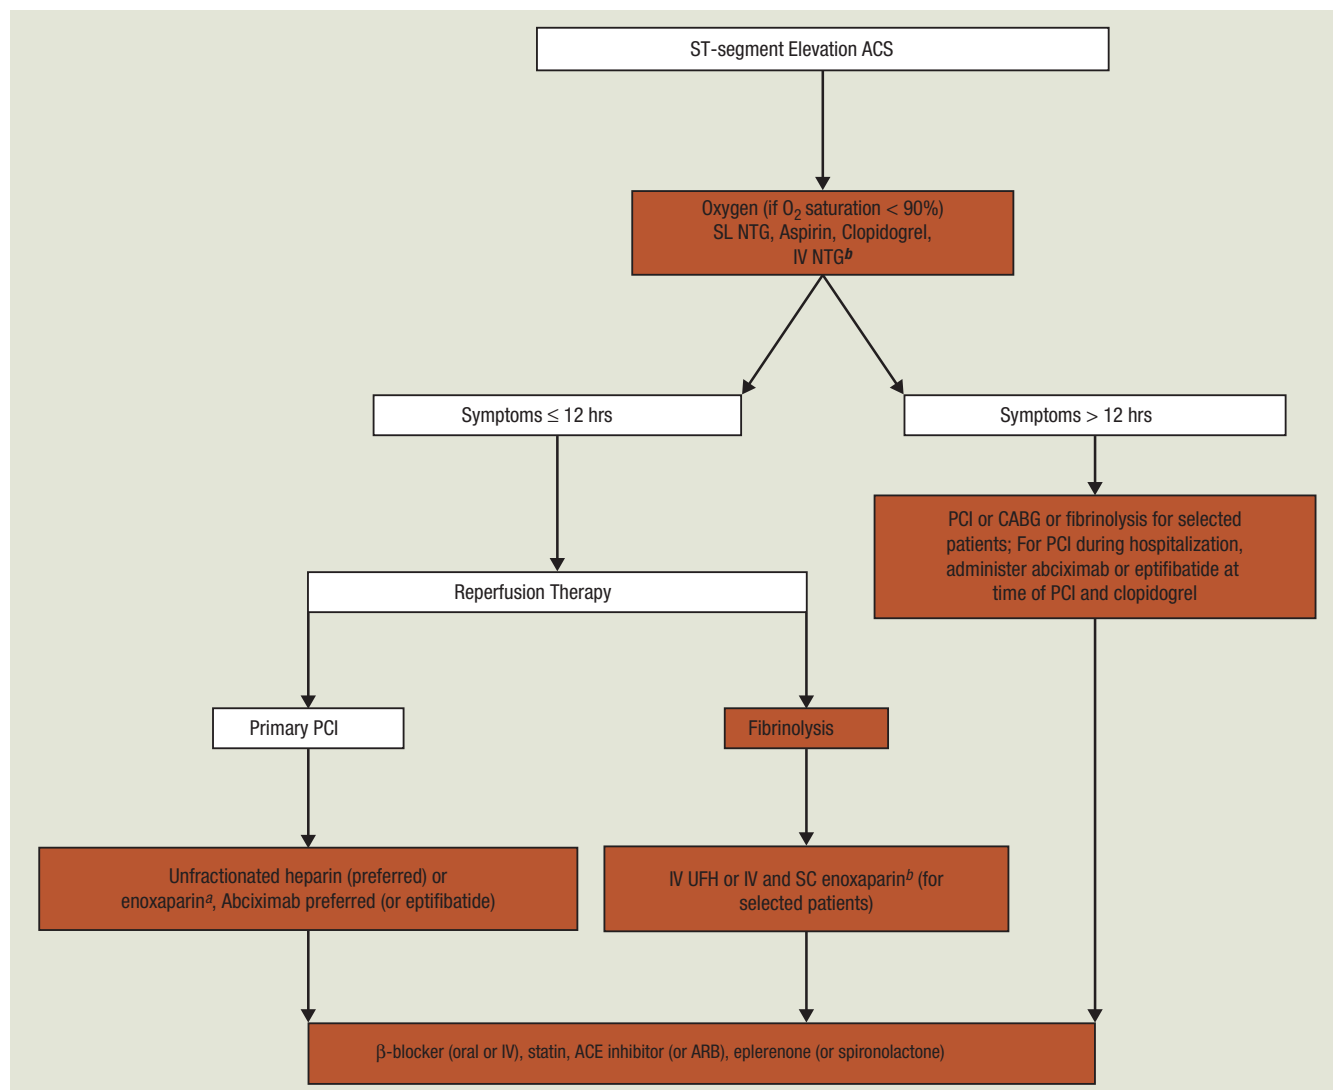

FIGURE 18-3. Initial pharmacotherapy for ST-segment elevation acute coronary syndromes. (ACE, angiotensin-converting enzyme; ACS, acute coronary syndrome; ARB, angiotensin receptor blocker; CABG, coronary artery bypass graft surgery; IV, intravenous; NTG, nitroglycerin; PCI, percutaneous coronary intervention; SC, subcutaneous; SL, sublingual; UFH, unfractionated heparin.) ^aAlthough recommended by the 2004 American College of Cardiology and American Heart Association practice guidelines, no dose recommendation is given. ^bSee Table 18-4 for dosing and specific types of patients who should not receive enoxaparin or IV NTG.) (Reprinted with permission from the American College of Clinical Pharmacy. Spinler SA. Acute coronary syndromes. In: Dunsworth TS, Richardson MM, Cheng JWM, et al, eds. *Pharmacotherapy Self-Assessment Program*, 6th ed. Cardiology II module. Kansas City: American College of Clinical Pharmacy, 2007:69–70.)

(NTG), aspirin, a β -blocker, unfractionated heparin (UFH) or enoxaparin, and fibrinolysis in eligible candidates. Morphine is administered to patients with refractory angina as an analgesic and a venodilator that lowers preload. These agents should be administered early, while the patient is still in the emergency department. An ACE inhibitor should be started within 24 hours of presentation, particularly in patients with LVEF $\leq 40\%$, signs of heart failure, or an anterior wall MI, in the absence of contraindications. Intravenous (IV) NTG and β -blockers should be administered to selected patients without contraindications as described in Table 18-4. Dosing and contraindications for SL and IV NTG, aspirin, β -blockers, UFH, enoxaparin, ACE inhibitors, and fibrinolytics are listed in Table 18-4.^{2,3,10,32,40}

Fibrinolytic Therapy

Administration of a fibrinolytic agent is indicated in patients with STE ACS who present to the hospital within 12 hours of onset of chest discomfort and have at least 1 mm of STE in two or more contiguous ECG leads or a new left bundle-branch block.³ Fibrinolytic therapy also should be considered in patients presenting within 12–24 hours

of onset of chest discomfort and have persistent symptoms of ischemia and at least 1 mm of STE in two or more contiguous leads. The mortality benefit of fibrinolysis is highest with early administration and diminishes after 12 hours. Fibrinolytic therapy is preferred over primary PCI in patients who present within 3 hours of symptom onset if primary PCI will be delayed, because a delay in access to a cardiac catheterization laboratory or a delay in obtaining patient vascular access would result in a “door-to-primary PCI” delay greater than 90 minutes.³ Other indications and contraindications for fibrinolysis are listed in Table 18-5.³ It is not necessary to obtain the results of biochemical markers before initiating fibrinolytic therapy. Because administration of fibrinolytics results in clot lysis, patients at high risk for major bleeding, including those with ICH, have either relative or absolute contraindications. Patients presenting with an absolute contraindication likely will not receive fibrinolytic therapy, and primary PCI is preferred. Patients with a relative contraindication can receive fibrinolytic therapy if the perceived risk of death from the MI is higher than the risk of major hemorrhage. For every 1,000 patients with anterior wall MI, treatment with fibrinolysis saves 37 lives compared with placebo. For patients with inferior wall MI, who

TABLE 18-4 Evidence-Based Pharmacotherapy for ST-Segment Elevation and Non-ST-Segment Elevation Acute Coronary Syndrome

Drug	Clinical Condition and ACC/AHA Guideline Recommendation ^a	Contraindications ^b	Dose and Duration of Therapy
Aspirin	STEMI, class I recommendation for all patients NSTEMI ACS, class I recommendation for all patients	Hypersensitivity Active bleeding Severe bleeding risk	162–325 mg orally once on hospital day 1 75–162 mg once daily orally starting hospital day 2 and continued indefinitely in patients not receiving an intracoronary stent 162–325 mg once daily orally for a minimum of 30 days in patients undergoing PCI receiving a bare metal stent, 3 months with a sirolimus-eluting stent and 6 months with a paclitaxel-eluting stent, followed by 75–162 mg once daily orally thereafter Continue indefinitely
Clopidogrel	STEMI, class I recommendation in patients allergic to aspirin NSTEMI ACS, class I recommendation for all hospitalized patients in whom a noninvasive approach is planned In PCI in STE and NSTEMI ACS, class I recommendations In STEMI with fibrinolytics, large randomized trial data published after 2004 guidelines	Hypersensitivity Active bleeding Severe bleeding risk	300 mg (class I recommendation) to 600 mg (class IIa recommendation in NSTEMI ACS) loading dose on hospital day 1 followed by a maintenance dose of 75 mg po once daily starting on hospital day 2; consider omitting the loading dose in patients >75 years old when given with fibrinolytics Administer indefinitely in patients with aspirin allergy (class I recommendation) Administer at least 9 months in patients with NSTEMI ACS who are managed medically (class I recommendation). For post-PCI stented patients, administer at least 12 months (AHA Science Advisory)
Unfractionated heparin (UFH)	STEMI, class I recommendation in patients undergoing PCI, and for patients treated with alteplase, reteplase, or tenecteplase, class IIa recommendation for patients not treated with fibrinolytic therapy NSTEMI ACS, class I recommendation in combination with aspirin PCI, class I recommendation (NSTEMI ACS and STEMI)	Active bleeding History of heparin-induced thrombocytopenia Severe bleeding risk Recent stroke	For STEMI, administer 60 units/kg IV bolus (maximum 4000 units) followed by a constant IV infusion at 12 units/kg/h (maximum 1000 units/h) For NSTEMI ACS, administer 60–70 units/kg IV bolus (maximum 5000 units) followed by a constant IV infusion at 12–15 units/kg/h (maximum 1000 units/h) Titrated to maintain an aPTT of 1.5–2.5 times control for NSTEMI ACS and 50–70 seconds for STEMI First aPTT should be measured at 4–6 hours for NSTEMI ACS and STEMI ACS in patients not treated with fibrinolytics First aPTT should be measured at 3 hours in patients with STEMI ACS who are treated with fibrinolytics Continue for at least 48 hours or until the end of PCI Enoxaparin 1 mg/kg SC every 12 hours for patients with NSTEMI ACS (CrCl ≥ 30 mL/min) Enoxaparin 1 mg/kg SC every 24 hours (CrCl 15–29 mL/min) for NSTEMI ACS or STEMI Dalteparin 120 IU/kg SC every 12 hours for patients with NSTEMI ACS (maximum single dose) For patients undergoing PCI following initiation of SC enoxaparin for NSTEMI ACS, a supplemental 0.3 mg/kg IV dose of enoxaparin should be administered at the time of PCI if the last dose of SC enoxaparin was given 8–12 hours prior to PCI For patients with STEMI receiving fibrinolytics: Age <75 years: administer enoxaparin 30-mg IV bolus followed immediately by 1 mg/kg SC every 12 hours (first two doses administer maximum of 100 mg for patients weighing >100 kg) For patients ≥ 75 yrs old with STEMI: administer enoxaparin 0.75 mg/kg SC every 12 hours (first two doses administer maximum of 75 mg for patients weighing >75 kg) Continue throughout hospitalization or up to 8 days for STEMI Continue for hospital stay or until the end of PCI for NSTEMI ACS For NSTEMI ACS, administer 0.1 mg/kg IV bolus followed by 0.25 mg/kg/h infusion For PCI, administer a second bolus of 0.5 mg/kg IV and increase infusion rate to 1.75 mg/kg/h Discontinue at end of PCI or continue for up to 4 hours For STEMI, 2.5-mg IV bolus followed by 2.5 mg SC once daily starting on hospital day 2 For NSTEMI ACS, 2.5 mg SC once daily For PCI, administer UFH 50–60 units/kg UFH (strategy not rigorously tested in clinical trials) Continue until hospital discharge
Low-molecular weight heparin	STEMI class IIb recommendation (and a large randomized trial) for patients treated with fibrinolytics and class IIa for patients not undergoing reperfusion therapy NSTEMI ACS, class I recommendation For PCI, class IIa recommendation as an alternative to UFH in patients with NSTEMI ACS For primary PCI in STEMI, class IIb recommendation as an alternative to UFH	Active bleeding History of heparin-induced thrombocytopenia Severe bleeding risk Recent stroke Avoid enoxaparin if CrCl <15 mL/min Avoid dalteparin if CrCl <30 mL/min Avoid if CABG surgery	
Bivalirudin	NSTEMI ACS class I recommendation for early invasive strategy	Active bleeding Severe bleeding risk	
Fondaparinux	NSTEMI ACS, class I recommendation Dosing information based on dose administered in OASIS-5 and OASIS-6 trials	Active bleeding Severe bleeding risk SCr ≥ 3.0 mg/dL

TABLE 18-4 Evidence-Based Pharmacotherapy for ST-Segment Elevation and Non-ST-Segment Elevation Acute Coronary Syndrome (continued)

Drug	Clinical Condition and ACC/AHA Guideline Recommendation ^a	Contraindications ^b	Dose and Duration of Therapy		
Calcium channel blockers	STEMI, class IIa recommendation and NSTEMI ACS, class I recommendation for patients with ongoing ischemia who are already taking adequate doses of nitrates and β -blockers For STEMI (diltiazem, verapamil, or amlodipine) For NSTEMI ACS, class I recommendation for diltiazem or verapamil for continuing ischemia in patients with a contraindication to a β -blocker; class IIa recommendation for patients with continuing ischemia who do not have a contraindication to a β -blocker; class IIb recommendation instead of a β -blocker	SBP <90 mm Hg Shock Signs and symptoms of heart failure Severe reactive airway disease Pulmonary edema Evidence of left ventricular dysfunction SBP <100 mm Hg PR ECG segment >0.24 second for verapamil and diltiazem 2nd- or 3rd-degree atrioventricular heart block for verapamil or diltiazem HR <60 beats/min for diltiazem or verapamil	Atenolol 5-mg IV dose followed in 5 minutes by a second 5-mg IV dose for a total of 10 mg followed in 1–2 hours by 50–100 mg by mouth once daily Initial IV therapy can be omitted and initial doses of oral therapy started Continue oral β -blocker indefinitely Diltiazem 120–360 mg sustained release orally once daily Verapamil 180–480 mg sustained release orally once daily Nifedipine 30–90 mg sustained release orally once daily Amlodipine 5–10 mg orally once daily Continue indefinitely if contraindication to oral β -blocker persists		
ACE inhibitors	STEMI and NSTEMI ACS, class I recommendation within the first 24 hours after hospital presentation for patients with clinical signs of heart failure or left ventricular EF <40% in the absence of contraindications class IIa recommendation for all other patients in the absence of contraindications STEMI and NSTEMI MI, class I recommendation for late hospital care and post-discharge care for patients with left ventricular EF <40%, diabetes mellitus, or chronic kidney disease Indicated indefinitely for all patients with EF <40%, class I recommendation	SBP <100 mm Hg History of intolerance to an ACE inhibitor Bilateral renal artery stenosis Serum potassium >5.5 mEq/L Acute renal failure Pregnancy	Drug	Initial Dose	Target Dose
			Captopril Enalapril Lisinopril Ramipril Trandolapril Continue indefinitely	6.25–12.5 mg 2.5–5.0 mg 2.5–5.0 mg 1.25–2.5 mg 1.0	50 mg twice daily orally to 50 mg three times daily 10 mg twice daily orally 10–20 mg once daily orally 5 mg twice daily or 10 mg once daily orally 4 mg once daily orally
Angiotensin receptor blockers	STEMI and NSTEMI ACS, class I recommendation for patients with an indication for an ACE inhibitor and a history of ACE inhibitor intolerance <40% STEMI and NSTEMI MI, class I recommendation for late hospital care and post-discharge care for patients with a history of ACE inhibitor intolerance STEMI and NSTEMI MI, class IIa recommendation as an alternative to an ACE inhibitor in patients presenting with signs of heart failure or left ventricular EF <40% STEMI and NSTEMI MI, class IIb recommendation added to an ACE inhibitor for long-term management of symptomatic heart failure in patients with left ventricular ejection fraction <40%	SBP <100 mm Hg Bilateral renal artery stenosis Serum potassium >5.5 mg/dL Acute renal failure Pregnancy	Drug	Initial Dose	Target Dose
			Candesartan Valsartan Continue indefinitely	4–8 mg 40 mg	32 mg once daily orally 160 mg twice daily orally
Aldosterone antagonists	STEMI and NSTEMI MI, class I recommendation for patients with EF \leq 40% and either diabetes mellitus or heart failure symptoms who are already receiving an ACE inhibitor	Hypotension Hyperkalemia, serum potassium >5.0 mEq/L SCr >2.5 mg/dL	Drug Eplerenone Spironolactone Continue indefinitely	Initial Dose 25 mg 12.5 mg	Maximum Dose 50 mg once daily orally 25–50 mg once daily orally

(continued)

TABLE 18-4 Evidence-Based Pharmacotherapy for ST-segment Elevation and Non-ST-segment Elevation Acute Coronary Syndrome (continued)			
Drug	Clinical Condition and ACC/AHA Guideline Recommendation ^a	Contraindications ^b	Dose and Duration of Therapy
Morphine sulfate	STE and NSTEMI ACS, class IIa recommendation for patients whose symptoms are not relieved after three serial SL nitroglycerin tablets or whose symptoms recur with adequate antiischemic therapy	Hypotension Respiratory depression Confusion Obtundation	2–5 mg IV bolus dose Can be repeated every 5–30 minutes as needed to relieve symptoms and maintain patient comfort

^aClass I recommendations are conditions for which there is evidence and/or general agreement that a given procedure or treatment is useful and effective. Class II recommendations are those conditions for which there is conflicting evidence and/or divergence of opinion about the usefulness/efficacy of a procedure or treatment. For Class IIa recommendations, the weight of the evidence/opinion is in favor of usefulness/efficacy. Class IIb recommendations are those for which usefulness/efficacy is less well established by evidence/opinion. Class III recommendations are those for which the procedure or treatment is not useful and may be harmful.

^bAllergy or prior intolerance contraindication for all categories of drugs listed.

^cChoice of specific agent is not as important as ensuring that appropriate candidates receive this therapy. If there are concerns about patient intolerance due to existing pulmonary disease, especially asthma, selection should favor a short-acting agent, such as propranolol or metoprolol or the ultrashort-acting agent esmolol. Mild wheezing or a history of chronic obstructive pulmonary disease should prompt a trial of a short-acting agent at a reduced dose (e.g., 2.5-mg IV metoprolol, 12.5-mg oral metoprolol, or 25 mcg/kg/min esmolol as initial doses) rather than complete avoidance of β -blocker therapy.

Data from references 2, 3, 10, 32, 55, and 108.

generally have smaller MIs and are at lower risk of death, treatment with fibrinolysis saves eight lives per 1,000 patients treated.²⁰

Fibrinolytic therapy is controversial in patients older than 75 years. More than 60% of all MI deaths occur in this group. Benefit in terms

of absolute mortality reduction compared with placebo varies from approximately 1% to 9%, with some observational studies suggesting higher mortality in the very elderly treated with fibrinolysis compared with no fibrinolysis. Stroke rates also grow in number with increasing patient age. The ICH rate is approximately 1% in younger patients versus 2% to 3% in older patients. There is no excess risk of stroke in patients younger than 55 years, whereas patients older than 75 years experience more than eight strokes per 1,000 patients treated.²⁰ However, the ACC/AHA practice guidelines recommend use of fibrinolytics in this age group, provided the patient has no contraindications.³ A 1% absolute mortality benefit is believed to be clinically significant, and the benefit in terms of lives saved per 1,000 patients treated has been reported to range from 10 to 80 in patients older than 75 years.²⁰ An AHA Scientific Statement concluded that a mortality benefit with fibrinolysis compared with no reperfusion was demonstrated in patients up to age 85 years and includes deaths related to ICH, stroke, and shock, which all are higher in the elderly compared to younger patients.⁴¹ Careful attention to correct dosing of UFH and enoxaparin can reduce ICH and bleeding rates.⁴¹ Because older patients may have cognitive impairment, careful history taking and assessment weighing the bleeding risk versus the benefit must be performed prior to administration of fibrinolysis.

The comparative pharmacology of commonly prescribed fibrinolytics is given in Table 18–6.⁴² According to the ACC/AHA STE ACS practice guidelines, a more fibrin-specific agent, such as alteplase, reteplase, or tenecteplase, is preferred over a non-fibrin-specific agent, such as streptokinase.³ Early administration of more fibrin-specific fibrinolytics opens a greater percentage of infarct arteries. Because an early open artery results in smaller infarcts, administration of fibrin-specific agents should result in lower mortality. This concept has been termed the *open-artery hypothesis*. In a large clinical trial, administration of alteplase reduced mortality by 1% (absolute reduction) and costs about \$30,000 per year of life saved compared with streptokinase.⁴³ Two other trials that compared alteplase with reteplase and alteplase with tenecteplase found similar mortality between agents.^{44,45} Therefore, alteplase, reteplase, or tenecteplase is acceptable as a first-line agent. Most hospitals have at least two of these agents on their formulary. Most often, formulary decisions are based on the frequency of use of fibrinolytics for other approved indications, such as ischemic stroke or pulmonary embolism, with alteplase having the most indications of the fibrin-specific agents. Administration considerations also guide formulary decision making and choice for patient treatment, with tenecteplase given as a single, weight-based dose and reteplase given as two fixed doses without weight adjustment. Therefore, both tenecteplase and reteplase are easier to administer than alteplase.

TABLE 18-5 Indications and Contraindications to Fibrinolytic Therapy According to ACC/AHA Guidelines for Management of Patients with ST-Segment Elevation Myocardial Infarction	
Indications	
1. Ischemic chest discomfort at least 20 minutes in duration but \leq 12 hours since symptom onset and ST-segment elevation of at least 1 mm in height in \leq 2 contiguous leads or New or presumed new left bundle-branch block	
2. Ongoing ischemic chest discomfort at least 20 minutes in duration 12–24 hours since symptom onset and ST-segment elevation of at least 1 mm in height in \geq 2 contiguous leads	
Absolute contraindications	
Active internal bleeding (not including menses) Previous intracranial hemorrhage at any time; ischemic stroke within 3 months Known intracranial neoplasm Known structural vascular lesion (e.g., arteriovenous malformation) Suspected aortic dissection Significant closed head or facial trauma within 3 months	
Relative contraindications	
Severe, uncontrolled hypertension on presentation (blood pressure $>$ 180/110 mm Hg) History of prior ischemic stroke $>$ 3 months, dementia, or known intracranial pathology not covered above under absolute contraindications Current use of anticoagulants Known bleeding diathesis Traumatic or prolonged ($>$ 10 minutes) CPR or major surgery ($<$ 3 weeks) Noncompressible vascular puncture (e.g., a recent liver biopsy or carotid artery puncture) Recent (within 2–4 weeks) internal bleeding For streptokinase administration, previous streptokinase use ($>$ 5 days) or prior allergic reactions Pregnancy Active peptic ulcer History of severe, chronic poorly controlled hypertension	

CPR, cardiopulmonary resuscitation.

Data from Antman EM, Anbe DT, Armstrong PW, Bates ER, et al. ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: Executive summary. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction). *Circulation* 2004;110:588–636.

TABLE 18-6 Comparison Between Fibrinolytic Agents

Agent	Fibrin Specificity	TIMI-3 Blood Flow Complete Perfusion at 90 Minutes	Systemic Bleeding Risk/ ICH Risk	Administration	Average Wholesale Price	Other Approved Uses
Streptokinase (Streptase)	+	35%	+++/+	Infusion over 60 minutes	\$563	Pulmonary embolism, deep-vein thrombosis, clearance of an occluded arteriovenous catheter, intrapleural administration for clearance of pulmonary effusion
Alteplase (rt-PA) (Activase)	+++	50%–60%	++/++	Bolus followed by infusions over 90 minutes, weight-based dosing	\$3,826	Pulmonary embolism, acute ischemic stroke, clearance of an occluded arteriovenous catheter
Reteplase (rPA) (Retavase)	++	50%–60%	++/++	Two bolus doses, 30 minutes apart	\$2,896	
Tenecteplase (TNK-tPA) (TNKase)	++++	50%–60%	+/++	Single bolus dose, weight-based dosing	\$2,918	

ICH, intracranial hemorrhage; TIMI, Thrombolysis in Myocardial Blood Flow (TIMI-3 blood flow indicates complete perfusion of the infarct artery).
Adapted from Spinler.¹⁰

ICH and major bleeding are the most serious side effects of fibrinolytic agents (see Table 18–6). The risk of ICH is higher with fibrin-specific agents than with streptokinase. Models for use in clinical practice are available to predict an individual patient's risk of ICH following administration of a fibrinolytic.³ The risk of systemic bleeding other than ICH is higher with streptokinase than with other, more fibrin-specific agents.⁴³

The percentage of eligible patients who receive reperfusion therapy is another quality performance measure of care in patients with STEMI (see Table 18–3).³³ The “door-to-needle time,” which is the time from hospital arrival to start of fibrinolytic therapy, is another quality performance measure (see Table 18–3).³³ Although the ACC/AHA guidelines recommend a door-to-needle time of less than 30 minutes, the median administration time in the United States in 2006 was 30 minutes, with only 50% of patients meeting the quality performance measure target of less than 30 minutes.⁵ Therefore, healthcare professionals should work to shorten fibrinolytic administration times.

Aspirin

Based on several randomized trials, aspirin has become the preferred antiplatelet agent for treatment of all ACSs.^{2,3} Early aspirin administration to all patients without contraindications within the first 24 hours of hospital admission is a quality care indicator (see Table 18–3).³³ The antiplatelet effects of aspirin are mediated by inhibition of thromboxane A₂ synthesis through irreversible inhibition of platelet cyclooxygenase-1 (COX-1).⁴⁶ Following administration of a non-enteric-coated formulation, aspirin rapidly (<10 minutes) inhibits thromboxane A₂ production in the platelets. Aspirin also has antiinflammatory actions, which decrease C-reactive protein and may contribute to its effectiveness in ACS.⁴⁶ In patients undergoing PCI, aspirin prevents acute thrombotic occlusion during the procedure.

The Second International Study of Infarct Survival (ISIS-2), which studied the impact of streptokinase and aspirin (162.5 mg/day) either alone or in combination, is a landmark clinical trial that convincingly demonstrated the value of aspirin in patients with STE ACS.⁴⁷ In this trial (n = 17,187), patients who received aspirin demonstrated a lower risk of 35-day vascular mortality compared with placebo (9.4% vs 11.8%; *P* < 0.0001). Use of aspirin was not associated with an increase in major bleeding, although the incidence of minor bleeding was increased. The combination of aspirin and streptokinase reduced mortality compared with placebo as well as compared with either agent alone, thereby highlighting the additive effects of combination antithrombotic therapy.

In patients experiencing an ACS, an initial dose equal to greater than 160 mg nonenteric aspirin is necessary to achieve rapid platelet inhibition (see Table 18–4).^{46,47} This first dose can be chewed in order to

achieve high blood concentrations and rapid platelet inhibition.^{2,3} The notion of chewing aspirin came from use of an enteric-coated formulation of aspirin in the ISIS-2 trial in order to break the enteric coating to ensure more rapid effect.⁴⁷ Current data suggest that although an initial dose of 160 to 325 mg is required, long-term therapy with doses of 75 to 150 mg daily are as effective as higher doses and, therefore,⁴⁸ a daily maintenance dose of 75 to 160 mg is recommended in most patients to inhibit the 10% of the total platelet pool that is regenerated daily.^{2,49} Whether these lower doses are as effective as a dose of 325 mg daily in patients undergoing intracoronary stent placement remains uncertain. Current AHA/ACC guidelines recommend the use of 162–325 mg daily for 1 month after placement of a bare-metal stent, 3 months after placement of a sirolimus-coated stent, and 6 months after placement of a paclitaxel-coated stent, after which a daily aspirin dose of 75 to 162 mg should be used indefinitely.⁴⁰ Therefore, although the risk of major bleeding, particularly gastrointestinal bleeding, appears to be reduced by using lower doses of aspirin, low-dose aspirin, taken chronically, is not free of adverse effects.^{49,50} Patients should be counseled on the potential risk of bleeding.

The ACC/AHA STE ACS guidelines specifically recommend that ibuprofen not be administered on a regular basis for pain relief concurrently with aspirin due to a reported drug interaction with aspirin whereby ibuprofen blocks aspirin's antiplatelet effects.³ Theoretically, such a risk is also possible with other nonsteroidal antiinflammatory drugs (NSAIDs), although these theoretical drug interactions remain to be clearly established. Finally, although some concern has been voiced regarding the possible increased risk of hemorrhagic stroke in patients taking aspirin, this risk appears to be very small and is outweighed by the benefit in reducing the risk of ischemic stroke and other vascular events.⁴⁸ The risk of hemorrhagic stroke appears to be minimal in patients with adequate blood pressure control,²⁰ and there are no specific contraindications to antiplatelet therapy in hypertensive patients presenting with ACS.⁵¹ Aspirin therapy should be continued indefinitely.³

Thienopyridines

Although aspirin is effective in the setting of ACS, it is a relatively weak platelet inhibitor that blocks platelet aggregation through only one pathway. The thienopyridines clopidogrel and ticlopidine are antiplatelet agents that mediate their antiplatelet effects through a blockade of ADP P2Y₁₂ receptors on platelets.² Because ticlopidine is associated with the occurrence of neutropenia that requires frequent monitoring of the complete blood count during the first 3 months of use,⁵² clopidogrel is the preferred thienopyridine for ACS and PCI patients⁴⁰ (see Table 18–4).

The AHA/ACC guidelines currently recommend clopidogrel as an alternative to aspirin in patients who have an allergy to aspirin.^{2,3} The

updated recommendations from these professional associations, expected in 2007, are likely to extend the recommendation regarding the use of clopidogrel to include most patients with STE ACS. A trial of more than 45,000 patients with STE ACS showed that early therapy with clopidogrel 75 mg once daily (started within 24 hours of hospital presentation), added to aspirin for the duration of hospitalization (average 15 days) or up to 28 days, reduced mortality and reinfarction compared to placebo in patients treated with medical therapy, including fibrinolytics, without increasing the risk of major bleeding.⁵³ Another smaller study showed that clopidogrel added to aspirin reduced the composite rate of 30-day death, MI, or stroke by 20% in patients ages 18 to 75 years with STE ACS treated with fibrinolytics. Clopidogrel or placebo was administered as an initial dose of 300 mg orally on day 1, followed by 75 mg daily. Angiography was encouraged as early as hospital day 2, and patients undergoing PCI at the time of angiography continued on open-label clopidogrel at a 300-mg loading dose followed by 75 mg once daily for the duration of the study. Patients who did not undergo revascularization received clopidogrel up to the time of discharge or hospital day 8. At the time of angiography, more open infarct arteries were present in the clopidogrel-treated patients.⁵⁴ Based on current data, therefore, clopidogrel (either 75 mg or 300 mg on day 1 followed by 75 mg once daily) should be given for at least 14 to 28 days in addition to aspirin in patients treated by fibrinolytics and in those receiving no revascularization therapy with either PCI or CABG surgery. The safety of the 300-mg loading dose has not been evaluated in patients older than over 75 years receiving a fibrinolytic.

Clopidogrel is recommended in addition to aspirin in patients undergoing primary PCI. For primary PCI, clopidogrel is administered as a 300-mg loading dose, followed by 75 mg once daily, in combination with aspirin 325 mg once daily, to prevent subacute stent thrombosis and long-term events cardiovascular CV events.^{2,32,40} Alternatively, an initial dose of 600 mg can be considered, although the clinical efficacy and safety of this dose is under investigation.⁴⁰ The duration of clopidogrel therapy depends on the type of stent implemented (either a bare-metal stent or a drug-eluting stent; see Table 18–4), the patient's presentation (ACS vs stable angina), and the patient's risk of bleeding.^{55,56}

The most frequent side effects of clopidogrel are nausea, vomiting, and diarrhea, which occur in approximately 5% of patients. Rarely, thrombotic thrombocytopenic purpura has been reported with clopidogrel.⁵² The most serious side effect of clopidogrel is bleeding (see Early Pharmacotherapy for NSTEMI ACS below).

GP IIb/IIIa Receptor Inhibitors

Abciximab is a first-line GP IIb/IIIa receptor inhibitor for patients undergoing primary PCI^{3,32,40,57} who have not received fibrinolytics. It should not be administered for medical management of patients with STE ACS who will not be undergoing PCI. Abciximab is preferred over eptifibatide and tirofiban in this setting because abciximab is the most common GP IIb/IIIa receptor inhibitor studied in primary PCI trials.^{3,32,40,57} Abciximab, in combination with aspirin, a thienopyridine, and UFH (administered as an infusion for the duration of the procedure) reduced mortality and reinfarction without increasing the risk of major bleeding in a meta-analysis of primary PCI clinical trials.⁵⁷

Dosing and contraindications for abciximab are listed in Table 18–4. GP IIb/IIIa receptor inhibitors block the final common pathway of platelet aggregation, namely, cross-linking of platelets by fibrinogen bridges between the GP IIb/IIIa receptors on the platelet surface. Abciximab typically is initiated at the time of PCI, and the infusion is continued for 12 hours. Administration of a GP IIb/IIIa receptor inhibitor may increase the risk of bleeding, especially if it is given in the setting of recent (<4 hours) administration of fibrinolytic therapy.^{57–59} An immune-mediated thrombocytopenia occurs in approximately 5% of patients.⁶⁰

Some trials suggest that early administration of abciximab results in early opening of the coronary artery, making primary PCI easier for the interventional cardiologist. Clinical trials performed to date suggest that the combination of early administration of a reduced dose of a fibrinolytic agent in combination with abciximab does not reduce mortality and increases the risk of bleeding, including ICH, in elderly patients with STE ACS.^{57–59} Additional clinical trials of combined antithrombotic therapy for STE PCI patients are ongoing.

Anticoagulants

Options for anticoagulant therapy for patients with STE ACS are outlined in Fig. 18–3 and Table 18–4. UFH, administered as an IV bolus followed by a continuous infusion, is a first-line anticoagulant for treatment of patients with STE ACS, both for medical therapy and for patients undergoing PCI.^{3,40} UFH binds to antithrombin and then inhibits the activity of clotting factors Xa and IIa (thrombin). Anticoagulant therapy should be initiated in the emergency department and continued for at least 48 hours in selected patients who will be bridged over to receive chronic warfarin anticoagulation following acute MI.³ If a patient undergoes PCI, UFH is discontinued immediately after the procedure. UFH dosing is listed in Table 18–4. The dose of UFH infusion is adjusted frequently to a target activated partial thromboplastin time (aPTT; see Table 18–4). When coadministered with a fibrinolytic, aPTTs above the target range are associated with an increased rate of bleeding, whereas aPTTs below the target range are associated with increased mortality and reinfarction.⁶¹

For more than 40 years UFH has been the traditional anticoagulant administered to patients with STE ACS for prevention of infarct artery reocclusion. Other beneficial effects of anticoagulation in patients with ACS are prevention of cardioembolic stroke and venous thromboembolism.³ When a fibrinolytic agent is administered, UFH is given concomitantly with alteplase, reteplase, and tenecteplase. UFH is not administered to patients receiving the non-fibrin-selective agent streptokinase because no benefit of combined therapy has been demonstrated.⁶² Rates of reinfarction are higher if UFH is not given in combination with fibrin-selective agents.⁶² UFH currently is the preferred anticoagulant in patients undergoing primary PCI.^{32,40}

Besides bleeding, the most frequent adverse effect of UFH is the immune-mediated clotting disorder heparin-induced thrombocytopenia (see Chapter 21), which occurs in up to 5% of patients treated with UFH. Heparin-induced thrombocytopenia is less common in patients receiving low-molecular-weight heparins (LMWHs).^{3,40} Because randomized controlled clinical trials comparing UFH to placebo are lacking, no conclusive data support a benefit of UFH over placebo in reducing mortality or reinfarction in STE ACS.⁶³ On the contrary, the results of a meta-analysis of more than 7,500 patients suggests that LMWHs reduce both mortality and reinfarction compared to placebo.⁶³

LMWHs, like UFH, bind to antithrombin and inhibit both factor Xa and IIa. However, because their composition is mostly short saccharide chain lengths, they preferentially inhibit factor Xa over factor IIa, which requires larger chain lengths for binding and inhibition. Although the possible superiority of LMWHs, particularly enoxaparin, has been suggested by many small trials,⁶³ their relative benefits have been properly compared only recently in the Enoxaparin and Thrombolysis Reperfusion for Acute Myocardial Infarction Treatment (ExTRACT)-Thrombolysis in Myocardial Infarction (TIMI) 25 trial.⁶⁴ In this large trial, enoxaparin administered for a median of 7 days significantly reduced the risk of death or nonfatal MI compared to UFH administered for a median of 2 days (see Table 18–4). The benefit, although modest, was already apparent after 48 hours of treatment. Enoxaparin use was associated with a small (2.1% vs 1.4%) but significant increased risk of major bleeding. Whether the observed benefits and increase in bleeding observed in this trial can be solely attributed to the pharmacokinetic

and pharmacodynamic differences between UFH and enoxaparin or the longer duration of treatment in the enoxaparin group is uncertain. Although the bleeding rates were increased in patients older than 75 years compared to younger patients, the rates of major bleeding between enoxaparin and UFH use were similar in the older patient subgroup.⁶⁵ Therefore, enoxaparin can be considered a valuable anticoagulant in the context of STEMI. Enoxaparin has not been studied in the setting of primary PCI.

Fondaparinux is an indirect-acting specific inhibitor of factor Xa that has recently been studied in the setting of STE ACS. Unlike UFH and LMWHs, fondaparinux does not cause heparin-induced thrombocytopenia. In the Sixth Organization for the Assessment of Strategies for Ischemic Syndromes (OASIS 6) trial, fondaparinux administered for a median of 8 days had similar efficacy and safety as UFH administered for a median of 2 days in patients receiving fibrinolytic therapy with alteplase, reteplase, or tenecteplase (see Table 18–4 for dosing).⁶⁶ A small reduction in mortality was observed in patients treated with fondaparinux versus placebo in patients treated with streptokinase or receiving no fibrinolytic therapy. No benefit of fondaparinux was observed in the subgroup of patients undergoing PCI during hospitalization.⁶⁶ Because of the lack of benefit of in the fondaparinux compared to UFH group as well as in the subgroup of patients undergoing PCI, coupled with the relatively long duration of administration, fondaparinux likely will not be used widely in practice for treatment of STEMI in the United States.

Nitrates

Nitrates promote the release of nitric oxide from the endothelium, which results in venous and arterial vasodilation at higher doses. Venodilation lowers preload and myocardial oxygen demand. Arterial vasodilation may lower blood pressure, thus reducing myocardial oxygen demand. Arterial vasodilation relieves coronary artery vasospasm, dilating coronary arteries to improve myocardial blood flow and oxygenation. One SL NTG tablet (0.4 mg) should be administered every 5 minutes for up to three doses to relieve myocardial ischemia. If patients have previously been prescribed SL NTG and ischemic chest discomfort persists for more than 5 minutes after the first dose, the patient should be instructed to contact emergency medical services before self-administering subsequent doses in order to activate emergency care sooner. IV NTG is indicated in patients with ACS who do not have a contraindication and who have persistent ischemic symptoms, heart failure, or uncontrolled blood pressure. It should be continued for approximately 24 hours after ischemia is relieved (see Table 18–4).³ Importantly, other lifesaving therapies, such as ACE inhibitors or β -blockers, should not be withheld for nitrates use because the mortality benefit of nitrates is unproven. Nitrates play a limited role in the treatment of ACS patients, with two large, randomized clinical trials failing to show a mortality benefit for IV followed by oral nitrate therapy in patients with acute MI.^{67,68} The most significant adverse effects of nitrates are tachycardia, flushing, headache, and hypotension. Nitrate administration is contraindicated in patients who have received oral phosphodiesterase-5 inhibitors, such as sildenafil and vardenafil, within the past 24 hours and tadalafil within the past 48 hours.

β -Blockers

A β -blocker should be administered early in the care of patients with STE ACS and continued indefinitely. Early administration of a β -blocker within the first 24 hours of hospitalization in patients lacking a contraindication is a quality care indicator (see Table 18–3).³³ In ACS, the benefit of β -blockers results mainly from the competitive blockade of β_1 -adrenergic receptors located on the myocardium. β_1 -blockade produces a reduction in heart rate, myocardial contractility, and blood pressure, decreasing myocardial oxygen demand. In

addition, the reduction in heart rate increases diastolic time, thus improving ventricular filling and coronary artery perfusion.⁶⁹ As a result of these effects, β -blockers reduce the risk for recurrent ischemic, infarct size, risk of reinfarction, and occurrence of ventricular arrhythmias in the hours and days following MI.⁶⁹

Landmark clinical trials have established the role of early β -blocker therapy in reducing MI mortality. Most of these trials were performed in the 1970s and 1980s before routine use of early reperfusion therapy.^{70–73} However, data regarding the acute benefit of β -blockers in MI in the reperfusion era are derived mainly from a large clinical trial reported in 2005. The trial suggests that although initiating IV followed by oral β -blockers early in the course of STEMI was associated with a lower risk of reinfarction or ventricular fibrillation, there may be an early risk of cardiogenic shock, especially in patients presenting with pulmonary congestion or systolic blood pressure <120 mm Hg.⁷⁴ Therefore, the use of β -blockers, particularly when administered IV, should be limited to patients who are hemodynamically stable and who do not demonstrate any signs or symptoms of decompensated heart failure. Careful assessment for signs of hypotension and heart failure should be performed following β -blocker initiation and prior to any dose titration. Early administration of β -blockers (to patients without contraindications) within the first 24 hours of hospital admission is a quality performance measure (see Table 18–3).^{3,33} The AHA and ACC now are reevaluating this recommendation given the results of the aforementioned trial. Current AHA guidelines for the management of hypertension in the setting of ACS suggest that β -blockers should be delayed in patients with hemodynamic instability or shock until resolution of heart failure symptoms and hypotension.⁵¹

The most serious side effects of β -blocker administration early in ACS are hypotension, acute heart failure, bradycardia, and heart block. Although initial acute administration of β -blockers is not appropriate for patients who present with decompensated heart failure, initiation of β -blockers can be attempted before hospital discharge in most patients following treatment of acute heart failure. It cannot be overemphasized that diabetes mellitus does not constitute a contraindication to β -blockers. Although the use of β -blockers may mask symptoms of hypoglycemia, except sweating, diabetics greatly benefit from β -blocker administration because they are at high risk for recurrent events.⁶⁹ In patients in whom a major concern exists regarding a possible intolerance to β -blockers, such as patients with bronchospastic pulmonary disease, a short-acting β -blocker, such as metoprolol or esmolol, initially should be administered IV.⁶⁹ β -Blockers are continued indefinitely.³

Calcium Channel Blockers

Administration of calcium channel blockers in the setting of STE ACS is reserved for patients who have contraindications to β -blockers and is given for relief of ischemic symptoms.³ In patients prescribed calcium channel blockers for treatment of hypertension who are not receiving β -blockers and who do not have a contraindication to β -blockers, the calcium channel blocker should be discontinued and a β -blocker initiated. Calcium channel blockers inhibit calcium influx into myocardial and vascular smooth muscle cells, causing vasodilation. Although all calcium channel blockers produce coronary vasodilation and decrease blood pressure, other effects are more heterogeneous between agents. Dihydropyridine calcium channel blockers (e.g., amlodipine, felodipine, and nifedipine) primarily produce their antiischemic effects through peripheral vasodilation, with no clinical effects on atrioventricular nodal conduction and heart rate. Diltiazem and verapamil, on the other hand, have additional antiischemic effects by reducing contractility and atrioventricular nodal conduction and slowing heart rate.⁷⁵

Current data suggest little benefit on clinical outcomes beyond symptom relief for calcium channel blockers in the setting of ACS.^{76,77} Moreover, the use of first-generation short-acting dihydropyridines,

such as nifedipine, should be avoided because they appear to worsen outcomes through their negative inotropic effects, induction of reflex sympathetic activation, tachycardia, and increased myocardial ischemia.⁷⁵ Therefore, the role of verapamil or diltiazem appears to be limited to relief of ischemia-related symptoms or control of heart rate in patients with supraventricular arrhythmias for whom β -blockers are contraindicated or ineffective.^{2,3}

Adverse effects and contraindications of calcium channel blockers are listed in Table 18–4. Verapamil, diltiazem, and first-generation dihydropyridines also should be avoided in patients with decompensated heart failure or LV dysfunction because these drugs can worsen heart failure and potentially increase mortality secondary to their negative inotropic effects. In patients with heart failure requiring treatment with a calcium channel blocker, amlodipine is the preferred agent.^{77,78}

Two groups of patients may benefit from calcium channel blockers as opposed to β -blockers as initial therapy. Cocaine-induced ACS and variant (or Prinzmetal) angina are two conditions in which coronary vasospasm plays an important role.^{2,3,75} Calcium channel blockers and/or NTG generally are considered the agents of choice in these patients because they can reverse coronary spasm by

inducing smooth muscle relaxation in the coronary arteries. In contrast, β -blockers generally should be avoided in these patients unless they have uncontrolled sinus tachycardia (>100 beats/min) or severe uncontrolled hypertension following cocaine use because β -blockers actually may worsen vasospasm through an unopposed β_2 -blocking effect on the smooth muscle cells.²

■ EARLY PHARMACOTHERAPY FOR NSTEMI ACS

In general, early pharmacotherapy for NSTEMI ACS (see Fig. 18–4) is similar to that for STE ACS with three exceptions:

1. Fibrinolytic therapy is not administered.
2. GP IIb/IIIa receptor blockers are administered to high-risk patients.
3. There are no standard quality performance measures for patients with NSTEMI ACS with unstable angina (not diagnosed with MI).

8 According to the ACC/AHA NSTEMI ACS practice guidelines, early pharmacotherapy for NSTEMI ACS should include intranasal

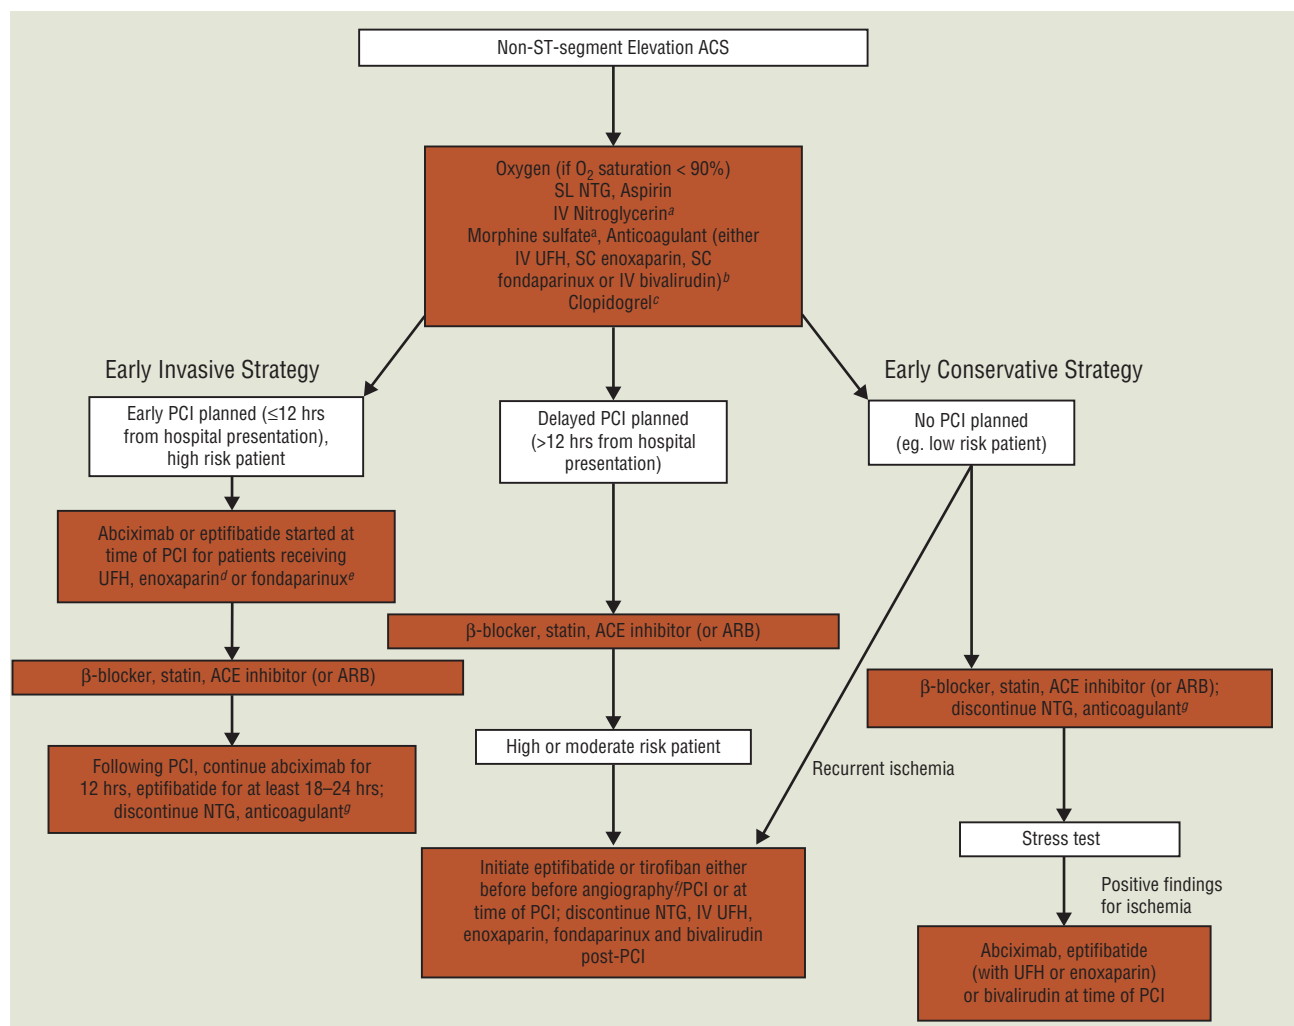

FIGURE 18-4. Initial pharmacotherapy for non-ST-segment elevation acute coronary syndrome. (ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; ACS, acute coronary syndrome; CABG, coronary artery bypass graft surgery; IV, intravenous; NTG, nitroglycerin; PCI, percutaneous coronary intervention; SC, subcutaneous; SL, sublingual; UFH, unfractionated heparin.) ^aFor selected patients, see Table 18–4. ^bEnoxaparin, UFH, fondaparinux, or bivalirudin for early invasive strategy; enoxaparin or fondaparinux preferred if no angiography/PCI planned but UFH acceptable; fondaparinux preferred if high risk for bleeding; UFH preferred anticoagulant for patients undergoing CABG. ^cIn patients unlikely to undergo CABG. ^dMay require an IV supplemental dose; see Table 18–4. ^eRequires supplemental UFH bolus for PCI; see Table 18–4. ^fFor signs and symptoms of recurrent ischemia. ^gSC enoxaparin or UFH can be continued at a lower dose for venous thromboembolism prophylaxis. (Adapted with permission from the American College of Clinical Pharmacy. Spinler SA. Acute coronary syndromes. In: Dunsworth TS, Richardson MM, Cheng JWM, et al, eds. *Pharmacotherapy Self-Assessment Program*, 6th ed. Cardiology II module. Kansas City: American College of Clinical Pharmacy, 2007: 69–70.)

oxygen (if oxygen saturation is <90%), SL NTG, aspirin, an oral β -blocker (IV β -blocker optional), and an anticoagulant (UFH, LMWH [enoxaparin], fondaparinux, or bivalirudin). Morphine is also administered to patients with refractory angina, as described previously in Early Pharmacotherapy for STE ACS. IV NTG should be administered in selected patients without contraindications as described in Table 18–4. These agents should be administered early, while the patient is still in the emergency department. Dosing and contraindications for SL and IV NTG, aspirin, β -blockers, UFH, and enoxaparin are listed in Table 18–4.^{2,3,10}

Fibrinolytic Therapy

Fibrinolytic therapy is not indicated in any patient with NSTEMI/ACS, even those who have positive biochemical markers (e.g., troponin) that indicate infarction. Because the risk of death from MI is lower in patients with NSTEMI/ACS whereas the risk for life-threatening adverse effects, such as ICH, with fibrinolytics is similar between patients with STE and NSTEMI/ACS, the risks of fibrinolytic therapy outweigh the benefit for NSTEMI/ACS patients. In fact, increased mortality has been reported with fibrinolytics compared with controls in clinical trials where fibrinolytics have been administered to patients with NSTEMI/ACS (patients with normal or ST-segment depression ECGs).²⁰

Aspirin

Aspirin reduces the risk of death or developing MI by about 50% (compared with no antiplatelet therapy) in patients with NSTEMI/ACS.⁴⁹ Therefore, aspirin remains the cornerstone of early treatment for all ACSs. Dosing of aspirin for NSTEMI/ACS is the same as that for STE ACS (see Table 18–4). Aspirin is continued indefinitely.

Thienopyridines

For patients with NSTEMI/ACS, the addition of clopidogrel started on the first day of hospitalization as a 300- to 600-mg loading dose followed the next day by 75 mg/day orally is recommended for most patients.² Although the use of aspirin in ACS is the mainstay of antiplatelet therapy, morbidity and mortality following an ACS remain high. Researchers explored whether combining two oral antiplatelet agents with different mechanisms of action, aspirin and clopidogrel, would result in additional clinical benefit over using aspirin alone. Efficacy and safety of this dual antiplatelet therapy were demonstrated in the Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial.^{79,80} In CURE, 12,562 patients with unstable angina or an NSTEMI/ACS and new ECG changes consistent with ischemia or positive cardiac markers were randomized to a loading dose of clopidogrel 300 mg, followed by a daily dose of 75 mg or placebo in addition to aspirin for a mean duration of 9 months. Clopidogrel reduced the combined risk of death from cardiovascular causes, nonfatal MI, or stroke from 11.4% to 9.4% compared with placebo, mainly through a reduction in the risk of MI. Cardiovascular mortality was similar between groups. Results from a second trial in PCI patients, the Clopidogrel for the Reduction of Events During Observation (CREDO) trial,⁸¹ in which patients were treated with long-term clopidogrel (1 year), demonstrated a lower risk of death, MI, or stroke compared with patients who received only 28 days of clopidogrel (8.5% vs 11.5%; $P = 0.02$). However, the interpretation of this study is limited in that the control group did not receive a loading dose of clopidogrel on the first day. According to the ACC/AHA 2007 guidelines, clopidogrel is indicated for up to 12 months in NSTEMI/ACS patients, with a minimum duration of treatment of 1 month after placement of a bare-metal stent and 12 months after placement of a sirolimus or paclitaxel coated stent.^{2,55} Whether or not treatment with clopidogrel should be extended to more than 1 year is questionable based on recent a large, randomized trial.⁸²

The major concern when combining two antiplatelet agents is the increased risk of bleeding. In CURE, the risk of major bleeding was increased in patients who received clopidogrel plus aspirin compared with aspirin alone (3.7% vs 2.7%; $P = 0.001$).⁷⁹ A post hoc analysis of CURE revealed that the rate of major bleeding depended on the dose of aspirin and showed that doses ≤ 100 mg daily reduced the risk of bleeding with similar efficacy compared with higher doses.⁸³ The recommendation to use a lower dose of aspirin with clopidogrel is also supported by the results of a recent systematic review of clinical trials that found no benefit to aspirin as a sole antiplatelet agent for chronic treatment in doses greater than 75 to 81 mg.⁴⁸ However, administration of a 325-mg dose of aspirin with clopidogrel is recommended for patients with recent intracoronary stent placement (see Early Pharmacotherapy for STE ACS) to prevent stent thrombosis.⁴⁰

In patients undergoing CABG, major bleeding was increased in those who underwent the procedure within 5 days of clopidogrel discontinuation (9.6% vs 6.3%; $P = 0.06$) but not in those in whom clopidogrel was discontinued more than 5 days before the procedure.⁷⁹ Aspirin was continued up to and after CABG. Therefore, in patients scheduled for CABG, clopidogrel should be withheld at least 5 days and preferably 7 days before the procedure.²

The timing of initiation of clopidogrel in patients presenting with NSTEMI/ACS is controversial. Although clopidogrel should be initiated as soon as possible in patients being treated with a noninterventional strategy or in patients who have a contraindication to aspirin, the need to delay CABG for 5 to 7 days following clopidogrel has led many to suggest that clopidogrel administration should be delayed until coronary angiography is performed and the need for CABG is excluded. This is particularly relevant in centers where the waiting time for CABG is less than 5 days. However, existing data also suggest that early treatment with clopidogrel before angiography is performed reduces the number of cardiovascular events following the procedure.⁸¹ Therefore, others have advocated the expanded use of early clopidogrel in all patients experiencing a NSTEMI/ACS.

GP IIb/IIIa Receptor Inhibitors

Administration of tirofiban or eptifibatide is recommended for high-risk NSTEMI/ACS patients as medical therapy without planned revascularization, and administration of either abciximab or eptifibatide is recommended for NSTEMI/ACS patients undergoing PCI. Administration of tirofiban or eptifibatide is also indicated in patients with continued or recurrent ischemia despite treatment with aspirin, clopidogrel, and an anticoagulant.² The pharmacologic similarities and differences between GP IIb/IIIa receptor inhibitors are reviewed in Chapter 17. As discussed in Chapter 17, the benefits of GP IIb/IIIa receptor inhibitors in PCI is well established, and they are considered first-line agents for reducing the risk of reinfarction and the need for repeat PCI.^{2,32,40}

Two large clinical trials highlight the role of GP IIb/IIIa receptor inhibitors in the setting of NSTEMI/ACS and PCI. In the Platelet Glycoprotein IIb/IIIa in Unstable Angina: Receptor Suppression Using Integrilin Therapy (PURSUIT) trial ($n = 10,948$), eptifibatide added to aspirin and UFH and continued for 48 to 96 hours reduced the combined end point of death or MI at 30 days (14.2% vs 15.7%) compared with aspirin and UFH alone.⁸⁴ In the Platelet Receptor Inhibition in Ischemic Syndrome Management in Patients Limited by Unstable Signs and Symptoms (PRISM-PLUS) study ($n = 1,915$), tirofiban added to aspirin and UFH and continued for up to 72 hours reduced the rate of death, MI, or refractory ischemia at 7 days compared with aspirin and UFH alone.⁸⁵ However, in these and other trials of GP IIb/IIIa inhibitors for NSTEMI/ACS, the benefit was mostly limited to patients undergoing PCI and not those treated without interventional therapy.⁸⁶ Therefore, medical therapy with GP IIb/IIIa receptor inhibitors is reserved for higher-risk patients,

such as those with positive troponin or ST-segment depression, and patients who have continued or recurrent ischemia despite other antithrombotic therapy.^{2,32,40} Patients undergoing PCI in these trials received several hours to days of pretreatment with the GP IIb/IIIa receptor inhibitor before proceeding to PCI.

The role of GP IIb/IIIa receptor antagonists in patients with NSTEMI/ACS undergoing PCI also was evaluated in two large clinical trials that used GP IIb/IIIa receptor inhibitors initiated at the time of PCI. In the Enhanced Suppression of the Platelet IIb/IIIa Receptor with Integrilin Therapy (ESPRIT) trial ($n = 1,024$), eptifibatide in combination with aspirin and UFH reduced the rate of death or MI up to 1 year in patients undergoing PCI.⁸⁷ The benefits of treatment in the ACS subgroup were more pronounced compared with the stable angina subgroup, thereby establishing a role for eptifibatide in ACS PCI patients.

Only one trial has compared two GP IIb/IIIa receptor inhibitors with each other. In the Do Tirofiban and ReoPro Give Similar Efficacy Outcomes Trial (TARGET), tirofiban, at a different dose from that used in the PRISM-PLUS study, was compared with abciximab in patients undergoing PCI.^{88,89} In the subgroup of patients with ACS, there was a statistically significant reduction in the composite end point of death, nonfatal MI, or need for repeat PCI at 30 days in patients randomized to receive abciximab compared with tirofiban (6.3% vs 9.3%).⁸⁹ Although the numerical benefit of a 3% absolute risk reduction was maintained at 6 months, it approached but was no longer statistically significant (hazard ratio 1.19, abciximab better than tirofiban, 95% confidence interval 0.99–1.42).⁸⁹ Following TARGET, the dose of tirofiban that was used in that trial has been shown to be ineffective at inhibiting platelet aggregation during the PCI procedure.⁹⁰ Therefore, tirofiban cannot be recommended for PCI unless the patient has been treated with tirofiban for several hours to days prior to PCI and adequate inhibition of platelet aggregation can be ensured. If a GP IIb/IIIa receptor inhibitor is initiated while the patient is undergoing the procedure, abciximab or eptifibatide should be used. Importantly, in patients with NSTEMI/ACS undergoing PCI, use of clopidogrel does not obviate the need for a GP IIb/IIIa inhibitor.⁹¹

As emphasized in the ACC/AHA guidelines,² the benefits of GP IIb/IIIa inhibitors are greater in patients undergoing PCI. A meta-analysis estimated that 30 adverse outcomes (either death or MI) are prevented for every 1,000 patients treated with a GP IIb/IIIa inhibitor before PCI, whereas only four events are prevented for medical management of patients with NSTEMI/ACS using GP IIb/IIIa inhibitors without PCI.⁹² This translates into a number needed to treat (NNT) of 32 patients to prevent one event if a GP IIb/IIIa inhibitor is administered before PCI and 250 patients to prevent one event if it is administered as medical therapy without PCI.⁹²

Doses and contraindications to GP IIb/IIIa receptor blockers are listed in Table 18–4, and common adverse effects are described in the preceding section. Administration of IV GP IIb/IIIa receptor inhibitor in combination with aspirin and either UFH or enoxaparin results in major bleeding rates of 0.4% to 10.6%^{84,85} but no increased risk of ICH in the absence of concomitant fibrinolytic treatment. Some studies suggest that although the risk of minor bleeding is higher, the risk of major bleeding with a GP IIb/IIIa inhibitor is similar to placebo in patients treated with UFH who undergo PCI.^{85,91} Risk factors that increase the chance of bleeding with a GP IIb/IIIa inhibitor include female gender, older age, and reduced renal function.⁹³ Older patients, especially women, are more likely to receive an excessive dose of a GP IIb/IIIa inhibitor, which can result in bleeding.⁹⁴ Because both eptifibatide and tirofiban require dose reductions for patients with renal insufficiency (see Table 18–4), careful attention to calculating creatinine clearance and dose adjustment is required for these agents. The risk of thrombocytopenia with tirofiban and eptifibatide appears to be lower than that with abciximab. Bleeding risks appear similar among agents.

CLINICAL CONTROVERSIES

A recent noninferiority study comparing early “upstream” administration of a GP IIb/IIIa inhibitor versus delayed selective therapy at the time of PCI in patients with NSTEMI/ACS showed no statistical difference in ischemic events but more bleeding events when a GP IIb/IIIa inhibitor (with either UFH or enoxaparin) was administered prior to angiography.⁹⁵ Ninety-eight percent of patients in the upstream arm received a GP IIb/IIIa inhibitor, but only 56% of patients received one in the selective arm, mostly because no PCI was performed and therefore a GP IIb/IIIa inhibitor was no longer indicated. The median duration of administration of a GP IIb/IIIa inhibitor prior to PCI in the upstream arm was short, only 4 hours, as were the overall median durations of administration in both groups, 18 hours in the upstream arm and 13 hours in the selective arm, indicating that statistical power may not have been sufficient. Because the difference in duration of administration between the two groups was small, some question whether this study was a true comparison of early versus deferred treatment. Therefore, although a GP IIb/IIIa inhibitor may be used in patients with NSTEMI/ACS the timing of administration, whether given early or deferred and used selectively at the time of angiography is controversial.

Anticoagulants

The recommendations for anticoagulants in the 2007 NSTEMI/ACS ACC/AHA guidelines are guided by the results of recent clinical trials.² For patients undergoing planned early angiography and revascularization with PCI, UFH, LMWH, fondaparinux, or bivalirudin should be administered to patients with NSTEMI/ACS.² Because more data support the use of enoxaparin,² it is the preferred LMWH for ACS. Therapy should be continued for up to at least 48 hours for UFH, until the patient is discharged from the hospital for either enoxaparin or fondaparinux or a maximum of 8 days, and until the end of PCI or angiography procedure (or up to 42 hours following PCI) for bivalirudin.² UFH is the preferred anticoagulant following angiography in patients subsequently undergoing CABG during the same hospitalization.² In patients in whom an initial conservative strategy is planned (i.e., are not anticipated to receive angiography and revascularization), enoxaparin, UFH, or fondaparinux is recommended.² For patients presenting with NSTEMI/ACS in whom cardiologists suspect a high risk for bleeding while receiving an anticoagulant, fondaparinux is the preferred anticoagulant recommended by the ACC/AHA NSTEMI/ACS guidelines.² In patients initiating warfarin therapy, UFH or LMWHs should be continued until the international normalized ratio (INR) with warfarin is in the therapeutic range.

Data supporting the addition of UFH to aspirin stems from a meta-analysis of six randomized trials demonstrating a 33% reduction in the risk of death or MI at 6 weeks with UFH plus aspirin compared with aspirin alone.⁹⁶ One trial compared the LMWH dalteparin plus aspirin with aspirin alone and found a 60% reduction in death or MI at 6 days.⁹⁷ Three clinical trials have compared UFH with LMWHs for medical management of NSTEMI/ACS.^{98–100} Two trials with a total of approximately 7,000 patients demonstrated a 15% reduction in the composite end point of death, MI, or recurrent ischemia with enoxaparin compared with UFH.^{98,99} One trial of dalteparin in approximately 1,400 patients demonstrated similar outcomes between dalteparin and UFH.¹⁰⁰ The results from these trials also showed no increased risk of major bleeding with LMWHs compared with UFH.^{98–100} Minor bleeding, mostly injection-site hematomas, was increased because the LMWHs are given by subcutaneous injection, whereas UFH was administered by continuous infusion.^{98–100} Because of a reduction in event rates compared with UFH, enoxaparin was mentioned as “preferred” over UFH in the ACC/AHA clinical practice guidelines.²

Previously, lack of data with LMWHs in NSTEMI ACS patients undergoing PCI has limited their use in this setting. Traditionally, interventional cardiologists monitor the degree of anticoagulation of UFH using the activated clotting time (ACT) in the cardiac catheterization laboratory. Because LMWHs have only a small effect on increasing the ACT owing to their preferential effect on activated factor X inhibition, the ACT cannot be used to monitor LMWH efficacy or toxicity. One large clinical trial of enoxaparin compared with UFH in this setting found similar efficacy with a higher risk of major bleeding with enoxaparin (9.1% vs 7.6%; $P = 0.008$).¹⁰¹ The authors concluded that use of enoxaparin resulted in a similar reduction in death or MI compared to UFH. This trial was confounded by a large number of patients who received both UFH and enoxaparin either prior to randomization or during PCI. A subgroup analysis of patients receiving only consistent therapy with either enoxaparin or UFH throughout the study demonstrated an 18% reduction in 30-day death or MI with enoxaparin ($P = 0.004$), but still with an increased risk of bleeding with enoxaparin compared to UFH.¹⁰² Switching between UFH and enoxaparin should be avoided.

The risk of major bleeding with UFH or LMWHs is higher in patients undergoing angiography because of an associated risk of hematoma at the femoral access site. The risk of heparin-induced thrombocytopenia is lower in some, but not all, clinical trials with LMWHs compared with UFH.

Because LMWHs are eliminated renally and patients with renal insufficiency generally are excluded from clinical trials, some practice protocols recommend UFH for patients with creatinine clearance rates less than 30 mL/min. (Creatinine clearance is calculated based on total patient body weight.) However, although recommendations for dosing adjustment of enoxaparin in patients with creatinine clearances between 10 and 30 mL/min are listed in the product manufacturer's label, the safety and efficacy of LMWH in this patient population remain vastly understudied (see Table 18–4). Administration of LMWHs should be avoided in dialysis patients with ACS. UFH is monitored and the dose adjusted to a target aPTT, whereas LMWHs are administered by a fixed, weight-based dose. Other dosing information and contraindications are listed in Table 18–4.

In OASIS-5, the largest NSTEMI ACS trial performed to date ($N = 20,078$), a low dose of fondaparinux, 2.5 mg administered once daily subcutaneously, was compared to the usual NSTEMI ACS dose of enoxaparin, 1 mg/kg administered every 12 hours.¹⁰³ Fondaparinux was found to be noninferior to enoxaparin with respect to the clinical end point of 9-day death, MI, or refractory ischemia (5.8% vs 5.7%, hazard ratio 1.01, 95% confidence interval 0.90–1.13). Fondaparinux also reduced the rate of major bleeding compared to enoxaparin (2.2% vs 4.1%, $P < 0.001$). At 30 days, mortality was lower in fondaparinux-treated patients (8.0 vs 8.6%, hazard ratio 0.83, 95% confidence interval 0.71–0.97), and the investigators suggested that the excess mortality observed in enoxaparin-treated patients was related to bleeding events. The major limitation of OASIS-5 is that only 30% of patients underwent PCI. In addition, the duration of study drug administration (median ≈ 5 days) was longer than usual in the United States, which may have increased bleeding events. Supplemental doses of UFH were administered to patients randomized to enoxaparin who underwent PCI. For patients randomized to fondaparinux who underwent PCI, the protocol was changed. The original protocol specified that IV fondaparinux be administered to patients undergoing PCI. When this practice was associated with catheter thrombosis, the protocol was changed to recommend administration of supplemental UFH (see Table 18–4 for recommendations) to fondaparinux-treated patients undergoing PCI. As a result, interventional cardiologists may be reluctant to use low-dose fondaparinux in patients undergoing PCI.

Bivalirudin is an IV direct thrombin inhibitor that has been compared to the combination of a heparin, either UFH or enoxaparin,

with a GP IIb/IIIa inhibitor in patients with NSTEMI ACS. Potential advantages of direct thrombin inhibitors over UFH are that they bind to and inhibit clot-bound thrombin in addition to circulating thrombin, and they have no significant binding to plasma proteins so they have a more predictable anticoagulant response. In addition, because thrombin is a potent stimulus for platelet aggregation, direct thrombin inhibitors have antiplatelet as well as anticoagulant activity. Like lepirudin, bivalirudin exhibits bivalent binding to thrombin, that is, it binds to both the active site and exosite-1, although argatroban binds to only to the active site. Unlike lepirudin, both argatroban and bivalirudin exhibit reversible binding to thrombin, whereas lepirudin binds irreversibly. After bivalirudin binds to thrombin, thrombin cleaves a bivalirudin Arg3–Pro4 bond, reexposing the thrombin catalytic site.¹⁰⁴ Thus, bivalirudin provides consistent anticoagulation when administered as an IV bolus and infusion, but its activity is short lived when the drug is discontinued. These potential advantages suggest that bivalirudin may have similar or superior efficacy and fewer bleeding complications compared to traditional anticoagulants.

In the Acute Catheterization and Urgent Intervention Triage Strategy (ACUITY) trial, 13,819 patients with NSTEMI ACS at moderate to high risk of death or MI (expected to undergo coronary angiography within the first 48–72 hours of hospital admission) were randomized to one of three antithrombotic treatment strategies: (1) heparin (UFH or enoxaparin) plus a GP IIb/IIIa inhibitor, (2) bivalirudin plus GP IIb/IIIa inhibitor, or (3) bivalirudin alone in a noninferiority trial (see Table 18–4 for dosing).¹⁰⁴ The primary end point was “net clinical outcome” at 30 days, which was a quadruple end point consisting of the composite ischemic end point (death, MI, or unplanned revascularization for ischemia) plus non-CABG major bleeding. The results of the quadruple end point were that bivalirudin alone was noninferior to bivalirudin plus a GP IIb/IIIa inhibitor and superior to heparin plus a GP IIb/IIIa inhibitor. The benefit of bivalirudin alone was that it reduced the rate of major bleeding by 47% compared to heparin plus a GP IIb/IIIa receptor inhibitor. Although numerically higher in the bivalirudin group, the ischemic end points were not statistically different between the groups.¹⁰⁵

With similar efficacy and a lower bleeding rate, on the surface bivalirudin alone appears the preferred therapy. However, several issues surround the study design and application to practice. The main issue surrounds the noninferiority margin of 25% used in the trial. This means that bivalirudin could be 25% “worse” than heparin plus GP IIb/IIIa inhibitor treatment and still be called “noninferior.” In fact, the upper boundary of the 95% confidence interval for the ischemic composite end point comparing bivalirudin alone with heparin plus a GP IIb/IIIa inhibitor was 1.24.¹⁰⁵ Other contemporary NSTEMI ACS trials, such as SYNERGY (Superior Yield of the New Strategy of Enoxaparin, Revascularization, and Glycoprotein Inhibitors), have used lower margins. More than 60% of patients received on average more than 14 hours of prerandomized treatment prior to study enrollment and were “crossed over” to study medications.¹⁰⁵ Study medications were administered for a median duration of less than 6 hours before coronary angiography and PCI, and the overall duration of study drug administration was less than 18 hours because most study drugs were discontinued after angiography.¹⁰⁵ Therefore, although patients were randomized, there was potential for the prerandomization therapy to impact study outcomes. Some have questioned whether the short duration of treatment was long enough to impact outcomes. Therefore, although bivalirudin is a choice for higher-risk patients anticipated to undergo angiography and PCI, it was not given a “preferred” recommendation in the 2007 NSTEMI ACS guidelines.

Because a variety of anticoagulants are recommended by the guidelines, practitioners should be familiar with the study designs, patient demographics, and results for recent NSTEMI ACS studies and develop protocols for dosing each agent that is on the hospital formulary.

Nitrates

In patients with ischemic chest discomfort, SL NTG 0.4 mg every 5 minutes for a total of three doses should be administered. IV NTG should be administered to all patients with NSTEMI ACS who have persistent ischemia, heart failure symptoms, or hypertension in the absence of contraindications (see Table 18–4).² The mechanism of action, dosing, contraindications, and adverse effects are the same as described in the section on Early Pharmacotherapy for STE ACS above. IV NTG typically is continued for approximately 24 hours following ischemia relief. The mechanism of action, dosing, contraindications, and adverse effects are the same as described in the section on Early Pharmacotherapy for STE ACS above.

β -Blockers

Oral β -blockers should be administered to all patients with NSTEMI ACS in the absence of contraindications.² IV β -blockers should be considered in hemodynamically stable patients who present with persistent ischemia, hypertension, or tachycardia. The mechanism of action, dosing, contraindications, and adverse effects are the same as described in the section on Early Pharmacotherapy for STE ACS above. β -Blockers are continued indefinitely.

Calcium Channel Blockers

Calcium channel blockers should not be administered to most patients with ACS.² Their role is a second-line treatment for patients with certain contraindications to β -blockers (as described in Table 18–4) and those with continued ischemia despite β -blocker and nitrate therapy. They are a first-line therapy for patients with Prinzmetal vasospastic angina and those with cocaine-associated ACS. Administration of amlodipine, diltiazem, or verapamil is preferred.² Agent selection based on heart rate and LV dysfunction (diltiazem and verapamil contraindicated in patients with bradycardia, heart block, or systolic heart failure) is described in more detail in the section on Early Pharmacotherapy for STE ACS above. Dosing and contraindications are described in Table 18–4.

Glycemic Control

Numerous guidelines and standards address the management of diabetes mellitus in the outpatient setting, but only recently has sufficient evidence warranted the development of standards of care to optimize inpatient glycemic control for hospitalized individuals with diabetes or illness-induced hyperglycemia. A joint practice guideline from the American Diabetes Association and the American College of Endocrinology recommends that the blood glucose level in critically ill patients, such as those with ACS, be kept as close as possible to 110 mg/dL (6.1 mmol/L).¹⁰⁶ This is supported by the 2004 ACC/AHA STEMI guidelines that recommend normalization of blood glucose during the first 24 to 48 hours of care.³ Elevated blood glucose levels are associated with higher mortality rates and larger infarct size in patients with acute MI.¹⁰⁶ Beneficial outcomes associated with “tight” glucose control include reductions in the development of renal dysfunction, infections, and length of mechanical ventilation.^{3,106} A meta-analysis of 35 clinical trials found a 15% reduction in mortality.¹⁰⁷ IV insulin infusions are commonly administered to critically ill patients hospitalized in the intensive care unit to maintain euglycemia.³ Additional information on management of hyperglycemia in the hospitalized patient can be found in Chapter 77.

■ SECONDARY PREVENTION FOLLOWING MI

The long-term goals following MI are as follow:

1. Control modifiable CHD risk factors
2. Prevent development of systolic heart failure

3. Prevent recurrent MI and stroke
4. Prevent death, including sudden cardiac death

9 Pharmacotherapy that has been proven to decrease mortality, heart failure, reinfarction, or stroke should be initiated prior to hospital discharge for secondary prevention. Guidelines from the ACC/AHA suggest that following MI from either STE or NSTEMI ACS, patients should receive indefinite treatment with aspirin, a β -blocker, and an ACE inhibitor.^{2,3,108} All patients should receive SL NTG or lingual spray and instructions for use in case of recurrent ischemic chest discomfort.² Clopidogrel should be considered for most patients, but the duration of therapy is individualized according to the type of ACS and whether the patient is treated medically or undergoes intracoronary stent implantation.² All patients should receive annual influenza vaccination.^{108,109} Selected patients (described below in Anticoagulation) also should be treated with long-term warfarin anticoagulation. Newer therapies include eplerenone, an aldosterone antagonist for heart failure. For all ACS patients, treatment and control of modifiable risk factors, such as hypertension, dyslipidemia, and diabetes mellitus, are essential. Most patients with CHD will require drug therapy for dyslipidemia, usually with a statin (hydroxymethylglutaryl coenzyme A reductase inhibitor). Benefits and adverse effects of long-term treatment with these medications are discussed in more detail below.

Aspirin

Aspirin decreases the risk of death, recurrent MI, and stroke following MI. An aspirin prescription at hospital discharge is a quality care indicator in MI patients (see Table 18–3).³³ The clinical value of aspirin in secondary prevention of ACS and other vascular diseases was demonstrated in a large number of clinical trials. Following an MI, aspirin is expected to prevent 36 vascular events per 1,000 patients treated for 2 years.⁴⁶ Because the benefit of antiplatelet agents appears to be sustained for at least 2 years following an MI,⁴⁹ aspirin should be given indefinitely to all patients, or clopidogrel to patients with a contraindication to aspirin.^{2,3}

The risk of major bleeding from chronic aspirin therapy is approximately 2% and is dose related. Although high doses of aspirin (>325 mg daily) are well established to have a higher risk of bleeding compared to lower doses, whether dose of 75 to 100 mg daily have a lower bleeding risk than doses >100 to 325 mg daily remains controversial.^{48,50} After an initial dose of 325 mg, chronic therapy with aspirin should be 75 to 81 mg once daily. The exception is patients in the setting of recent intracoronary stent placement for whom the AHA/ACC recommend 162–325 mg of aspirin once daily for at least 30 days following placement of a bare-metal stent, 3 months after a sirolimus-coated stent, and 6 months after a paclitaxel-coated, followed thereafter by a daily dose of 75 to 162 mg.⁴⁰

In order to minimize the risk of bleeding, use of aspirin with other agents that can induce bleeding, including clopidogrel and warfarin, should be avoided, unless the combination is clinically indicated and the increased risk of bleeding has been considered in evaluating the potential benefit of using such a combination.

Other gastrointestinal disturbances, including dyspepsia and nausea, are infrequent when low-dose aspirin is used.⁴⁶

Thienopyridines

For patients with NSTEMI ACS, clopidogrel decreases the risk of developing death, MI, or stroke. The benefit derives primarily from reducing the rate of MI.⁷⁹ Most patients with NSTEMI ACS should receive clopidogrel, in addition to aspirin, for up to 12 months.^{2,108} For patients with an STEMI treated medically without revascularization including PCI or CABG, clopidogrel can be given for 14 to 28 days.^{53,54} In patients in whom an intracoronary stent has been implanted, clopidogrel can be continued for up to 12 months in patients at low

risk for bleeding, with a minimum duration of treatment contingent upon the type of stent placed.^{2,48}

The most common adverse effects in patients receiving clopidogrel are rash (5%) and gastrointestinal upset (3%).⁷⁹

Anticoagulation

Warfarin should be considered in selected patients following an ACS, including patients with an LV thrombus, patients demonstrating extensive ventricular wall-motion abnormalities on cardiac echocardiogram, and patients with a history of thromboembolic disease or chronic atrial fibrillation.³ A more detailed discussion regarding the use of warfarin is given in Chapter 21.

Because of the importance of thrombus formation in the pathophysiology of ACS and the findings from several studies suggesting residual thrombus at the site of plaque rupture even months following an MI, anticoagulants, primarily warfarin, have been the subject of many clinical trials of patients after an ACS. These trials have produced varying and inconsistent results. Because the intensity of anticoagulation varied among these trials, it is important to take into consideration the intensity of the anticoagulation when interpreting the results of these trials.

Data from two large, randomized trials demonstrate that use of low, fixed-dose warfarin (mean INR 1.4) combined with aspirin¹¹⁰ or of low-intensity anticoagulation (mean INR 1.8) monotherapy¹¹¹ provided no significant clinical benefit compared with aspirin monotherapy but significantly increased the risk of major bleeding. Therefore, warfarin therapy targeted to INR <2 cannot be recommended for secondary prevention of CHD events following MI.

Subsequently, in two other large, randomized trials, a strategy of combining intermediate-intensity anticoagulation (target INR 2–2.5) with low-dose aspirin reduced the combined end point of death, MI, or stroke in patients following MI compared with aspirin alone. The Antithrombotics in Secondary Prevention of Events in Coronary Thrombosis-2 (ASPECT-2)¹¹² and the Warfarin-Aspirin Re-Infarction Study (WARIS II)¹¹³ reported that warfarin alone targeted to a high-intensity INR and medium-intensity warfarin plus low-dose aspirin were superior to aspirin alone in preventing the combined end point of death, MI, or stroke. The target INR in the high-intensity warfarin monotherapy group was 3 to 4¹¹¹ and 2.8 to 4.2,¹¹³ respectively. The target INR in the more effective medium-intensity warfarin and low-dose aspirin group was 2 to 2.5 in both trials. No significant differences in efficacy were observed between the combination of medium-intensity anticoagulation and low-dose aspirin and monotherapy with high-intensity anticoagulation. A meta-analysis of 14 clinical trials in more than 25,000 patients following either STE or NSTEMI found that the addition of warfarin (target INR of 2 to 3) to aspirin reduced the risk of death, MI or stroke, whereas the addition of warfarin with a target INR outside this target was of no benefit.¹¹⁴ Nonetheless, this benefit was obtained at the cost of doubling the risk of major bleeding.¹¹⁴

Many consider this net benefit to be small in comparison with the large management issues related to warfarin therapy, such as INR monitoring and drug interactions. In the meta-analysis described above,¹¹⁴ the NNT to prevent one event was 33, whereas the number needed to harm (NNH) was 100. In addition, WARIS II and ASPECT-2 were conducted in the Netherlands and in Norway, two countries renowned for the quality of their anticoagulation programs and clinics, thereby limiting generalization of the findings. Furthermore, a large proportion of ACS patients in North America undergo coronary revascularization with subsequent intracoronary stent implementation for which patients require a combination of aspirin and clopidogrel to prevent stent thrombosis, a platelet-dependent phenomenon that warfarin does not effectively prevent.¹¹⁵ Therefore, because of the complexity of managing current anticoagulants, use of warfarin is unlikely to gain wide acceptance (see Clinical Controversies). Despite the superiority of warfarin plus aspirin over aspirin alone, warfarin

currently is not recommended as a preferred regimen by any professional association practice guidelines in the absence of the conditions for selected patients outlined previously.

CLINICAL CONTROVERSIES

No prospective, randomized trials have evaluated whether the addition of warfarin to aspirin plus clopidogrel therapy is safe or effective. However, the combination is used in select patients in practice. Clinical situations in which aspirin, clopidogrel, and warfarin can be used together include placement of an intracoronary stent (where aspirin and clopidogrel are indicated) in patients with an indication for anticoagulant therapy including atrial fibrillation, acute deep vein thrombosis, presence of a mechanical heart valve, and MI with a low EF. In such cases, the duration of use of this triple antithrombotic drug combination should be minimized and the INR monitored closely. The most recent guidelines from the ACC/AHA recommend a lower target INR of 2.0 to 2.5 in patients receiving this combination, but no prospective randomized trials have been reported.²

β -Blockers, Nitrates, and Calcium Channel Blockers

Current treatment guidelines recommend that, following an ACS, patients should receive a β -blocker indefinitely,^{2,3,107} whether or not they have residual symptoms of angina.¹¹⁶ β -Blocker prescription at hospital discharge in the absence of contraindications is a quality performance measure (see Table 18–3).³³ Overwhelming data support the use of β -blockers in patients with a previous MI. Data from a systematic review of long-term trials of patients with recent MI demonstrate that the NNT for 1 year with a β -blocker to prevent one death is only 84 patients.¹¹⁶ Because the benefit from β -blockers appears to be maintained for at least 6 years following an MI,¹¹⁷ it is recommended that all patients receive β -blockers indefinitely in the absence of contraindications or intolerance.^{2,3} Currently, no data support the superiority of one β -blocker over another. Although β -blockers with intrinsic sympathomimetic activity are generally not recommended, one study of modest size showed that acebutolol, a β -blocker with intrinsic sympathomimetic activity, was beneficial following MI.¹¹⁸

Although β -blockers should be avoided in patients with decompensated heart failure from LV systolic dysfunction complicating an MI, clinical trial data suggest that initiation of β -blockers prior to hospital discharge is safe in these patients once heart failure symptoms have resolved.¹¹⁹ These patients actually may benefit more than those without LV dysfunction.¹²⁰

Despite the overwhelming benefit demonstrated in clinical trials, β -blockers are still widely underused, perhaps because clinicians fear that patients will experience adverse reactions, including depression, fatigue, and sexual dysfunction. A systematic review of 15 trials that included more than 35,000 patients demonstrated that withholding β -blocker therapy in such a group was unfounded because β -blockers do not significantly increase the risk of depression and only modestly increase the risk of fatigue and sexual dysfunction.¹²¹

In patients who cannot tolerate or have a contraindication to a β -blocker, a calcium channel blocker can be used to prevent anginal symptoms but should not be used routinely in the absence of such symptoms.^{2,3,122} Finally, all patients should be prescribed short-acting SL NTG or lingual NTG spray to relieve any anginal symptoms when necessary and should be instructed on its use.^{2,3} Chronic long-acting nitrate therapy has not been shown to reduce CHD events following MI. Therefore, IV NTG is not followed routinely by chronic, long-acting oral nitrate therapy in ACS patients who have undergone revascularization unless they have chronic stable angina or significant coronary stenoses that were not revascularized.¹²²

ACE Inhibitors and Angiotensin Receptor Blockers

ACE inhibitors should be initiated in all patients following MI to reduce mortality, decrease reinfarction, and prevent development of heart failure.^{2,3,108} Dosing and contraindications are described in Table 18–4. The benefit of ACE inhibitors in patients with MI most likely derives from their ability to prevent cardiac remodeling. Other proposed mechanisms include improvement in endothelial function, reduction in atrial and ventricular arrhythmias, and promotion of angiogenesis, leading to a reduction in ischemic events. The largest reduction in mortality is observed for patients with LV dysfunction (low LVEF) or heart failure symptoms. Use of ACE inhibitors in relatively unselected patients without a contraindication to ACE inhibitors can be expected to save five lives per 1,000 patients treated for 30 days.¹²³ Long-term studies in patients with LV systolic dysfunction with or without heart failure symptoms demonstrate greater benefit because mortality reductions are larger (23.4% vs 29.1%; $P < 0.0001$) such that only 17 patients need treatment to prevent one death, with 57 lives saved for every 1,000 patients treated.¹²⁴ ACE inhibitor prescription at hospital discharge following MI, in the absence of contraindications, to patients with depressed LV function (EF <40%) currently is a quality care indicator, and plans are being made to make administration of an ACE inhibitor in all patients without contraindications a quality care indicator (see Table 18–3).³³

Early initiation (within 24 hours) of an *oral* ACE inhibitor appears to be crucial during an acute MI because 40% of the 30-day survival benefit is observed during the first day, 45% from days 2 to 7, and approximately only 15% from days 8 to 30.¹²³ However, current data do not support the early administration of *IV* ACE inhibitors in patients experiencing an MI because mortality may be increased.¹²⁵ Hypotension should be avoided because coronary artery filling may be compromised. Because the benefits of ACE inhibitor administration have been documented for up to 12 years following therapy for 2 to 4 years post-MI in patients with LV dysfunction,^{124,126} administration should continue indefinitely.

Additional data suggest that most patients with CAD, not just ACS or heart failure, benefit from an ACE inhibitor. In the Heart Outcome Prevention Evaluation (HOPE) trial, ramipril significantly reduced the risk of death, MI, or stroke in high-risk patients aged 55 years or older with chronic CAD or with diabetes and one cardiovascular risk factor.¹²⁷ The European Trial on Reduction of Cardiac Events with Perindopril in Stable Coronary Artery Disease (EUROPA) extended the benefit of chronic therapy with ACE inhibitors, in this case perindopril, to patients with stable CAD at moderate risk for cardiovascular events.¹²⁸ However, a trial of low-risk patients with stable CAD and normal LV function has suggested that the benefit of ACE inhibitors may not extend to these populations.¹²⁹ Importantly, in this trial, patients were treated more aggressively with both medical therapy and revascularization than in HOPE and EUROPA, and risk factors were more optimally managed. Recent AHA/ACC guidelines on secondary prevention of coronary and other vascular diseases have highlighted that although an ACE inhibitor should be started and continued indefinitely in all patients with LVEF $\leq 40\%$ and in those with hypertension, diabetes, or chronic kidney disease, unless contraindicated, and that these agents should be considered for all other patients, use of ACE inhibitors may be considered optional in low-risk patients with normal LVEF in whom cardiovascular risk factors are well controlled and revascularization has been performed.¹⁰⁸ Therefore, although all patients with an ACS initially should be treated with an ACE inhibitor, it may be appropriate to reevaluate their long-term use in selected low-risk individuals who may want to limit the number of medications they receive.

Many patients cannot tolerate chronic ACE inhibitor therapy secondary to adverse effects outlined in the next paragraph. However, trials have documented that the angiotensin receptor blockers

(ARBs) candesartan and valsartan improve clinical outcomes in patients with heart failure.^{130,131} Therefore, either an ACE inhibitor or candesartan or valsartan is an acceptable choice for chronic therapy for patients with a low EF and heart failure following MI. Because more than five different ACE inhibitors have proven benefits in MI but only two ARBs have been studied, the benefits of ACE inhibitors are generally considered a class effect while the benefits of ARBs are still under study. ACE inhibitor prescription (or alternatively an ARB) at hospital discharge following MI, in the absence of contraindications, to patients with depressed LV function (EF <40%) currently is a quality performance measure,³³ and plans are being made to make administration of an ACE inhibitor in all patients without contraindications a quality care measure.

Besides hypotension, the most frequent adverse reaction to an ACE inhibitor is cough, which may occur in up to 30% of patients. Patients with ACE inhibitor cough and either clinical signs of heart failure or LVEF <40% can be prescribed an ARB.³ Other less common but more serious adverse effects of ACE inhibitors and ARBs include acute renal failure and hyperkalemia. Although the incidence of angioedema appears higher in patients receiving ACE inhibitors (0.1%–1.0% with ACE inhibitor), ARBs also have been associated with angioedema, including recurrent angioedema in patients with a history of angioedema while receiving an ACE inhibitor.¹³² Therefore, although ARBs are not contraindicated, the severity of angioedema while receiving an ACE inhibitor (e.g., tongue or laryngeal edema necessitating intubation and mechanical ventilation) should be considered before starting an ARB in a patient with prior ACE inhibitor-associated angioedema.

Although some data have suggested that aspirin use may decrease the benefits of ACE inhibitor treatment, a systematic review of more than 20,000 patients demonstrated that ACE inhibitors improve outcome irrespective of treatment with aspirin.¹³³

Aldosterone Antagonists

Administration of an aldosterone antagonist, either eplerenone or spironolactone, should be considered within the first 2 weeks following MI in all patients already receiving an ACE inhibitor who have EF $\leq 40\%$ and either heart failure symptoms or a diagnosis of diabetes mellitus to reduce mortality.^{3,108} Aldosterone plays an important role in heart failure and MI because it promotes vascular and myocardial fibrosis, endothelial dysfunction, hypertension, LV hypertrophy, sodium retention, potassium and magnesium loss, and arrhythmias. Experimental and human studies have shown that aldosterone blockers attenuate these adverse effects.¹³⁴ As discussed in Chapter 16, the benefit of aldosterone blockade in patients with stable, severe heart failure was highlighted in the Randomized Aldactone Evaluation Study (RALES), in which spironolactone decreased the risk of all-cause mortality.¹³⁵

Eplerenone, like spironolactone, is an aldosterone blocker that blocks the mineralocorticoid receptor. In contrast to spironolactone, eplerenone has no effect on the progesterone or androgen receptor, thereby minimizing the risk of gynecomastia, sexual dysfunction, and menstrual irregularities.¹³⁴ The Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS) evaluated the effect of aldosterone antagonism in patients with an MI complicated by heart failure or LV dysfunction. Patients ($n = 6,642$) were randomized 3 to 14 days following the MI to eplerenone or placebo.¹³⁶ Eplerenone significantly reduced the risk of mortality (14.4% vs 16.7%; $P = 0.008$). Data from EPHESUS suggest that eplerenone reduced mortality from sudden death, heart failure, and MI. Eplerenone also reduced the risk of hospitalizations for heart failure. Most patients in EPHESUS also were being treated with aspirin, a β -blocker, and an ACE inhibitor. Approximately half the patients were also receiving a statin. Therefore, the mortality reduc-

tion observed was in addition to that resulting from standard therapy for secondary CHD prevention. These benefits were obtained at the expense of an increased risk of severe hyperkalemia (5.5% vs 3.9%; $P = 0.002$), defined as a potassium concentration ≥ 6 mEq/L. Patients with serum creatinine concentration >2.5 mg/dL or serum potassium concentration >5 mEq/L at baseline were excluded. The risk of hyperkalemia was particularly alarming in patients with creatinine clearance <50 mL/min. This highlights the importance of close monitoring of potassium levels and renal function in patients being treated with eplerenone. No increase in gynecomastia, breast pain, or impotence was noted.

The results from EPHESUS have raised the question of which aldosterone blocker, spironolactone or eplerenone, should be used preferentially. Currently, no data support that the more selective but more expensive eplerenone is superior to, or should be preferred to, the less expensive generic spironolactone unless a patient has experienced gynecomastia, breast pain, or impotence while receiving spironolactone. Finally, it should be noted that hyperkalemia is just as likely to appear with both these agents.

Lipid-Lowering Agents

Overwhelming data now support the benefits of statins in patients with CAD for the prevention of total mortality, cardiovascular mortality, and stroke. According to the National Cholesterol Education Program (NCEP) Adult Treatment Panel recommendations, all patients with CAD should receive dietary counseling and pharmacologic therapy in order to reach a low-density lipoprotein (LDL) cholesterol concentration <100 mg/dL, with statins the preferred agents for lowering LDL cholesterol.^{108,137,138} Although the primary effect of statins is to decrease LDL cholesterol, statins are believed to produce many non-lipid-lowering or “pleiotropic” effects. These effects, which include improvement in endothelial dysfunction, antiinflammatory and antithrombotic properties, and decreased matrix metalloproteinase activity, may be relevant in patients experiencing an ACS and result in short-term (<1 year) benefit. In a meta-analysis of randomized, controlled clinical trials of almost 18,000 patients with recent ACS (<14 days), statin therapy reduced mortality by 19%, with benefits observed after approximately 4 months of treatment.¹³⁹

Newer recommendations from the NCEP give an optional goal of LDL cholesterol <70 mg/dL for secondary prevention.^{2,138} This recommendation is based upon a large clinical trial evaluating recurrence of major cardiovascular events in patients with a history of an ACS occurring within the past 10 days. This trial documented the benefit of lowering LDL cholesterol to, on average, 62 mg/dL, with 80 mg of atorvastatin compared to 95 mg/dL in patients treated with pravastatin 40 mg daily.¹⁴⁰ Whether a statin should be used routinely in all patients irrespective of their baseline LDL cholesterol level is currently being investigated, but preliminary data from the Heart Protection Study suggest that patients benefit from statin therapy irrespective of their baseline LDL cholesterol level.¹⁴¹ The 2007 ACC/AHA NSTE ACS guidelines recommend statin therapy, in addition to diet, for all ACS patients, regardless of LDL cholesterol level, although the exact target LDL, if the patient’s LDL cholesterol at hospital presentation is already <70 mg/dL is not stated.²

A fibrate or niacin should be considered in selective patients with a low high-density lipoprotein (HDL) cholesterol concentration (<40 mg/dL) and/or a high triglyceride level (>200 mg/dL).^{2,108,137} In a large, randomized trial of men with established CAD and low levels of HDL cholesterol, use of gemfibrozil (600 mg twice daily) significantly decreased the risk of nonfatal MI or death from coronary causes.¹⁴² No such benefit was observed with fenofibrate in a large multicenter primary and secondary prevention study in patients with diabetes mellitus.¹⁴³ Due to the increased risk of myopathy, gemfibrozil is not recommended in patients receiving a statin.¹⁴⁴

Additional discussion, dosing, monitoring, and adverse effects of using lipid-lowering drugs for secondary prevention can be found in Chapter 23.

Fish Oils (Marine-Derived ω -3 Fatty Acids)

Eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) are ω -3 polyunsaturated fatty acids that are most abundant in fatty fish such as sardines, salmon, and mackerel. Epidemiologic and randomized trials have demonstrated that a diet high in EPA plus DHA or supplementation with these fish oils reduces the risk of cardiovascular mortality, reinfarction, and stroke in patients who have experienced an MI.¹⁴⁵ Although the exact mechanism responsible for the beneficial effects of ω -3 fatty acids has not been clearly elucidated, potential mechanisms include triglyceride-lowering effects, antithrombotic effects, retardation in the progression of atherosclerosis, endothelial relaxation, mild antihypertensive effects, and reduction in ventricular arrhythmias.¹⁴⁵

The Gruppo Italiano per lo Studio della Sopravvivenza nell’Infarto (GISSI)-Prevenzione trial, the largest randomized trial of fish oils published to date, evaluated the effects of open-label EPA plus DHA (Lovaza) in 11,324 patients with recent MI who were randomized to receive 850 to 882 mg/day of n -3 polyunsaturated fatty acid (EPA plus DHA) at an EPA/DHA ratio of 1.2:1, 300 mg of vitamin E, both, or neither.^{146,147} Use of EPA plus DHA reduced the risk of death, nonfatal acute MI, or nonfatal stroke, whereas use of vitamin E had no significant impact on this combined clinical end point. Therefore, based on current data, the AHA recommends that CHD patients consume approximately 1 g EPA plus DHA per day, preferably from oily fish.^{108,145} Because oil content in fish varies, the number of 6-oz servings of fish that would need to be consumed to provide 7 g EPA plus DHA per week varies from approximately four to more than 14 for secondary prevention. The average diet only contains one tenth to one fifth the recommended amount.¹⁴⁵ Supplements could be considered in selected patients who do not eat fish, have limited access to fish, or who cannot afford to purchase fish. Approximately three 1-g fish oil capsules per day should be consumed to provide 1 g of ω -3 fatty acids, depending on the brand of supplement.¹⁴⁵ Alternatively, the prescription drug Lovaza can be used at a dose of 1 g/day. Finally, current guidelines suggest that higher doses of EPA plus DHA (2–4 g/day) can be considered for the management of hypertriglyceridemia.^{2,108,145} Adverse effects from fish oils include fishy aftertaste, nausea, and diarrhea.¹⁴⁵

Other Modifiable Risk Factors

Smoking cessation, control of hypertension, weight loss, and tight glucose control for patients with diabetes mellitus, in addition to treatment of dyslipidemia, are important treatments for secondary prevention of CHD events.^{3,108} All patients with CAD should receive annual influenza vaccination.^{108,109} Influenza-related deaths are highest among patients with CVD compared to patients with other medical conditions.¹⁰⁹ Randomized controlled clinical trials have shown that annual influenza vaccination reduces cardiovascular mortality and MI.¹⁰⁹ Smoking cessation is accompanied by a significant reduction in all-cause mortality in patients with CAD.¹⁴⁸ Smoking cessation counseling at the time of discharge following MI is a quality care indicator (see Table 18–3).³³ Use of nicotine patches or gum or of bupropion alone or in combination with nicotine patches should be considered in appropriate patients.³ Following MI, hypertension should be strictly controlled to a target blood pressure $<130/80$ and even lower, and to $<120/80$ in patients with LV dysfunction according to recently published guidelines from AHA.⁵¹ Patients who are overweight should be educated on the importance of regular exercise, healthy eating habits, and of reaching and maintaining an ideal weight.¹⁴⁹ Finally, because diabetics have up to a fourfold increased

risk of mortality compared with nondiabetics, the importance of tight glucose control, as well as other CHD risk factor modification, cannot be understated.¹⁵⁰

Therapies Not Useful and Potentially Harmful following MI

Administration of hormone-replacement therapy to all women following MI does not prevent recurrent CHD events and may be harmful.^{151,152} According to the NSTE and NSTE ACS guidelines, postmenopausal women already taking estrogen plus progestin should not continue, especially while at bedrest in hospital, because of an increased risk of venous thromboembolism.^{2,3} The U.S. Preventative Services Task Force as well as the ACC/AHA have concluded that the administration of vitamins A, C, or E, multivitamins with vitamins B₆, B₁₂, folic acid, or a combination of antioxidants for secondary prevention are ineffective following MI.^{2,146,153–157} Furthermore, they caution against the use of β -carotene supplementation, particularly in heavy smokers, because of an apparent increased risk of lung cancer.¹⁵⁴ A stepped-care approach using acetaminophen, small doses of narcotics, and nonacetylated salicylates are preferable to COX-2-selective NSAIDs for treatment of chronic musculoskeletal pain. Use of the nonselective NSAID naproxen is recommended over more COX-2-selective agents, which have been associated with risks for MI.²

ADHERENCE TO THERAPY

Medication noncompliance poses a problem in patients following ACS. Medication discontinuation has been associated with an increased risk of cardiovascular events and mortality in patients with various types of CVD.^{158–160} In clinical trials, poor adherence is associated with poor outcome, regardless of treatment assignment,¹⁶⁰ highlighting that this behavior may be related with other health-related behaviors in patients. Increased adherence to statins and β -blockers has been associated with lower long-term mortality.¹⁶¹

The discontinuation of clopidogrel may be particularly problematic in patients treated with a drug-eluting stent,¹⁶² because this action places the patient at increased risk for stent thrombosis.⁵⁵ Current data suggest that long-term adherence and persistence to statins in patients with an ACS and in patients with chronic CAD is variable.^{163–166} Early initiation of statins in patients with ACS appears to increase long-term adherence with statin therapy, which should result in clinical benefit.¹³⁹ Therefore, statin therapy initiation should not be delayed in patients with an ACS, and statins should be prescribed at or prior to discharge in most patients.

Several clinical trials have documented the value of a pharmacist in the management of improving adherence and persistence to medication, which in turn can significantly improve the treatment of risk factors such as hypertension, heart failure, and dyslipidemia.^{167,168}

TABLE 18-7 Therapeutic Drug Monitoring for Adverse Effects of Pharmacotherapy for Acute Coronary Syndromes

Drug	Adverse Effects	Monitoring
Aspirin	Dyspepsia, bleeding, gastritis	Clinical signs of bleeding; ^a gastrointestinal upset; baseline CBC and platelet count; CBC platelet count every 6 months
Clopidogrel	Bleeding, TTP (rare), diarrhea, rash	Clinical signs of bleeding; ^a baseline CBC and platelet count; CBC and platelet count every 6 months following hospital discharge
Unfractionated heparin	Bleeding, heparin-induced thrombocytopenia	Clinical signs of bleeding; ^a baseline CBC, platelet count, aPTT and INR; aPTT every 6 hours until target then every 24 hours; daily CBC; platelet count every 2 days (minimum, preferably every day)
Low-molecular-weight heparins (enoxaparin and dalteparin)	Bleeding, heparin-induced thrombocytopenia	Clinical signs of bleeding; ^a baseline CBC, platelet count, SCr, aPTT and INR; daily CBC, platelet count every 2–3 days (minimum, preferably every day); SCr daily
Fondaparinux	Bleeding	Clinical signs of bleeding; ^a baseline CBC, platelet count, INR, SCr, and aPTT; daily CBC and SCr
Bivalirudin	Bleeding	Clinical signs of bleeding; ^a baseline CBC, platelet count, INR, SCr, and aPTT; daily CBC and SCr
Fibrinolytics	Bleeding, especially intracranial hemorrhage	Clinical signs of bleeding; ^a baseline CBC, platelet count, INR, and aPTT; mental status every 2 hours for signs of intracranial hemorrhage; daily CBC
Glycoprotein IIb/IIIa receptor blockers	Bleeding, acute profound thrombocytopenia	Clinical signs of bleeding; ^a baseline CBC and platelet count; daily CBC; platelet count at 4 hours after initiation then daily
Intravenous nitrates	Hypotension, flushing, headache, tachycardia	BP and HR every 2 hours
β -Blockers	Hypotension, bradycardia, heart block, bronchospasm, heart failure, fatigue, depression, sexual dysfunction, nightmares, masking hypoglycemia symptoms in diabetic patients	BP, RR, HR, 12-lead ECG, and clinical signs of heart failure every 5 minutes during bolus intravenous dosing; BP, RR, HR, and clinical signs of heart failure every shift during oral administration during hospitalization, then BP and HR every 6 months following hospital discharge
Diltiazem or verapamil	Hypotension, bradycardia, heart block, heart failure, gingival hyperplasia, constipation	BP and HR and signs of clinical heart failure every shift during oral administration during hospitalization, then every 6 months following hospital discharge; dental examination and teeth cleaning every 6 months
Amlodipine	Hypotension, dependent peripheral edema, gingival hyperplasia	BP every shift during hospitalization, then every 6 months following hospital discharge; dental examination and teeth cleaning every 6 months
Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs)	Hypotension, cough (with ACE inhibitors), hyperkalemia, prerenal azotemia, angioedema (ACE inhibitors >ARBs)	BP every 2 hours \times 3 for first dose, then shift during oral administration during hospitalization, then once every 6 months following hospital discharge; baseline SCr and potassium; daily SCr and potassium while hospitalized, then every 6 months (or 1–2 weeks after each outpatient dose titration); closer monitoring required in selected patients (e.g., those taking spironolactone or eplerenone or with renal insufficiency); counsel patient on throat, tongue, and facial swelling
Aldosterone antagonists	Hypotension, hyperkalemia, prerenal azotemia	BP and HR every shift during oral administration during hospitalization, then once every 6 months; baseline SCr and serum potassium concentration; SCr and potassium at 48 hours, monthly for 3 months then every 3 months thereafter
Statins	Myalgia, myopathy, elevated LFTs, rhabdomyolysis, teratogenic in first trimester	Baseline LFTs, then repeat LFTs at 6 weeks and when patient titrated to target maintenance dose; if LFTs >3 times upper limit of normal, decrease dose or discontinue; if myalgia and/or brown urine, monitor creatine kinase for rhabdomyolysis
Morphine sulfate	Hypotension, respiratory depression	BP and RR 5 minutes after each bolus dose

^aClinical signs of bleeding include bloody stools, melena, hematuria, hematemesis, and bruising and oozing from arterial or venous puncture sites.

aPTT, activated partial thromboplastin time; BP, blood pressure; CBC, complete blood count; ECG, electrocardiogram; HR, heart rate; INR, international normalized ratio; LFT, liver function test; RR, respiratory rate; SCr, serum creatinine; TTP, thrombotic thrombocytopenic purpura.

PHARMACOECONOMIC CONSIDERATIONS

The risks of CHD events, such as death, recurrent MI, and stroke, are higher for patients with established CHD and a history of MI than for patients with no known CHD. Because the costs for chronic preventative pharmacotherapy are the same for primary and secondary prevention while the risk of events is higher with secondary prevention, secondary prevention is more cost effective than primary prevention of CHD.¹⁶⁹ Pharmacotherapy, which has demonstrated cost effectiveness in preventing death in ACS and post-MI patient, includes fibrinolytics (\$2,000–\$33,000 cost per year of life saved),^{169,170} aspirin,¹⁷¹ GP IIb/IIIa receptor blockers (\$13,700–\$16,500 per year of life added),¹⁷² β -blockers (<\$5,000–\$15,000 cost per year of life saved),¹⁷³ ACE inhibitors (\$3,000–\$5,000 cost per year of life saved),^{174,175} eplerenone (\$15,300–\$32,400 per life year gained),¹⁷⁶ statins (\$4,500–\$9,500 per year of life saved),¹⁷⁷ gemfibrozil (\$17,000 per year of life saved),¹⁷⁸ and fish oil.¹⁷⁹ Because cost-effectiveness ratios less than \$50,000 per added life-year are considered economically attractive from a societal perspective,¹⁶⁹ pharmacotherapy for ACS and secondary prevention are standards of care because of their efficacy and cost attractiveness to payors.

EVALUATION OF THERAPEUTIC OUTCOMES

The monitoring parameters for *efficacy* of nonpharmacologic and pharmacotherapy for both STE and NSTEMI ACS are similar:

- Relief of ischemic discomfort
- Return of ECG changes to baseline
- Absence or resolution of heart failure signs

Monitoring parameters for recognition and prevention of *adverse effects* from ACS pharmacotherapy are given in Table 18–7. In general, the most common adverse reactions to ACS therapies are hypotension and bleeding. Treatment for bleeding and hypotension involves discontinuation of the offending agent(s) until symptoms resolve. Severe bleeding resulting in hypotension secondary to hypovolemia may require blood transfusion.

CONCLUSIONS

The AHA and ACC published evidence-based practice guidelines for the treatment of patients with STE and NSTEMI ACS. Mainstays of therapy include risk stratification, primary PCI for STE ACS, and early angiography and revascularization with either PCI or CABG for patients with NSTEMI ACS at high risk for MI and death. Pharmacotherapy for acute treatment includes SL NTG, antiplatelets, anticoagulants, and β -blockers. Insulin infusions can be administered to maintain euglycemia in patients with diabetes mellitus. Pharmacotherapy for secondary prevention of recurrent ACS, MI, and CHD death includes aspirin, clopidogrel, lipid-lowering therapy (statin preferred), β -blockers and either an ACE inhibitor or an ARB. Ensuring selection of evidence-based therapies in all patients without contraindications results in lower mortality. Pharmacists have an important role in encouraging patient adherence and persistence to pharmacotherapy.

In January 2008, the AHA/ACC published an update to the 2004 STE MI guidelines. (Antman EM, Hand M, Armstrong PW, et al. 2007 focused update of the ACC/AHA 2004 guidelines for the management of patients with ST-elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation* 2008 Jan 15;117(2):296–329.) The most significant changes in this guideline compared to the 2004 guidelines are:

1. Emphasis on oral beta-blocker therapy administered within the first 24 hours with monitoring for hemodynamic instability

(hypotension and bradycardia) rather than immediate therapy with intravenous beta-blocker (Class I recommendation).

2. Reinforcement of a short time to reperfusion (Class I recommendations)
 - a. If a patient arrives at a hospital capable of performing primary PCI, the hospital arrival-to-balloon time for PCI should be within 90 minutes.
 - b. If a patient arrives at a hospital that is not capable of performing primary PCI, the door-to-needle time for initiation of fibrinolytic therapy should be within 30 minutes.
 - c. If a patient arrives at a hospital that is not capable of performing primary PCI, the patient can be transferred to a hospital that can perform primary PCI if there is a contraindication to fibrinolysis and PCI can be initiated at the receiving hospital within 90 minutes of arrival at the first hospital or if fibrinolysis was administered but was not successful at opening the coronary artery.
3. A PCI performed after successful fibrinolysis therapy (i.e. facilitated PCI) is associated with excess bleeding, stroke, and mortality risk, and is not recommended (Class III recommendation).
4. Either enoxaparin, UFH, or fondaparinux may be administered in combination with a fibrinolytic agent (Grade I recommendation).
5. For patients undergoing PCI, either UFH, enoxaparin, or fondaparinux in combination with UFH may be administered (Class I recommendations) as fondaparinux alone is associated with PCI-related catheter thrombosis (Class III recommendation).
6. Clopidogrel 75 mg daily (Class I recommendation) should be administered to all patients regardless of whether or not they undergo reperfusion therapy and should be continued for at least 14 days (Class I recommendation) and up to one year (Class IIa recommendation).
7. A loading dose of clopidogrel of 300 mg may be administered as the initial dose (Class IIa recommendation).
8. In patients who do not undergo reperfusion therapy, it is reasonable to administer anticoagulant therapy for the duration of hospitalization, up to 8 days (Class IIa recommendation).
9. In patients requiring warfarin for clinical indications such as atrial fibrillation, atrial flutter, or presence of LV thrombus who also receive clopidogrel and aspirin, it is recommended that the INR be maintained at 2.0 to 2.5 and that a lower dose of aspirin be used, 75 mg to 81 mg (Class I recommendation).
10. Nonselective nonsteroidal antiinflammatory agents (except aspirin) as well as COX-2 selecting antiinflammatory agents should be discontinued at the time of STE MI secondary to increased risk of mortality, reinfarction, heart failure, and myocardial rupture (Class III recommendation).

CYNTHIA A. SANOSKI, MARIEKE DEKKER SCHOEN, AND JERRY L. BAUMAN

KEY CONCEPTS

- 1 The use of antiarrhythmic drugs in the United States has declined because of major trials that show increased mortality with their use in several clinical situations, the realization of proarrhythmia as a significant side effect and the advancing technology of nondrug therapies such as ablation and the implantable cardioverter-defibrillator (ICD).
- 2 Antiarrhythmic drugs frequently cause side effects and are complex in their pharmacokinetic characteristics. The therapeutic range of these agents provide only a rough guide to modifying treatment; it is preferable to attempt to define an individual's effective (or target) concentration and match that during long-term therapy.
- 3 The most commonly prescribed antiarrhythmic drug is now amiodarone. This agent is effective in terminating and preventing a wide variety of symptomatic supraventricular and ventricular tachycardias. However, because this antiarrhythmic drug is plagued by frequent side effects, it requires close monitoring. The most concerning toxicity is pulmonary fibrosis; side-effect profiles of the intravenous (IV) (acute, short-term) and oral (chronic, long-term) forms differ substantially.
- 4 In patients with atrial fibrillation (AF), therapy is traditionally aimed at controlling ventricular response (digoxin, nondihydropyridine calcium channel blockers [CCBs], β -blockers), preventing thromboembolic complications (warfarin, aspirin), and restoring and maintaining sinus rhythm (antiarrhythmic drugs, direct-current cardioversion [DCC]). Studies show there is no need to aggressively pursue strategies to maintain sinus rhythm (i.e., long-term antiarrhythmic drugs); rate control alone (leaving the patient in AF) is often sufficient in patients who can tolerate it. Nonetheless, it is not uncommon for patients to have remaining troublesome symptoms with the rate-control strategy alone, necessitating oral antiarrhythmic drug therapy.
- 5 Paroxysmal supraventricular tachycardia (PSVT) is usually a result of reentry in or proximal to the atrioventricular (AV) node or AV reentry incorporating an extranodal pathway; common tachycardias can be terminated acutely with AV nodal-blocking agents such as adenosine, and recurrences can be prevented by ablation with radiofrequency current.
- 6 Patients with Wolff-Parkinson-White (WPW) Syndrome may have several different tachycardias that are acutely treated by different strategies: orthodromic reentry (adenosine), antidromic reentry (adenosine or procainamide), and AF (procainamide or amiodarone). Atrioventricular nodal-blocking drugs are contraindicated in patients with WPW and AF.
- 7 Because of the results of the Cardiac Arrhythmia Suppression Trial (CAST) and other trials, antiarrhythmic drugs (with the exception of β -blockers) should not be routinely used in patients with prior myocardial infarction (MI) or left ventricular (LV) dysfunction and minor ventricular rhythm disturbances (e.g., premature ventricular complexes [PVCs]).
- 8 Patients with hemodynamically significant ventricular tachycardia (VT) or ventricular fibrillation (VF) not associated with an acute MI who are successfully resuscitated (electrical cardioversion, vasopressors, amiodarone) are at high risk for sudden cardiac death (SCD) and should receive an ICD ("secondary prevention").
- 9 Implantation of an ICD should be considered for the primary prevention of SCD in certain high-risk patient populations. High-risk patients include those with a history of MI and LV dysfunction (regardless of whether they have inducible sustained ventricular arrhythmias), as well as those with New York Heart Association (NYHA) class II or III heart failure (HF) as a result of either ischemic or nonischemic causes.
- 10 Life-threatening ventricular proarrhythmia generally takes two forms: sinusoidal or incessant monomorphic VT (type Ic antiarrhythmic drugs) and torsade de pointes (TdP) (type Ia or III antiarrhythmic drugs and many other noncardiac drugs).

The heart has two basic properties, namely an electrical property and a mechanical property. The synchronous interaction between these two properties is complex, precise, and relatively enduring. The study of the electrical properties of the heart has grown at a steady rate, interrupted by periodic salvos of scientific breakthroughs. Einthoven's pioneering work allowed graphic electrical tracings of cardiac rhythm and probably represents the first of these breakthroughs. This discovery (of the surface electrocardiogram [ECG]) has remained the cornerstone of diagnostic tools for cardiac rhythm disturbances. Since then, intracardiac recordings and programmed cardiac stimulation have advanced our understanding of arrhythmias, and microelectrode, voltage-clamping, and patch-clamping techniques have allowed considerable insight into the electrophysiologic actions and mechanisms of antiarrhythmic drugs. Certainly, the new era of molecular biology and mapping of the human genome promises even greater insights into mechanisms (and potential therapies) of arrhythmias. Noteworthy in this regard is the discovery of genetic abnormalities in the ion channels that control electrical repolarization (heritable long QT syndrome) or depolarization (Brugada syndrome).

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

The clinical use of drug therapy started with the use of digitalis and then quinidine, followed somewhat later by a surge of new agents in the 1980s. A theme of drug discovery during this decade was initially to find orally absorbed lidocaine-congeners (such as mexiletine and tocainide); later, the emphasis was on drugs with extremely potent effects on conduction (i.e., flecainide-like agents). The most recent focus of investigational antiarrhythmic drugs are the potassium channel blockers, with dofetilide being the most recently approved in the United States. Previously, there was some expectation that advances in antiarrhythmic drug discovery would lead to a highly effective and nontoxic agent that would be effective for a majority of patients (i.e., the so-called magic bullet). Instead, significant problems with drug toxicity and proarrhythmia have resulted in a decline in the overall volume of antiarrhythmic drug usage in the United States since 1989. ❶ The other phenomenon, which has significantly contributed to the decline in antiarrhythmic drug usage, is the development of extremely effective nondrug therapies. Technical advances have made it possible to permanently interrupt reentry circuits with radiofrequency ablation, which renders long-term antiarrhythmic drug use unnecessary in certain arrhythmias. Furthermore, the impressive survival data associated with the use of ICDs for the primary and secondary prevention of SCD has led most clinicians to choose “device” therapy as the first-line treatment for patients who are at high-risk for life-threatening ventricular arrhythmias. Both of these nondrug therapies have become increasingly popular for the management of arrhythmias so that the potential proarrhythmic effects and organ toxicities associated with antiarrhythmic drugs can be avoided. What does the future hold for the use of antiarrhythmic drugs? Certainly new knowledge and technologic advances have forced investigators and clinicians to rethink the concept of traditional membrane-active drugs. Although some degree of enthusiasm exists for some of the newer or investigational agents, the overall impact of these drugs has yet to be determined.

This chapter reviews the principles involved in both normal and abnormal cardiac conduction and addresses the pathophysiology and treatment of the more commonly encountered arrhythmias. Certainly, many volumes of complete text could be (and have been) devoted to basic and clinical electrophysiology. Consequently, this chapter briefly addresses those principles necessary for clinicians.

ARRHYTHMOGENESIS

NORMAL CONDUCTION

Electrical activity is initiated by the sinoatrial (SA) node and moves through cardiac tissue by a tree-like conduction network. The SA node initiates cardiac rhythm under normal circumstances because this tissue possesses the highest degree of automaticity or rate of spontaneous impulse generation. The degree of automaticity of the SA node is largely influenced by the autonomic nervous system in that both cholinergic and sympathetic innervations control sinus rate. Most tissues within the conduction system also possess varying degrees of inherent automatic properties. However, the rates of spontaneous impulse generation of these tissues are less than that of the SA node. Thus these latent automatic pacemakers are continuously overdriven by impulses arising from the SA node (primary pacemaker) and do not become clinically apparent.

From the SA node, electrical activity moves in a wave front through an atrial specialized conducting system and eventually gains entrance to the ventricle via the atrioventricular (AV) node and a large bundle of conducting tissue referred to as the bundle of His. Aside from this AV nodal–Hisian pathway, a fibrous AV ring that will not permit electrical stimulation separates the atria and ventricles. The conducting tissues bridging the atria and ventricles

are referred to as the junctional areas. Again, this area of tissue (junction) is largely influenced by autonomic input, and possesses a relatively high degree of inherent automaticity (about 40 beats/min, less than that of the SA node). From the bundle of His, the cardiac conduction system bifurcates into several (usually three) bundle branches: one right bundle and two left bundles. These bundle branches further arborize into a conduction network referred to as the Purkinje system. The conduction system as a whole innervates the mechanical myocardium and serves to initiate excitation–contraction coupling and the contractile process. After a cell or group of cells within the heart is electrically stimulated, a brief period of time follows in which those cells cannot again be excited. This time period is referred to as the refractory period. As the electrical wavefront moves down the conduction system, the impulse eventually encounters tissue refractory to stimulation (recently excited) and subsequently dies out. The SA node subsequently recovers, fires spontaneously, and begins the process again.

Prior to cellular excitation, an electrical gradient exists between the inside and the outside of the cell membrane. At this time the cell is polarized. In atrial and ventricular conducting tissue, the intracellular space is approximately 80 to 90 mV negative with respect to the extracellular environment. The electrical gradient just prior to excitation is referred to as resting membrane potential (RMP) and is the result of differences in ion concentrations between the inside and the outside of the cell. At RMP, the cell is polarized primarily by the action of active membrane ion pumps, the most notable of these being the sodium-potassium pump. For example, this specific pump (in addition to other systems) attempts to maintain the intracellular sodium concentration at 5 to 15 mEq/L and the extracellular sodium concentration at 135 to 142 mEq/L; the intracellular potassium concentration at 135 to 140 mEq/L and the extracellular potassium concentration at 3 to 5 mEq/L. The RMP can be calculated by using the Nernst equation:

$$\text{RMP} = 61.5 \log \left(\frac{[\text{K}^+]_{\text{outside}}}{[\text{K}^+]_{\text{inside}}} \right)$$

Electrical stimulation (or depolarization) of the cell will result in changes in membrane potential over time or a characteristic action potential curve (Fig. 19–1). The action potential curve results from the transmembrane movement of specific ions and is divided into different phases. Phase 0 or initial, rapid depolarization of atrial and ventricular tissues is caused by an abrupt increase in the permeability of the membrane to sodium influx. This rapid depolarization more than equilibrates (overshoots) the electrical potential, resulting in a brief initial repolarization or phase 1. Phase 1 (initial depolarization) is caused by a transient and active potassium efflux (i.e., the I_{Kto} current). Calcium begins to move into the intracellular space at about –60 mV (during phase 0) causing a slower depolarization. Calcium influx continues throughout phase 2 of the action potential (plateau phase) and is balanced to some degree by potassium efflux. Calcium entrance (only through L channels in myocardial tissue) distinguishes cardiac conducting cells from nerve tissue, and provides the critical ionic link to excitation–contraction coupling and the mechanical properties of the heart as a pump (see Chap. 16). The membrane remains permeable to potassium efflux during phase 3, resulting in cellular repolarization. Phase 4 of the action potential is the gradual depolarization of the cell and is related to a constant sodium leak into the intracellular space balanced by a decreasing (over time) efflux of potassium. The slope of phase 4 depolarization determines, in large part, the automatic properties of the cell. As the cell is slowly depolarized during phase 4, an abrupt increase in sodium permeability occurs, allowing the rapid cellular depolarization of phase 0. The juncture of phase 4 and phase 0 where rapid sodium influx is initiated

FIGURE 19-1. Purkinje fiber action potential showing specific ion flux responsible for the change in membrane potential. Ions outside of the line (e.g., sodium) move from the extracellular space to the intracellular space and ions on the inside of the line (e.g., potassium) move from the inside of the cell to the outside. Below the line is the corresponding ventricular excitation and recovery from the surface ECG. One can see that excessive sodium channel block from drugs may lead to QRS prolongation and excessive potassium channel block from drugs may lead to QT prolongation.

is referred to the threshold potential of the cell. The level of threshold potential also regulates the degree of cellular automaticity.

Not all cells in the cardiac conduction system rely on sodium influx for initial depolarization. Some tissues depolarize in response to a slower inward ionic current caused by calcium influx. These “calcium-dependent” tissues are found primarily in the SA and AV nodes (both L and T channels) and possess distinct conduction properties in comparison to “sodium-dependent” fibers. Calcium-dependent cells generally have a less-negative RMP (−40 to −60 mV) and a slower conduction velocity. Furthermore, in calcium-dependent tissues, recovery of excitability outlasts full repolarization, whereas in sodium-dependent tissue, recovery is prompt after repolarization. These two types of electrical fibers also differ dramatically in how drugs modify their conduction properties.

Ion conductance across the lipid bilayer of the cell membrane occurs via the formation of membrane pores or “channels” (Fig. 19-2). Selective ion channels probably form in response to specific electrical potential differences between the inside and the outside of the cell (voltage dependence). The membrane itself is composed of both

organized and disorganized lipids and phospholipids in a dynamic sol-gel matrix. During ion flux and electrical excitation, changes in this sol-gel equilibrium occur and permit the formation of activated ion channels. Besides channel formation and membrane composition, intrachannel proteins or phospholipids, referred to as gates also regulate the transmembrane movement of ions. These gates are thought to be positioned strategically within the channel to modulate ion flow (Fig. 19-2). Each ion channel conceptually has two types of gates: an activation gate and an inactivation gate. The activation gate opens during depolarization to allow the ion current to enter or exit from the cell, and the inactivation gate later closes to stop ion movement. When the cell is in a rested state, the activation gates are closed and the inactivation gates are open. The activation gates then open to allow ion movement through the channel, and the inactivation gates later close to stop ion conductance. Thus, the cell cycles between three states: resting, activated or open, and inactivated or closed. Activation of SA and AV nodal tissue is dependent on a slow depolarizing current through calcium channels and gates, whereas the activation of atrial and ventricular tissue is dependent on a rapid depolarizing current through sodium channels and gates.

ABNORMAL CONDUCTION

The mechanisms of tachyarrhythmias have been classically divided into two general categories: those resulting from an abnormality in impulse generation or “automatic” tachycardias and those resulting from an abnormality in impulse conduction or “reentrant” tachycardias.

Automatic tachycardias depend upon spontaneous impulse generation in latent pacemakers and may be a result of several different mechanisms. Experimentally, chemicals, such as digitalis glycosides or catecholamines, and conditions, such as hypoxemia, electrolyte abnormalities (e.g., hypokalemia), and fiber stretch (cardiac dilation), may lead to an increased slope of phase 4 depolarization in cardiac tissues other than the SA node. These factors, which experimentally lead to abnormal automaticity, are also known to be arrhythmogenic in clinical situations. The increased slope of phase 4 causes heightened automaticity of these tissues and competition with the SA node for dominance of cardiac rhythm. If the rate of spontaneous impulse generation of the abnormally automatic tissue exceeds that of the SA node, then an automatic tachycardia may result. Automatic tachycardias have the following characteristics: (a) the onset of the tachycardia is unrelated to an initiating event

FIGURE 19-2. Lipid bilayer, sodium channel, and possible sites of action of the type I agents (A). Type I antiarrhythmic drugs may theoretically inhibit sodium influx at an extracellular, intramembrane, or intracellular receptor site. However, all approved agents appear to block sodium conductance at a single receptor site by gaining entrance to the interior of the channel from an intracellular route. Active ionized drugs block the channel predominantly during the activated or inactivated state and bind and unbind with specific time constants (described as fast on-off, slow on-off, and intermediate).

such as a premature beat; (b) the initiating beat is usually identical to subsequent beats of the tachycardia; (c) the tachycardia cannot be initiated by programmed cardiac stimulation; (d) the onset of the tachycardia is usually preceded by a gradual acceleration in rate and termination is usually preceded by a gradual deceleration in rate. Clinical tachycardias resulting from the classic forms of enhanced automaticity described above are not as common as once thought. Examples are sinus tachycardia and junctional tachycardia.

Triggered automaticity is also a possible mechanism for abnormal impulse generation. Briefly, triggered automaticity refers to transient membrane depolarizations that occur during repolarization (early after-depolarizations [EADs]) or after repolarization (late after-depolarizations [LADs]) but prior to phase 4 of the action potential. After-depolarizations may be related to abnormal calcium and sodium influx during or just after full cellular repolarization. Experimentally, EADs may be precipitated by hypokalemia, type Ia antiarrhythmic drugs, or slow stimulation rates—any factor that blocks the ion channels (e.g., potassium) responsible for cellular repolarization. Early after-depolarizations provoked by drugs that block potassium conductance and delay repolarization are the underlying cause of TdP. Late after-depolarizations may be precipitated by digitalis or catecholamines and suppressed by CCBs, and have been suggested as the mechanism for multifocal atrial tachycardia, digitalis-induced tachycardias and exercise-provoked VT. Triggered automatic rhythms possess some of the characteristics of automatic tachycardias and some of the characteristics of reentrant tachycardias (described below).

As previously mentioned, the impulse originating from the SA node in an individual with sinus rhythm eventually meets previously excited and thus refractory tissue. Reentry is a concept that involves indefinite propagation of the impulse and continued activation of previously refractory tissue. There are three conduction requirements for the formation of a viable reentrant focus: two pathways for impulse conduction; an area of unidirectional block (prolonged refractoriness) in one of these pathways; and slow conduction in the other pathway (Fig. 19–3). Usually a critically timed premature beat initiates reentry. This premature impulse enters both conduction pathways but encounters refractory tissue in one of the pathways at the area of unidirectional block. The impulse dies out because it is still refractory from the previous (sinus) impulse. Although it fails to propagate in one pathway, the impulse may still proceed in a forward direction (antegrade) through the other pathway because of this pathway's

relatively shorter refractory period. The impulse may then proceed through a loop of tissue and “reenter” the area of unidirectional block in a backward direction (retrograde). Because the antegrade pathway has slow conduction characteristics, the area of unidirectional block has time to recover its excitability. The impulse can proceed retrograde through this (previously refractory) tissue and continue around the loop of tissue in a circular fashion. Thus, the key to the formation of a reentrant focus is crucial conduction discrepancies in the electrophysiologic characteristics of the two pathways. The reentrant focus may excite surrounding tissue at a rate greater than that of the SA node and a clinical tachycardia results. The above model is anatomically determined in that there is only one pathway for impulse conduction with a fixed circuit length. Another model of reentry, referred to as a functional reentrant loop or leading circle model, may also occur (Fig. 19–4).¹ In a functional reentrant focus, the length of the circuit may vary depending on the conduction velocity and recovery characteristics of the impulse. The area in the middle of the loop is continually kept refractory by the inwardly moving impulse. The length of the circuit is not fixed, but is the smallest circle possible, such that the leading edge of the wavefront is continuously exciting tissue just as it recovers; that is, the head of the impulse nearly catches its tail. It differs from the anatomic model in that the leading edge of the impulse is not preceded by an excitable gap of tissue, and it does not have an obstacle in the middle or a fixed anatomic circuit. Clinically, many reentrant foci probably have both anatomic and functional characteristics. In the figure 8 model, a zone of unidirectional block is present; allowing for two impulse loops that join and reenter the area of block in a retrograde fashion to form a pretzel-shaped reentrant circuit. This model combines functional characteristics with an excitable gap. All of these theoretical models require a critical balance of refractoriness and conduction velocity within the circuit and as such have helped to explain the effects of drugs on terminating, modifying, and causing cardiac rhythm disturbances.

What causes reentry to become clinically manifest? Reentrant foci may occur at any level of the conduction system: within the branches of the specialized atrial conduction system, the Purkinje network, and even within portions of the SA and AV nodes. The anatomy of the Purkinje system appears to provide a suitable substrate for the formation of microreentrant loops and is often used as a model to facilitate the understanding of reentry concepts (see Fig. 19–4). Of course, because reentry does not usually occur in normal, healthy conduction tissue, various forms of heart disease or conduction abnormalities must usually be present before reentry becomes manifest. In other words, the various forms of heart disease (e.g., ischemic heart disease, LV dysfunction) can result in changes in conduction in the pathways of a suitable reentrant substrate. An often-used example is reentry occurring as a consequence of ischemic or hypoxic damage: with inadequate cellular oxygen, cardiac tissue resorts to anaerobic glycolysis for adenosine triphosphate production. As high-energy phosphate concentration diminishes, the activity of the transmembrane ion pumps declines and RMP rises. This rise in RMP causes inactivation in the voltage-dependent sodium channel and the tissue begins to assume slow conduction characteristics. If changes in conduction parameters occur in a discordant manner due to varying degrees of ischemia or hypoxia, then a reentry circuit may become manifest. Furthermore, an ischemic, dying cell liberates intracellular potassium, which also causes a rise in RMP. In other cases, reentry may occur as a consequence of anatomic or functional variants in the normal conduction system. For instance, patients may possess two (instead of one) conduction pathways near or within the AV node, or have an anomalous extranodal AV pathway that possesses different electrophysiologic characteristics from the normal AV nodal pathway. Reentry in these cases may occur within the AV node or encompass both atrial and ventricular tissue. Reentrant tachycardias have the following characteristics: (a) the onset of the tachycardia is

FIGURE 19-3. Conduction system of the heart. The magnified portion shows a bifurcation of a Purkinje fiber traditionally explained as the etiology of reentrant ventricular tachycardia. A premature impulse travels to the fiber, damaged by heart disease or ischemia. It encounters a zone of prolonged refractoriness (area of unidirectional block; *cross-hatched area*) but fails to propagate because it remains refractory to stimulation from the previous impulse. However, the impulse may slowly travel (*squiggly line*) through the other portion of the Purkinje twig and will “reenter” the cross-hatched area if the refractory period is concluded and it is now excitable. Thus, the premature impulse never meets refractory tissue; circus movement ensues. If this site stimulates the surrounding ventricle repetitively, clinical reentrant ventricular tachycardia results.

FIGURE 19-4. A. Possible mechanism of proarrhythmia in the anatomic model of reentry. (1a) Nonviable reentrant loop due to bidirectional block (shaded area). (1b) Instance where a drug slows conduction velocity without significantly prolonging the refractory period. The impulse is now able to reenter the area of unidirectional block (shaded area) because slowed conduction through the contralateral limb allows recovery of the block. A new reentrant tachycardia may result. (2a) Nonviable reentrant loop due to a lack of a unidirectional block. (2b) Instance where a drug prolongs the refractory period without significantly slowing conduction velocity. The impulse moving antegrade meets refractory tissue (shaded area) allowing for unidirectional block. A new reentrant tachycardia may result. B. Mechanism of reentry and proarrhythmia. (a) Functionally determined (leading circle) reentrant circuit. This model should be contrasted with anatomic reentry; here the circuit is not fixed (it does not necessarily move around an anatomic obstacle) and there is no excitable gap. All tissue inside is held continuously refractory. (b) Instance where a drug prolongs the refractory period without significantly slowing conduction velocity. The tachycardia may terminate or slow in rate as shown as a consequence of a greater circuit length. The dashed lines represent the original reentrant circuit prior to drug treatment. (c) Instance where a drug slows conduction velocity without significantly prolonging the refractory period (i.e., type Ic agents) and accelerates the tachycardia. The tachycardia rate may increase (proarrhythmia) as shown as a consequence of a shorter circuit length. The dashed lines represent the original reentrant circuit prior to drug treatment. (From McCollam PL, Parker RB, Beckman KJ, et al. Proarrhythmia: A paradoxical response to antiarrhythmic agents. *Pharmacotherapy* 1989;9:146, with permission.)

usually related to an initiating event (i.e., premature beat), (b) the initiating beat is usually different in morphology from subsequent beats of the tachycardia, (c) the initiation of the tachycardia is usually possible with programmed cardiac stimulation, and (d) the initiation and termination of the tachycardia is usually abrupt without an acceleration or deceleration phase. There are many examples of reentrant tachycardias including AF, atrial flutter, AV nodal or AV reentrant tachycardia, and recurrent VT.

ANTIARRHYTHMIC DRUGS

In a theoretical sense, drugs may have antiarrhythmic activity by directly altering conduction in several ways. First, a drug may depress the automatic properties of abnormal pacemaker cells. An agent may do this by decreasing the slope of phase 4 depolarization and/or by elevating threshold potential. If the rate of spontaneous impulse generation of the abnormally automatic foci becomes less than that of the SA node, normal cardiac rhythm can be restored. Second, drugs may alter the conduction characteristics of the pathways of a reentrant loop.^{1,2} An agent may facilitate conduction (shorten refractoriness) in the area of unidirectional block, allowing antegrade conduction to proceed. On the other hand, an antiarrhythmic may further depress conduction (prolong refractoriness) in either the area of unidirectional block or in the pathway with slowed conduction and a relatively shorter refractory period. If refractoriness is prolonged in the area of unidirectional block, retrograde propagation of the impulse is not permitted, causing a “bidirectional” block. In the anatomic model, if refractoriness is prolonged in the pathway with slow conduction, antegrade conduction of the impulse is not permitted through this route. In either case, drugs that reduce the discordance and cause uniformity in conduction properties of the two pathways may suppress the reentrant substrate. In the functionally determined model, if refractoriness is prolonged without significantly slowing conduction velocity, the tachycardia may terminate or slow in rate as a consequence of a greater circuit length (see Fig. 19-4). There are other theoretical ways to stop reentry: a drug may eliminate the critically timed premature impulse that triggers reentry; a drug may slow conduction velocity to such an extent that conduction is extinguished; or a drug may reverse the underlying form of heart disease that was responsible for the conduction abnormalities that led to the arrhythmia (i.e., “reverse remodeling”).

Antiarrhythmic drugs have specific electrophysiologic actions that alter cardiac conduction in patients with or without heart disease. These actions form the basis of grouping antiarrhythmics into specific categories based upon their electrophysiologic actions *in vitro*. Vaughan Williams proposed the most frequently used classification system (Table 19-1).² This classification has been criticized because (a) it is incomplete and does not allow for the classification of agents such as digoxin or adenosine; (b) it is not pure and many agents have properties of more than one class of drugs; (c) it does not incorporate drug characteristics such as mechanisms of tachycardia termination/prevention, clinical indications, or side effects; and (d) agents become “labeled” within a class although they may be distinct in many regards.³ These criticisms formed the basis for an attempt to reclassify antiarrhythmic agents based upon a variety of basic and clinical characteristics (called the Sicilian Gambit³). Nonetheless, the Vaughan Williams classification remains the most frequently used despite many proposed modifications and alternative systems.

The type Ia antiarrhythmic drugs—quinidine, procainamide, and disopyramide—slow conduction velocity, prolong refractoriness, and decrease the automatic properties of sodium-dependent (normal and diseased) conduction tissue. Although type Ia agents are primarily considered sodium channel blockers, their electrophysiologic actions can also be attributed to blockade of potassium channels. In reentrant tachycardias, these drugs generally depress conduction and prolong refractoriness, theoretically transforming the area of unidirectional block into a bidirectional block. Clinically, type Ia drugs are broad-spectrum antiarrhythmics that are effective for both supraventricular and ventricular arrhythmias.

The type Ib antiarrhythmic drugs—lidocaine and phenytoin—were historically categorized separately from quinidine-like drugs. This was a result of early work demonstrating that lidocaine had distinctly different electrophysiologic actions. In normal tissue models, lidocaine generally facilitates actions on cardiac conduction by

TABLE 19-1 Classification of Antiarrhythmic Drugs

Type	Drug	Conduction Velocity ^a	Refractory Period	Automaticity	Ion Block
Ia	Quinidine Procainamide Disopyramide	↓	↑	↓	Sodium (intermediate) Potassium
Ib	Lidocaine Mexiletine	0/↓	↓	↓	Sodium (fast on-off)
Ic	Flecainide Propafenone ^b Moricizine ^c	↓↓	0	↓	Sodium (slow on-off) Potassium ^d
II ^e	β-blockers	↓	↑	↓	Calcium (indirect)
III	Amiodarone ^e Dofetilide Sotalol ^b Ibutilide	0	↑↑	0	Potassium
IV ^e	Verapamil Diltiazem	↓	↑	↓	Calcium

AV, atrioventricular; SA, sinoatrial.

^aVariables for normal tissue models in ventricular tissue.

^bAlso has type II, β-blocking actions.

^cClassification controversial.

^dNot clinically manifest.

^eVariables for SA and AV nodal tissue only.

^fAlso has sodium, calcium, and β-blocking actions; see Table 19–2.

shortening refractoriness and having little effect on conduction velocity. Thus, it was postulated that these agents could improve antegrade conduction, eliminating the area of unidirectional block. Of course, arrhythmias do not usually arise from normal tissue, leading investigators to study the actions of lidocaine and phenytoin in ischemic and hypoxic tissue models. Interestingly, studies have shown these drugs to possess type Ia quinidine-like properties in diseased tissues. Therefore, it is probable that lidocaine acts in clinical tachycardias in a similar fashion to the type Ia drugs (i.e., prolong refractoriness in diseased ischemic tissues leading to bidirectional block in a reentrant circuit). Lidocaine and similar agents have accentuated effects in ischemic tissue caused by the local acidosis and potassium shifts that occur during cellular hypoxia. Changes in pH alter the time that local anesthetics occupy the sodium channel receptor, thereby affecting the agent's electrophysiologic actions. In addition, the intracellular acidosis that ensues as a consequence of ischemia could cause lidocaine to become "trapped" within the cell, allowing increased access to the receptor. The type Ib agents are considerably more effective in ventricular arrhythmias than supraventricular arrhythmias. As a group these drugs are relatively weak sodium channel antagonists (at normal stimulation rates).

The type Ic antiarrhythmic drugs include propafenone, flecainide, and moricizine. These agents are extremely potent sodium blockers, profoundly slowing conduction velocity while leaving refractoriness relatively unaltered. The type Ic drugs theoretically eliminate reentry by slowing conduction to a point where the impulse is extinguished and cannot propagate further. Although the type Ic drugs are effective for both ventricular and supraventricular arrhythmias, their use for ventricular arrhythmias has been limited by the risk of proarrhythmia.

Type I agents are grouped together because of their common action in blocking sodium conductance. The receptor site for these antiarrhythmics is probably inside the sodium channel so that, in effect, the drug plugs the pore. The agent may gain access to the receptor either via the intracellular space through the membrane lipid bilayer or directly through the channel. Several principles are inherent in antiarrhythmic sodium channel receptor theories⁴:

1. Type I antiarrhythmics have predominant affinity for a particular state of the channel (e.g., during activation or inactivation).

For example, lidocaine and flecainide block sodium current primarily when the cell is in the inactivated state, whereas quinidine is predominantly an open (or activated)-channel blocker.

2. Type I antiarrhythmics have specific binding and unbinding characteristics to the receptor. For example, lidocaine binds to and dissociates from the channel receptor quickly (termed "fast on-off") but flecainide has very "slow on-off" properties. This explains why flecainide has such potent effects on slowing ventricular conduction whereas lidocaine has little effect on normal tissue (at normal heart rates). In general the type Ic antiarrhythmics are slow on-off, the type Ib antiarrhythmics are fast on-off, and the type Ia antiarrhythmics are intermediate in their binding kinetics.
3. Type I antiarrhythmics possess rate dependence (i.e., sodium channel blockade and slowed conduction are greatest at fast heart rates and least during bradycardia). For slow on-off drugs, sodium channel blockade is evident at normal rates (60 to 100 beats/min) but for fast on-off agents, slowed conduction is only apparent at rapid rates of stimulation.
4. Type I antiarrhythmics (except phenytoin) are weak bases with a $pK_a > 7.0$ and block the sodium channel in their ionized form. Consequently, pH will alter these actions: acidosis accentuates and alkalosis diminishes sodium channel blockade.
5. Type I antiarrhythmics appear to share a single receptor site in the sodium channel. It should be noted, however, that a number of type I antiarrhythmics have other electrophysiologic properties. For instance, quinidine has potent potassium channel blocking activity (manifest predominantly at low concentrations) as does *N*-acetylprocainamide (manifest predominantly at high concentrations), the primary metabolite of procainamide. Additionally propafenone has β-blocking actions.

These principles are important in understanding additive drug combinations (e.g., quinidine and mexiletine), antagonistic combinations (e.g., flecainide and lidocaine), and potential antidotes to excess sodium channel blockade (sodium bicarbonate or propranolol). They also explain a number of clinical observations, such as why lidocaine-like drugs are relatively ineffective for supraventricular

lar tachycardia. The type Ib antiarrhythmics are fast on-off, inactivated sodium blockers; atrial cells, however, have a very brief inactivated phase relative to ventricular tissue.

The β -blockers are classified as type II antiarrhythmic drugs. For the most part, the clinically relevant acute antiarrhythmic mechanisms of the β -blockers result from their antiadrenergic actions. Because the SA and AV nodes are heavily influenced by adrenergic innervation, β -blockers would be most useful in tachycardias in which these nodal tissues are abnormally automatic or are a portion of a reentrant loop. These agents are also helpful in slowing ventricular response in atrial tachycardias (e.g., AF) by their effects on the AV node. Furthermore, some tachycardias are exercise-related or precipitated by states of high sympathetic tone (perhaps through triggered activity), and β -blockers may be useful in these instances. β -adrenergic stimulation results in increased conduction velocity, shortened refractoriness, and increased automaticity of the nodal tissues; β -blockers will antagonize these effects. Propranolol is often noted to have “local anesthetic” or quinidine-like activity; however, suprapharmacologic concentrations are usually required to elicit this action. In the nodal tissues, β -blockers interfere with calcium entry into the cell by altering catecholamine-dependent channel integrity and gating kinetics. In sodium-dependent atrial and ventricular tissue, β -blockers shorten repolarization somewhat, but otherwise have little direct effect. The antiarrhythmic properties of β -blockers observed with long-term, chronic therapy in patients with heart disease are less well understood. Although it is clear that β -blockers decrease the likelihood of SCD (presumably arrhythmic death) after myocardial infarction (MI), the mechanism for this benefit remains unclear but may relate to the complex interplay of changes in sympathetic tone, damaged myocardium, and ventricular conduction. In patients with HF, drugs such as β -blockers, angiotensin-converting enzyme inhibitors, and angiotensin II receptor blockers may prevent arrhythmias such as AF by attenuating the structural remodeling process in the myocardium and subsequently improving ventricular performance over time.^{5,6}

The type III antiarrhythmic drugs include those agents that specifically prolong refractoriness in atrial and ventricular tissue. This class includes very different drugs: bretylium, amiodarone, sotalol, ibutilide, and dofetilide; they share the common effect of delaying repolarization by blocking potassium channels. While rarely used, bretylium has complex pharmacology: in addition to blocking potassium channels and delaying repolarization, it first releases then depletes catecholamines. Bretylium increases the VF threshold and seems to have selective antifibrillatory but not anti-tachycardic effects. In other words, bretylium can be effective in VF, whereas it is often ineffective in VT.

In contrast, amiodarone and sotalol are effective in most supraventricular and ventricular tachycardias. Amiodarone displays electrophysiologic characteristics of all the classes within the Vaughan Williams scheme; it is a sodium channel blocker with relatively fast on-off kinetics, has noncompetitive, nonselective β -blocking actions,

blocks potassium channels and also has a small degree of calcium antagonist activity (Table 19–2). At normal heart rates and with chronic use, its predominant effect is to prolong repolarization. Upon IV administration, its onset is relatively quick (unlike the oral form) and β -blockade predominates initially. Theoretically, amiodarone, like type I agents, may interrupt the reentrant substrate by transforming an area of unidirectional block into an area of bidirectional block. However, electrophysiologic studies using programmed cardiac stimulation imply that amiodarone may leave the reentrant loop intact. In addition, the potent β -blocking properties of amiodarone may contribute significantly to both its acute and chronic efficacy. The impressive effectiveness of amiodarone coupled with its low proarrhythmic potential has challenged the notion that selective ion channel blockade by antiarrhythmic agents is preferable. Sotalol is a potent inhibitor of outward potassium movement during repolarization and also possesses nonselective β -blocking actions. Unlike amiodarone and sotalol, ibutilide and dofetilide are only used for the treatment of supraventricular arrhythmias. Both ibutilide (only available IV) and dofetilide (only available orally) can be used for the acute conversion of AF or atrial flutter to sinus rhythm. Dofetilide can also be used to maintain sinus rhythm in patients with AF or atrial flutter of longer than 1 week’s duration who have been converted to sinus rhythm. Both of these agents are structurally similar to sotalol and exert their electrophysiologic effects by blocking the rapid component of the delayed potassium rectifier current (I_{Kr}).

There are a number of different potassium channels which function during normal conduction; all approved type III antiarrhythmic drugs inhibit the delayed rectifier current (I_K) responsible for phases 2 and 3 repolarization. Subcurrents make up I_K ; an ultrarapid component (I_{Kur}), a rapid component (I_{Kr}), and the slow component (I_{Ks}). *N*-acetylprocainamide, sotalol, ibutilide, and dofetilide selectively block I_{Kr} , whereas amiodarone and azimilide (investigational) block both I_{Kr} and I_{Ks} . New drugs that selectively block I_{Kur} (found predominantly in the atrium but not ventricle) are being investigated for supraventricular arrhythmias. The clinical relevance of selectively blocking components of the delayed rectifier current remains to be determined. Potassium current blockers (particularly those with selective I_{Kr} blocking properties) display “reverse use dependence” (i.e., their effects on repolarization are greatest at low heart rates). Sotalol and drugs like it also appear to be much more effective in preventing VF (in dog models) than the traditional sodium channel blockers. They also decrease defibrillation threshold in contrast to type I agents, which tend to increase this parameter. This could be important in patients with ICDs, as concurrent therapy with type I drugs may require more energy for successful cardioversion or may render the ICD ineffective in terminating the ventricular tachyarrhythmia. The Achilles’ heel of all type III agents is an extension of their underlying ionic mechanism (i.e., by blocking potassium channels and delaying repolarization, they may also cause proarrhythmia in the form of TdP by provoking EADs).

TABLE 19-2 Time Course and Electrophysiologic Effects of Amiodarone

Class	Mechanism	EP	ECG	IV		Oral	
				Min-Hrs	Hrs-Days	Days-Wks	Wks-Mos
Type I	Na ⁺ block	↑ HV	↑ QRS	0	+	+	++
Type II	β -block	↑ AH	↑ PR ↓ HR	++	++	++	++
Type III	K ⁺ block	↑ VERP ↑ AERP	↑ QT	0	+	++	++++
Type IV	Ca ²⁺ block ^a	↑ AH	↑ PR	+	+	+	+

^aRate-dependent.

AERP, atrial effective refractory period; AH, atria-His interval; ECG, electrocardiographic effects; EP, electrophysiologic actions; HR, heart rate; HV, His-ventricle interval; VERP, ventricular effective refractory period.

The nondihydropyridine CCBs—verapamil and diltiazem—comprise the type IV antiarrhythmic category. At least two types of calcium channels are operative in SA and AV nodal tissues: an L-type channel and a T-type channel. Both L-channel blockers (verapamil and diltiazem) and selective T-channel blockers (mibefradil—previously approved but withdrawn from the market) will slow conduction, prolong refractoriness, and decrease automaticity (e.g., due to EADs or LADs) of the calcium-dependent tissue in the SA and AV nodes. Therefore, these agents are effective in automatic or reentrant tachycardias, which arise from or use the SA or AV nodes. In supraventricular arrhythmias (e.g., AF), these drugs can slow ventricular response by slowing AV nodal conduction. Furthermore, because calcium entry seems to be integral to exercise-related tachycardias and/or tachycardias caused by some forms of triggered automaticity, these agents may be effective in the treatment of these types of arrhythmias. In all likelihood, verapamil and diltiazem work at different receptor sites because of their dissimilar chemical structures and pharmacologic actions. Calcium channel blockers can slightly shorten repolarization in normal sodium-dependent tissue, but otherwise have little effect. The dihydropyridine CCBs (e.g., nifedipine) do not have significant antiarrhythmic activity because a reflex increase in sympathetic tone caused by vasodilation counteracts their direct negative dromotropic action.

All antiarrhythmic agents currently available have an impressive side-effect profile (Table 19–3). A considerable percentage of patients cannot tolerate long-term therapy with these drugs and chances are good that an agent will have to be discontinued because of side effects. **2** In one trial,⁷ more than 50% of patients had to discontinue long-term procainamide (mostly because of a lupus-like syndrome) after MI. In another study,⁸ disopyramide caused anticholinergic side effects in approximately 70% of patients. Flecainide, propafenone, and disopyramide may precipitate congestive HF in a significant number of patients with underlying LV systolic dysfunction; consequently, these drugs should be avoided in this patient population.⁹ The type Ib agents, such as tocainide and mexiletine, cause neurologic and/or gastrointestinal toxicity in a high percentage of patients. Tocainide, specifically, has been reported to cause both pulmonary fibrosis and leukopenia, the significance of which came to light after its approval by the Food and Drug Administration; it has now been withdrawn from the market and is currently unavailable. One of the most frightening adverse effects related to antiarrhythmic drugs is the aggravation of underlying ventricular arrhythmias or the precipitation of new (and life-threatening) ventricular arrhythmias.¹⁰

Amiodarone has assumed a prominent place in the treatment of both chronic and acute supraventricular and ventricular arrhythmias and is now the most commonly prescribed antiarrhythmic drug.¹¹ Once considered a drug of last resort, it is now the first drug considered in many symptomatic tachycardias. Yet amiodarone is a peculiar and complex drug, displaying unusual pharmacologic effects, pharmacokinetics, dosing schemes, and multiorgan side effects. Amiodarone has an extremely long elimination half-life and large volume of distribution; consequently, its onset of action with the oral form is delayed (days to weeks) despite a loading regimen and its effects persist long (months) after discontinuation. Amiodarone inhibits P-glycoprotein and most cytochrome P450 (CYP) enzymes, resulting in the potential for numerous drug interactions (e.g., it will cause digoxin levels to approximately double and one must reduce the maintenance dose of warfarin by one-third to one-half). Acute administration of amiodarone is usually well-tolerated by patients, but severe organ toxicities may result with chronic use. Severe bradycardia (sometimes requiring pacing to allow the patient to remain on amiodarone), hyper- and hypothyroidism, photosensitivity, and a blue-gray skin discoloration on exposed areas are common. Fulminant hepatitis (uncommon) and pulmonary fibrosis (5% to 10% of patients) have caused death.^{12,13} Although amiodarone can

TABLE 19-3 Side Effects of Antiarrhythmic Drugs	
Quinidine	Cinchonism, diarrhea, abdominal cramps, nausea, vomiting, hypotension, TdP, aggravation of underlying HF, conduction disturbances or ventricular arrhythmias, fever, hepatitis, thrombocytopenia, hemolytic anemia
Procainamide	Systemic lupus erythematosus, diarrhea, nausea, vomiting, TdP, aggravation of underlying HF, conduction disturbances or ventricular arrhythmias, agranulocytosis
Disopyramide	Anticholinergic symptoms (dry mouth, urinary retention, constipation, blurred vision), nausea, anorexia, TdP, HF, aggravation of underlying conduction disturbances and/or ventricular arrhythmias
Lidocaine	Dizziness, sedation, slurred speech, blurred vision, paresthesia, muscle twitching, confusion, nausea, vomiting, seizures, psychosis, sinus arrest, aggravation of underlying conduction disturbances
Mexiletine	Dizziness, sedation, anxiety, confusion, paresthesia, tremor, ataxia, blurred vision, nausea, vomiting, anorexia, aggravation of underlying conduction disturbances or ventricular arrhythmias
Moricizine	Dizziness, headache, fatigue, insomnia, nausea, diarrhea, blurred vision, aggravation of underlying conduction disturbances or ventricular arrhythmias
Flecainide	Blurred vision, dizziness, dyspnea, headache, tremor, nausea, aggravation of underlying HF, conduction disturbances or ventricular arrhythmias
Propafenone	Dizziness, fatigue, bronchospasm, headache, taste disturbances, nausea, vomiting, bradycardia or AV block, aggravation of underlying HF, conduction disturbances or ventricular arrhythmias
Amiodarone	Tremor, ataxia, paresthesia, insomnia, corneal microdeposits, optic neuropathy/neuritis, nausea, vomiting, anorexia, constipation, TdP (<1%), bradycardia or AV block (IV and oral use), pulmonary fibrosis, liver function test abnormalities, hepatitis, hypothyroidism, hyperthyroidism, photosensitivity, blue-gray skin discoloration, hypotension (IV use), phlebitis (IV use)
Dofetilide	Headache, dizziness, TdP
Ibutilide	Headache, TdP, hypotension
Sotalol	Dizziness, weakness, fatigue, nausea, vomiting, diarrhea, bradycardia, TdP, bronchospasm, aggravation of underlying HF

AV, atrioventricular; HF, heart failure; IV, intravenous; TdP, torsades de pointes.

cause corneal microdeposits (which usually do not affect vision) in virtually every patient, it has also been associated with the development of optic neuropathy/neuritis, which can lead to blindness. All of these side effects mandate close and continued monitoring (liver enzymes, thyroid function tests, eye exams, chest radiographs, pulmonary function tests) and have led to a proliferation of “amiodarone clinics” designed just for patients receiving this agent on a chronic basis (Table 19–4). **3**¹⁴

Table 19–5 summarizes the pharmacokinetics of the antiarrhythmic agents and Table 19–6 lists recommended dosages of the oral dosage forms. Table 19–7 lists the dosing recommendations for the corresponding IV forms.

SUPRAVENTRICULAR ARRHYTHMIAS

The common supraventricular tachycardias that often require drug treatment are (a) AF or atrial flutter, (b) PSVT, and (c) automatic atrial tachycardias. Other common supraventricular arrhythmias that usually do not require drug therapy include premature atrial complexes, wandering atrial pacemaker, sinus arrhythmia, and sinus tachycardia. As an example, premature atrial complexes rarely cause symptoms, never cause hemodynamic compromise, and therefore drug therapy is usually not indicated. Likewise, sinus tachycardia is usually the result of underlying metabolic or hemodynamic disorders (e.g., infection, dehydration, hypotension) and therapy should be directed at the underlying cause, not the tachycardia per se. Of course,

TABLE 19-4 Amiodarone Monitoring

Side Effect	Monitoring Recommendations	Management of Side Effect
Pulmonary fibrosis	Chest radiograph (baseline, then every 12 months) Pulmonary function tests (if symptomatic)	Discontinue amiodarone immediately; initiate corticosteroid therapy
Hypothyroidism	Thyroid function tests (baseline, then every 6 months)	Thyroid hormone supplementation (e.g., levothyroxine)
Hyperthyroidism	Thyroid function tests (baseline, then every 6 months)	Antithyroid drugs
Optic neuritis/neuropathy	Ophthalmologic examination (baseline, then every 12 months)	Discontinue amiodarone immediately
Corneal microdeposits	Slit-lamp examination (routine monitoring not necessary)	No treatment necessary
Increased LFTs	LFTs (baseline, then every 6 months)	Consider lowering the dose or discontinuing amiodarone if LFTs >3× normal
Bradycardia/heart block	ECG (baseline, then every 3–6 months)	Lower the dose, if possible, or discontinue amiodarone if severe
Tremors, ataxia, peripheral neuropathy	History/physical examination (each office visit)	Lower the dose, if possible, or discontinue amiodarone if severe
Photosensitivity/blue-gray skin discoloration	History/physical examination (each office visit)	Advise patients to wear sunblock while outdoors

ECG, electrocardiogram; LFTs, liver function tests.

TABLE 19-6 Typical Maintenance Doses of Oral Antiarrhythmic Drugs

Drug	Dose	Dose Adjusted
Quinidine	200–300 mg sulfate salt q 6 h 324–648 gluconate salt q 8–12 h	HEP, age >60 yr
Procainamide	500–1,000 mg q 6 h (Pronestyl SR) 1,000–2,000 mg q 12 h (Procanbid)	HEP, REN ^a
Disopyramide	100–150 mg q 6 h 200–300 mg q 12 h (SR form)	HEP, REN
Mexiletine	200–300 mg q 8 h	HEP
Flecainide	50–150 mg q 8 h	HEP, REN
Propafenone	150–300 mg q 8 h	HEP
Moricizine	200 mg q 8 h	HEP, REN
Sotalol	80–160 mg q 12 h	REN ^b
Dofetilide	500 mcg q 12 h	REN ^c
Amiodarone	400 mg two to three times daily until 10 g total, then 200–400 mg daily ^d	

HEP, hepatic disease; REN, renal dysfunction; SR, sustained release.

^aAccumulation of parent compound or metabolite (e.g., NAPA) may occur.

^bShould not be used for atrial fibrillation when creatinine clearance <40 mL/min.

^cDose should be based upon creatinine clearance; should not be used when creatinine clearance <20 mL/min.

^dUsual maintenance dose for atrial fibrillation is 200 mg/day (may further decrease dose to 100 mg/day with long-term use if patient clinically stable in order to decrease risk of toxicity); usual maintenance dose for ventricular arrhythmias is 300–400 mg/day.

there are exceptions to these suggestions. For example, sinus tachycardia may be deleterious in patients after cardiac surgery or MI. In another unusual tachycardia termed *nonparoxysmal sinus tachycardia*, chronically elevated heart rates may cause alterations in LV function. In both of these instances, antiarrhythmic drugs, such as β -blockers, may be indicated. Stated in another way, although many arrhythmias generally do not require therapy, clinical judgment and patient-specific variables play an important role in this decision. Nevertheless, for the purpose of this discussion, only the tachycardias usually requiring antiarrhythmic drug therapy, as listed above, are addressed.

CLINICAL PRESENTATION: SUPRAVENTRICULAR TACHYCARDIA

Atrial Fibrillation/Flutter

General

- These rhythms are usually not directly life-threatening nor do they generally cause hemodynamic collapse or syncope; 1:1 atrial flutter (ventricular response ~300 beats/min) is an exception. Also, patients with underlying forms of heart disease that are heavily reliant on atrial contraction to maintain adequate cardiac output (e.g., mitral stenosis, obstructive cardiomyopathy) display more severe symptoms of AF or atrial flutter.

Symptoms

- Most often, patients complain of rapid heart rate/palpitations and/or worsening symptoms of HF (shortness of breath, fatigue). Medical emergencies are severe HF (i.e., pulmonary edema, hypotension) or AF occurring in the setting of acute MI.

Diagnostic Tests/Signs (ECG; See Text for Details)

- Atrial fibrillation is an irregularly, irregular supraventricular rhythm with no discernible, consistent atrial activity (P waves). Ventricular response is usually 120 to 180 beats/min and the pulse is irregular. Atrial flutter is (usually) a regular supraventricular rhythm with characteristic flutter waves (or sawtooth pattern) reflecting more organized atrial activity. Commonly, the ventricular rate is in factors of 300 beats/min (e.g., 150, 100, or 75 beats/min).

Paroxysmal Supraventricular Tachycardia caused by Reentry General

- These rhythms can be transient, resulting in little, if any, symptoms.

Symptoms

- Patients frequently complain of intermittent episodes of rapid heart rate/palpitations that abruptly start and stop, usually without provocation (but occasionally as a result of exercise). Severe symptoms include syncope. Often (in particular, those with AV nodal reentry), patients complain of a chest pressure or neck sensation. This is caused by simultaneous AV contraction with the right atrium contracting against a closed tricuspid valve. Life-threatening symptoms (syncope, hemodynamic collapse) are associated with an extremely rapid heart rate (e.g., >200 beats/min) and AF associated with an accessory AV pathway.

Diagnostic Tests/Signs (ECG; See Text for Details)

- Most commonly, PSVT is a rapid, narrow QRS tachycardia (regular in rhythm) that starts and stops abruptly. Atrial activity, although present, is difficult to ascertain on surface ECG because P waves are “buried” on the QRS or T wave.

ATRIAL FIBRILLATION AND ATRIAL FLUTTER

Mechanisms and Background

Atrial fibrillation and atrial flutter are common supraventricular tachycardias. These tachycardias occur more often in men and the

TABLE 19-7 Intravenous Antiarrhythmic Dosing

Drug	Clinical Situation	Dose
Amiodarone	Pulseless VT/VF	300 mg IV/IO push (can give additional 150 mg IV/IO push if persistent VT/VF), followed by infusion of 1 mg/min for 6 h, then 0.5 mg/min
	Stable VT (with a pulse)	150 mg IV over 10 min, followed by infusion of 1 mg/min for 6 h, then 0.5 mg/min
	AF (termination)	5 mg/kg IV over 30 min, followed by infusion of 1 mg/min for 6 h, then 0.5 mg/min
Diltiazem	PSVT; AF (rate control)	0.25 mg/kg IV over 2 min (may repeat with 0.35 mg/kg IV over 2 min), followed by infusion of 5–15 mg/h
Ibutilide	AF (termination)	1 mg IV over 10 min (may repeat if needed)
Lidocaine	Pulseless VT/VF	1–1.5 mg/kg IV/IO push (can give additional 0.5–0.75 mg/kg IV/IO push every 5–10 min if persistent VT/VF [maximum cumulative dose = 3 mg/kg]), followed by infusion of 1–4 mg/min (1–2 mg/min if liver disease or HF)
	Stable VT (with a pulse)	1–1.5 mg/kg IV push (can give additional 0.5–0.75 mg/kg IV push every 5–10 min if persistent VT [maximum cumulative dose = 3 mg/kg]), followed by infusion of 1–4 mg/min (1–2 mg/min if liver disease or HF)
Procainamide	AF (termination); stable VT (with a pulse)	15–18 mg/kg IV over 60 min, followed by infusion of 1–4 mg/min
Verapamil	PSVT; AF (rate control)	2.5–5 mg IV over 2 min (may repeat up to maximum cumulative dose of 20 mg); can follow with infusion of 2.5–10 mg/h

AF, atrial fibrillation; IO, intraosseous; IV, intravenous; PSVT, paroxysmal supraventricular tachycardia; VF, ventricular fibrillation; VT, ventricular tachycardia.

elderly. In the general population, the overall prevalence of AF is 0.4% to 1% and this increases with age (e.g., approximately an 8% prevalence in patients >80 years old).¹⁵ The prevalence of AF also appears to increase as patients develop more severe HF, increasing from 4% in asymptomatic NYHA functional class I patients to 50% in patients with NYHA functional class IV HF.¹⁵

Atrial flutter and AF may present as a chronic, established tachycardia, an acute tachycardia, or a self-terminating, paroxysmal form. The following semantics and definitions are sometimes used specifically for AF:^{15,16} acute AF (onset within 48 hours); paroxysmal AF (terminates spontaneously in <7 days); recurrent AF (two or more episodes); persistent AF (duration >7 days and does not terminate spontaneously); and permanent AF (does not terminate with attempts at pharmacologic or electrical cardioversion). Atrial fibrillation is characterized as an extremely rapid (atrial rate of 400 to 600 beats/min) and disorganized atrial activation. With this disorganized atrial activity, there is a loss of the contribution of synchronized atrial contraction (atrial kick) to forward cardiac output. Supraventricular impulses penetrate the AV conduction system in variable degrees resulting in an irregular activation of the ventricles and an *irregularly, irregular* pulse. The AV junction will not conduct most of the supraventricular impulses causing ventricular response to be considerably slower (120 to 180 beats/min) than the atrial rate. It is sometimes stated that “AF begets AF”; that is, the arrhythmia tends to perpetuate itself. Long episodes are more difficult to terminate perhaps because of tachycardia-induced changes in atrial function (mechanical and/or electrical “remodeling”).

Atrial flutter occurs less frequently than AF, but is similar in its precipitating factors, consequences, and drug therapy approach. This arrhythmia is characterized by rapid (270 to 330 atrial beats/min) but regular atrial activation. The slower and regular electrical activity results in a regular ventricular response that is in approximate factors of 300 beats/min (i.e., 1:1 AV conduction = ventricular rate of 300 beats/min; 2:1 AV conduction = ventricular rate of 150 beats/min; 3:1 AV conduction = ventricular rate of 100 beats/min). Atrial flutter may occur in two distinct forms (type I and type II). Type I flutter is the more common classic form with atrial rates of approximately 300 beats/min and the typical “sawtooth” pattern of atrial activation as shown by the surface ECG. Type II flutter tends to be faster, being somewhat of a hybrid between classic atrial flutter and AF. Although the ventricular response usually has a regular pattern, atrial flutter with varying degrees of AV block or that occur with episodes of AF (“fib-flutter”) can cause an irregular ventricular rate.

It is generally accepted that the predominant mechanism of AF and atrial flutter is reentry. Atrial fibrillation appears to result from multiple atrial reentrant loops (or wavelets) while atrial flutter is caused by a single, dominant, reentrant substrate (counterclockwise circus movement in the right atrium around the tricuspid annulus). Atrial fibrillation or flutter usually occurs in association with various forms of structural heart disease that cause atrial distension, including myocardial ischemia or infarction, hypertensive heart disease, valvular disorders such as mitral stenosis or mitral insufficiency, congenital abnormalities such as septal defects, dilated or hypertrophic cardiomyopathy, and obesity. Disorders that cause right atrial stretch and are associated with AF or atrial flutter include acute pulmonary embolus and chronic lung disease resulting in pulmonary hypertension and cor pulmonale. Atrial fibrillation may also occur in association with states of high adrenergic tone such as thyrotoxicosis, surgery, alcohol withdrawal, sepsis, and excessive physical exertion. Atrial fibrillation that develops in the absence of clinical, electrocardiographic, radiographic, and echocardiographic evidence of structural heart disease is defined as lone AF. Other states in which patients are predisposed to episodes of AF are the presence of an anomalous AV pathway (i.e., Kent bundle) and sinus node dysfunction (i.e., tachy-brady or sick sinus syndrome).

Patients with AF or atrial flutter may experience the entire range of symptoms associated with other supraventricular tachycardias, although syncope as a presenting symptom is uncommon. Because atrial kick is lost with the onset of AF, patients with LV systolic or diastolic dysfunction may develop worsening signs and symptoms of HF as they often depend on the contribution of their atrial kick to maintain an adequate cardiac output. Thromboembolic events, resulting from atrial stasis and poorly adherent mural thrombi, are an additional complication of AF. Of course, the most devastating complication in this regard is the occurrence of an embolic stroke. Approximately 15% of all strokes in the United States can be attributed to AF.¹⁷ The average rate of ischemic stroke in patients with AF who are not receiving antithrombotic therapy is approximately 5% per year.^{17,18} Stroke can precede the onset of documented AF, probably as a result of undetected paroxysms prior to the onset of established AF. The risk of stroke significantly increases with age, with the annual attributable risk increasing from 1.5% in individuals ages 50 to 59 years to almost 24% in those ages 80 to 89 years of age.¹⁷ Patients with concomitant AF and rheumatic heart disease are at particularly high risk for stroke, with their risk being increased 17-fold compared to patients in sinus rhythm.¹⁷ Other risk factors for stroke identified from recent trials are previous ischemic stroke, transient ischemic attack, or other systemic embolic event; moderate or severe LV systolic dysfunction and/or congestive HF; hypertension; and diabetes.¹⁷ Younger patients (age <65 years) with AF in whom precipitating factors cannot be identified (i.e., lone AF) are considered to be at low risk for stroke.¹⁷ The risk of stroke in patients with only atrial flutter has been traditionally believed to be low, prompting some to recommend only aspirin for prevention of thromboembolism in this particular patient population. However, because patients with atrial flutter may also intermittently have episodes of AF, this patient population also may be at risk for a thromboembolic event. Although the role of antithrombotic therapy in patients with atrial flutter has not been adequately studied in clinical trials, the most recent guidelines suggest that the same risk stratification scheme and antithrombotic recommendations used in patients with AF also be applied to those with atrial flutter.¹⁷

Management

The traditional approach to the treatment of AF can be organized into several sequential goals: (a) First, evaluate the need for acute treatment (usually the administration of drugs that slow ventricular rate). (b) Next, contemplate methods to restore sinus rhythm taking into consideration the risks (e.g., thromboembolism). (c) Last, consider ways to prevent the long-term complications of AF such as arrhythmia recurrences and thromboembolism. **4** One of the biggest controversies in the management of AF is whether or not the restoration and maintenance of sinus rhythm is a desirable goal for all patients with AF. A review of the management of AF/atrial flutter, including a discussion of this controversy follows, organized according to the goals outlined above. Figure 19–5 shows an algorithm for the management of AF and atrial flutter. In addition, Table 19–8 summarizes the recommendations for pharmacologically controlling ventricular rate and restoring and maintaining sinus rhythm from the most recent AF guidelines developed by the American College of Cardiology (ACC)/American Heart Association (AHA)/European Society of Cardiology (ESC).¹⁵

Acute Treatment First, consider the patient with new-onset, symptomatic AF or atrial flutter. Although uncommon, patients may present with signs and/or symptoms of hemodynamic instability (e.g., severe hypotension, angina, or pulmonary edema), which qualifies as a medical emergency. In these situations, DCC is indicated as first-line therapy in an attempt to immediately restore sinus rhythm (without regard to the risk of thromboembolism).

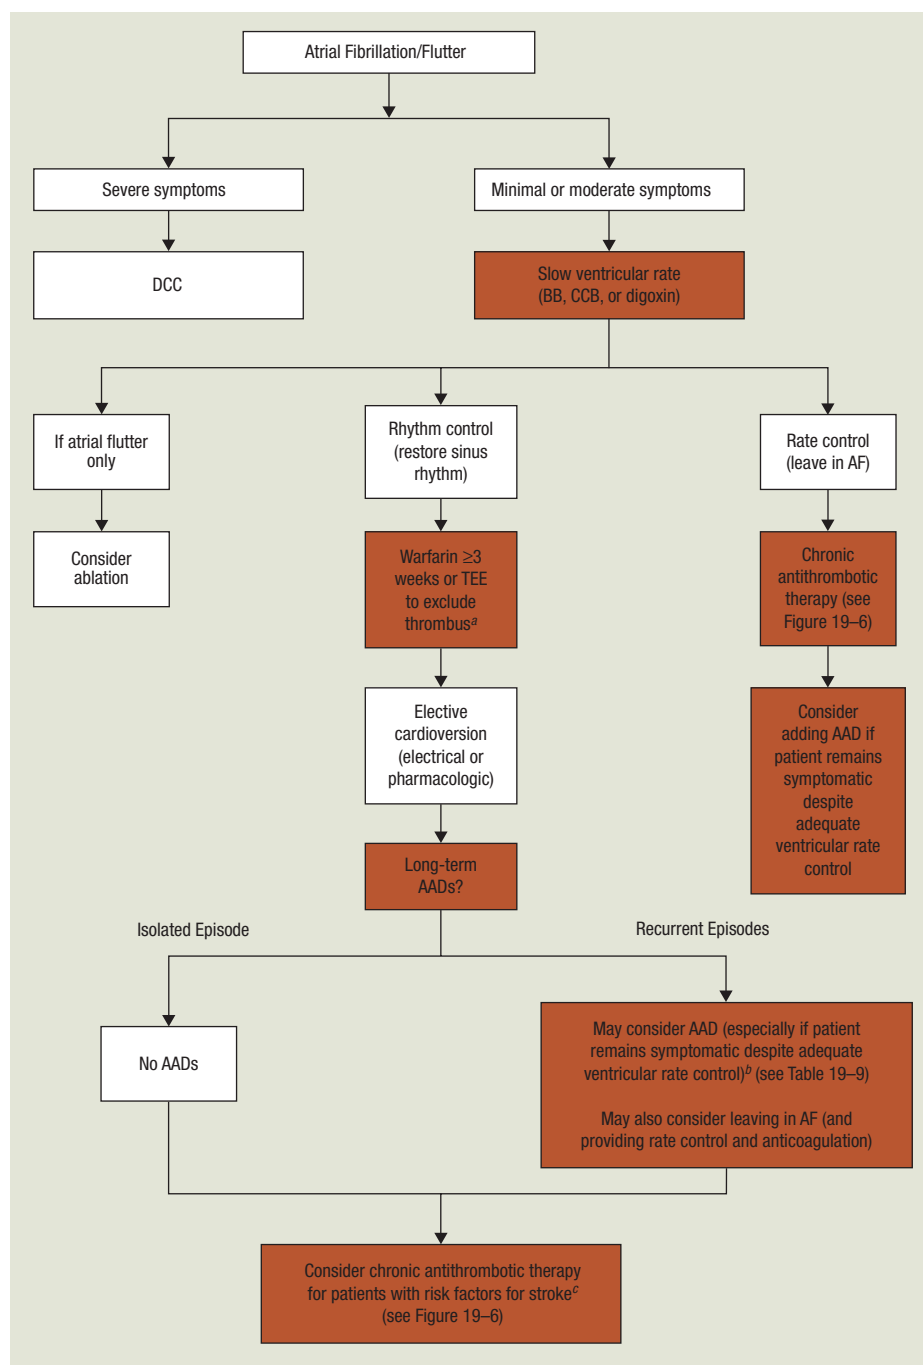

FIGURE 19-5. Algorithm for the treatment of atrial fibrillation and atrial flutter. ^aIf AF <48 hours, anticoagulation prior to cardioversion is unnecessary; may consider TEE if patient has risk factors for stroke. ^bAblation may be considered for patients who fail or do not tolerate ≥ 1 AAD. ^cChronic antithrombotic therapy should be considered in all patients with AF and risk factors for stroke regardless of whether or not they remain in sinus rhythm. (AAD, antiarrhythmic drug; AF, atrial fibrillation; BB, β -blocker; CCB, calcium channel blocker [i.e., verapamil or diltiazem]; DCC, direct-current cardioversion; TEE, transesophageal echocardiogram.)

Atrial flutter often requires relatively low energy levels of counter-shock (i.e., 50 joules), whereas AF often requires higher energy levels (i.e., greater than 200 joules).

If patients are hemodynamically stable, there is no emergent need to restore sinus rhythm. Instead, the focus should be directed toward controlling the patient's ventricular rate. Achieving adequate ventricular rate control should be a treatment goal for all patients with AF. To achieve this goal, drugs that slow conduction and increase refractoriness in the AV node (e.g., β -blockers, nondihydropyridine CCBs, or digoxin) should be used as initial therapy. Although loading dosages of digoxin have been historically recommended as first-line treatment to slow ventricular rate, use of this drug for achieving ventricular rate control, especially in patients with normal LV systolic function (left ventricular ejection fraction [LVEF] >40%) has declined.¹¹ In this patient population, IV β -blockers (propranolol, metoprolol, esmolol), diltiazem, or verapamil is preferred. A few of the potential reasons for the declining use of digoxin in this patient population are its relatively slow onset and its inability to control the

heart rate during exercise. Although an initial decrease in the ventricular rate can sometimes be observed within 1 hour of IV administration, full control (heart rate <80 beats/min at rest and <100 beats/min during exercise) is usually not achieved for 24 to 48 hours. In addition, digoxin tends to be ineffective for controlling ventricular rate under conditions of increased sympathetic tone (i.e., surgery, thyrotoxicosis) because it slows AV nodal conduction primarily through vagotonic mechanisms. In contrast, IV β -blockers and nondihydropyridine CCBs have a relatively quick onset and can effectively control the ventricular rate at rest and during exercise. β -blockers are also effective for controlling ventricular rate under conditions of increased sympathetic tone.

Based on the most recent guidelines for the treatment of AF, the selection of a drug to control ventricular rate in the acute setting should be primarily based on the patient's LV function.¹⁵ In patients with normal LV function (LVEF >40%), IV β -blockers, diltiazem, or verapamil is recommended as first-line therapy to control ventricular rate.¹⁵ All of these agents have proven efficacy in controlling the

TABLE 19-8 Evidence-Based Pharmacologic Treatment Recommendations for Controlling Ventricular Rate, Restoring Sinus Rhythm, and Maintaining Sinus Rhythm in Patients with Atrial Fibrillation

Treatment Recommendations	ACC/AHA/ESC Guideline Recommendation
Ventricular rate control (acute setting)	
In the absence of an accessory pathway, IV β -blockers, or IV nondihydropyridine CCBs are recommended for patients without hypotension or HF.	Class I
In the absence of an accessory pathway, IV digoxin or IV amiodarone is recommended for patients with HF.	Class I
IV amiodarone can be used to control the ventricular rate in patients who are refractory to or have contraindications to IV β -blockers, nondihydropyridine CCBs, or digoxin.	Class IIa
IV procainamide or ibutilide is a reasonable alternative in patients with an accessory pathway when DCC is not necessary.	Class IIa
IV procainamide, ibutilide, or amiodarone may be considered for hemodynamically stable patients with an accessory pathway.	Class IIb
IV nondihydropyridine CCBs are not recommended in patients with decompensated HF.	Class III
Ventricular rate control (chronic setting)	
Oral digoxin is effective for controlling the ventricular rate at rest in patients with HF or LV dysfunction, and in those who are sedentary.	Class I
Combination therapy with oral digoxin and either an oral β -blocker or nondihydropyridine CCB is reasonable to control the ventricular rate both at rest and during exercise.	Class IIa
Oral amiodarone can be used when the ventricular rate cannot be adequately controlled at rest and during exercise with an oral β -blocker, nondihydropyridine CCB, and/or digoxin.	Class IIb
Digoxin should not be used as the only agent for controlling the ventricular rate in patients with paroxysmal AF.	Class III
Restoration of sinus rhythm	
Flecainide, dofetilide, propafenone, or ibutilide is recommended for pharmacologic cardioversion of AF.	Class I
Amiodarone is a reasonable option for pharmacologic cardioversion of AF.	Class IIa
The "pill-in-the-pocket" approach (see text) can be used to terminate persistent AF on an outpatient basis once the treatment has been used safely in the hospital, in patients without sinus or AV node dysfunction, bundle-branch block, QT interval prolongation, Brugada syndrome, or structural heart disease (Note: AV node must be adequately blocked before initiating this therapy.)	Class IIa
Amiodarone can be used on an outpatient basis in patients with paroxysmal or persistent AF when rapid restoration of sinus rhythm is not necessary.	Class IIa
Quinidine or procainamide might be considered for pharmacologic cardioversion of AF, but their efficacy is not well established.	Class IIb
Digoxin and sotalol should not be used for pharmacologic cardioversion of AF (may be harmful).	Class III
Quinidine, procainamide, disopyramide, and dofetilide should not be initiated on an outpatient basis	Class III
Maintenance of sinus rhythm	
Antiarrhythmic therapy can be useful for maintaining sinus rhythm and preventing tachycardia-induced cardiomyopathy.	Class IIa
Outpatient initiation of antiarrhythmic therapy is reasonable in patients without structural heart disease.	Class IIa
Propafenone or flecainide may be initiated on an outpatient basis in patients with paroxysmal AF who have no structural heart disease and are in sinus rhythm at the time therapy is initiated.	Class IIa
Sotalol may be initiated on an outpatient basis in patients without structural heart disease, QT interval prolongation, electrolyte abnormalities, or other risk factors for proarrhythmia.	Class IIa
An antiarrhythmic drug should not be used when patients have risk factors for proarrhythmia with that particular agent.	Class III
Antiarrhythmic therapy is not recommended in patients with sinus or AV node dysfunction unless a pacemaker is present.	Class III

Adapted from reference 15.

ventricular rate in patients with AF. Propranolol and metoprolol can be administered as intermittent IV boluses, whereas esmolol (because of its very short half-life of 5 to 10 minutes) must be administered as a series of loading doses followed by a continuous infusion. Likewise, because control of ventricular rate can be transient with a single bolus, verapamil or diltiazem can be given as an initial IV bolus followed by a continuous infusion.¹⁹ These continuous infusions can be adjusted in monitored settings to the desired ventricular response (e.g., acutely <100 beats/min). In situations where AF or atrial flutter is precipitated by states of increased adrenergic tone, IV β -blockers can be highly effective and should be considered first.

In patients with LV dysfunction (LVEF $\leq 40\%$), IV diltiazem or verapamil should be avoided because of their potent negative inotropic effects. Intravenous β -blockers should be used with caution in this patient population and should be avoided if patients are in the midst of an episode of decompensated HF. In those patients who are having an exacerbation of HF symptoms, IV administration of either digoxin or amiodarone should be used as first-line therapy to achieve ventricular rate control.¹⁵ Intravenous amiodarone can also be used in patients who are refractory to or have contraindications to β -blockers, nondihydropyridine CCBs, and digoxin.¹⁵ However, clinicians should be aware that the use of amiodarone for controlling ventricular rate may also stimulate the conversion of AF to sinus rhythm, and place the patient at risk for a thromboembolic event, especially if the AF is at least 48 hours or of unknown duration.

Patients may present with a slow ventricular response (in the absence of AV nodal-blocking drugs) and thus, do not require therapy with β -blockers, nondihydropyridine CCBs, or digoxin. This type of presentation should alert the clinician to the possibility of preexisting SA or AV nodal conduction disease such as sick sinus syndrome. In these patients, DCC should not be attempted without a temporary pacemaker in place.

Restoration of Sinus Rhythm? After treatment with AV nodal-blocking agents and a subsequent decrease in the ventricular rate, the patient should be evaluated for the possibility of restoring sinus rhythm if AF persists. Within the context of this evaluation, several factors should be considered. First, many patients spontaneously convert to sinus rhythm without intervention, obviating therapy needed to achieve this goal. For instance, AF occurs frequently as a complication of cardiac surgery and often spontaneously reverts to sinus rhythm without therapy. Second, restoring sinus rhythm is not a necessary or realistic goal in some patients. To date, a total of five clinical trials (Pharmacological Intervention in Atrial Fibrillation [PIAF], Rate Control versus Electrical Cardioversion for Persistent Atrial Fibrillation [RACE], Atrial Fibrillation Follow-up Investigation of Rhythm Management [AFFIRM], Strategies of Treatment of Atrial Fibrillation [STAF], and How to Treat Chronic Atrial Fibrillation [HOT-CAFE]), have been published that have shed some light on this particular issue.^{20–24} Of these, the AFFIRM is the largest study to

compare the effects of a rate-control (controlling ventricular rate; patient remains in AF) and rhythm-control (restoring and maintaining sinus rhythm) strategy in patients with AF.²² In the AFFIRM trial, patients with AF and at least one risk factor for stroke were randomized to either a rate-control or rhythm-control group. Rate-control treatment involved AV nodal-blocking drugs (digoxin, β -blockers, and/or CCBs) first, then nondrug treatment (AV nodal ablation with pacemaker implantation), if necessary. All patients in this group were anticoagulated with warfarin to achieve an international normalized ratio (INR) of 2.0 to 3.0. In the rhythm-control group, type I or type III antiarrhythmic drugs were used to maintain sinus rhythm. The choice of antiarrhythmic therapy was left up to each patient's physician; however, by the end of the trial, more than 60% of patients had received at least one trial of amiodarone and approximately 40% of patients had received at least one trial of sotalol. In this group, anticoagulation was encouraged but could be discontinued if sinus rhythm had been maintained for at least 4 weeks. After a mean follow-up period of 3.5 years, overall mortality was not statistically different between the two strategies but tended ($P = 0.08$) to be higher in the rhythm-control group. The results of the PIAF, RACE, STAF, and HOT-CAFE trials were consistent with those of the AFFIRM trial.^{20,21,23,24} In addition, a recently published meta-analysis of the data from all of these trials demonstrated no significant difference in overall mortality between rate-control and rhythm-control strategies, which persisted even when the results from the AFFIRM trial were excluded from this analysis.²⁵ Overall, the results of these trials collectively demonstrate that a rate-control strategy is a viable alternative to a rhythm-control strategy in patients with persistent AF.

Clearly, these important findings temper the old approach of aggressively attempting to maintain sinus rhythm. Because a rhythm-control strategy does not confer any advantage over a rate-control strategy in the management of AF, it now remains acceptable to allow patients to remain in AF, while being chronically treated with AV nodal-blocking agents to achieve adequate ventricular rate control (e.g., heart rate <80 beats/min at rest and <100 beats/min during exercise).⁴ Overall, the selection of an AV nodal-blocking agent to control ventricular rate in the chronic setting should be primarily based on the patient's LV function.¹⁵ In patients with normal LV function (LVEF >40%), oral β -blockers, diltiazem, or verapamil are preferred over digoxin because of their relatively quick onset and maintained efficacy during exercise. When adequate ventricular rate control cannot be achieved with one of these agents, the addition of digoxin may provide an additive lowering of the heart rate. If adequate ventricular rate control during rest and exercise cannot be achieved with β -blockers, nondihydropyridine CCBs, and/or digoxin, oral amiodarone can be used as alternative therapy to control the heart rate.¹⁵ Verapamil and diltiazem should not be used in patients with LV dysfunction (LVEF \leq 40%). Instead, β -blockers (i.e., metoprolol, carvedilol, or bisoprolol) and digoxin are preferred in these patients, as these agents are also concomitantly used to treat chronic HF; if possible, β -blockers should be considered over digoxin in this situation because of their survival benefits in patients with LV systolic dysfunction. If patients are having an episode of decompensated HF, digoxin is preferred as first-line therapy to achieve ventricular rate control. Occasionally, patients may be encountered who are highly refractory to AV nodal-blocking agents (including combination drug therapy) and continue to have a rapid ventricular rate. In this situation, aggressive attempts to lower the heart rate are necessary as chronic tachycardia can result in a progressive decline in LV function causing so-called *tachycardia-induced cardiomyopathy*. Hence, in drug-refractory patients, ablation or modification of the AV node by a transvenous catheter delivering radiofrequency current is indicated.^{15,26} This procedure often completely blocks conduction from the atrium to the ventricle, requiring the concurrent implantation of a permanent pacemaker with a ventricular lead. Regardless of the

situation, if the decision is made to allow a patient to remain in AF, consideration must be given to selecting the most appropriate antithrombotic therapy for these patients as they continue to be at risk for thromboembolic complications (see below).

Because a rate-control strategy is now considered a reasonable approach for the chronic management of AF, the question that remains to be answered is, "In which patients should restoration of sinus rhythm be considered?" Given the results of the AFFIRM trial, this decision should be left to clinical judgment but one could imagine that several groups of patients should undergo electrical or pharmacologic cardioversion. They include those patients who are judged to have a relatively low chance of recurrence (e.g., first episode of lone AF in young individuals, transient states of high sympathetic tone) and those with troublesome symptoms despite adequate ventricular rate control. In the former patient population, chronic antiarrhythmic therapy is usually not needed since the AF is often self-limiting.

In those patients in whom it is decided to restore sinus rhythm, one must consider that this very act (regardless of whether an electrical or pharmacologic method is chosen) places the patient at risk for a thromboembolic event. The reason for this is that the return of sinus rhythm restores effective contraction in the atria, which may dislodge poorly adherent thrombi. Administering antithrombotic therapy prior to cardioversion not only prevents clot growth and the formation of new thrombi but also allows existing thrombi to become organized and well-adherent to the atrial wall. It is a generally accepted principle that patients become at increased risk of thrombus formation and a subsequent embolic event if the duration of the AF exceeds 48 hours. Therefore, it is vital for clinicians to estimate the duration of the patient's AF, so that appropriate antithrombotic therapy can be administered prior to cardioversion, if needed. According to the most recent guidelines derived from the Seventh American College of Chest Physicians Consensus Conference on Antithrombotic Therapy, patients with AF for longer than 48 hours or an unknown duration should receive warfarin treatment (target INR 2.5; range: 2.0 to 3.0) for at least 3 weeks prior to cardioversion.¹⁷ The common clinical scenario is to discharge the patient from the hospital, monitor them on an ambulatory basis, and readmit for elective cardioversion after this time period. After restoration of sinus rhythm, full atrial contraction does not occur immediately. Rather, it returns gradually to a maximum contractile force over a 3- to 4-week period. Consequently, warfarin should be continued for at least 4 weeks after effective cardioversion and return of sinus rhythm. To shorten the time to cardioversion, these patients may alternatively undergo transesophageal echocardiography (TEE) to provide guidance regarding the need for antithrombotic therapy prior to cardioversion. If no thrombus is noted on TEE, then these patients can be cardioverted without the mandatory 3 weeks of warfarin pretreatment. However, IV unfractionated heparin should still be administered during the TEE and cardioversion procedures to prevent the formation of thrombi during the pericardioversion and postcardioversion periods. After effective cardioversion and return of sinus rhythm, these patients should receive 4 weeks of warfarin therapy, as their atria may still be mechanically stunned during this period. If the TEE performed prior to cardioversion reveals thrombus, patients should then be anticoagulated indefinitely, and cardioversion should not be attempted until there is absence of thrombus on repeat TEE. Overall, the use of TEE in this manner has been compared to the conventional 3 weeks of anticoagulation before cardioversion in patients with AF.²⁷ In this large, multicenter, randomized trial, the incidence of thromboembolic events was not different between the two strategies, but bleeding episodes were higher in the "3 weeks of warfarin" group. Patients in the TEE strategy group had a higher success rate of achieving sinus rhythm, probably because it's more difficult to terminate AF the longer a patient remains in it (i.e., "AF begets AF").

In patients with AF that is less than 48 hours in duration, anticoagulation prior to cardioversion is unnecessary because there has not been sufficient time to form atrial thrombi.¹⁷ However, it is recommended that these patients should receive either IV unfractionated heparin or a low-molecular-weight heparin (subcutaneously at treatment doses) at presentation prior to cardioversion. If these patients have risk factors for stroke, a TEE could alternatively be performed prior to cardioversion to exclude the presence of thrombus. Patients with AF that is less than 48 hours in duration do not require the 4 weeks of postcardioversion anticoagulation therapy unless they have risk factors for stroke or if the AF recurs.

After prior anticoagulation or TEE, the methods available to restore sinus rhythm can be considered. There are two methods of restoring sinus rhythm in patients with AF or atrial flutter: pharmacologic cardioversion and DCC. Which of these is the method of choice is generally a matter of clinical preference. The disadvantages of pharmacologic cardioversion are the risk of significant side effects (e.g., drug-induced TdP),²⁸ the inconvenience of drug-drug interactions (e.g., digoxin–amiodarone), and the fact that drugs are generally less effective when compared to DCC. The advantages of DCC are that it is quick and more often successful (80% to 90% success rate). The disadvantages of DCC are the need for prior sedation/anesthesia and a risk (albeit small) of serious complications such as sinus arrest or ventricular arrhythmias. Contrary to past beliefs, DCC carries very little risk in patients who are receiving digoxin and have no evidence of digitalis toxicity.

Nonetheless, despite the relatively high success rate associated with DCC, some clinicians elect to use antiarrhythmic drugs first, then resort to DCC in the event that these agents fail. Pharmacologic cardioversion appears to be most effective when initiated within 7 days after the onset of AF.¹⁵ According to the most recent treatment guidelines for AF, there is relatively strong evidence for efficacy of the type III pure I_K blockers (ibutilide and dofetilide), the type Ic antiarrhythmics (e.g., flecainide and propafenone), and amiodarone (oral or IV).¹⁵ Type Ia antiarrhythmics have limited efficacy in this setting. Sotalol is not effective for cardioversion of paroxysmal or persistent AF. Single, oral loading doses of propafenone (600 mg) and flecainide (300 mg) are effective compared to placebo for conversion of recent-onset AF and provide a simple regimen.²⁹ A method called the “pill-in-the-pocket” approach was recently endorsed by the treatment guidelines.¹⁵ With this method, outpatient, patient-controlled self-administration of a single, oral loading dose of either flecainide or propafenone can be a relatively safe and effective approach for the termination of recent-onset AF in a selected patient population that does not have sinus or AV node dysfunction, bundle-branch block, QT interval prolongation, Brugada syndrome, or structural heart disease.³⁰ In addition, this treatment regimen should only be considered in patients who have been successfully cardioverted with these drugs on an inpatient basis. In patients with AF that is longer than 7 days in duration, only dofetilide, amiodarone, and ibutilide have proven efficacy for cardioversion.¹⁵ The types Ia and Ic antiarrhythmics have limited efficacy in this setting.

Overall, when considering pharmacologic cardioversion, the selection of an antiarrhythmic drug should be based on whether the patient has structural heart disease (e.g., LV dysfunction, coronary artery disease, valvular heart disease, LV hypertrophy).¹⁵ In the absence of any type of structural heart disease, the use of a single, oral loading dose of flecainide or propafenone is a reasonable approach for cardioversion; the “pill-in-the-pocket” approach should only be used in select patients (see above). Ibutilide can also be used as an alternative agent in this patient population; however, this agent can only be administered in the hospital because it is only available in IV form. In patients with underlying structural heart disease, these antiarrhythmics should be avoided because of the increased risk of proarrhythmia, and amiodarone or dofetilide should be used instead.

Although amiodarone can be administered safely on an outpatient basis because of its low proarrhythmic potential, dofetilide can only be initiated in the hospital. Additionally, it should be remembered that a patient’s ventricular rate should be adequately controlled with AV nodal-blocking drugs prior to administering a type Ic (or Ia) antiarrhythmic for cardioversion. The types Ia and Ic agents may paradoxically increase ventricular response. Traditionally, this observation has been attributed to the vagolytic action of these drugs despite the fact that only disopyramide displays significant anticholinergic side effects. Therefore, a more likely alternative explanation exists: all of these agents slow atrial conduction, decreasing the number of impulses reaching the AV node; as a result, the AV node paradoxically allows more impulses to gain entrance to the ventricular conduction system (increasing ventricular rate).

Long-Term Complications There are two forms of therapy that the clinician must consider in each patient: long-term antithrombotic therapy to prevent stroke, and long-term antiarrhythmic drugs to prevent recurrences of AF. Consider the issue of antithrombotic therapy first. In the past, patients with AF were not routinely anticoagulated (unless there was a history of stroke or concurrent mitral valve disease) because it was believed that the risk of warfarin exceeded its potential (though unknown) benefit. In the past several years, a large number of randomized, placebo-controlled trials designed to evaluate this issue have been published. All possess relatively similar findings and many were terminated prematurely because of a significant effect in the treatment group (warfarin). In all, these studies culminated in the following recommendations from the Seventh American College of Chest Physicians Consensus Conference on Antithrombotic Therapy for patients with paroxysmal, persistent, or permanent AF¹⁷: warfarin (target INR: 2.5; range: 2.0 to 3.0) should be prescribed to all patients who are at high risk for stroke (rheumatic mitral valve disease; previous ischemic stroke, transient ischemic attack, or other systemic embolic event; age >75 years; moderate or severe LV systolic dysfunction and/or congestive HF; hypertension; or prosthetic heart valve); those at intermediate risk (age 65 to 75 years with none of the above high-risk factors) should receive either warfarin (target INR: 2.5; range: 2.0 to 3.0) or aspirin 325 mg/day; and those at low risk (age <65 years with none of the above high-risk factors) should receive aspirin 325 mg/day. In the intermediate-risk group, the decision of whether to use warfarin or aspirin should be based on such factors as the patient’s risk for bleeding, patient preference, potential drug interactions with warfarin, and the availability of an appropriate monitoring system for warfarin therapy. Although it was previously an acceptable practice to continue antithrombotic therapy for only 4 weeks after successful cardioversion (with the belief that a patient’s risk for thromboembolism had abated since they were in sinus rhythm), recent data from the PIAF, RACE, AFFIRM, STAF, and HOT-CAFE trials strongly suggest that patients with AF and other risk factors for stroke continue to be at risk for stroke even when maintained in sinus rhythm.^{20–24} It is possible that these patients may be having undetected episodes of paroxysmal AF, placing them at risk for stroke. Consequently, the updated treatment guidelines for AF recommend that chronic antithrombotic therapy be considered for all patients with AF and risk factors for stroke regardless of whether or not they remain in sinus rhythm.¹⁵ Figure 19–6 is an algorithm for preventing thromboembolism in patients with AF.

The second form of chronic therapy to be considered is antiarrhythmic drugs to prevent recurrences of AF. With some exceptions (e.g., postoperative situations or transient states of high sympathetic tone), AF often recurs after initial cardioversion because most patients have irreversible, underlying heart or lung disease. Large atrial size, poor LV function, and the presence of long-standing AF are factors that make the restoration and maintenance of sinus

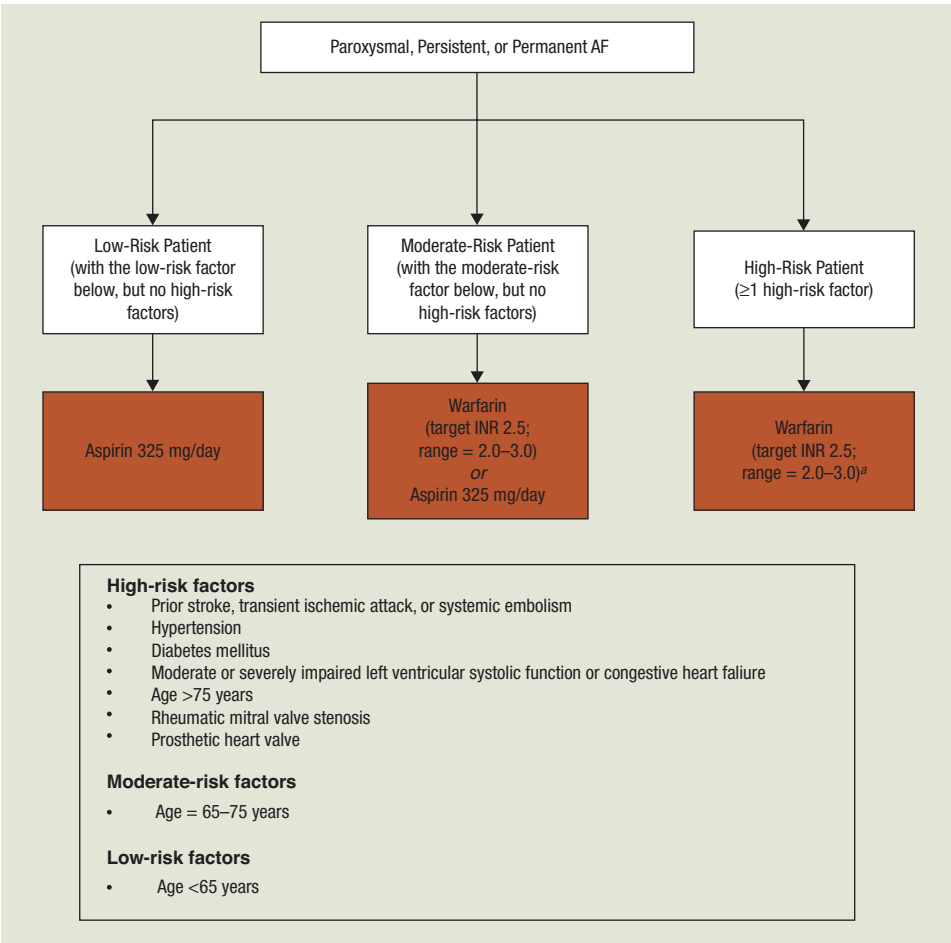

FIGURE 19-6. Algorithm for the prevention of thromboembolism in paroxysmal, persistent, or permanent atrial fibrillation. ^aThe target INR for patients with prosthetic heart valves should be based upon the type of valve that is present. (AF, atrial fibrillation; INR, international normalized ratio.)

rhythm difficult if not impossible. Nevertheless, historically, many clinicians have aggressively attempted to maintain sinus rhythm by prescribing oral antiarrhythmic drugs (usually quinidine) to prevent these recurrences despite the fact that only small studies with conflicting results existed evaluating this approach. To evaluate the efficacy of quinidine in preventing AF, a well-known meta-analysis of the existing literature was completed.³¹ This meta-analysis demonstrated that indeed more patients remain in sinus rhythm with quinidine therapy (compared to placebo); however, approximately 50% have recurrences of AF within a year despite quinidine. However, this reported effectiveness was at the cost of an associated increase in mortality (presumably due, in part, to proarrhythmia) in the quinidine-treated patients. These disturbing results (published soon after the CAST³²) became widely quoted and highly visible, making clinicians question the wisdom of long-term prevention of recurrences of AF with antiarrhythmic drugs. Although the results were questioned because some of the reported causes of death in the treated patients could not be directly attributed to quinidine, subsequent studies³³ tended to support the findings of the meta-analysis.

These results coupled with the recent findings of the PIAF, RACE, AFFIRM, STAF, and HOT-CAFE trials question the need to use antiarrhythmic drugs to prevent recurrences of AF.^{20–24} Perhaps this practice should now be totally abandoned, allowing patients to remain in AF once recurrences happen and only using strategies to control rate and prevent thromboembolism. Although it is true that these data have certainly led to a less-aggressive approach, patients with paroxysmal AF who continue to have intolerable symptoms during recurrences do require antiarrhythmic drugs to prevent these symptomatic attacks.

According to the recent treatment guidelines for AF, the type Ic or type III antiarrhythmic drugs are reasonable to consider to maintain patients in sinus rhythm (Table 19–9).¹⁵ The role of the type Ia antiarrhythmic drugs for maintenance of sinus rhythm has been

deemphasized throughout these updated guidelines as they are considered less effective or incompletely studied compared to the type Ic and type III agents. Realistically, however, these agents can still be considered as last-line therapy in patients without structural heart disease and in patients with hypertension (without significant LV hypertrophy) or coronary artery disease (with normal LV systolic function).

TABLE 19-9 Guidelines for Selecting Antiarrhythmic Drug Therapy for Maintenance of Sinus Rhythm in Patients with Recurrent Paroxysmal or Recurrent Persistent Atrial Fibrillation

No structural heart disease^a First line: flecainide, propafenone, or sotalol Second line: amiodarone or dofetilide (catheter ablation could also be considered as an alternative to antiarrhythmic therapy)
Heart failure^a First line: amiodarone or dofetilide Second line: catheter ablation
Coronary artery disease^a First line: sotalol (to be used only if patients have normal LV systolic function) Second line: amiodarone or dofetilide (catheter ablation could also be considered as an alternative to antiarrhythmic therapy)
Hypertension^a Presence of significant LVH First line: amiodarone Second line: catheter ablation Absence of significant LVH: First line: flecainide, propafenone, or sotalol Second line: amiodarone or dofetilide (catheter ablation could also be considered as an alternative to antiarrhythmic therapy)

LV, left ventricular; LVH, left ventricular hypertrophy.
^aDrugs are listed alphabetically and not in order of suggested use.

The type Ic antiarrhythmics, flecainide and propafenone, are effective for maintaining sinus rhythm. However, because of the increased risk for proarrhythmia, these drugs should be avoided in patients with structural heart disease.

Although all of the oral type III antiarrhythmic drugs have demonstrated efficacy in preventing recurrences of AF, amiodarone is clearly the most effective agent and is now the most frequently chosen despite its impressive organ toxicity.¹¹ Since 2000, the superiority of amiodarone over other antiarrhythmics for maintaining patients in sinus rhythm has been demonstrated in a number of clinical trials. In the Canadian Trial of Atrial Fibrillation, amiodarone was significantly more effective than sotalol or propafenone in maintaining sinus rhythm in patients with persistent or paroxysmal AF.³⁴ Furthermore, in a substudy of the AFFIRM trial, amiodarone appeared to be the most effective antiarrhythmic agent of those used in the study.³⁵ In the more recently published Sotalol Amiodarone Atrial Fibrillation Efficacy Trial, amiodarone and sotalol were equally effective at converting AF to sinus rhythm.³⁶ However, amiodarone was significantly more effective than sotalol at maintaining sinus rhythm in all patient subgroups, except for those with ischemic heart disease where the efficacy of these two drugs was comparable.

Although sotalol is not effective for conversion of AF, it is an effective agent for maintaining sinus rhythm. Sotalol has been shown to be at least as effective as quinidine or propafenone in preventing recurrences of AF.^{34,37} However, treatment with either quinidine or sotalol is associated with a similar incidence of TdP. Because this form of proarrhythmia primarily occurs with higher doses of sotalol (quinidine usually causes TdP at low or therapeutic concentrations), it may be more easily predicted and therefore avoided. Nonetheless, sotalol may increase mortality in patients with AF similar to quinidine; however, this requires further study.³⁸

Dofetilide is effective in preventing recurrences of AF³⁹ but has not been directly compared with either amiodarone or sotalol. In a large, multicenter trial,⁴⁰ dofetilide (dose adjusted for renal function and QT interval) was more effective than placebo in maintaining sinus rhythm (approximately 35% to 50% at 1 year). The efficacy of dofetilide for the maintenance of sinus rhythm has also specifically been demonstrated in patients with LV dysfunction.⁴¹ Like sotalol and quinidine, dofetilide also has significant potential to cause TdP (in a dose-related fashion).

Overall, the use of antiarrhythmic drug therapy to maintain sinus rhythm is reasonable to consider in patients with recurrent paroxysmal or persistent AF who develop intolerable symptoms during episodes of AF. As with cardioversion, the selection of an antiarrhythmic drug for maintaining sinus rhythm should be based on whether the patient has structural heart disease.¹⁵ For those patients with no underlying structural heart disease, flecainide, propafenone, or sotalol should be considered initially because they have the most optimal long-term safety profile. However, amiodarone or dofetilide could be used as alternative therapy if the patient fails or does not tolerate one of these initial antiarrhythmic drugs. In the presence of structural heart disease, flecainide and propafenone, should be avoided because of the risk of proarrhythmia. If LV dysfunction is present (LVEF $\leq 40\%$), amiodarone should be considered the antiarrhythmic of choice. Dofetilide can be used as an alternative if patients develop intolerable side effects with amiodarone. In patients with coronary artery disease, sotalol can be used initially, provided that the patient's LV function is normal. Amiodarone or dofetilide could be used as an alternative therapy if the patient fails or does not tolerate sotalol. The presence of LV hypertrophy may predispose the myocardium to proarrhythmic events. Because of its low proarrhythmic potential, amiodarone should be considered first-line therapy in these patients.

Nondrug forms of therapy, designed to maintain sinus rhythm are becoming increasingly popular treatment options for patients with AF or atrial flutter. For patients who have "pure" (i.e., not associated
