with concurrent AF) type I atrial flutter, ablation of the reentrant substrate with radiofrequency current is highly effective ($\sim 80\%$)⁴² and can be considered first-line treatment of atrial flutter to prevent recurrences.⁴³ For patients with AF, an innovative surgical procedure, referred to as the "maze" operation, has been used for more than a decade.⁴⁴ Because of its highly complex and invasive nature, the maze procedure is often reserved for highly drug-refractory patients. Over the past several years, most of the emerging data in the literature regarding nondrug treatment of AF have primarily focused on the safety and efficacy of catheter ablation techniques. Patients with AF have been found to have arrhythmogenic foci that occur in atrial tissue near and within the pulmonary veins. During the ablation procedure, radiofrequency energy can be delivered to these areas in an attempt to abolish the foci. Historically, this procedure was often considered last-line therapy for patients who had failed all antiarrhythmic drugs, including amiodarone. However, in some of the recent trials, the use of catheter ablation in patients with AF has been associated with a significant reduction in recurrent episodes of AF and an improvement in quality of life when compared with antiarrhythmic drug therapy.^{45,46} There is even some evidence⁴⁷ to suggest that this procedure may be superior to antiarrhythmic drugs as first-line therapy of symptomatic AF; however, these results will have to be validated in larger trials. Based on this recent data, the guidelines now recommend that catheter ablation be considered as a reasonable treatment alternative for patients with symptomatic episodes of recurrent AF who fail or do not tolerate at least one antiarrhythmic drug.¹⁵ This procedure is not without its risks, as major complications, such as pulmonary vein stenosis, thromboembolic events, cardiac tamponade, and new atrial flutter, have been reported in up to 6% of patients.⁴⁸

PAROXYSMAL SUPRAVENTRICULAR TACHYCARDIA CAUSED BY REENTRY

Paroxysmal supraventricular tachycardia arising by reentrant mechanisms includes those arrhythmias caused by AV nodal reentry, AV reentry incorporating an anomalous AV pathway, SA nodal reentry, and intraatrial reentry. Atrioventricular nodal reentry and AV reentry are by far the most common of these tachycardias. **5**

Mechanisms

The underlying substrate of AV nodal reentry is the functional division of the AV node into two (or more) longitudinal conduction pathways or "dual" AV nodal pathways.⁴⁹ Most clinicians now believe that there are not two distinct anatomic pathways inside the AV node itself; rather, it is likely that a fan-like network of perinodal fibers inserts into the AV node and represents the second pathway. The two pathways possess key differences in conduction characteristics: one is a fast conducting pathway with a relatively long refractory period (fast pathway), and the other is a slower conducting pathway with a shorter refractory period (slow pathway). The presence of dual pathways does not necessarily imply that the patient will have clinical PSVT. In fact, it is estimated that between 10% and 50% of patients have discernible dual pathways but the incidence of PSVT is considerably lower.⁴⁹ Sustainance of the tachycardia depends on the critical electrophysiologic discrepancies and the ability of one pathway (usually the slow) to allow repetitive antegrade conduction, and the ability of the other pathway (usually the fast) to allow repetitive retrograde conduction. During sinus rhythm, a patient with dual pathways conducts supraventricular impulses antegrade through both pathways. Electrical activity reaches the distal common pathway at the level of or above the His bundle and continues to depolarize the ventricles in an antegrade direction. Conduction proceeds via the two pathways but reaches the distal common pathway first through the

FIGURE 19-7. Reentry mechanism of dual AV nodal pathway PSVT. *A.* Sinus rhythm: The impulse travels from the atrium through the fast pathway (*F*) and then to the His-Purkinje system (*His*). The impulse also travels through the slow pathway (*S*) but is stopped when refractory tissue is encountered. *B.* Dual AV nodal reentry: A critically timed premature impulse (*) is stopped in the fast pathway (because of prolonged refractoriness) but is able to travel antegrade down the slow pathway and retrograde through the fast pathway.

fast AV nodal route (Fig. 19-7). For this reason, a short PR interval is sometimes observed during sinus rhythm.

Paroxysmal supraventricular tachycardia caused by AV nodal reentry may occur by the following sequence of events. The occurrence of an appropriately timed premature impulse penetrates the AV node, but is blocked in the fast pathway that is still refractory from the previous beat. However, the slow pathway, which has a shorter refractory period, permits antegrade conduction of the premature impulse. By the time the impulse has reached the distal common pathway, the fast pathway has recovered its excitability and now will permit retrograde conduction. The impulse reaches the common proximal pathway, preceded by an excitable gap of tissue, and reenters the slow pathway. A reentrant circuit that does not require atrial or ventricular tissue is completed within (or nearly so) the AV node, and a tachycardia is thereby initiated (see Fig. 19-7). The common form of this tachycardia uses the slow pathway for antegrade conduction and the fast pathway for retrograde conduction; an uncommon form exists in which the reentrant impulse travels in the opposite direction.

Atrioventricular reentrant tachycardia depends upon the presence of an anomalous, or accessory, extranodal pathway that bypasses the normal AV conduction pathway. Several different types of accessory pathways have been described, depending on the specific anatomic areas they connect (e.g., AV bundles or nodoventricular tracts); some are also referred to as eponyms, such as the Kent bundle. A Kent bundle is an extranodal AV connection that is associated with WPW syndrome. During sinus rhythm (Fig. 19-8), patients with WPW syndrome depolarize the ventricles simultaneously through both AV pathways (AV nodal pathway and the Kent bundle), creating a fusion pattern on the early portion of the QRS complex (delta wave). The degree of ventricular “preexcitation” depends on the contribution of antegrade ventricular activation through the accessory pathway. Patients may have an accessory pathway that is not evident on ECG, which is referred to as a “concealed” Kent bundle. These concealed

FIGURE 19-8. Reentry mechanism for AV accessory pathway PSVT in Wolff-Parkinson-White syndrome. *A.* Sinus rhythm: The impulse travels from the atrium to the ventricle by two pathways—the AV node and an accessory bypass pathway. *B.* AV reentry: A critically timed premature impulse (*) is stopped in the Kent bundle (because of prolonged refractoriness) but travels antegrade through the AV node and retrograde through the Kent bundle. (AV, atrioventricular; His, His-Purkinje system; LB, left bundle-branch; RB, right bundle-branch; SA, sinoatrial.)

accessory pathways are often incapable of antegrade conduction and can only accept electrical stimulation in a retrograde fashion. The electrocardiographic expression of preexcitation (delta wave) depends on the location of the accessory pathway, the distance from the wavefront of sinus activation and the conduction characteristics of the various structures involved. It should be noted that (similar to patients with dual AV nodal pathways) not all patients with preexcitation with an accessory AV pathway are capable of having clinical PSVT.

Patients with an accessory AV pathway may have three forms of supraventricular tachycardia: orthodromic reentry, antidromic reentry, and/or AF or atrial flutter. Atrioventricular reentrant PSVT usually occurs by the following sequence of events. Analogous to AV nodal reentry, two pathways (the normal AV nodal pathway and the accessory AV pathway) exist that have different electrophysiologic characteristics. The AV nodal pathway usually has a relatively slower conduction velocity and shorter refractory period, and the accessory pathway has a faster conduction velocity and a longer refractory period. A critically timed premature impulse may be blocked in the accessory pathway because this area is still refractory from the previous sinus beat. However, the AV nodal pathway, with a relatively shorter refractory period, may accept antegrade conduction of the premature impulse. Meanwhile, the accessory pathway may recover its excitability and now allow retrograde conduction. A macroreentrant tachycardia is thereby initiated in which the antegrade pathway is the AV nodal pathway; the distal common pathway is the ventricle; the retrograde pathway the accessory pathway; and the proximal common pathway is the atrium (see Fig. 19-8). This sequence of events (down the node, up the Kent bundle), termed *orthodromic PSVT*, is the common variety of reentry in patients with an accessory AV pathway, resulting in a narrow QRS tachycardia. In the uncommon variety, conduction proceeds in the opposite direction (down the Kent bundle, up the node), resulting in a wide QRS tachycardia, which is termed *antidromic PSVT*. Patients with WPW syndrome can have a third type of tachycardia, namely AF. The occurrence of AF in the setting of an accessory AV pathway (i.e., WPW syndrome) can be extremely serious and has been documented. As AF is an extremely

rapid atrial tachycardia, conduction can proceed down the accessory AV pathway, resulting in a very fast ventricular response or even VF. Unlike the AV nodal pathway, the refractory period of the accessory bundle shortens in response to rapid stimulation rates.

Sinus node reentry and intraatrial reentry occur less commonly and are not as well-described as AV nodal reentry and AV reentry. Aside from a characteristic abrupt onset and termination, coupled with subtle changes in P-wave morphology, these tachycardias can be difficult to diagnose. Electrophysiologic studies may be necessary to determine the ultimate mechanism of the PSVT.

Management

Both pharmacologic and nonpharmacologic methods have been used to treat patients with PSVT. Drugs used in the treatment of PSVT can be divided into three broad categories: (a) those that directly or indirectly increase vagal tone to the AV node (e.g., digoxin); (b) those that depress conduction through slow, calcium-dependent tissue (e.g., adenosine, β -blockers, and CCBs); and (c) those that depress conduction through fast, sodium-dependent tissue (e.g., quinidine, procainamide, disopyramide, and flecainide). Drugs within these categories alter the electrophysiologic characteristics of the reentrant substrate so that PSVT cannot be sustained.^{50,51} In PSVT caused by AV nodal reentry, type I antiarrhythmic drugs, such as procainamide, act primarily on the retrograde fast pathway. Digoxin and β -blockers may work on either the retrograde fast or the antegrade slow limb. Verapamil, diltiazem, and adenosine prolong conduction time and

increase refractoriness primarily in the slow antegrade pathway of the reentrant loop. In PSVT caused by AV reentry incorporating an extranodal pathway, type I drugs increase refractoriness in the fast accessory pathway or within the His-Purkinje system. β -blockers, digoxin, adenosine, and verapamil all act by their effects on the AV nodal (antegrade, slow) portion of the reentrant circuit. Regardless of the mechanism, treatment measures are directed at first terminating an acute episode of PSVT and then preventing symptomatic recurrences of the arrhythmia.

For those patients with PSVT who present with severe symptoms (syncope, near syncope, angina, or severe HF), synchronized DCC is the treatment of choice. Even at low energy levels (such as 25 joules), DCC is almost always effective in quickly restoring sinus rhythm and correcting symptomatic hypotension. Patients with only mild to moderate symptoms usually do not require DCC and nondrug measures that increase vagal tone to the AV node can be used initially. Unilateral carotid sinus massage, Valsalva maneuver, ice water facial immersion, induced retching, and other more elaborate vagomimetic measures are often successful in terminating PSVT, although carotid massage and Valsalva maneuver are the simplest, least obtrusive, and most frequently used of these techniques.

In the event that vagal maneuvers fail (approximately 80% of acute episodes) in those patients with tolerable symptoms, drug therapy is the next option. Figure 19-9 shows a therapeutic approach to the acute treatment of the different forms of reentrant PSVT. **6** This approach is based on analysis of the electrocardiographic characteristics of the rhythm because PSVT is not always discernible from other

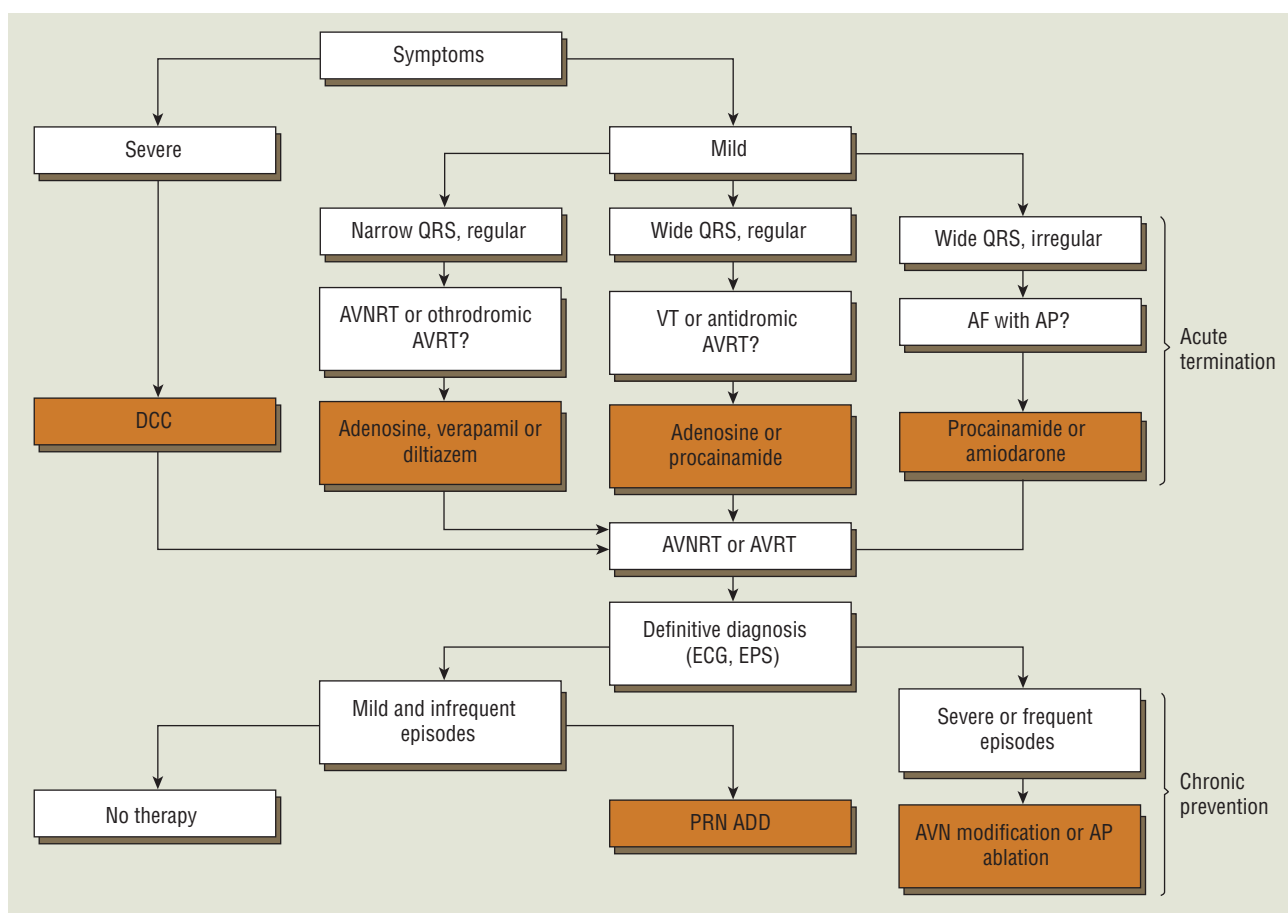

FIGURE 19-9. Algorithm for the treatment of acute (top portion) paroxysmal supraventricular tachycardia and chronic prevention of recurrences (bottom portion). Note: For empiric bridge therapy prior to radiofrequency ablation procedures, calcium channel blockers (or other AV nodal blockers) should not be used if the patient has AV reentry with an accessory pathway. (AAD, antiarrhythmic drugs; AF, atrial fibrillation; AP, accessory pathway; AV, atrioventricular; AVN, atrioventricular nodal; AVNRT, atrioventricular nodal reentrant tachycardia; AVRT, atrioventricular reentrant tachycardia; DCC, direct current cardioversion; ECG, electrocardiographic monitoring; EPS, electrophysiologic studies; PRN, as needed; VT, ventricular tachycardia.)

arrhythmias, and some forms of PSVT require different treatment. In patients with a narrow QRS, regular arrhythmia (AV nodal reentry or orthodromic AV reentry), IV verapamil (5 to 10 mg), IV diltiazem (15 to 25 mg), or adenosine (6 to 12 mg) are all equally efficacious. Approximately 80% to 90% of PSVT episodes will revert to sinus rhythm within 5 minutes of IV verapamil, diltiazem, or adenosine therapy.⁵² Both verapamil and diltiazem have the advantage in terms of cost, being available in generic formulations; whereas adenosine (although it has a higher frequency of side effects) may be safer because of its ultrashort duration of action. Adenosine should not be used in patients with severe asthma because of the potential risk of bronchospasm. The most recent guidelines for cardiopulmonary resuscitation (CPR) and emergency cardiovascular care from the AHA,⁵³ and practice guidelines from the ACC/AHA/ESC,⁴³ promote adenosine as the drug of first choice in patients with PSVT. **5** These recommendations are particularly important when treating a patient who presents with a wide QRS, regular tachycardia that may be VT or PSVT (antidromic AV reentry or as a result of aberrancy). Because of its short duration of action (seconds), adenosine will not cause the severe and prolonged hemodynamic compromise seen in patients with VT who were mistakenly treated with verapamil and suffer from its negative inotropic effects and vasodilator properties.⁵⁴ If, in fact, the arrhythmia is PSVT, adenosine will likely terminate it. An alternative treatment for this type of patient is IV procainamide, which works on the fast, sodium-dependent extranodal pathway, and is also effective for VT. Likewise, IV procainamide, or perhaps amiodarone (particularly in patients with LV dysfunction), should be used for the patient who presents with a wide QRS, irregular arrhythmia that is hemodynamically stable.⁵³ This rhythm could represent AF with rapid ventricular activation occurring primarily through an extranodal pathway. Administration of IV verapamil, diltiazem, digoxin, or adenosine to these patients could result in a paradoxical increase in ventricular response, causing severe symptoms requiring cardioversion. Consequently, these agents are considered contraindicated in this specific setting.

Once the acute episode of PSVT is terminated, a decision on long-term preventive therapy must follow. Most patients require long-term therapy; preventive treatment is indicated if: (a) frequent episodes occur that necessitate therapeutic intervention (i.e., emergency room visits or interference with the patient's lifestyle), or (b) infrequent but severely symptomatic symptoms occur. For those patients in whom a preventive treatment is deemed necessary, two methods of management have been used: preventive drug therapy and ablation.

Antiarrhythmic drugs are no longer the treatment of choice to prevent recurrences of reentrant PSVT for the following reasons: (a) life-long treatment is necessary in these generally young, but otherwise healthy, individuals; (b) there are few, if any, large controlled or comparative trials to assist the clinician in rationally choosing effective agents, and most importantly; (c) other nondrug treatments are clearly more effective. Nevertheless, occasionally one must resort to the use of drug therapy in these patients. A trial-and-error approach on an ambulatory basis may be considered for those patients with frequently recurrent, mildly symptomatic PSVT. Ambulatory electrocardiographic recordings (Holter) or telephonic transmissions of cardiac rhythm (event monitors) can be used to objectively document the efficacy or failure of drug therapy. Drugs known to be effective in preventing recurrences of PSVT are the AV nodal-blocking agents (digoxin, β -blockers, nondihydropyridine CCBs, and combinations of these agents) and the type Ic antiarrhythmic drugs (flecainide, propafenone). Agents such as quinidine, disopyramide, amiodarone, and dofetilide, although effective in some patients, should be discouraged because of the risk of toxicity with long-term treatment. One concept that can serve as an aid to arriving at an effective regimen is that there are patterns of drug

response in patients with PSVT; in other words, the tachycardia behaves as if it has a "weak link." Patients who respond to agents that act on one limb of the reentrant loop are less likely to respond to drugs that block conduction on the other limb. For instance, in a patient with AV nodal reentry, one may first choose a nondihydropyridine CCB or β -blocker (to affect the antegrade, slow pathway). If symptomatic recurrences are subsequently documented, it may be prudent to switch to a type Ic agent (to affect the retrograde, fast pathway) in an attempt to find the weak link or susceptible pathway. Patients with evidence of preexcitation (delta waves during sinus rhythm) should not be treated with only AV nodal-blocking agents. If AF were to occur, these agents would facilitate rapid conduction over the accessory pathway. The trial-and-error method for determining drug effectiveness in this setting has inherent shortcomings. If the PSVT episodes are infrequent, a considerable time period may be consumed before an effective regimen is realized, or if the patient has moderate to severe symptoms associated with PSVT, he/she may experience several troublesome episodes before the correct agent is identified. Consequently, a method of serial testing of antiarrhythmic agents by invasive electrophysiologic techniques has been used to determine effective long-term therapy in those patients with sporadic and/or symptomatic PSVT and this method represents another strategy to find an effective antiarrhythmic regimen. Using this method, the patient's clinical tachycardia is replicated in the laboratory by inserting appropriately timed, premature extra stimuli via a transvenous right-heart catheter. The patient is first studied off of antiarrhythmic therapy; induction of the tachycardia by premature stimuli by programmed stimulation serves as a control study. Then, over a period of several days, specific drugs are administered in a serial fashion and tested for efficacy in preventing the induction of PSVT.⁵⁰ The goal is to find an effective drug regimen in a short period of time, obviating the recurrence of highly symptomatic or rare episodes that may occur in the trial-and-error method. Occasionally, one encounters a patient with uncommon and very-well-tolerated recurrences of PSVT. Similar to those with paroxysmal AF, self-administered, single-dose oral therapy (i.e., the "pill-in-the-pocket" strategy) has been shown effective. Specifically, 120 mg of oral diltiazem coupled with 80 mg of oral propranolol has been shown to be superior to single-dose flecainide in terminating PSVT, decreasing the need to visit the emergency department for treatment.⁵⁵ Nonetheless, *all* forms of drug treatment designed to prevent or terminate the arrhythmia by self-administered therapy should probably be avoided in most patients because of the superior efficacy of nondrug treatment strategies.

Transcutaneous catheter ablation using radiofrequency current on the PSVT substrate has dramatically altered the traditional treatment of these patients (Fig. 19–10). **5** Radiofrequency energy delivered through a transvenous or arterial catheter causes small, discrete lesions through thermal energy. During invasive electrophysiologic studies, portions of the reentrant circuit can be located (or "mapped") by the use of a number of catheters. Once this is completed, radiofrequency energy is applied, creating thermal injury in the tissue necessary for reentry. In this way, the substrate for reentry is destroyed, "curing" the patient of recurrent episodes of PSVT and obviating the need for chronic drug therapy. Historically, ablation procedures were reserved for drug-refractory patients because they necessitated open-heart surgery. However, breakthroughs in technology initially included transvenous catheter approaches, followed by the use of radiofrequency (rather than direct current) energy. Complications, although unusual, include tamponade, pericarditis, valvular insufficiency, and AV block. Radiofrequency ablation is highly effective, preventing the recurrences of PSVT in 85% to 98% of patients.^{56,57} The procedure was originally used in patients with WPW syndrome.⁵⁶ In these patients, the extranodal pathway is most often located at the left lateral free

FIGURE 19-10. Drawing showing catheter placement for radiofrequency ablation of a left lateral free wall accessory pathway. Here, a venous (atrial) transseptal puncture to gain access to the Kent bundle is shown; a retrograde arterial approach has also been used. (From Lerman BB, Basson CT. High risk patients with ventricular preexcitation: A pendulum in motion. *N Engl J Med* 2003;349:1787–1789, with permission.)

wall of the left ventricle (Fig. 19–10). After the pathway is located, the catheter is put as close to the site as possible and radiofrequency current is applied to make small burns in the tissue. Ablation of the extranodal connection occurs promptly and evidence of preexcitation (delta waves) disappears. Thereafter, a similar approach was developed for patients with AV nodal reentry, placing the catheter in the coronary sinus, proximal to the AV node.⁵⁷ The preferred method in these individuals is to apply small amounts of radiofrequency current to the slow pathway of the reentrant circuit in order to modify its properties enough so that PSVT can not recur.

It has been suggested that *all* patients with symptomatic PSVT undergo radiofrequency catheter ablation.⁵⁸ This is because it is highly effective and curative, rarely results in complications, and obviates the need for chronic antiarrhythmic drug therapy. In other

words, it should be considered in *any* patient who would previously be considered for chronic antiarrhythmic drug treatment. Radiofrequency ablation is also a cost-effective approach (in the long-term) because, if effective, the costs of drugs and repeated hospital visits are avoided. In one cost-effectiveness analysis, radiofrequency ablation improved quality of life and reduced lifetime medical expenditures by nearly \$30,000 compared to chronic drug treatment.⁵⁹

AUTOMATIC ATRIAL TACHYCARDIAS

Automatic atrial tachycardias, such as multifocal atrial tachycardia, appear to arise from supraventricular foci that have enhanced automatic properties.⁶⁰ It is presumed that multifocal atrial tachycardia is the result of multiple ectopic atrial pacemakers, which account for the variable and differing P-wave morphology. In unifocal atrial tachycardia (more often referred to as ectopic atrial tachycardia), a single P-wave morphology, different from that of sinus rhythm, is recorded. In either case, the underlying, precipitating disorder present in the majority (60% to 80%) of these patients is severe pulmonary disease. Other disease states associated with these arrhythmias include acute infection (pneumonia and sepsis) and dilated congestive cardiomyopathy. It should be noted that young patients without associated precipitating factors might rarely present with rapid atrial tachycardias from unknown etiologies. In these cases, long-standing tachycardias cause the cardiomyopathic state. Effective treatment of the tachycardia may result in reversal of the LV dysfunction. Traditionally, many factors (i.e., electrolyte disturbances, hypoxia, catecholamines, and tissue stretch) may cause an elevated slope of phase 4 depolarization and theoretically result in abnormal heightened automaticity. Noteworthy is that many of these factors are often clinically present in patients with concurrent pulmonary disease and automatic atrial tachycardia. However, it appears that triggered activity (i.e., LADs) is a more likely mechanism in the genesis of these tachycardias. Atrial tachycardias with AV block or a slow ventricular response should alert the clinician to the possibility of digitalis toxicity.

The first step in the treatment of automatic atrial tachycardia is to correct the underlying, precipitating factors.⁶⁰ One should ensure proper oxygenation and ventilation and correct acid–base or electrolyte disturbances. These measures alone may result in the return of sinus rhythm, but in some cases, the tachycardia will persist. Patients with an asymptomatic atrial tachycardia and a relatively slow ventricular rate usually require no drug therapy. In symptomatic patients, medical therapy can be tailored to either control ventricular rate or to restore sinus rhythm. Type I antiarrhythmic drugs, such as procainamide and quinidine, are only occasionally effective in restoring sinus rhythm, and are usually not considered first-line therapy. Direct-current cardioversion is ineffective in restoring sinus rhythm, and the use of programmed stimulation will not replicate the clinical tachycardia; consequently, serial drug testing is of no value. The use of IV β -blockers to slow ventricular rate is usually contraindicated because of the frequent coexistence of bronchospastic pulmonary disease or decompensated HF. Digoxin has been used but is controversial because of its ability to increase the automatic properties of atrial tissue and the high sympathetic state of these patients frequently overrides the vagotonic effects of digoxin, rendering it ineffective. Nondihydropyridine CCBs, such as verapamil, are most effective and are now considered first-line drug therapy.⁶¹ Interestingly, verapamil seems to decrease ventricular rate by altering atrial automaticity, not by slowing AV nodal conduction.⁶¹ Intravenous magnesium (independent of serum magnesium) can also be effective, but high doses are required and its effects are transient, rendering it impractical.⁶⁰ Both verapamil and parenteral magnesium probably act by suppressing calcium-mediated LADs.

CLINICAL PRESENTATION: VENTRICULAR ARRHYTHMIAS

Premature Ventricular Contractions

- Premature ventricular contractions are non-life-threatening and usually asymptomatic. Occasionally, patients will complain of palpitations or uncomfortable heart beats. Since the PVC, by definition, occurs early and the ventricle contracts when it is incompletely filled, patients do not feel the PVC. Rather, the next beat (after the PVC and a compensatory pause) is usually responsible for the patient's symptoms.

Ventricular Tachycardia

- The symptoms of VT (monomorphic VT or TdP), if prolonged (i.e., sustained), can vary from nearly completely asymptomatic to pulseless, hemodynamic collapse. Fast heart rates and underlying poor LV function will result in more severe symptoms. Symptoms of nonsustained, self-terminating VT also correlate with duration of episodes (e.g., patients with 15-second episodes will be more symptomatic than those with 3-beat episodes).

Ventricular Fibrillation

- By definition, VF results in hemodynamic collapse, syncope, and cardiac arrest. Cardiac output and blood pressure are not recordable.

VENTRICULAR ARRHYTHMIAS

The common ventricular arrhythmias include: (a) PVCs, (b) VT, and (c) VF. These arrhythmias may result in a wide variety of symptoms. Premature ventricular complexes often cause no symptoms or only mild palpitations. Ventricular tachycardia may be a life-threatening situation associated with hemodynamic collapse or may be totally asymptomatic. Ventricular fibrillation, by definition, is an acute medical emergency necessitating CPR.

PREMATURE VENTRICULAR COMPLEXES AND PREVENTION OF SUDDEN CARDIAC DEATH

Premature ventricular complexes are very common ventricular rhythm disturbances that occur in patients with or without structural heart disease. Experimental models show that premature ventricular depolarizations may be elicited by abnormal automaticity, triggered activity, or by reentrant mechanisms. It is well known that PVCs are commonly observed in apparently healthy individuals; in these patients, the PVCs seem to have little if any prognostic significance. Premature ventricular contractions occur more frequently and in more complex forms in patients with structural heart disease than in healthy individuals. The prognostic meaning of PVCs has been well studied in patients with MI (acute or remote) with several consistent themes. Patients with some forms of PVCs are at higher risk for "sudden death" than if they did not have these minor rhythm disturbances. Sudden cardiac death can be defined as unexpected death occurring in a patient within 1 hour of experiencing symptoms. Studies of patients who experienced SCD (and happened to be wearing an electrocardiographic monitor at the time) often demonstrate the cause to be VF preceded by a short run of VT and frequent PVCs.⁶² Therein lies the basis of the so-called "PVC hypothesis" (i.e., preventing more minor arrhythmias, such as PVCs, may prevent the occurrence of SCD).

Significance

Historically, investigators promoted the concept that patients in the acute phase of MI may have types of PVCs that are predictive of VF and SCD. These types of PVCs were referred to as "warning arrhyth-

mias" and included frequent ventricular ectopy (more than 5 beats/min), multiform configuration (different morphology), couplets (two in a row), and R-on-T phenomenon (PVCs occurring during the repolarization phase of the preceding sinus beat in the vulnerable period of ventricular recovery). However, as a result of using continuous electrocardiographic monitoring techniques, it has become apparent that almost all patients have warning arrhythmias in the acute infarct setting. In those patients who experience VF, warning arrhythmias are no more common than in those without VF. Consequently, warning arrhythmias observed during acute MI are neither sensitive nor specific for determining which patients will have VF. Thus, there is little need to direct drug therapy specifically at PVC suppression in these particular patients. Studies show that effective prevention of VF in the acute infarct setting may be achieved without the abolition of PVCs.

Conversely, data strongly imply that PVCs documented in the convalescence period of MI do carry important long-term prognostic significance.⁶³ Premature ventricular complexes occurring after a MI seem to be a risk factor for patient death that is independent of the degree of LV dysfunction or the extent of coronary atherosclerosis. Ruberman et al.⁶³ employed a simple classification of PVCs: simple or benign (infrequent and monomorphic) versus "complex" (≥ 5 PVCs/min, couplets, R-on-T beats, and multiform). These investigators found that the presence of complex (but not simple) ventricular ectopy in the setting of ischemic heart disease was associated with a higher incidence of overall mortality and cardiac death. One can see that within the controversy of the significance of PVCs is a basic question: Are complex forms of PVCs simply an unimportant marker of underlying structural heart disease or are PVCs an important electrical disorder that should be addressed independently?

Because PVCs without associated structural heart disease, in apparently healthy individuals, carry little or no risk, drug therapy is unnecessary. However, because of the prognostic significance of complex PVCs in patients with structural heart disease, the use of antiarrhythmic drug therapy to suppress them has been controversial. Historically, many supported the aggressive use of antiarrhythmic drug therapy designed to suppress a high percentage of PVCs, based on the underlying premise of eliminating a risk factor for SCD in patients with coronary disease (namely the presence of complex PVCs). However, others favored a more conservative approach and disregarded drug therapy in the absence of significant symptoms. An important study, the CAST,³² abruptly put an end to this debate in noteworthy fashion and its results are reviewed below because of its great historical significance and lingering impact.

The Cardiac Arrhythmia Suppression Trial

The CAST^{32,64} was initiated by the National Institutes of Health in 1987 to determine if suppression of ventricular ectopy with encainide, flecainide, or moricizine could decrease the incidence of death from arrhythmia in patients who had suffered a MI. **7** Entrance criteria included documented MI between 6 days and 2 years prior to enrollment, and ≥ 6 PVCs per hour (associated with no or minimal symptoms) without runs of VT greater than 15 beats in length. Also, patients were required to have a LVEF $\leq 55\%$ if recruited within 90 days of MI or $\leq 40\%$ if recruited 90 days or more after infarction. Patients with a LVEF $< 30\%$ were randomized only to encainide or moricizine. Patients were randomized to receive drug therapy or placebo after demonstrating PVC suppression with one of the agents. The drug and dose were determined during an open-label, dose-titration phase that preceded randomization.

In April 1989, a routine, preliminary review of the study by the Safety and Monitoring Board revealed alarming results and the study was interrupted. The results showed that compared to placebo, treatment with encainide or flecainide was associated with a significantly higher rate of total mortality and death due to arrhythm-

FIGURE 19-11. Life table curves from the Cardiac Arrhythmia Suppression Trial (CAST), specifically for patients receiving encainide or flecainide (lighter line) and matching placebo (darker line). Note the divergent slopes of each line, implying a sustained risk of death (presumed proarrhythmia). (From The CAST Investigators. Preliminary report: Effect of encainide and flecainide on mortality in a randomized trial of arrhythmia suppression after myocardial infarction. *N Engl J Med* 1989;321:406–412, with permission.)

mia, presumably caused by proarrhythmia (Fig. 19–11). Analysis of the moricizine arm indicated neither harm nor benefit from this therapy; therefore, only this portion of the study was allowed to continue as CAST II.⁶⁴ However, in July 1991, CAST II was also prematurely stopped because there was a trend toward an increase in mortality in moricizine-treated patients. This increase in mortality was primarily observed during the initiation of moricizine therapy (dose-titration phase) but not during the chronic treatment phase. The overall results of the two CASTs conclusively prove that that the use of antiarrhythmic drug therapy (beyond the general use of β -blocking agents) to suppress PVCs in patients after a MI does not improve survival and is most likely detrimental. These studies also put into perspective the risk associated with the use of antiarrhythmic therapy and the need to carefully select only those patients with a defined therapeutic benefit.

Even though the CAST was conducted nearly 2 decades ago, it is considered one of the most important trials ever undertaken and has had a tremendous influence on the overall approach to the treatment of arrhythmias, as well as a far-reaching impact on new drug development. The results of the CAST have clearly had a negative influence on the long-term use of all antiarrhythmics, causing a broad skepticism in the risk-versus-benefit analysis of this class of drugs. Consequently, pharmaceutical companies have shifted their drug discovery and investigative efforts away from potent sodium channel blockers. As immediate fallout, encainide was withdrawn from the market, and another type Ic agent, indecainide, was not even brought to market despite approval by the Food and Drug Administration. The findings of the CAST also provided additional fuel for the pursuit of nondrug therapies for arrhythmias, such as ablation and implantable devices.

Despite the discouraging results of the CAST, post-MI patients with complex ventricular ectopy remain at risk for death. Other drugs, besides the type Ic agents, have been studied, including sotalol. Sotalol is marketed as a racemic mixture of a *d* and *l* isomer: both are type III potassium blockers but the *l* isomer has β -blocking actions. Chronic therapy with *d*-sotalol was studied in patients with remote MI complicated by complex ectopy in the Survival With Oral *d*-Sotalol trial.⁶⁵ Unlike the CAST, *d*-sotalol treatment was not designed to cause PVC suppression, yet (like the CAST) the trial was halted prematurely because of excessive mortality in the treatment arm. Again, the presumed reason for this observation was *d*-sotalol–related proarrhythmia. Currently, only two antiarrhythmic drugs have been

shown *not* to increase mortality with long-term use: amiodarone and dofetilide. A number of trials^{66,67} have shown amiodarone to decrease the incidence of sudden (or arrhythmic) death, but not total mortality, in post-MI patients with complex ventricular ectopy. A meta-analysis of all trials (6,553 combined patients) demonstrated a reduction in total mortality (by 13%) with long-term amiodarone therapy.⁶⁸ It is unclear if these findings can be attributed to one property (e.g., β -blocking) or a combination of amiodarone's complex pharmacologic effects on conduction. Noteworthy is that in two major studies, patients treated with amiodarone *and* a β -blocker generally did better than when no β -blocker was used.^{66,67} Clearly, because of its impressive adverse effect profile and its inability to improve survival, amiodarone cannot routinely be recommended in patients with heart disease such as remote MI and complex PVCs. Two randomized, controlled trials^{69,70} showed that chronic therapy with dofetilide has no effect on overall mortality in patients who have suffered MI with LV dysfunction. Dofetilide (not approved for prevention of sudden death) caused TdP in approximately 5% of patients, necessitating a protocol amendment with dosage adjustments during both trials (particularly in those with renal disease because its primary route of elimination is through the kidney).

How should the clinician approach the patient with documented asymptomatic PVCs? Clearly, attempts to suppress asymptomatic PVCs should not be made with any antiarrhythmic drug. Indeed, those patients who are at risk for arrhythmic death (recent MI, LV dysfunction, complex PVCs) should not be routinely given *any* type I or III antiarrhythmic agent.⁷¹ If these patients have symptomatic PVCs, chronic drug therapy should be limited to the use of β -blockers. The use of β -blockers in post-MI patients is associated with a decrease in the incidence of total mortality and SCD, especially in the presence of LV dysfunction. These agents can also be used in patients without underlying structural heart disease to suppress symptomatic PVCs. **7**

VENTRICULAR TACHYCARDIA

Mechanisms and Types of VT

Ventricular tachycardia is a wide QRS tachycardia that may acutely occur as a result of metabolic abnormalities, ischemia, or drug toxicity, or chronically recur as a paroxysmal form. On electrocardiographic inspection, VT may appear as either repetitive monomorphic or polymorphic ventricular complexes. The definition of VT is three or more consecutive PVCs occurring at a rate greater than 100 beats/min. An acute episode of VT may be precipitated by severe electrolyte abnormalities (hypokalemia), hypoxemia, or digitalis toxicity, or (most commonly) may occur during an acute MI or ischemia complicated by HF. In these cases, correction of the underlying precipitating factors will usually prevent further recurrences of VT. As an example, if VT occurs during the first 24 hours of an acute MI, it will probably not reappear on a chronic basis after the infarcted area has been reperfused or healed with scar formation. This form of acute VT may be caused by a transient reentrant mechanism within temporarily ischemic or dying ventricular tissue. In contrast, some patients have a chronic recurrent form of VT that is almost always associated with some type of underlying structural heart disease. Common examples are paroxysmal VT associated with idiopathic dilated cardiomyopathy or remote MI with a LV aneurysm. Indeed, severe LV dysfunction and aneurysm formation are risk factors for the development of VT on a recurrent basis after MI. In chronic, recurrent VT, microentry within the distal Purkinje network is presumed to be responsible for the underlying substrate in a large majority of patients (see Fig. 19–3). Theoretically, electrophysiologic discrepancies occur as a result of structural damage and heart disease within the ventricular conducting system. The reentrant circuit may possess both anatomically determined and functional properties coursing through

normal tissue, damaged (but not dead) tissue and islands of necrosed tissue. In a minority of patients, macro-reentrant circuits may be responsible for recurrent VT, including reentry incorporating the bundle branches.

Patients with acute VT associated with a precipitating factor often suffer severe symptoms, requiring immediate treatment measures. Chronic recurrent VT may also cause severe hemodynamic compromise, but may also be associated with only mild symptoms, which are generally well tolerated. Sustained VT is that which requires therapeutic intervention to restore a stable rhythm or persists for a relatively long time (usually longer than 30 seconds). Nonsustained VT is that which self-terminates after a brief duration (usually less than 30 seconds). If the patient has VT more frequently than sinus rhythm (i.e., VT is the dominant rhythm), this is referred to as incessant VT. In monomorphic VT, the QRS complexes are similar in morphologic characteristics from beat to beat. In polymorphic VT, the QRS complexes vary in shape between beats. A characteristic type of polymorphic VT, in which the QRS complexes appear to undulate around a central axis and is associated with evidence of delayed ventricular repolarization (long QT interval or prominent U waves), is referred to as TdP.

Most but not all forms of recurrent VT occur in patients with extensive structural heart disease. Ventricular tachycardia occurring in a patient without structural heart disease is sometimes referred to as “idiopathic VT” and may take several forms.^{72–74} Fascicular tachycardia arises from a fascicle of the left bundle branch (usually posterior) and is usually not associated with severe underlying structural heart disease. In distinct contrast to the common form of recurrent VT associated with extensive structural heart disease, nondihydropyridine CCBs (but not adenosine) are effective in terminating an acute episode of fascicular VT. Ventricular outflow tract tachycardia (usually originating from the right ventricular outflow tract) originates from near the pulmonic valve (or uncommonly the aortic valve) and also occurs in patients with normal LV function without discernible cardiac disease.⁷⁴ Unlike other forms of VT, right ventricular outflow tract tachycardia often terminates with adenosine and may be prevented with β -blockers and/or nondihydropyridine CCBs.

Some unusual forms of VT are congenital or heritable (Table 19–10). Torsade de pointes can be associated with heritable defects in the flux of ions that govern ventricular repolarization. Although nine syndromes and genetic mutations have been described, the more common examples are long QT syndrome 1 (depressed I_{Ks}), long QT syndrome 2 (depressed I_{Kr}), and long QT syndrome 3 (enhanced inward sodium ion flux during repolarization).^{75,76} Polymorphic VT (without a long QT interval) or VF may also occur as a result of a heritable defect in the sodium channel. This is the case in Brugada syndrome, described as a typical ECG pattern (ST-segment elevation in leads V_1 to V_3) in sinus rhythm associated with SCD, commonly in males of Asian descent.⁷⁷ It is estimated that Brugada syndrome accounts for approximately 40% of all cases of VF in patients without heart disease.

Management

Consider the patient with the more common form of sustained monomorphic VT (i.e., those with structural heart disease, usually ischemic in nature). Like other rapid tachycardias, the initial management of an acute episode of VT (with a pulse) requires a quick assessment of the patient’s status and symptoms. If severe symptoms are present (i.e., severe hypotension, angina, pulmonary edema), synchronized DCC should be delivered immediately to attempt to restore sinus rhythm. An investigation should be made into possible precipitating factors and these should be corrected if possible. The diagnosis of acute MI should be entertained. If the episode of VT is thought to be an isolated electrical event associated with a transient initiating factor (such as acute myocardial ischemia or digitalis toxicity), there is no need for long-term antiarrhythmic therapy once the precipitating factors are corrected (e.g., an infarct has been reperfused and healed and the patient is stable). Nevertheless, the patient should be monitored closely for possible recurrences of VT.

Patients presenting with an acute episode of VT (with a pulse) associated with only mild symptoms can be initially treated with antiarrhythmic drugs (synchronized DCC should be readily available). The reader is referred to the most recent guidelines for CPR and emergency cardiovascular care put forth by the AHA.⁵³ Intravenous amiodarone is now recommended as first-line antiarrhythmic therapy in this situation. Intravenous procainamide or lidocaine are suitable alternatives, although in one small study comparing these two agents, procainamide was shown to be superior in terminating VT.⁷⁸ Synchronized DCC should be delivered if the patient’s status deteriorates, VT degenerates to VF (would be unsynchronized in this situation), or drug therapy fails.

Once an acute episode of sustained VT has been successfully terminated by electrical or pharmacologic means and an acute MI has been ruled out, the possibility of a patient having recurrent episodes of VT should be considered. Evidence for the possibility of VT recurrence can often be gleaned from invasive electrophysiologic studies using programmed ventricular stimulation. The management of the patient with chronic, recurrent, sustained VT deserves considerable attention. Because these patients are at extremely high risk for death, trial-and-error attempts to find effective therapy are unwarranted. To gain some objective evidence of a response to a specific antiarrhythmic regimen, serial testing of these drugs using the following two surrogate end points has been used: (a) inability to induce sustained VT with programmed extrastimuli by invasive electrophysiologic studies and (b) suppression of ventricular ectopic beats by serial 24-hour continuous electrocardiographic (Holter) monitoring. These two strategies have been compared^{79,80} but largely abandoned for several reasons. First, the yield for finding an effective drug is low. For instance, sustained monomorphic VT can be rendered noninducible or nonsustained by programmed stimulation protocols in only 20% to 25% of patients. Therefore, the clinician frequently must search for other therapeutic options or settle for other treatment end

TABLE 19-10 Heritable Polymorphic Ventricular Tachycardia

Syndrome	Channel Defect	Mutant Gene	Characteristics	Treatment
LQTS ₁	$\downarrow I_{Ks}$	KVLQT1	SCD/TdP with exercise	BB/ICD
LQTS ₂	$\downarrow I_{Kr}$	HERG	SCD/TdP with arousal	BB/ICD
LQTS ₃	$\uparrow I_{Na}^+$ during plateau/repolarization	SCN5A	SCD/TdP at rest/sleep	Flecainide Mexiletine/ICD
Brugada	$\downarrow I_{Na}^+$	SCN5A	SCD/PMVT or VF at rest/sleep in Asian males	ICD/quinidine

BB, β -blocker; ICD, implantable cardioverter-defibrillator; LQTS, long QT syndrome; PMVT, polymorphic ventricular tachycardia; SCD, sudden death; TdP, torsade de pointes; VF, ventricular fibrillation.

Note: LQTS can be provoked by potassium channel blockers (e.g., quinidine, sotalol) and Brugada syndrome can be provoked by potent sodium channel blockers (e.g., cocaine, flecainide). LQTS₃ and Brugada syndrome may coexist.

points such as slower and more tolerable inducible VT. Second, amiodarone is clearly the most effective (approximately 50% effective after 2 years) agent in patients with recurrent VT; however, electrophysiologic drug testing does not necessarily predict the clinical efficacy of amiodarone. Patients may have continued inducibility of VT on amiodarone despite long-term success. Indeed, empiric amiodarone has been compared to therapy (with other agents) guided by electrophysiologic testing in patients at high risk for recurrent VT.⁸¹ In this trial, amiodarone therapy without invasive testing was superior in preventing SCD and recurrences of severe ventricular arrhythmias at all time points. Third, the recurrence rate of life-threatening VT is high (20% to 50% per year depending on the drug chosen), regardless of the method of acute drug testing. Fourth, is the substantial side-effect profile of the type I and type III antiarrhythmic agents referred to previously. Lastly, and perhaps most importantly, is the impressive demonstrated effectiveness of nondrug approaches to the treatment of recurrent VT/VF.⁸² For instance, some forms of recurrent VT are amenable to catheter ablation therapy using radiofrequency current. This approach is highly effective (approximately 90%) in idiopathic VT (right ventricular outflow tract or fascicular VT), but less so in recurrent VT associated with a cardiomyopathic process or remote MI with LV aneurysm. In the latter patients, ablation is usually regarded as second-line therapy after other methods have failed.

The Implantable Cardioverter-Defibrillator The introduction of and advances in the ICD (Fig. 19–12) have obviated the need for serial drug testing (by invasive or noninvasive methods).⁸³

8 Numerous advancements in device technology have allowed the ICD to become smaller, less invasive to implant, and programmable. Early ICDs required a thoracotomy to place the generator in the abdomen, whereas with the newer, smaller models, the leads are implanted transvenously with the generator placed into the pectoral region in a manner similar to cardiac pacemakers. Modern ICDs now employ a “tiered-therapy approach” meaning that overdrive pacing (i.e., antitachycardia pacing) can be attempted first to terminate the tachyarrhythmia (no painful shock delivered), followed by low-energy cardioversion, and, finally, by painful, high-energy defibrillation

shocks. In addition, backup antibradycardia pacing and extended battery lives have made these newer devices much more attractive. All models store recordings during delivery of pacing shocks; this is extremely important in discerning appropriate from inappropriate shocks (i.e., delivers shock for AF with rapid ventricular rate) and in documenting true recurrences of the patient’s tachycardia.

Although the ICD is a highly effective method for preventing SCD due to recurrent VT or VF,⁸⁴ several problems remain. First, the device itself, implantation procedure, electrophysiologic studies, hospitalization, and physician fees are costly. Given that the indications for receiving an ICD have significantly expanded over the past several years, the total cost associated with the implantation of this device is likely to place a great burden on the healthcare system. Second, many patients (as high as 70% of patients) end up receiving antiarrhythmic drugs (usually amiodarone or sotalol) in addition to the ICD.^{85,86} Antiarrhythmic drugs can be initiated in these patients for a number of reasons, including: (a) decreasing the frequency of VT/VF episodes to subsequently reduce the frequency of appropriate shocks; (b) reducing the rate of VT so that it can be terminated with antitachycardia pacing; and (c) decreasing episodes of supraventricular arrhythmias (e.g., AF, atrial flutter) that may trigger inappropriate shocks. As result of these potential benefits, the concomitant use of antiarrhythmic drugs can minimize patient discomfort and prolong the battery life of the ICD. The decision to initiate concomitant antiarrhythmic therapy should be individualized, with treatment usually being reserved for those with frequent shocks because of VT or AF. If antiarrhythmic drugs are added to ICD therapy, one should note that many agents alter defibrillation thresholds; consequently, the device should be reprogrammed to account for this alteration.⁸⁷

Secondary Prevention of Sudden Cardiac Death Over the past decade, numerous trials have established the ICD as a superior treatment over antiarrhythmic therapy not only for the secondary prevention of SCD in patients who have been resuscitated from cardiac arrest or had sustained VT (“secondary prevention”), but also for the prevention of an initial episode of SCD in certain high-risk patient populations (“primary prevention”). With regard to the use of ICDs for secondary prevention, the results of three trials, the Antiarrhythmics Versus Implantable Defibrillators (AVID), Cardiac Arrest Study Hamburg (CASH), and Canadian Implantable Defibrillator Study (CIDS), definitively support this device as first-line therapy in this patient population.^{88–90} Of these, the AVID trial was the largest, randomizing more than 1,000 patients with resuscitated VF, sustained VT with syncope, or hemodynamically significant sustained VT (with LVEF $\leq 40\%$) to either an ICD or antiarrhythmic drugs (~95% receiving amiodarone at discharge).⁸⁸ The trial was stopped early because of a demonstrated superiority of the ICD; patients in the ICD group had a better overall survival when compared to those in the antiarrhythmic drug group (75% vs. 64%, respectively, at 3 years). Although they were smaller trials, both CASH and CIDS demonstrated the efficacy of an ICD compared with amiodarone in patients with a history of sustained VT or VF, with the ICD reducing overall mortality by 20% to 25%.^{89,90} Despite the high costs, the results of AVID, CASH, and CIDS provide strong support for the aggressive use of the ICD in patients who are at high risk for recurrent, life-threatening ventricular arrhythmias. Implantation of an ICD can be cost-effective, particularly in patients with poor LV function. Although nearly all clinicians now consider the ICD as first-line treatment for secondary prevention of SCD, there is at least one possible patient group that may do as well with antiarrhythmic drug therapy alone. In the AVID trial, there was no difference in survival between ICD and antiarrhythmic drug treatment in patients with mild LV dysfunction (LVEF $>35\%$), which suggests that long-term amiodarone therapy may be appropriate to use in this lower-risk patient population.⁸⁸ However, because this data was obtained from a post-hoc analysis, additional trials need to be performed to confirm these findings.

FIGURE 19-12. Drawing showing implantable cardioverter defibrillator. (From reference 83 with permission.)

Primary Prevention of Sudden Cardiac Death Over the past decade, the above trials have established the ICD as an effective treatment for the secondary prevention of SCD in patients who have previously suffered a documented episode of VT or VF. Most of the studies that have been performed in the past several years have focused on the efficacy of the ICD for primary prevention in patients deemed to be at high risk for SCD.^{91–94}

One of the patient populations that appears to be at high risk for a first episode of SCD are those with a prior MI, LV dysfunction, and nonsustained VT. The use of antiarrhythmic drugs to prevent SCD in this high-risk group has been significantly limited by the results of the CAST and other similar trials that have collectively demonstrated that these drugs may actually increase the risk of mortality in these patients. As a result of these trials, clinicians have sought a more clearly defined strategy for risk stratification in these patients before initiating drug therapy.

Traditionally, there are three strategies to approach the treatment of nonsustained VT: (a) conservative (i.e., no antiarrhythmic drug treatment beyond β -blockers), (b) empiric amiodarone, and (c) aggressive (i.e., electrophysiologic studies with possible insertion of an ICD) (Fig. 19–13). **9** A number of early studies^{95,96} suggested that tests such as electrophysiologic studies could be used to determine long-term risk in patients with nonsustained VT. For instance, Wilbur et al.⁹⁵ demonstrated that post-MI patients with nonsustained VT and inducible sustained VT after programmed stimulation were at increased risk for subsequent VT/VF or SCD compared to those in whom sustained VT could not be induced. These data provided the basis for the Multicenter Automatic Defibrillator Implantation Trial (MADIT) and the Multicenter Unsustained Tachycardia Trial (MUSTT).^{91,92} The MADIT was the first of these trials to be conducted to evaluate the efficacy of ICD therapy in this high-risk patient population. Specifically, this trial randomized patients with a previous MI, LVEF $\leq 36\%$, asymptomatic nonsustained VT, and inducible VT that was not suppressed with the use of IV procainamide to receive an ICD or conventional medical therapy (74% of patients in this particular group received amiodarone).⁹¹ This trial was terminated prematurely after a significant survival benefit was detected in the ICD group. The findings of the MADIT were subsequently supported by those of the MUSTT. In the MUSTT, patients with a history of MI, LVEF $\leq 40\%$, asymptomatic nonsustained VT, and inducible sustained VT were randomized to the conservative approach (no antiarrhythmic drug therapy beyond β -blockers) or electrophysiologically-guided therapy (antiarrhythmic drugs and/or ICD).⁹² The results showed that the conservative approach had a significantly higher event rate (cardiac arrest or death from arrhythmia). However, when the results of the electrophysiologically-guided group were further stratified, those receiving only antiarrhythmic drugs (no ICD) were no different in terms of outcomes than those who received no treatment. In other words, only those treated with an ICD had a significantly lower event rate and greater survival. One problem with the MUSTT, however, is that because of when the trial was initiated (1989), nearly 50% of patients received type I antiarrhythmic drugs or drugs that are now known not to improve survival in patients with coronary artery disease, LV dysfunction, and ventricular arrhythmias; only 10% of patients received the most effective agent in this setting, amiodarone. Based on the results of the MADIT and MUSTT, it is reasonable for patients with coronary artery disease, LV dysfunction, and nonsustained VT to undergo electrophysiologic testing;⁹⁷ that is, invasive electrophysiologic studies with programmed stimulation are used to determine risk and guide subsequent therapy. If these patients do not have inducible sustained VT/VF, chronic antiarrhythmic drug therapy is unnecessary; however, if these patients do have inducible sustained VT/VF, implantation of an ICD is warranted.

Although the MADIT and MUSTT provided clinicians with important information regarding risk stratification, both of these

trials targeted patients who had a history of nonsustained VT. The results of two landmark trials, the MADIT II and Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT), have provided clinicians with additional information regarding the treatment of other groups of high-risk patients who have no prior history of ventricular arrhythmia (see Fig. 19–13).^{93,94} In the MADIT II, patients with a prior MI and LVEF $\leq 30\%$ were randomized to receive either an ICD or conventional therapy (routine post-MI and HF therapy).⁹³ Neither a history of ventricular arrhythmia nor electrophysiologic testing was required for inclusion in this study. Patients in the ICD group experienced a significant reduction in mortality when compared to the conventional therapy group; the reduction in mortality in the ICD group was primarily due to a reduction in arrhythmic death. Whereas the MADIT, MUSTT, and MADIT II limited enrollment to patients with ischemic cardiomyopathy, the SCD-HeFT is the largest trial, to date, to evaluate the efficacy of an ICD in a nonischemic HF population. In this trial, patients with NYHA class II or III HF (of either ischemic or nonischemic etiology) and LVEF $\leq 35\%$ were randomized to receive placebo, amiodarone, or an ICD.⁹⁴ All patients were treated with appropriate HF therapies, as indicated. Implantation of an ICD resulted in a significantly lower mortality rate compared to treatment with either placebo or amiodarone (there was no difference between placebo and amiodarone). The survival benefits of the ICD were observed regardless of the etiology of the HF.

Overall, as the ICD trials have evolved over the past decade, the indications for implanting these devices have significantly expanded (Table 19–11).⁹⁷ Based on the results of the MUSTT, MADIT, MADIT II, and SCD-HeFT, many patients will be eligible for an ICD. **9** In fact, just based on the results of the MADIT II and SCD-HeFT alone, it is estimated that an additional 500,000 Medicare beneficiaries will now qualify for implantation of an ICD for primary prevention of SCD.

VENTRICULAR PROARRHYTHMIA

All antiarrhythmic agents have the potential to aggravate existing arrhythmias or to cause new arrhythmias. It is believed that antiarrhythmic drugs may cause proarrhythmia in 5% to 20% of patients.¹⁰ Although drug-induced arrhythmias have been recognized for several years, only recently has this adverse effect gained widespread attention. Many definitions for proarrhythmia have been proposed; however, in the simplest terms, it indicates the development of a significant new arrhythmia (such as VT, VF, or TdP) or worsening of an existing arrhythmia (episodes are longer, faster, or more frequent). As with all arrhythmias, the consequences of proarrhythmia are varied. Some patients who develop proarrhythmia may be totally asymptomatic, others may notice a worsening of symptoms, and some may die suddenly from this side effect. The development of proarrhythmia results from the same mechanisms that cause arrhythmias in general (e.g., quinidine-induced TdP due to EADs) or from an alteration in the underlying substrate due to the antiarrhythmic agent (e.g., development of an accelerated tachycardia caused by flecainide which decreases conduction velocity without significantly altering the refractory period) (see Fig. 19–4).¹⁰ The diagnosis of proarrhythmia is sometimes difficult to make because of the variable nature of the underlying arrhythmias. However, in all cases, the agent should be discontinued if proarrhythmia is detected or suspected.

Incessant Monomorphic VT

The prototypical form of proarrhythmia caused by the type Ic antiarrhythmic drugs is a rapid, sustained, monomorphic VT with a characteristic sinusoidal QRS pattern that is often resistant to resuscitation with cardioversion or overdrive pacing. **10** It is sometimes referred to as sinusoidal or incessant VT and is the result of excessive sodium

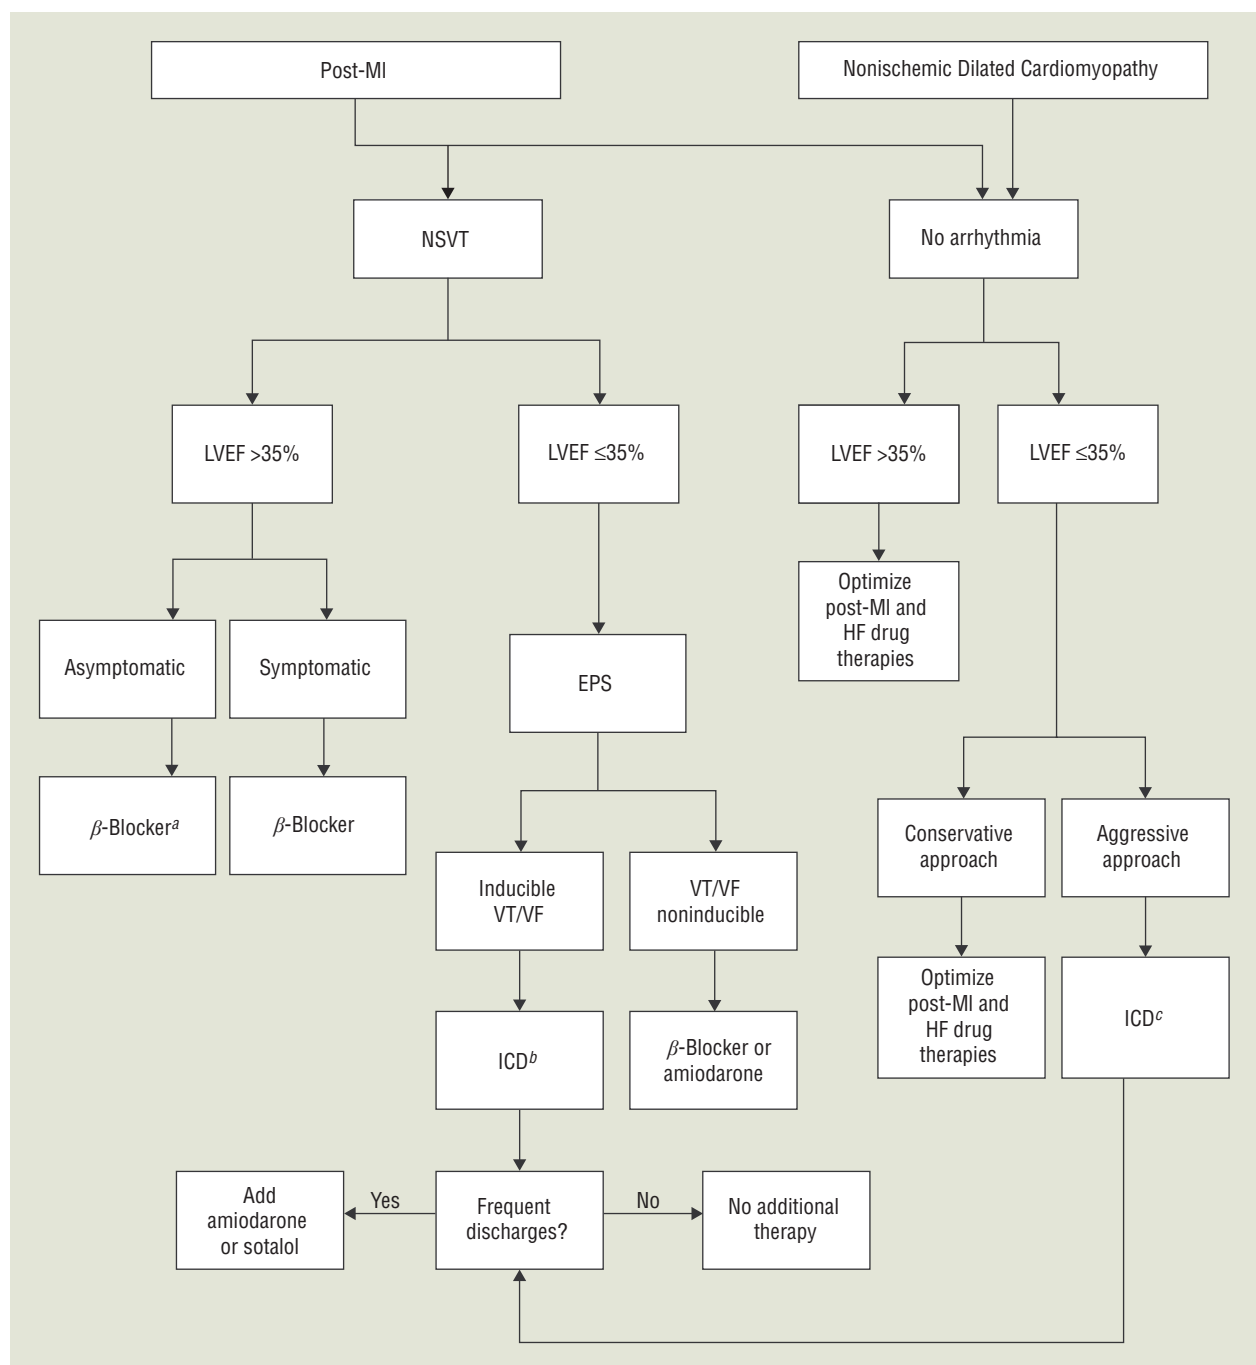

FIGURE 19-13. Algorithm for the primary prevention of sudden cardiac death in patients with a history of myocardial infarction or with a nonischemic dilated cardiomyopathy. ^aIn these patients, the β -blocker is being used to reduce post-MI mortality. ^bPatients should be >40 days post-MI prior to insertion of ICD. ^cPatients with an ischemic cardiomyopathy should be >40 days post-MI prior to insertion of ICD. (EPS, electrophysiologic study; HF, heart failure; ICD, implantable cardioverter-defibrillator; LVEF, left ventricular ejection fraction; MI, myocardial infarction; NSVT, nonsustained VT; VF, ventricular fibrillation; VT, ventricular tachycardia.)

channel blockade and slowed conduction. Sinusoidal VT caused by the type Ic drugs was thought to occur within the first several days of drug initiation; however, the results of the CAST indicate that the risk for this type of proarrhythmia may exist as long as the agent is continued. Factors that definitely predispose a patient to this form of proarrhythmia are: (a) the presence of underlying ventricular arrhythmias, (b) ischemic heart disease, and (c) LV dysfunction. Provocation of proarrhythmia by the type Ic drugs is sometimes reported during exercise, which is most likely a result of augmented slowed conduction at rapid heart rates (i.e., rate-dependent sodium blockade). The incidence of proarrhythmia caused by type Ic drugs is greatest in patients with all three risk factors (approximately 10% to 20%) and extremely

uncommon in those without risks, such as patients with supraventricular tachycardias and normal LV function. In one study, in patients with risk factors, the incidence of death due to proarrhythmia from encainide and flecainide was approximately the same as the chance of long-term effectiveness!⁹⁸ Other factors that have a less well-defined association with proarrhythmia are elevated antiarrhythmic serum concentrations and rapid dosage escalation. It has been proposed that the presence of underlying ventricular conduction delays may also pose a risk for proarrhythmia. As mentioned earlier, this arrhythmia is resistant to resuscitation; however, some have had success with lidocaine (competes for sodium channel receptor) or sodium bicarbonate (reverses the excessive sodium channel blockade).

TABLE 19-11 Current Indications for ICD Implantation

Secondary prevention indications

- 1. Documented episode of cardiac arrest caused by VF (not a result of transient or reversible cause)^a
- 2. Documented sustained VT, either spontaneous or induced at electrophysiologic study, not associated with an acute MI and not a result of transient or reversible cause

Primary prevention indications

- 1. Documented familial or inherited conditions with a high-risk of life-threatening VT (i.e., long QT syndrome, Brugada syndrome, or hypertrophic cardiomyopathy)
- 2. Coronary artery disease (with prior MI >40 days before ICD insertion), LVEF ≤35%, and sustained VT or VF induced at electrophysiologic study^a
- 3. Prior MI (>40 days before ICD insertion) and LVEF ≤30%
- 4. Ischemic dilated cardiomyopathy, prior MI (>40 days before ICD insertion), NYHA class II or III HF, and LVEF ≤35%
- 5. Nonischemic dilated cardiomyopathy (>9 months), NYHA class II or III HF, and LVEF ≤35%
- 6. Nonischemic dilated cardiomyopathy (>3 months but <9 months), NYHA class II or III HF, and LVEF ≤35%
- 7. Patients meeting requirements for cardiac resynchronization therapy with NYHA class IV HF

HF, heart failure; ICD, implantable cardioverter-defibrillator; LVEF, left ventricular ejection fraction; MI, myocardial infarction; NYHA, New York Heart Association; VF, ventricular fibrillation; VT, ventricular tachycardia.

^aThe electrophysiologic study must be performed >4 weeks after the MI.

Torsade de Pointes

As defined previously, TdP is a rapid form of polymorphic VT (Fig. 19-14) that is associated with evidence of delayed ventricular repolarization (long QT interval or prominent U waves) on ECG. It is important to note that most forms of polymorphic VT occurring in the setting of a normal QT interval are similar to monomorphic VT in terms of etiology and treatment strategies (thus, a long QT interval is crucial to the diagnosis of TdP). Much has been learned about the underlying etiology of TdP. Basic defects (genetic, drugs or diseases) that delay repolarization by influencing ion movement (usually by blocking potassium efflux) provoke EADs, preferentially in cells deep in the heart muscle (termed *M cells*), which, in turn, trigger reentry and TdP. Drugs that cause TdP usually delay ventricular repolariza-

tion in an inhomogeneous way (termed *dispersion of refractoriness*), which facilitates the formation of multiple reentrant loops in the ventricle.⁹⁹ Torsade de pointes may occur in association with hereditary syndromes or as an acquired form (i.e., a result of drugs or diseases). The underlying etiology in both cases is delayed ventricular repolarization due to blockade of potassium conductance. It is possible, however, that some individuals have a partially expressed form of these congenital syndromes but never suffer TdP unless some other external factor (drugs, diseases) further delays ventricular repolarization. Acquired forms of TdP are associated with electrolyte disturbances (hypokalemia or hypomagnesemia), subarachnoid hemorrhage, myocarditis, liquid protein diets, arsenic poisoning, hypothyroidism, or, most commonly, drug therapy (notably phenothiazines, antibiotics, antihistamines, antidepressants, and antiarrhythmics) (Table 19-12). **10**

The type Ia antiarrhythmic drugs (especially quinidine) and type III *I_{Kr}* blockers are most notorious for precipitating TdP; the types Ib and Ic antiarrhythmic drugs rarely, if ever, cause TdP. Most antiarrhythmic drugs with *I_{Kr}* blocking activity cause TdP in approximately 2% to 4% of patients, with the exception being amiodarone (<1%). Risk factors and associated features of drug-induced TdP have been identified and can be summarized as follows^{28,100}: (a) high dosages or plasma concentrations of the offending agent (“dose-related”) (except for quinidine-induced TdP, which tends to occur more frequently at low-to-therapeutic concentrations); (b) concurrent structural heart disease (e.g., ischemic heart disease, HF, and/or LV hypertrophy); (c) evidence of mild delayed repolarization (prolonged QT interval) at baseline; (d) evidence of a prolonged QT interval shortly after initiation of the offending agent; (e) concomitant electrolyte disturbances such as hypokalemia or hypomagnesemia; (f) female gender; and (g) a characteristic long-short initiating sequence (so-called “pause” dependence) of the episode of TdP (see Fig. 19-14). However, none of these associations are absolute prerequisites to the occurrence of drug-induced TdP. For instance, although usually documented early in the course of therapy, patients may suffer TdP during chronic quinidine treatment.¹⁰¹ The reason for quinidine’s relatively unique propensity for causing TdP at relatively low dosages and concentrations requires explanation. Quinidine’s ability to block *I_{Kr}* is clinically manifest at low concentrations; at higher

FIGURE 19-14. Torsade de pointes caused by quinidine. Note the presence of a couplet and two triplets following each extra systolic pause. The pause gets progressively longer until it is long enough to result in an episode of sustained torsade de pointes. Also, as the pause lengthens, discernible U waves (labeled ↑) (EADs?) begin to appear. The amplitude of the U wave is somewhat greater with the longest pause. (From Bauman JL. Drug safety: Cardiac arrhythmias. Antihistamine update symposium. Hosp Med 1995;31:24, with permission.)

concentrations its sodium-blocking properties predominate. Other agents that block I_{Kr} usually do so in a concentration-dependent fashion. The observation that most patients who suffer drug-induced TdP have evidence of mildly delayed repolarization (long QT intervals) even before they are prescribed the offending agent has stimulated a search for a potential genetically linked risk. Could it be that patients with drug-induced TdP have a partially expressed form of the congenital long QT syndrome? Indeed, it does appear that at least some of these patients with acquired drug-induced TdP appear to possess mutations of genes that encode for I_{Kr} or I_{Ks} .¹⁰⁰

The common underlying electrophysiologic cause of TdP is a delay in ventricular repolarization (provoking EADs), which usually results from inhibition (drug-induced or genetic) of I_K current and manifests as QT interval prolongation on the ECG. Therefore, the extent of QT interval prolongation has been used as a measurement of risk of TdP; however, considerable controversy exists. Amiodarone, for example, commonly causes significant QT prolongation but is a relatively infrequent cause of TdP. Nonetheless, the QT interval should be measured and monitored in all patients prescribed drugs that have a high potential for causing TdP (see Table 19–12). Patients with a baseline QT_c interval (QT interval corrected for heart rate) >450 msec should not be given these agents; an increase in the QT_c interval to ≥ 560 msec after the initiation of the drug is an indication to discontinue the agent or, at least, to reduce its dosage and carefully observe and monitor. The QT_c interval can be calculated using Bazett's formula: $QT_c = QT \text{ measured} / \sqrt{R-R \text{ interval}}$.

Drug-induced TdP has become an extremely visible hazard plaguing new drugs, sometimes resulting in public health disasters. For instance, six drugs (cisapride, astemizole, terodiline, levomethadyl, grepafloxacin, and terfenadine) have been withdrawn from the market in the United States because of TdP. One of the most visible and striking examples was with regard to the popular nonsedating antihistamine, terfenadine. Terfenadine is a potent I_{Kr} blocker but is rapidly metabolized by CYP3A4 to an active moiety (fexofenadine) that is not associated with delayed repolarization. Consequently, in the presence of drugs that block the CYP3A4 isoenzyme (e.g., ketoconazole, erythromycin, diltiazem), accumulation of the parent compound, terfenadine, causes clinically significant blockade of I_{Kr} that could result in TdP and even death.¹⁰² Because of experiences like this, all new drug entities under investigation are screened for their ability to block I_K and cause significant QT prolongation.

Acute treatment of TdP is different than treatment for the more common acute monomorphic VT. For an acute episode of TdP, most patients will require and respond to DCC. However, TdP tends to be paroxysmal in nature and often will rapidly recur after DCC. Therefore, after the initial restoration of a stable rhythm, therapy designed to prevent recurrences of TdP should be instituted. Drugs that further prolong repolarization such as IV procainamide are absolutely contraindicated. Lidocaine is usually ineffective. Although there are no true efficacy trials, IV magnesium sulfate, by suppressing EADs, is now considered the drug of choice in preventing recurrences of TdP.¹⁰³ If IV magnesium sulfate is ineffective, treatment strategies designed to increase heart rate, shorten ventricular repolarization, and prevent the pause dependency should be initiated. Either temporary transvenous pacing (105 to 120 beats/min) or pharmacologic pacing (isoproterenol or epinephrine infusion) can be initiated for this purpose. All agents that prolong QT interval should be discontinued and exacerbating factors (such as hypokalemia or hypomagnesemia) should be corrected.

VENTRICULAR FIBRILLATION

Background and Prevention

Ventricular fibrillation is electrical anarchy of the ventricle resulting in no cardiac output and cardiovascular collapse. Death will ensue

TABLE 19-12 Potential Causes of QT Prolongation and Torsade de Pointes

Conditions

Congenital long QT syndromes
Myocarditis
Myocardial ischemia/infarction
Heart failure
Severe bradycardia (<50 beats/min)
Hypokalemia
Severe hypothermia
Hypomagnesemia
Severe starvation/liquid-protein diets
Subarachnoid hemorrhage

Drugs

Antiarrhythmic drugs
Quinidine
Procainamide (also *N*-acetylprocainamide)
Disopyramide
Amiodarone
Dofetilide
Sotalol
Ibutilide
Bepiridil^a
Psychotropics
Phenothiazines (e.g. thioridazine, mesoridazine, chlorpromazine)
Tricyclic and tetracyclic antidepressants
Haloperidol/droperidol
Pimozide
Atypical antipsychotics (e.g. quetiapine, ziprasidone)
Toxins
Organophosphate insecticides
Arsenic
Antihistamines
Terfenadine^a
Astemizole^a
Antibiotics
Pentamidine
Macrolides (erythromycin and clarithromycin)
Trimethoprim-sulfamethoxazole
Fluoroquinolones (grepafloxacin,^a sparfloxacin,^a moxifloxacin, gatifloxacin, gemifloxacin)
Voriconazole
Pain
Methadone
Levomethadyl^a
Miscellaneous
Liquid-protein diets^b

Terodiline^a
Tacrolimus

^aWithdrawn from market because of torsade de pointes.

^bMore than likely a result of severe electrolyte imbalance.

Note: For a complete list, see www.qtdrugs.org.

rapidly if effective treatment measures are not taken. Patients who die abruptly (within 1 hour of initial symptoms) and unexpectedly (i.e., “sudden death”) usually have VF recorded at the time of death.⁶¹ Sudden cardiac death accounts for about 330,000 deaths per year in the United States. Sudden cardiac death occurs most commonly in patients with ischemic heart disease and primary myocardial disease associated with LV dysfunction; it occurs less commonly in those with WPW syndrome or mitral valve prolapse, and occasionally in those without associated heart disease (e.g., Brugada syndrome). Patients who have SCD (not associated with acute MI) but survive because of

appropriate CPR, often have inducible sustained VT and/or VF during electrophysiologic studies. These individuals are at high risk for the recurrence of VT and/or VF.

In contrast, patients who have VF associated with acute MI (i.e., within the first 24 hours after symptoms) usually have little risk of recurrence. Of all patients who die as a result of an acute MI, approximately 50% die suddenly prior to hospitalization. Ventricular fibrillation associated with acute MI can be subdivided into two types: primary VF and complicated or secondary VF. Primary VF occurs in an uncomplicated MI not associated with HF; secondary VF occurs in an MI complicated by HF. The time course, incidence, mechanisms, treatment, and complications of these two forms of VF are different. For example, approximately 2% to 6% of patients with acute MI suffer primary VF within 24 hours of chest pain, but the risk of VF declines rapidly over time and is nearly zero after the initial 24-hour period. Complicated or secondary VF does not follow such a predictable time course and may occur in the late infarction period. The premise of prophylactic antiarrhythmic drugs administered to all patients with uncomplicated MI is based on (a) the inability to predict which patients are at risk for primary VF and (b) the predictable time course of primary VF (in contrast to complicated VF). Of the prophylactic therapies used, lidocaine has been the most widely debated and studied. Lie et al.¹⁰⁴ performed the classic study showing the effectiveness of lidocaine in preventing primary VF. Although lidocaine significantly reduced the incidence of VF compared to placebo, there was no significant difference in mortality due to VF between the groups. This data, along with the effectiveness of rapidly instituted DCC in modern coronary care units with sophisticated monitoring techniques, have caused most to reject the notion of prophylactic lidocaine administration for all patients with uncomplicated MI. In support of this, two meta-analyses^{105,106} concluded against the routine use of prophylactic lidocaine because of a possible increase in mortality in lidocaine-treated patients¹⁰⁵ as well as the declining incidence of primary VF documented in recent years (probably a result of the more aggressive and rapid use of β -blockers, thrombolytics, and percutaneous intervention for the treatment of acute coronary syndromes).¹⁰⁶

The use of IV magnesium sulfate has also been entertained for the prevention of VF during the acute infarct period. Small trials implying its effectiveness were subsequently incorporated into a meta-analysis.¹⁰⁷ This meta-analysis found a decrease in the incidence of VT/VF and a reduction in total mortality with magnesium therapy. A subsequent large multicenter trial¹⁰⁸ found similar results, although most of the reduction in mortality was (surprisingly) attributed to HF deaths rather than to deaths caused by ventricular arrhythmia. These results would lead one to conclude that magnesium sulfate should be routinely administered to patients with suspected MI because of its ease of administration and safety. However, data from another large trial apparently has verified no such effectiveness of magnesium therapy in this setting.¹⁰⁹ Hence, prophylactic magnesium cannot be recommended. Indeed, no therapy (lidocaine, magnesium, or other antiarrhythmic drugs) has shown a conclusive benefit to prevent VF in the acute infarct period and no form of therapy can be recommended at this time.

Acute Management

A patient with pulseless VT or VF (with or without associated myocardial ischemia) should be managed according to the most recent AHA guidelines for CPR and emergency cardiovascular care.⁵³ To summarize, in patients with an unwitnessed arrest, five cycles (or 2 minutes) of CPR (one cycle of CPR = 30 chest compressions followed by 2 breaths) should be given before defibrillation. When the arrest is witnessed, and a defibrillator is readily available, defibrillation should be instituted immediately

after two rescue breaths are provided; in these patients, there is no need for an initial period of CPR. Because of the increased availability of biphasic defibrillators which have a higher first-shock efficacy than monophasic defibrillators, delivery of only one shock at a time is recommended. For biphasic defibrillators, the dose of the shock to be used is device-specific; however, 200 joules can be used as the default if the effective dose range of the device is unknown. For all subsequent shocks, the initial dose or a higher dose can be used. If a monophasic defibrillator is used, 360 joules should be used for the initial as well as all subsequent shocks. After delivery of the initial shock, five cycles of CPR should be delivered, followed by a check of the patient's pulse and rhythm. If pulseless VT/VF is still present, another shock can be delivered, followed by five cycles of CPR. This general sequence of providing shocks followed by CPR can be followed as long as the patient remains in pulseless VT/VF.

Although there is very little, if any, evidence that demonstrates an increased survival rate with either vasopressor or antiarrhythmic agents in patients with pulseless VT/VF, these drugs still continue to play a role in the management of these ventricular arrhythmias.⁵³ To minimize interruptions in chest compressions, any vasopressor or antiarrhythmic administered during the course of the cardiac arrest should be given during CPR either before or after a shock. With regard to vasopressor therapy, either epinephrine or vasopressin can be administered if pulseless VT/VF persists after delivery of one or two shocks plus CPR. More specifically, epinephrine can be administered every 3 to 5 minutes while the patient remains in pulseless VT/VF. Alternatively, one dose of vasopressin can be given to replace either the first or second dose of epinephrine. In a recent comparative trial, patients with out-of-hospital cardiac arrest (60% with asystole or pulseless electrical activity, 40% with VF) were randomized to receive up to two doses of either vasopressin or epinephrine, followed by an additional dose of epinephrine if a stable rhythm was not restored.¹¹⁰ Overall, no significant differences were observed between the treatment groups with regard to the end points of survival to hospital admission or survival to hospital discharge (in patients with asystole, however, vasopressin was superior for both of these end points).

If pulseless VT/VF persists after delivery of two or three shocks plus CPR and after administration of a vasopressor, antiarrhythmic therapy can then be initiated.⁵³ It appears clear from the most recent AHA guidelines for CPR and emergency cardiovascular care that IV amiodarone continues to be the antiarrhythmic drug of first choice in patients with pulseless VT/VF. Amiodarone's status as the first-line antiarrhythmic drug during pulseless VT/VF (and lidocaine's resulting role as second-line antiarrhythmic therapy) is the result of (a) a lack of data demonstrating the effectiveness of other antiarrhythmic agents; (b) the Amiodarone in Out-of-Hospital Resuscitation of Refractory Sustained Ventricular Tachyarrhythmias (ARREST) trial;¹¹¹ and (c) the Amiodarone versus Lidocaine in Prehospital Ventricular Fibrillation Evaluation (ALIVE) trial.¹¹² In the ARREST trial,¹¹¹ significantly more patients with out-of-hospital pulseless VT/VF who received 300 mg of IV amiodarone survived to hospital admission than did a corresponding placebo group. Noteworthy was that survival to hospital discharge was no different between the groups (although the study was not powered to determine this end point). In the ALIVE trial,¹¹² IV amiodarone was significantly more effective than lidocaine in increasing survival to hospital admission in patients with out-of-hospital VF. Again, there were no differences in survival to hospital discharge between the groups. Nonetheless, the results of these trials stimulated a change (away from lidocaine and toward amiodarone) in the treatment of pulseless VT/VF. In the event that a patient remains in pulseless VT/VF despite the administration of IV amiodarone and/or lidocaine, it is interesting to note that IV procainamide is no longer recommended in the treatment algorithm because of limited evidence and the need for a prolonged infusion.⁵³

Once the patient is successfully resuscitated, antiarrhythmics should be continued until the patient's rhythm and overall status is stable. If the episode of pulseless VT/VF was associated with acute ischemia, long-term antiarrhythmic drugs are probably unnecessary provided that the patient undergoes successful revascularization; however, the patient should be monitored closely for recurrence of VT and/or VF. If, on the other hand, the pulseless VT/VF was not associated with acute MI (or a known precipitating factor), the patient should undergo ICD implantation.

BRADYARRHYTHMIAS

SINUS NODE DYSFUNCTION

The previous sections reviewed the pathophysiology and treatment of tachyarrhythmias, and this section serves to briefly consider the bradyarrhythmias. For the most part, the symptoms of bradyarrhythmias result from a decline in cardiac output. Because cardiac output decreases as heart rate decreases (to a point), patients with bradyarrhythmias may experience symptoms in association with hypotension, such as dizziness, syncope, fatigue, and confusion. If LV dysfunction exists, patients may experience worsening HF symptoms. Except in the case of recurrent syncope, symptoms associated with bradyarrhythmias are often subtle and nonspecific.

SINUS BRADYCARDIA

Sinus bradyarrhythmias (heart rate <60 beats/min) is a common finding, especially in young, athletically active individuals, and usually is neither symptomatic nor requires therapeutic intervention. On the other hand, some patients, particularly the elderly, have sinus node dysfunction. This may be the result of underlying structural heart disease and the normal aging process which, over time, attenuate SA nodal function. Sick sinus syndrome refers to this process resulting in symptomatic sinus bradycardia and/or periods of sinus arrest.^{113,114} Sinus node dysfunction is usually reflective of diffuse conduction disease, and accompanying AV block is relatively common. Furthermore, symptomatic bradyarrhythmias may be accompanied by alternating periods of paroxysmal tachycardias such as AF. In this instance, AF sometimes presents with a rather slow ventricular response (in the absence of AV nodal blocking drugs) because of diffuse conduction disease. The occurrence of alternating bradyarrhythmias and tachyarrhythmias is referred to as the “tachi-brady syndrome.” The occurrence of paroxysmal AF in a patient with sinus node dysfunction may be a result of underlying structural heart disease with atrial dysfunction or to atrial escape in response to reduced sinus node automaticity. In fact, because the rate of impulse generation by the sinus node is generally depressed or may fail altogether, other automatic pacemakers within the conduction system may “rescue” the sinus node. These rescue rhythms often present as paroxysmal atrial rhythms (e.g., AF) or as a junctional escape rhythm.

The treatment of sinus node dysfunction involves the elimination of symptomatic bradycardia and the possibility of managing alternating tachycardias such as AF. In general, the long-term therapy of choice is a permanent ventricular pacemaker. Dual-chamber, rate-adaptive chronic pacing clearly improves symptoms and overall quality of life and decreases the incidence of paroxysmal AF and systemic embolism.¹¹³ Drugs that are commonly employed to treat supraventricular tachycardias should be used with caution, if at all, in the absence of a functioning pacemaker. Antiarrhythmic drugs prescribed to prevent recurrences of AF may also suppress the escape or rescue rhythms that appear in severe sinus bradycardia or sinus arrest. In this way, these drugs may transform an asymptomatic patient with bradycardia into a symptomatic one. It is also important to remember that the addition of type I antiarrhythmic agents can affect pacemaker

threshold and result in loss of capture if the pacemaker is not appropriately interrogated and adjusted.⁸⁷ Other drugs that depress SA or AV nodal function, such as β -blockers and nondihydropyridine CCBs, may also significantly exacerbate bradycardia. Even agents with indirect sympatholytic actions, such as methyl dopa and clonidine, may worsen sinus node dysfunction. The use of digoxin in these patients is controversial, but in most cases, it can be used safely.

Other Causes

Another reason for paroxysmal bradycardia and sinus arrest that is not directly due to sinus node dysfunction is carotid-sinus hypersensitivity.^{115,116} Again, this syndrome occurs commonly in the aged with underlying structural heart disease, and may precipitate falls and hip fractures. Symptoms occur when the carotid sinus is stimulated, resulting in an accentuated baroreceptor reflex. Often, however, symptoms are not well correlated with the obvious physical manipulation of the carotid sinus (in the lateral neck region). Patients may experience intermittent episodes of dizziness or syncope because of sinus arrest caused by increased vagal tone and sympathetic withdrawal (the cardioinhibitory type), a drop in systemic blood pressure caused by sympathetic withdrawal (the vasodepressor type), or both (mixed cardioinhibitory and vasodepressor types). The diagnosis can be confirmed by performing carotid-sinus massage with electrocardiographic and blood pressure monitoring in controlled conditions. Symptomatic carotid-sinus hypersensitivity should also be treated with permanent pacemaker therapy.¹¹⁵ However, some patients, particularly those with a significant vasodepressor component, still experience syncope or dizziness. The choice of definitive drug therapy in this situation is marred by the lack of controlled trials although α -adrenergic stimulants such as midodrine are often tried in addition to the pacemaker.¹¹⁶

Vasovagal syndrome, by causing bradycardia, sinus arrest, and/or hypotension, is the cause of syncope in many patients who present with recurrent fainting of unknown origin.^{117–119} By history, many individuals can recount rare instances of fainting spells at times of duress or fear. These are most often caused by vasovagal syncope. However, some have extremely frequent, unexpected syncopal episodes that interfere with the patient's quality of life and cause physical danger (sometimes referred to as neurocardiogenic syncope syndrome or malignant vasovagal syndrome). Vasovagal syncope is presumed to be a neurally mediated, paradoxical reaction involving stimulation of cardiac mechanoreceptors (i.e., Bezold-Jarisch reflex). Forceful contraction of the ventricle (e.g., as with adrenergic stimulation) coupled with low ventricular volumes (e.g., with upright posture or dehydration) provide a powerful stimulus for cardiac mechanoreceptors. Syncope results from the spontaneous development of transient hypotension (sympathetic withdrawal) and bradycardia (vagotonia). However, the true mechanism of vasovagal syncope remains to be definitively determined. For instance, patients with denervated hearts (e.g., heart transplant recipients) can still experience this form of syncope. This observation has led some to question the ultimate role of the Bezold-Jarisch reflex in these patients. Regardless, patients believed to have frequent episodes of vasovagal syncope have been evaluated and diagnosed using the upright body-tilt test,¹²¹ a potent stimulus for the development of vasovagal symptoms. Although commonly used, the sensitivity and reproducibility of this test has been questioned.¹²⁰

Traditionally, oral β -blockers, such as metoprolol, were frequently chosen as the drugs of choice in preventing episodes of vasovagal syncope. Although these agents may seem inappropriate to treat a syndrome resulting from vasodilation and bradycardia, the therapeutic approach is designed to block an inappropriate vasovagal reaction (i.e., they inhibit the sympathetic surge that causes forceful ventricular contraction and precedes the onset of hypotension and bradycardia). To most clinicians' surprise, most controlled trials of the use of β -blockers in patients with severe vasovagal syncope have shown no

effect compared to placebo in preventing syncopal episodes.¹²² Some trials have suggested that β -blockers are more effective and should be used in older patients (>40 years of age) with vasovagal syncope rather than the relatively young.¹²³ Other drugs that have been used successfully (with or without β -blockers) include mineralocorticoids as volume expanders (fludrocortisone), anticholinergic agents (scopolamine patches, disopyramide), α -adrenergic agonists (midodrine), adenosine analogs (theophylline, dipyridamole), and selective serotonin receptor antagonists (sertraline, paroxetine).¹²⁴ Permanent pacing has been used for patients with malignant vasovagal syncope but its routine use is controversial. Chronic pacing has been used with some success but should be reserved for drug-refractory patients.^{118,119} Because of the questionable effectiveness of β -blockers and the paucity of controlled or comparative trials, there is not a true drug of choice for severe vasovagal syncope and clinicians are left with choosing agents and judging clinical effectiveness in individual patients on a case-by-case basis.

ATRIOVENTRICULAR BLOCK

Conduction delay or block may occur in any area of the AV conduction system: the AV node, the His bundle, or the bundle branches. Atrioventricular block is usually categorized into three different types based on ECG findings (Table 19–13). First-degree AV block is 1:1 AV conduction with a prolonged PR interval. Second-degree AV block is divided into two forms: Mobitz I AV block (Wenckebach periodicity) is less than 1:1 AV conduction with progressively lengthening PR intervals until a ventricular complex is dropped; Mobitz II AV block is intermittently dropped ventricular beats in a random fashion without progressive PR lengthening. Third-degree AV block is complete heart block where AV conduction is totally absent (AV dissociation). By using intracardiac His bundle ECGs, the actual site of conduction delay/block can be correlated to the above diagnosis. First-degree AV block usually represents prolonged conduction in the AV node. Mobitz I, second-degree AV block is also usually caused by prolonged conduction in the AV node. Indeed, Wenckebach periodicity is a normal AV nodal response to rapid supraventricular stimulation or high vagal tone. In contrast, Mobitz II AV block is usually caused by conduction disease below the AV node (i.e., His bundle). Third-degree AV block may be caused by disease at any level of the AV conduction system: complete AV nodal block, His bundle block, or trifascicular block. In this situation, the ventricle beats independently of the atria (AV dissociation), and the rate of ventricular activation and QRS configuration are determined by the site of AV block. The usual degree of automaticity of ventricular pacemakers progressively declines as impulses move down the conduction system. Therefore, the ventricular escape rate in cases of trifascicular block will be significantly less than complete AV nodal block.

Atrioventricular block may be found in patients without underlying structural heart disease such as trained athletes or during sleep

when vagal tone is high. Also, AV block may be transient where the underlying etiology is reversible such as in myocarditis, myocardial ischemia, after cardiovascular surgery, or during drug therapy. β -blockers, digoxin, or nondihydropyridine CCBs may cause AV block, primarily in the AV nodal area. Type I antiarrhythmic agents may exacerbate conduction delays below the level of the AV node (sodium-dependent tissue). In other cases, AV block may be irreversible, such as that caused by acute MI, rare degenerative diseases, primary myocardial disease, or congenital forms.

If patients with Mobitz II AV block or third-degree AV block develop signs or symptoms of poor perfusion (e.g., altered mental status, chest pain, hypotension, shock) associated with bradycardia or AV block, transcutaneous pacing should be initiated immediately.^{53,125} Intravenous atropine (0.5 mg given every 3 to 5 minutes, up to 3 mg total dose) should be given as the leads for pacing are being placed. Drugs such as atropine will facilitate the effectiveness of transcutaneous pacing. In the past, isoproterenol infusion was frequently chosen for this purpose but is now not recommended because of its vasodilating properties and its ability to increase myocardial oxygen consumption (particularly during acute MI). If patients do not respond to atropine, transcutaneous pacing is usually indicated. Sympathomimetic infusions such as epinephrine (2 to 10 mcg/min) or dopamine (2 to 10 mcg/kg/min) can also be used in the event of atropine failure and are particularly effective in sinus bradycardia/arrest and AV nodal block. These agents usually do not help when the site of AV block is below the AV node (e.g., Mobitz II or trifascicular AV block). If patients with bradycardia or AV block present with signs and symptoms of adequate perfusion, no therapy other than close observation is recommended.

Patients with chronic symptomatic AV block should be treated with the insertion of a permanent pacemaker. Patients without symptoms can sometimes be followed closely without the need for a pacemaker. The reader is referred for more detail to the national consensus guidelines for pacemaker implantation, which were last updated in 2002.¹²⁵ Because symptoms often correlate with the ventricular rate and the ventricular rate corresponds to the site of block, pacemaker therapy is usually necessary in distal AV blocks such as those occurring in the His bundle or the bundle branches. Patients with acute MI and evidence of new AV block or conduction disturbances will often require the insertion of a temporary transvenous pacemaker. Atrioventricular block more commonly occurs as a complication of inferior wall infarcts because of high vagal innervation at this site, and the coronary blood flow to the nodal areas usually supplies the inferior wall. However, the AV block may only be transient, obviating the need for permanent pacing. In patients with chronic AV conduction disturbances, intracardiac recordings (His bundle ECGs) are sometimes used to document the actual site of block and define the potential need for and specific type of pacemaker therapy.

EVALUATION OF THERAPEUTIC AND ECONOMIC OUTCOMES

Generally, patients who suffer from tachyarrhythmias can be monitored for one or several possible therapeutic outcomes. Obviously, the presence or recurrence of any arrhythmia can be documented by electrocardiographic means (e.g., surface ECG, Holter monitor, or event monitor). Furthermore, patients may experience a decrease in blood pressure that may result in symptoms ranging from lightheadedness to abrupt syncope, depending on the rate of the arrhythmia and the status of the underlying heart disease. For some patients, the potential alteration in hemodynamics may result in death if the arrhythmia is not detected and treated immediately. Besides these clinical outcomes, many patients with tachyarrhythmias experience alterations in quality of life as a result of recurrent symptoms of the

TABLE 19-13 Forms of Atrioventricular Block

Type	Criteria	Site of Block
First-degree block	Prolonged PR interval (>0.2 sec); 1:1 AV conduction	Usually AVN
Second-degree block		
Mobitz I	Progressive PR prolongation until QRS is dropped; <1:1 AV conduction	AVN
Mobitz II	Random nonconducted beats (absence of QRS); <1:1 AV conduction	Below AVN
Third-degree block	AV dissociation Absence of AV conduction	AVN or below

AV, atrioventricular; AVN, atrioventricular node.

TABLE 19-14 Arrhythmia Outcomes

Mortality
Total, all-cause
Arrhythmic death (i.e., sudden cardiac death)
Recurrences documented by electrocardiogram
Time to recurrence
Frequency of recurrences
Tolerance
Symptoms

Number of premature ventricular contractions/day
Inducibility of tachycardia with programmed stimulation
Necessity of nondrug interventions (e.g., ICD)
ICD shocks
Side effects of drugs/treatment complications
Quality of life
Economics
Outcomes specific to tachycardia (e.g., systemic embolism in atrial fibrillation)

ICD, implantable cardioverter-defibrillator.

arrhythmia or from side effects of therapy. And, finally, there are the economic considerations of medical or surgical intervention, continued medical care, and chronic drug or nondrug treatment.^{126,127} Most of the studies are limited to the use of nondrug therapies such as the ICD or radiofrequency ablation.^{43,97} Because that technology is rapidly evolving, what is not very cost-effective now, indeed may be cost-effective in the next several years. For example, original cost-effectiveness analysis of the ICD showed it to be highly sensitive to the life of the generator, yet newer-generation devices have made significant advances in not only the size, but also with regard to battery life. More recent data on the effect of the ICD on mortality coupled with the declining costs of an ICD imply that the device is indeed cost-effective in certain subsets of patients, not unlike well-proven drug therapies used for other disorders.⁹⁷ Other nondrug treatments, such as radiofrequency ablation, for PSVT not only improve quality of life, but also save money on medical expenditures compared to chronic drug therapy.⁴³

There are some therapeutic outcomes that are unique to certain arrhythmias. For instance, patients with AF or atrial flutter need to be monitored for thromboembolism and for complications of anticoagulation therapy (bleeding, drug interactions) prescribed to prevent thromboembolic events. However, the most important monitoring parameters for most patients fall into the following categories: (a) mortality (total and arrhythmic), (b) arrhythmia recurrence (duration, frequency, symptoms), (c) hemodynamic consequences (heart rate, blood pressure, symptoms), and (d) treatment complications (need for alternative or additional drugs, devices, surgery) (Table 19-14). When evaluating the arrhythmia literature, care should be taken to consider real outcomes. For example, total mortality is more meaningful than only SCD rates; it is possible an intervention prevents arrhythmic death but patients die from other causes, leaving all-cause mortality unaltered. Likewise, surrogate markers of drug efficacy (e.g., noninducible tachycardia, suppression of minor arrhythmias) should be judged with a degree of skepticism. One should ask: Did the treatment make patients live longer (reduce mortality)? Did it make them feel better (improve humanistic outcomes or quality of life)? Was it economically worth it (cost-effective)?

JEAN M. NAPPI AND ROBERT L. PAGE, II

KEY CONCEPTS

- 1 Diastolic heart failure is a frequent cause of heart failure (prevalence 35% to 50%) and has a significant effect on mortality (25% to 35% 5-year mortality rate) and morbidity (50% 1-year readmission rate).
- 2 Hypertension is a common cause of diastolic heart failure.
- 3 The diagnosis of diastolic heart failure can be made when a patient has both (a) symptoms and signs of congestive heart failure on physical examination and (b) preserved left ventricular (LV) function.
- 4 Treatment should be targeted at symptom reduction, causal clinical disease, and underlying basic mechanisms. Patients with diastolic heart failure may be treated differently than those with systolic dysfunction.
- 5 Symptom-targeted therapy includes decreasing pulmonary venous pressure, maintaining atrial contraction and atrioventricular synchrony, and reducing heart rate. Exercise tolerance is increased by reducing exercise-induced increases in blood pressure and heart rate.
- 6 Disease-targeted therapy includes preventing or treating myocardial ischemia and preventing or regressing LV hypertrophy.
- 7 Future directions may include modifying neurohormonal activation, inhibiting endothelin, and altering intracellular mechanisms and extracellular matrix structures.
- 8 Treatment strategies for patients with hypertrophic cardiomyopathy (HCM) are aimed at improving symptoms and preventing sudden cardiac death.
- 9 Patients with HCM who are at high risk for sudden cardiac death should receive an implantable cardioverter-defibrillator.
- 10 Patients with HCM who are symptomatic may benefit from β -blockade or verapamil.
- 11 Antibiotic prophylaxis for endocarditis is appropriate for HCM patients with evidence of outflow obstruction.

DIASTOLIC HEART FAILURE

Heart failure (HF) may be caused by a primary abnormality in systolic function, diastolic function, or both. Making the distinction is important because the prevalence, prognosis, and treatment of HF may be quite different depending on whether the predominant mechanism causing the symptoms is systolic or diastolic dysfunction. Clinical studies have reported that up to 74% of patients with HF have preserved left ventricular (LV) ejection fraction (EF), variably defined as exceeding 40%, 45%, or 50%.¹⁻³ When patients with preserved EF exhibit symptoms consistent with effort intolerance and dyspnea, especially in the presence of venous congestion and edema, the term *diastolic heart failure* (DHF) is used.⁴ Despite recognition of its importance, no strong consensus exists regarding appropriate terminology for this syndrome; therefore, the terms DHF and HF with preserved EF may be used synonymously.

DHF can be defined as a condition in which myocardial relaxation and filling are impaired and incomplete. The ventricle is unable to accept an adequate volume of blood from the venous system, does not fill at low pressure, and/or is unable to maintain normal stroke volume. In its most severe form, DHF results in overt symptoms of HF. In modest DHF, symptoms of dyspnea and fatigue occur only during stress or activity, when heart rate and/or end-diastolic volume increase. In its mildest form, DHF can be manifested as a slow or delayed pattern of relaxation and filling with little or no elevation in diastolic pressure and few or no cardiac symptoms. The congestive symptoms that occur with DHF are a manifestation of increased pulmonary venous pressures. DHF is caused by impaired myocardial relaxation and/or increased diastolic stiffness. When HF is caused by a predominant abnormality in diastolic function, the ventricular chamber is not enlarged, and EF may normal or even elevated.⁵ Figure 20-1 shows the pressure-volume relationship in a patient with normal versus abnormal diastolic function. Changes in the myocardium are associated with a shift upward and to the left of the

FIGURE 20-1. Diastolic pressure-volume relationship in a normal patient (*right trace*) and a patient with diastolic dysfunction (*left trace*).

pressure–volume curve so that for any increase in LV volume, diastolic pressure rises to a much greater level than normally would occur. Clinically, patients present with reduced exercise tolerance and dyspnea when they have elevated LV diastolic pressures. Patients with DHF have a predominant abnormality in diastolic function, whereas patients with systolic heart failure (SHF) have a predominant abnormality in systolic function of the LV.⁶

EPIDEMIOLOGY

Recent studies suggest that as many as half of patients presenting with overt HF have preserved EF.^{7,8} The prevalence of DHF depends on a number of determinants: patient age, patient gender, study design, particular population under consideration, and EF. It is important to recognize that these determinants are not independent but interdependent. The most important determinant appears to be patient age. DHF is relatively uncommon in young and middle-aged patients. The prevalence of DHF increases with age, approximating 15% in patients younger than 60 years, 35% in patients between 60 and 70 years, and 50% in patients older than 70 years. Prospective community-based studies showed that in patients older than 70 years, the prevalence of DHF approaches 50%.^{9,10} As the proportion of the population older than 65 years continues to grow, it has been estimated that DHF may eventually become the most common form of HF.¹¹

ETIOLOGY

Several disorders can impair ventricular function and play a role in the development of DHF. DHF is seen often in patients with hypertension, coronary artery disease (CAD), valvular heart disease, atrial fibrillation, diabetes, and hypertrophic cardiomyopathies.^{11–13} Hypertension is the most common underlying cardiovascular disorder in patients with DHF.¹⁴ There are several proposed mechanisms by which hypertension may impair diastolic function. Hypertension can alter diastolic function through its effects on (a) wall tension, (b) myocardial hypertrophy and fibrosis, (c) small-vessel structure and function, and (d) by predisposing to epicardial CAD. An association between impaired LV filling and subnormal high-energy phosphate metabolism has been shown in hypertensive patients, even in the absence of left ventricular hypertrophy (LVH).¹⁵

LVH plays a central role in the adaptation of the myocardium to pressure overload. Severe and long-standing pressure overload has been associated with phenotypic alterations at the myocyte level, which differs from the physiologic hypertrophy seen in athletes.¹⁶ Long-term chronic pressure overload stimulates cardiac growth and collagen production, which lead to an increase in myocardial mass and structural remodeling. The results of these changes are an increase in myocardial stiffness and a decrease in diastolic filling.

Diastolic dysfunction has been reported to be present in 90% of patients with CAD.¹⁷ Patients with CAD, such as those with (a) exercise-induced ischemia but normal function at rest, (b) myocardial stunning, and (c) previous myocardial infarction (MI), all may exhibit signs of diastolic dysfunction.

PATHOPHYSIOLOGY

The pathologic disease processes that cause DHF include myocardial ischemia with or without epicardial CAD, pressure overload hypertrophy, and genetic hypertrophy. Hypertrophy consequent to the physiologic adaptation to pregnancy, hypertrophy that occurs in athletes, and volume-overload hypertrophy do not cause abnormalities in diastolic function and do not result in the development of DHF.

Hypertrophic cardiomyopathy (HCM) is a prototype for DHF. The grossly thickened myocardium, structural changes, and inter-

TABLE 20-1 Potential Pathologic Mechanisms of Diastolic Heart Failure

Mechanisms directly affecting myocardial tissue	
Cardiomyocyte	Increased intracellular calcium, producing calcium overload <i>Myofilaments</i> Increased troponin C calcium binding and increased myofilament calcium sensitivity <i>Cytoskeleton</i> Changes in cytoskeletal proteins <i>Energetics</i> Decrease in ATP availability, leading to decreased rate or extent of actomyosin dissociation
Extracellular matrix	Increased content of fibrillar collagen Thickening of existing fibrillar collagen Decreased MMP and/or increased TIMP
Neurohormones	Increased renin–angiotensin–aldosterone Increased endothelin
Extramycardial mechanisms	
Increased hemodynamic load: pre-load or afterload	
Increased heterogeneity	
Systemic neurohormones	Increased levels of angiotensin II
Pericardium	Pericardium may have a constraining effect as LV filling pressure and end-diastolic volume increase

ATP, adenosine triphosphate; LV, left ventricular; MMP, matrix metalloproteinase; TIMP, tissue inhibitor of MMP.

stitial fibrosis severely alter the passive elastic properties of the myocardium. Patients with HCM and LV outflow obstruction are sensitive to small changes in volume such that a small decrease in filling pressure can lead to a decrease in LV end-diastolic volume and a dramatic fall in stroke volume and cardiac output.

The basic mechanisms by which pressure-overload hypertrophy and genetic hypertrophy cause DHF include extramycardial factors and factors intrinsic to the myocardium, which include changes in the cardiac muscle cell and in the extracellular matrix that surrounds the cardiomyocyte (Table 20–1).^{18,19} Intracellular processes, such as changes in calcium homeostasis, contractile and noncontractile proteins, energetics, and the cytoskeleton, contribute to abnormalities in myocardial relaxation and stiffness. Changes in the extracellular matrix, particularly changes in fibrillar collagen, alter relaxation and stiffness. In addition to the cardiomyocyte and the extracellular matrix, local myocardial neuroendocrine activation can impair relaxation and increase stiffness. Activation of neurohormones such as the renin–angiotensin–aldosterone system may act directly to alter diastolic properties or act indirectly by altering calcium homeostasis. Finally, extramycardial changes in loading conditions and changes in heterogeneity occur in hypertrophied ventricles and contribute to changes in relaxation and stiffness so that even when the myocardium itself is normal, changes in these extramycardial factors can cause abnormalities in diastolic function.¹⁹

Myocardial ischemia, particularly in the subendocardial region, is common when ventricular hypertrophy is present. Slow or delayed myocardial relaxation and perivascular fibrosis can adversely affect coronary blood flow and coronary blood flow reserve. This may contribute to the development of myocardial ischemia and sudden death.^{20,21} Therefore, myocardial ischemia may be part of the clinical syndrome of DHF even if no epicardial CAD is present.

Endothelial dysfunction is associated with the progression of myocardial diastolic dysfunction in patients with CAD.²² Both in the acute manifestation of myocardial ischemia and within the chronic consequences of myocardial fibrosis, epicardial CAD is frequently the underlying pathologic cause of DHF.²³ Myocardial ischemia caused by either an acute decrease in supply or an increase in demand (exercise and tachycardia) results in impaired relaxation

and an acute increase in myocardial stiffness.^{5,15} Chronic coronary occlusions may result in myocardial fibrosis, remodeling, and DHF. It is clear that the same basic mechanisms causing diastolic dysfunction in the presence of pressure-overload hypertrophy also underlie changes produced by CAD.

DIAGNOSIS

3 The criteria used to make the diagnosis of DHF remain controversial. However, making an accurate diagnosis is extremely important. Guidelines from the European Society of Cardiology (ESC) propose that three requirements must be present to make the diagnosis of DHF: (a) symptoms or signs of HF, (b) normal or only mildly abnormal systolic function (EF exceeding 45% to 50%), and (c) abnormal diastolic function (e.g., abnormal relaxation, filling, distensibility, or stiffness).²⁴ The first two requirements appear to be well justified; the third requirement may not be.⁶

CLINICAL PRESENTATION OF DIASTOLIC DYSFUNCTION

General

- The majority of patients do not show symptoms at rest but in response to stress conditions. Symptoms may be induced or worsened by physical exercise but also by events such as anemia, fever, tachycardia, and systemic pathologies.

Symptoms

- The patient may complain of exertional dyspnea, orthopnea, paroxysmal dyspnea, and exercise intolerance.

Signs

- Pulmonary congestion (rales)
- Exaggerated rise in blood pressure and heart rate in response to exercise
- Presence of an S4 gallop

Laboratory Tests

- B-type natriuretic peptide and N-terminal pro-B-type natriuretic peptide will be elevated.

Other Diagnostic Tests

- Two-dimensional echocardiography will show a normal or elevated ejection fraction, normal or decreased cardiac output, and LVH and/or concentric remodeling.
- Doppler echocardiography will show elevated pulmonary venous pressures.
- Chest radiography will show pulmonary congestion.
- Electrocardiography may reflect LVH.

Vasan and Levy proposed criteria for DHF according to the degree of diagnostic certainty.²⁵ Three conditions would be met for a definite diagnosis of DHF: (a) definitive evidence of HF, (b) objective evidence of normal LV systolic function within 72 hours of a HF event, and (c) objective evidence of LV diastolic dysfunction. If the third criterion is lacking, then the patient would have *probable* DHF. If the objective evidence for normal systolic function is not apparent at the time of the HF event and there is no conclusive information on LV dysfunction, then the patient would be classified as having *possible* DHF.

With few exceptions, DHF cannot be distinguished from SHF on the basis of the history, physical examination, chest x-ray, and electrocardiogram (ECG) alone. The frequency with which patients have symptoms of HF and signs of HF on physical examination or chest x-ray is not dependent on whether they have SHF or DHF.²¹ Patients with DHF are often elderly, hypertensive females.¹ In one

study, patients with DHF had a higher prevalence of hypertension with higher systolic, diastolic, and pulse pressures when compared with control patients and patients with SHF.²⁶

The data from a number of studies demonstrate that signs and symptoms of HF do not predict EF. In contrast, they do predict the presence of increased LV diastolic pressure. The question then becomes whether the increase in LV diastolic pressure occurs in association with normal LV volume and EF, as would occur in DHF, or whether the increase in LV diastolic pressure occurs in association with an increased LV volume and decreased EF, as would occur with SHF. Therefore, determining whether HF is caused by systolic or diastolic dysfunction requires some estimate of LV size and EF. These measurements can be made using echocardiography, radionuclide ventriculography, or contrast ventriculography. When a patient presents with dyspnea, pulmonary rales, and radiographic evidence of pulmonary venous hypertension, the detection of normal LV end-diastolic volume and normal EF supports the diagnosis of DHF. Conditions such as mitral stenosis, pulmonary disease, sleep apnea, anemia, cirrhosis, hypothyroidism, and drug-induced fluid retention must be ruled out because they can cause similar symptoms.²⁷

B-type natriuretic peptide (BNP) and its biologically inactive fragment N-terminal proBNP (NT-proBNP) are cardiac neurohormones secreted from the myocardium in response to increases in ventricular volume and pressure. Both are used as an aid in the differential diagnosis of dyspnea. The Breathing Not Properly study evaluated 452 patients with echocardiography within 30 days of an emergency department visit. Of the 452 patients, 165 (36.5%) had EF >45% (mean EF 59%).²⁸ In these patients with preserved EF who had been admitted to the hospital for dyspnea, BNP levels were significantly lower than those found in patients with SHF (413 versus 821 pg/mL). However, there was considerable overlap in the BNP levels in patients with DHF compared with those without HF, making BNP levels less useful. Furthermore, the sensitivity, specificity, and predictive accuracy of BNP levels in DHF are limited in part because BNP is altered by age, adiposity, gender, and other factors. Similar findings have been documented with NT-proBNP. In a study of 68 symptomatic patients with isolated DHF (EF >50%), NT-proBNP was significantly increased in patients with isolated DHF and correlated with disease severity. Compared to conventional echocardiography, Doppler imaging, and heart catheterization, NT-proBNP exhibited the best negative predictive value for detection of DHF.²⁹

PROGNOSIS

The prognosis in patients with DHF, although less ominous than in patients with SHF, is worse than that of age-matched control patients. The 5-year mortality of these patients approximates 25%, although mortality rates as high as 13% over a 6-month period have been reported.^{1,7} In comparison, the annual mortality of patients with SHF approximates 10% to 15%, whereas age-matched control mortality approaches 1%. However, in a population-based cohort study of 2,802 patients with HF, no significant difference was demonstrated in the adjusted 1-year mortality rate for patients with EF <40% compared to those with EF >50%.³⁰ Unfortunately, compared to SHF, little improvement in the survival rate among patients with DHF has been seen.¹¹

In patients with DHF, the prognosis is also affected by the clinical pathologic etiology causing the disease. When patients with CAD are excluded, the annual mortality for DHF approximates 2% to 3%. In addition to the clinical pathologic etiology causing HF, other predictors of mortality include impaired renal function ≤ 60 mL/min/m², worse functional class (New York Heart Association [NYHA] class III–IV), male gender, and older age >74 years).^{31,32}

The mode of death appears similar in patients with systolic versus diastolic HF. Sudden death and death from progressive pump failure occurred with equal frequency in patients with SHF versus those with DHF. Morbidity also is similar between patients with SHF and DHF. The 1-year hospital readmission rate can approach 50%, thereby placing significant expenditures on healthcare resources. However, compared to patients with SHF, those with DHF appear to have a higher risk of nonfatal MI and stroke.^{12,30}

TREATMENT

Diastolic Heart Failure

The general principles used to guide the treatment of SHF are based on numerous large, randomized, double-blind, multicenter trials. Until recently, no such randomized trials had been performed in patients with DHF. Consequently, the guidelines for the management of DHF are based primarily on clinical investigations in relatively small groups of patients, clinical experience, and concepts based on the knowledge and understanding of the pathophysiology of the disease process. The treatment regimen outlined in Table 20-2 applies to patients with DHF who have clear manifestations of congestion either at rest or with exertion. Whether treatment of asymptomatic diastolic dysfunction confers any benefit has not been examined.

■ DESIRED OUTCOME

4 Treatment should be targeted at reducing symptoms, principally those of increased pulmonary venous pressure. Treatment should include decreasing diastolic pressure by decreasing LV volume, maintaining atrial contraction, and reducing heart rate without reducing cardiac output. Second, treatment should be targeted at the pathologic diseases that cause DHF. For example, CAD, hypertensive heart disease, and aortic stenosis provide relatively specific therapeutic targets, such as lowering blood pressure, inducing LVH regression, performing aortic valve replacement, and treating ischemia by increasing myocardial blood flow and reducing myocardial oxygen demand. Third, treatment should be targeted at the underlying mechanisms that are altered by the disease processes just mentioned.³³

■ NONPHARMACOLOGIC THERAPY

Diet and Lifestyle

The initial effort in the treatment of DHF is aimed at decreasing symptoms. The first step in this effort is to decrease pulmonary

congestion by decreasing LV volume using sodium and fluid restriction. A low-sodium diet (≤ 2 g/day) and moderate fluid restriction will help to prevent volume overload. Both sodium and fluid restriction must be done with care. Excessive restriction can lead to hypotension, low-output state, and/or renal insufficiency. Daily weights may help to assess volume status. Dietary and lifestyle factors that decrease the risk of development of epicardial CAD and high blood pressure should be encouraged.²⁴

Exercise

Moderate aerobic exercise to improve cardiovascular conditioning is beneficial to maintain a slower heart rate, improve cardiac reserve, and maintain skeletal muscle function. Isometric exercise should be avoided.³⁴

Interventional/Surgical Procedures

An important step in symptom-targeted therapy that acts to decrease pulmonary venous pressures is to maintain atrial contraction and atrioventricular (AV) synchrony. Maintaining atrial contraction and AV synchrony is important both in preserving normal cardiac output and in keeping LV diastolic pressure low. Chemical or electrical cardioversion of persistent atrial tachyarrhythmias will decrease diastolic pressure, increase cardiac output, and resolve pulmonary edema. An AV sequential pacemaker should be used to treat bradyarrhythmias in patients requiring pacing.

Therapy also should be aimed at preventing or treating the underlying pathologic cause of DHF. Aortic valve replacement should be performed in symptomatic patients with pressure-overload hypertrophy caused by aortic stenosis. Revascularization should be performed in selected patients with DHF caused by CAD-induced myocardial ischemia. In addition, myocardial oxygen consumption and myocardial blood flow should be increased using medical treatment, including nitrates, β -blockers, and calcium channel blockers.²³

Indications for Hospitalization

Patients with DHF may present with an acute onset of pulmonary edema. A number of potential causes for the acute decompensation of these patients include volume overload, uncontrolled hypertension, acute myocardial ischemia, progressive valvular disease (aortic stenosis), and new-onset or uncontrolled tachyarrhythmias. Treatment strategies for these patients eventually may include the need for surgery, as in the case of valvular disease.

The initial management focuses on relieving pulmonary congestion and maintaining oxygenation. Intravenous diuretic agents and nesiritide for patients are effective for volume overload. Caution

TABLE 20-2 Targeted Approach to Treatment of Diastolic Heart Failure

Symptom-targeted treatment		
Decrease pulmonary venous pressure	Reduce left ventricular volume	Diuretics, nitrates, salt restriction
	Maintain atrial contraction	Cardioversion of atrial fibrillation
	Reduce heart rate	β -Blockers, diltiazem, verapamil
	As above	
Disease-targeted treatment		
Prevent/treat myocardial ischemia		β -Blockers, diltiazem, verapamil, nitrates
Prevent/regress ventricular hypertrophy		Antihypertensive therapy
Mechanism-targeted treatment		
Modify myocardial and extramyocardial mechanisms		Possibly ACE inhibitors or angiotensin receptor blockers, diuretics, spironolactone
Modify intracellular and extracellular mechanisms		Possibly ACE inhibitors or angiotensin receptor blockers, spironolactone

ACE, angiotensin-converting enzyme.

must be exercised to avoid overdiuresis or excessive lowering of LV end-diastolic volume, which can lead to a decrease in stroke volume. Morphine and nitroglycerin also are effective in reducing LV end-diastolic pressure.³⁵

■ PHARMACOLOGIC TREATMENT

Drug Treatments of First Choice

With a few notable exceptions, many of the drugs used to treat SHF are the same as those used to treat DHF. However, the rationale for their use, the pathophysiologic process that is being altered by the drug, and the dosing regimen may be entirely different depending on whether the patient has SHF or DHF. For example, β -blockers are recommended for the treatment of both SHF and DHF. In DHF, however, β -blockers are used to decrease heart rate, increase diastolic duration, and modify the hemodynamic response to exercise. In SHF, β -blockers are used in the long run to increase inotropic state and modify LV remodeling. Diuretics also are used in the treatment of both SHF and DHF. However, the doses of diuretics used to treat DHF are in general much smaller than the doses used to treat SHF. Antagonists of the renin–angiotensin–aldosterone system are useful in lowering blood pressure and reducing LVH. Some drugs, however, are used only to treat either SHF or DHF but not both. Calcium channel blockers such as diltiazem, nifedipine, and verapamil have little utility in the treatment of SHF. In contrast, each of these drugs has been proposed as being useful in the treatment of DHF.

Published Guidelines

Much less objective information on the treatment of DHF is available. This relative paucity of objective information is reflected in guidelines for the diagnosis and management of HF published from the American College of Cardiology (ACC)/American Heart Association (AHA), the ESC, and the Heart Failure Society of America (HFSA).^{24,36,37} In general, all three guidelines recommend treating comorbid conditions by controlling heart rate and blood

pressure, alleviating causes of myocardial ischemia, reducing volume, and restoring and maintaining sinus rhythm. Table 20–3 summarizes the therapeutic recommendations from the HFSA.

General Information

Although dozens of trials evaluating pharmacologic therapy have been conducted in patients with SHF, few trials have focused on patients with isolated DHF. In fact, most published HF trials have specifically excluded patients with preserved EF. A few published large clinical studies and several trials examining various agents in the treatment of DHF are underway (Table 20–4). With these studies and others that currently are under development, an effective treatment for DHF will be defined more completely.

Alternative Drug Treatment

As a result of the controversy regarding the diagnosis of DHF, the development and design of large clinical trials have been hindered. At this time, most antihypertensive agents would be acceptable forms of therapy for hypertensive heart disease, with the exception of α -blockers (e.g., doxazosin). In the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), the doxazosin treatment arm was dropped because patients randomized to doxazosin had an increased risk for developing HF and stroke compared with the chlorthalidone arm.³⁸

Special Populations

DHF is associated with hypertension and aging, making it a common diagnosis in elderly white women. Because these women often are frail and have low muscle mass, their creatinine clearance and renal function may be compromised. Special care must be taken when selecting and titrating doses of drugs, monitoring levels of serum creatinine and electrolytes, and using diuretics, angiotensin-converting enzyme (ACE) inhibitors, and angiotensin receptor blockers.³⁹

Diabetes is often a comorbid condition in patients with HF. Because the thiazolidinediones (pioglitazone and rosiglitazone) are associated with fluid retention, caution is warranted when initiating these drugs in

TABLE 20-3 Evidence-Based Pharmacotherapy for Diastolic Heart Failure

Recommendations	Recommendation Grade ^a
Diuretics	
• A loop and a thiazide diuretic should be considered for patients with volume overload. However, with more severe volume overload or inadequate response to a thiazide, a loop diuretic should be implemented. Caution is warranted not to lower preload excessively, which may reduce stroke volume and cardiac output.	C
ACE inhibitors	
• ACE inhibitors should be considered in all patients.	C
• ACE inhibitors should be considered in all patients who have symptomatic atherosclerotic cardiovascular disease or diabetes and one additional risk factor.	C
Angiotensin receptor blockers	
• Angiotensin receptor blockers should be considered in all patients.	B
• In patients who are intolerant of ACE inhibitors, an angiotensin receptor blocker can be considered an alternative.	C
β-Blockers	
• β -Blockers should be considered in patients with one or more of the following conditions:	
Myocardial infarction	A
Hypertension	B
Atrial fibrillation requiring ventricular rate control.	B
Calcium channel blockers	
• In patients with atrial fibrillation warranting ventricular rate control who either are intolerant to or have not responded to a β -blocker, diltiazem or verapamil should be considered.	C
• A nondihydropyridine or dihydropyridine calcium channel blocker can be considered for symptom-limiting angina.	A
• A nondihydropyridine or dihydropyridine calcium channel blocker can be considered for hypertension; however, amlodipine is recommended.	C

^aStrength of recommendations: A, randomized controlled clinical trials; B, cohort and case control studies based upon observations from observational studies or registries, post hoc, subgroup, and meta-analysis; C, expert opinion, epidemiologic findings from observational studies, and safety findings from large-scale use.

ACE, angiotensin-converting enzyme.

Data from Heart Failure Society of America.³⁶

TABLE 20-4 Completed and Ongoing Large Clinical Trials for Diastolic Heart Failure

Trial (No. of Patients)	Treatment	Inclusion Criteria	Primary End Point	Results
DIG Ancillary Study ³⁰ (n = 988)	Digoxin vs placebo for a mean of 37 months. Patients received ACE inhibitor (86%) and diuretics (85%).	EF >45%, NYHA II–IV, normal sinus rhythm	Composite of HF hospitalization or HF mortality	No significant difference was found in the primary end point between treatment groups (HR = 0.82, <i>P</i> = 0.136). Digoxin had no effect on all-cause mortality or cause-specific mortality or on all-cause or CV hospitalization. Compared to placebo, digoxin use was associated with a trend toward a reduction in HF hospitalizations (HR = 0.79, <i>P</i> = 0.094) and an increase in unstable angina admissions (HR = 1.37, <i>P</i> = 0.061).
CHARM-Preserved ¹³ (n = 3,023)	Candesartan vs placebo for a mean of 36.6 months. Patients continued their background HF medications: ACE inhibitor (19%), β -blocker (55%), diuretics (75%), spironolactone (11%).	EF >40%, NYHA II–IV, ≥ 1 hospitalization for CV reason	Composite of CV mortality or HF hospitalization	No significant difference was found in the primary end point between treatment groups (adjusted HR = 0.86, <i>P</i> = 0.051) or in CV deaths (adjusted HR = 0.95, <i>P</i> = 0.635). Compared to placebo, candesartan use was associated with fewer HF admissions (<i>P</i> = 0.017), lower incidence of new diabetes (HR = 0.60, <i>P</i> = 0.005), and a reduction in the composite of CV death, HF hospitalization, nonfatal MI, and nonfatal stroke (adjusted HR = 0.91, <i>P</i> = 0.037).
PEP-CHF ⁴⁶ (n = 850)	Perindopril vs placebo for a mean of 2.1 years.	Clinical criteria for HF, EF $\geq 40\%$, age ≥ 70 years	Composite of total mortality and HF hospitalization	At 1 year and at study completion, no significant difference was found in the primary end point between treatment groups (HR = 0.69, <i>P</i> = 0.055; HR = 0.70, <i>P</i> = 0.545). In a subgroup analysis, patients ≤ 75 years of age (HR = 0.29, <i>P</i> = 0.035) and with a history of MI (HR = 0.38, <i>P</i> = 0.004) showed a reduction in the primary end point. Compared to placebo, perindopril use at 1 year was associated with fewer unplanned hospital admissions (HR = 0.63, <i>P</i> = 0.033), greater improvements in exercise tolerance (<i>P</i> = 0.011), and improvement in NYHA class (<i>P</i> = 0.030).
I-Preserve ⁶⁵ (n = 4,100)	Irbesartan vs placebo for 2 years. ACE inhibitor can be used for any indication other than HTN.	Clinical criteria for HF or hospitalized within 6 months for HF, age ≥ 60 years, NYHA II–IV, EF $\geq 45\%$	Composite of all-cause mortality or CV hospitalization	Expected to be completed in 2007
TOPCAT ⁶⁵ (n = 4,500)	Spironolactone vs placebo for 2 years.	Clinical criteria for HF, age ≥ 50 years, EF $\geq 45\%$, ≥ 1 hospitalization for HF, controlled SBP	CV mortality, aborted cardiac arrest, HF hospitalization	Expected to be completed in 2011

Trials: CHARM, Candesartan in Heart Failure: Assessment of Reduction in Mortality and Morbidity; DIG, Digitalis Investigational Group; I-Preserve, Irbesartan in Heart Failure with Preserved EF; PEP-CHF, Perindopril for Elderly Persons with Chronic Heart Failure; TOPCAT, Trial of Aldosterone Antagonist Therapy in Adults with Preserved Ejection Fraction Congestive Heart Failure.

patients with a history of DHF. Thiazolidinediones should be discontinued in patients with symptoms related to volume overload.^{3,37}

■ DRUG CLASS INFORMATION

Diuretics

5 Diuretics can provide symptom-targeted therapy by decreasing systemic and LV volume. By decreasing LV diastolic volumes, LV pressures slide down the curvilinear diastolic pressure–volume relationship toward a lower, less steep portion of the curve. As pressure throughout diastole falls, mean diastolic pressure, pulmonary capillary wedge pressure, and pulmonary venous pressure fall. These agents effectively reduce the central blood volume and lower diastolic pressures, thus alleviating the symptoms of the congestive state. Diuretics can provide disease-targeted therapy by decreasing blood pressure and favorably affecting the myocardial oxygen supply-versus-demand ratio. Lower LV diastolic pressures may increase subendocardial blood flow, preventing or alleviating the imbalance between myocardial oxygen supply and demand (see Fig. 20–1). Diuretics alone and especially in combination with other antihypertensive drugs are an effective approach to therapy.

Treatment with diuretics should be initiated at low doses in order to avoid hypotension and fatigue. Hypotension can be a significant problem in the treatment of DHF because these patients have a very steep LV diastolic pressure–volume curve such that a small change in volume causes a large change in filling pressure and cardiac output. After the acute treatment of DHF has been completed, long-term treatment should include small-to-moderate doses of diuretics (furosemide 20 to 40 mg/day orally or hydrochlorothiazide 12.5 to 25 mg/day orally). If prompt and sustained diuresis is not achieved, the dosage of a single diuretic should be increased, or a loop and thiazide or thiazide-like diuretic should be used in combination. Aldosterone antagonists such as spironolactone and eplerenone may be especially effective for long-term use because of their potassium-sparing effects and because their antagonism of renin–angiotensin–aldosterone system activation may alter intramyocardial and extramyocardial mechanisms causing abnormalities in diastolic function.⁴⁰ Thiazide diuretics generally are ineffective as diuretics in patients with a creatinine clearance <30 mL/min.

Excessive diuresis may result in hypotension, low-output syndrome, and worsening renal insufficiency. In some cases, loop diuretics may be withdrawn safely from elderly patients without any worsening of HF symptoms and with improvement in symptoms of orthostatic

hypotension.⁴¹ Electrolyte imbalances, including hypokalemia and hypomagnesemia, are common with diuretics. Carbohydrate intolerance and hyperuricemia are dose-related adverse drug reactions seen with thiazide diuretics. Spironolactone can cause hyperkalemia and gynecomastia. Eplerenone may be used as an alternative to spironolactone in patients who complain of gynecomastia. In general, diuretic agents are very cost-effective agents in the management of DHF.

Nitrates

6 Similar to diuretics, nitrates can provide symptom-targeted therapy by acting to decrease LV volume by increasing venous capacitance. In addition, nitrates can provide disease-targeted therapy by providing antiischemic effects in patients with DHF due to CAD.

Like diuretics, therapy should be initiated at low doses in order to avoid hypotension. Isosorbide dinitrate 10 mg three or four times daily, isosorbide mononitrate (Imdur) 30 mg/day, nitroglycerin paste 0.5 to 1 inch every 4 to 6 hours, and nitroglycerin patch 0.1 to 0.2 mg/h applied each day are common initial doses. Doses can be increased during long-term therapy and titrated against symptoms. Nitrate tolerance has not been studied in this patient population but probably occurs (for more detail regarding nitrate tolerance, see Chap. 17). Similar to diuretics, nitrates can cause hypotension and a low-output syndrome. Headaches are common but may be less frequent with continued use.

Sublingual nitroglycerin tablets or nitroglycerin spray may be used for patients who develop shortness of breath with mild exercise, and they can be used much in the same way as in patients with ischemic symptoms. Nitroglycerin will decrease LV end-diastolic volume, resulting in relief of breathlessness.

β -Adrenergic Blockers

β -Blockers can provide symptom-targeted therapy by decreasing heart rate and can provide disease-targeted therapy by treating high blood pressure and CAD. By decreasing heart rate and increasing the duration of diastole, β -blockers can help to lower and maintain low pulmonary venous pressures. Tachycardia is poorly tolerated in patients with DHF for several reasons. First, rapid heart rates cause an increase in myocardial oxygen demand and a decrease in coronary perfusion time. This rapid rate can promote ischemic diastolic dysfunction even in the absence of epicardial CAD, especially in patients with LVH. Second, incomplete relaxation between cardiac cycles may result in an increase in diastolic pressure relative to volume. Thus, LV distensibility is reduced. Third, a rapid rate reduces diastolic filling time and ventricular filling. Fourth, hearts with diastolic dysfunction exhibit a flat or even negative relaxation rate versus frequency relationship. Thus, as heart rate increases in these hearts, relaxation does not become augmented and may become slower and incomplete, causing diastolic pressures, especially early in diastole, to increase.⁹ For these and other reasons, most clinicians use β -blockers (and calcium channel blockers) to prevent excessive tachycardia and produce a relative bradycardia in patients with diastolic dysfunction. However, excessive bradycardia can result in a fall of cardiac output despite an increase in LV filling. Such considerations underscore the need for individualizing therapeutic interventions that affect heart rate. Although the optimal heart rate must be individualized, an initial goal might be a resting heart rate of approximately 60 beats/min with a blunted exercise-induced increase in heart rate not to exceed 110 beats/min.⁹

No evidence suggests a specific therapeutic advantage of one β -blocker over another. Selective and nonselective β -blockers appear equally effective in DHF. In general, it is not necessary to start the drug at an extremely low dose and titrate the β -blocker in a slow, progressive fashion in DHF, as it is in SHF. Because the population

is older, it is prudent to start with a moderate dose of β -blockers, such as metoprolol tartrate 25 mg twice daily, metoprolol succinate 25 mg daily, atenolol 25 mg daily, or carvedilol 3.125 mg twice daily and titrate to a higher dose with a treatment target of a heart rate of approximately 60 beats/min.

Prinzmetal vasospastic angina, occlusive peripheral vascular disease, type 1 diabetes mellitus that is prone to hypoglycemia, severe heart block, and excessive bradycardia are contraindications to β -blockers. β -Blockers may be considered in patients with reactive airway disease or asymptomatic bradycardia but should be used with extreme caution. The main side effects of β -blockers are depression, fatigue, bradycardia, bronchospasm, and impotence. Many of the β -blockers are eliminated via hepatic metabolism and may be affected by other drugs that either inhibit (e.g., cimetidine and verapamil) or enhance (e.g., barbiturates) hepatic enzymes. Because the doses are titrated to patient response, these interactions are managed easily.

Calcium Channel Blockers

Calcium channel blockers can provide symptom-targeted treatment by decreasing heart rate and increasing exercise tolerance. They can provide disease-targeted treatment by treating high blood pressure and CAD. However, the beneficial effect of these agents on exercise tolerance is not always paralleled by improved LV diastolic function or increased relaxation rate. Nonetheless, a number of small clinical trials have shown that the use of these agents results in both short-term and long-term improvement in exercise capacity in patients with DHF.^{33,36}

Of the calcium channel blockers, the nondihydropyridines (verapamil and diltiazem) are the most effective because they lower heart rate in addition to lowering blood pressure.⁴² Sustained-release nifedipine, because of its strong vasodilator properties, tends to cause hypotension and reflex tachycardia. In addition, nifedipine causes peripheral edema. These characteristics make it less useful in DHF. Amlodipine may be effective because it reduces blood pressure. Initial doses are verapamil 120 to 240 mg/day, diltiazem 90 to 120 mg/day, and amlodipine 2.5 mg/day.

Heart block is a contraindication for the nondihydropyridines. The most common side effects are bradycardia and heart block (for the nondihydropyridines). Peripheral edema and headache also are common. Nondihydropyridines exacerbate the bradycardic effects of β -blockers, and verapamil raises digoxin serum concentrations by 70%. Diltiazem raises cyclosporine, tacrolimus, and sirolimus serum concentrations. Intravenous calcium salts inhibit the pharmacologic effect of calcium channel blockers. Generic formulations or similar products, but not necessarily generic equivalents to the original brand names, are available for some of the calcium channel blockers.

Neurohormonal Antagonists

7 Both basic and clinical studies suggest that DHF is associated with activation of systemic and local cardiac neuroendocrine systems such as the renin-angiotensin-aldosterone system. One mechanism causing fluid retention and the increases in central and systemic volume in patients with DHF is activation of these neuroendocrine systems. Therefore, treatment of DHF should include agents such as ACE inhibitors, angiotensin receptor blockers, and aldosterone antagonists that attenuate the fluid retention caused by neuroendocrine activation. In addition to promoting fluid retention, neuroendocrine activation can have direct effects on cellular and extracellular mechanisms that contribute to the development of DHF. Modulation of neuroendocrine activation may provide mechanism-targeted treatment by decreasing fibroblast activity and interstitial fibrosis, improving intracellular calcium handling, and

decreasing myocardial stiffness. Finally, renin–angiotensin–aldosterone system antagonists provide disease-targeted treatment by treating hypertension.⁴³

The mechanisms that evoke activation of the neuroendocrine system remain incompletely understood in patients with DHF. A number of factors have been suggested. Myocardial ischemia, uncontrolled hypertension, and excessive dietary sodium or sodium-retaining medications may contribute to neuroendocrine activation. Limited distensibility of the atria may attenuate the secretion of atrial natriuretic factor and thereby reduce its diuretic effect. In others, low systemic vascular resistance and/or low arterial pressure may contribute to an increase in renin–angiotensin–aldosterone system activation and salt and water retention. Elevated venous pressure may cause renal sodium retention directly. The reduction in blood volume that follows the use of diuretics triggers an increase in sympathetic tone and further activation of the renin–angiotensin–aldosterone system. Such neurohormonal activation can lead to vasoconstriction and a worsening of the congestive state. Some vasodilators, particularly nitrates and pure arteriolar vasodilators, evoke a similar response. By contrast, ACE inhibitors, aldosterone antagonists, and β -blockers blunt neurohormonal activation and decrease the salt and water retention that complicates the treatment of HF.

Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors can provide symptom-targeted treatment by decreasing LV volume and directly improving relaxation. They can provide disease-targeted treatment by treating high blood pressure, preventing LVH, promoting regression, and preventing fibrosis. Treatment of high blood pressure with ACE inhibitors has been shown to normalize load, prevent and/or regress LVH, correct the abnormality in intracellular processes, and modify the extracellular matrix response.⁴³ ACE inhibitors may reduce the incidence of HF by 23% among patients with CAD and preserved EF.⁴⁴

A small, prospective, double-blind, randomized trial compared lisinopril with hydrochlorothiazide in 35 patients with primary hypertension, LVH, and LV diastolic dysfunction.⁴⁵ After 6 months of therapy, lisinopril caused regression of myocardial fibrosis and improved LV diastolic function, although LVH was unchanged. However, the largest study, the Perindopril for Elderly Persons with Chronic Heart Failure (PEP-CHF) trial, failed to find a significant effect on clinical outcomes at 1 year in patients with DHF who received perindopril (see Table 20–4). Based on these limited data, it appears that ACE inhibitors may improve HF symptomatology and exercise capacity while not impacting mortality.⁴⁶

At this time, no evidence suggests an advantage of one ACE inhibitor over another. Their effects appear to be a class effect. Initial doses should be small to moderate in order to avoid hypotension, especially if the patient examination does not indicate volume overload. Examples of initial starting doses are captopril 6.25 mg three times daily, enalapril 2.5 mg/day, or lisinopril 2.5 mg/day.

Severe renal failure, history of angioedema, and pregnancy are contraindications to ACE inhibitors. Hyperkalemia, persistent cough, hypotension, taste disturbances, and worsening renal function are common side effects but are managed by decreasing the dose or discontinuing the drug.

Angiotensin Receptor Blockers

Angiotensin receptor blockers can provide symptom-targeted treatment by decreasing LV pressure, decreasing LV volume, and increasing exercise tolerance. They can provide disease-targeted treatment by lowering blood pressure. The Candesartan in Heart Failure: Assessment of Reduction in Mortality and Morbidity (CHARM)-Preserved trial (see Table 20–4) was the first large prospective study to demonstrate the benefits of an angiotensin

receptor blocker in patients with preserved EF currently receiving usual treatment.¹³ However, 22% of candesartan-treated patients discontinued therapy because of hypotension ($P = 0.009$), increased serum creatinine ($P = 0.0005$), and hyperkalemia ($P = 0.029$).

Presently, no angiotensin receptor blocker has yet been shown to have any major advantage over another. Initial doses of candesartan start at 4 mg/day, irbesartan 150 mg/day, losartan 25 mg/day, telmisartan 40 mg/day, and valsartan 80 mg/day. As with the ACE inhibitors, angiotensin receptor blockers are contraindicated in pregnancy. The side effects of angiotensin receptor blockers are similar to those of ACE inhibitors, but they are not associated with persistent cough.

Aldosterone Antagonists

Aldosterone antagonists can provide improved myocardial functioning by decreasing LV volume and chamber stiffness.^{47,48} They can provide disease-targeted treatment by decreasing the fibrosis that accompanies LVH. An analysis of the Randomized Aldactone Evaluation Study (RALES) found that spironolactone significantly decreased the levels of serum markers for cardiac collagen turnover. The benefit from spironolactone was seen in patients with higher levels of collagen synthesis markers. This was the first study to show that serum levels of markers of cardiac collagen synthesis were associated with a poor clinical outcome and could be decreased with spironolactone. This property distinguishes spironolactone from other diuretics that have no effect on myocardial necrosis or collagen turnover.

Like other diuretics, spironolactone should be initiated at a low dose and increased to treat symptoms. Spironolactone may be initiated at doses of 12.5 to 25 mg/day. Spironolactone should be avoided in patients severe renal failure. Hyperkalemia and gynecomastia are the most common side effects. Eplerenone is a viable alternative to spironolactone in patients complaining of sex hormone-related side effects and may be initiated at 25 mg/day.⁴⁰

Positive Inotropic Agents

Positive inotropic agents, such as β -agonists and phosphodiesterase inhibitors, generally are not used in the treatment of patients with isolated DHF because LV EF is preserved and there appears to be little potential for a beneficial effect. Positive inotropic agents have the potential to worsen DHF by adversely affecting energetics, inducing ischemia, raising heart rate, and inducing arrhythmias.⁹ In contrast to long-term use, positive inotropic drugs may be beneficial in the short-term treatment of pulmonary edema associated with DHF. These agents can enhance sarcoplasmic reticular function, promote more rapid and complete relaxation, increase splanchnic blood flow, increase venous capacitance, and facilitate diuresis.⁹ However, these agents should be used with caution, if they are used at all, because the risk-to-benefit ratio is not clearly established.

Digitalis Derivatives

Digoxin, by inhibiting the Na^+, K^+ -adenosine triphosphatase (ATPase) pump, augments intracellular calcium and thereby augments contractile state. In this manner, digoxin produces an increase in systolic energy demands while adding to a relative calcium overload in diastole. These effects may not be apparent clinically under many circumstances, but during hemodynamic stress or ischemia, digoxin may promote or contribute to diastolic dysfunction.⁹ However, based on the data from the Digitalis Investigational Group (DIG) Ancillary Study (see Table 20–4), it appears that digoxin has, at most, a very limited role in the management of patients with DHF in normal sinus rhythm.⁴⁹

TABLE 20-5 Characteristics of the Cardiomyopathies

	Dilated	Hypertrophic	Restrictive
Myocardial mass	↑→↑↑	↑↑↑	nl→↑
Ventricular cavity size	↑↑↑↑↑	↓↓→nl	nl→↓
Contractile function	↓↓↓	↑↑→	nl→↓
LV filling pressure	↑↑	nl→↑	↑
Chest x-ray film	Moderate to marked cardiac enlargement	Mild to moderate cardiac enlargement	Mild cardiac enlargement
Electrocardiogram	ST-segment and T-wave abnormalities	ST-segment and T-wave abnormalities, LV hypertrophy	Low voltage, conduction defects
Echocardiogram	LV dilation and dysfunction	Asymmetric septal hypertrophy, systolic anterior motion of the mitral valve	Increased LV wall thickness possible
Radionuclide studies	LV dilatation and dysfunction	Vigorous systolic function	Normal systolic function

↑, increased; ↓, decreased; LV, left ventricular; nl, normal.

PHARMACOECONOMIC CONSIDERATIONS

Frequent admission to the hospital is common in patients with DHF. Unfortunately, there are no pharmacoeconomic data associated with the only large clinical outcome trial (CHARM-Preserved) published to date. Because DHF is primarily a disease of the elderly, comorbid conditions will create challenges in any trial designed. At the present time, cost to the patient should be considered because adherence to an antihypertensive regimen is paramount to a beneficial outcome.

CLINICAL CONTROVERSIES

- Digoxin may increase hospitalizations for unstable angina in patients with DHF and normal sinus rhythm.
- Drugs that antagonize the renin–angiotensin–aldosterone system may be the preferred antihypertensive drugs for patients with DHF.

EVALUATION OF THERAPEUTIC OUTCOMES

The end points used in assessing effective therapies for DHF include mortality, hospitalization for worsening HF, functional status or quality-of-life indicators, and cost. Other end points may target underlying mechanisms of disease, such as calcium homeostasis or regression of fibrosis. A number of clinical trials addressing this important clinical problem are underway.

CARDIOMYOPATHIES

Diastolic dysfunction plays a role in the presentation of some types of cardiomyopathy. Over the past decade, the terminology and classification used for the cardiomyopathies have been confusing because of overlap among the diseases and/or classification schemes. In 2006, the ACC/AHA suggested a broader definition for the cardiomyopathies. The expert panel defined the cardiomyopathies as “a heterogeneous group of diseases of the myocardium associated with mechanical and/or electrical dysfunction that usually (but not invariably) exhibit inappropriate ventricular hypertrophy or dilation and are due to variety of causes that frequently are genetic. Cardiomyopathies either are confined to the heart (*primary* cardiomyopathy) or are part of generalized systemic disorders (*secondary* cardiomyopathy), often leading to cardiovascular death or progressive HF-related disability.”⁵⁰

The *primary* cardiomyopathies are further divided into genetic, mixed (genetic and nongenetic), and acquired. Endocrine conditions, inflammation, metabolic disorders, infiltrative diseases, and toxins are a few of the causative factors of secondary cardiomyopathy.⁵⁰ It is important to note that this new contemporary classification does not include pathologic myocardial processes that are a direct result of other cardiovascular conditions such as valvular heart disease, hyper-

tension, and CAD. Therefore, the commonly used term “ischemic cardiomyopathy” is not considered a “true” cardiomyopathy.

Frequently, a specific etiology is not evident. Therefore, another commonly used categorization of the cardiomyopathies is based on the structural and/or functional abnormalities present. The three groups of primary cardiomyopathies usually are described as dilated, hypertrophic, and restrictive. An understanding of the pathophysiologic basis for each type of cardiomyopathy leads to a rational selection of drug therapy or other treatment modality. The characteristics for each of the types of cardiomyopathy are listed in Table 20–5. The distinction among the cardiomyopathies is not absolute, and there is some overlap in the functional abnormalities.

In dilated cardiomyopathy, the cardinal feature is ventricular chamber enlargement. Systolic function is abnormal with normal LV wall thickness, leading to a decreased cardiac output. In patients with HCM, the ventricular cavity is not dilated, but the ventricular muscle mass is increased, existing in the absence of known causes of LVH. Ventricular cavity size is normal or decreased, and systolic function often is preserved. Patients with HCM may have an obstructive or nonobstructive form. Patients with restrictive cardiomyopathy have inadequate ventricular compliance causing diastolic dysfunction as a result of endocardial and/or myocardial disease. The clinical presentation is similar to that of constrictive pericarditis.

HYPERTROPHIC CARDIOMYOPATHY

HCM is a primary, genetic cardiomyopathy that is inherited as an autosomal dominant trait caused by mutations in any of 10 genes. The distribution of the hypertrophy usually is asymmetric, meaning that segments of the LV are thickened to varying degrees. There also may be enlargement of the atria, thickening of the mitral valve leaflets, and fibrotic areas within the ventricular wall. In the past, the terms of *idiopathic hypertrophic subaortic stenosis* and *hypertrophic obstructive cardiomyopathy* were used to describe patients with HCM with an outflow obstruction. These terms are used less frequently now because they overemphasize the obstructive component of the disease, which is present in a minority of patients.⁵⁰

Epidemiology

Recent epidemiologic investigations estimate the prevalence of phenotypically expressed HCM in the general adult population to be approximately 0.2% (1:500), making it the most frequently occurring cardiomyopathy. HCM is the most common genetic cardiovascular disease. However, many individuals have a mutant gene but go undetected.⁵¹

Etiology

The genetic predisposition to HCM is thought to be an autosomal dominant trait with variable penetrance. Because of the wide variability of presentation, not all cases in a family may be detected.

HCM usually is caused by mutations in the genes for β -myosin heavy chain, myosin-binding protein C, and cardiac troponin T.⁵²

Pathophysiology

HCM appears to have several different pathophysiologic mechanisms leading to similar clinical manifestations, although the prognoses for patients will vary. The pathophysiology of HCM is a complex relationship among several factors, including (a) asymmetric LVH, (b) diastolic dysfunction, (c) dynamic obstruction of the outflow tract, and (d) myocardial ischemia. Each of these components contributes to the overall presentation of the patient to a varying degree.^{51,52}

Left Ventricular Hypertrophy The hypertrophy seen in HCM usually is diffuse and involves the septum and LV anterolateral free wall to a greater degree than the posterior segment. Asymmetric septal hypertrophy is a sensitive marker for HCM but is not specific for this disorder. In patients with outflow obstruction, the basal septum usually is markedly thickened at the level of the mitral valve. In patients with nonobstructive HCM, the outflow tract is larger, and the septal hypertrophy that occurs has a more distal or apical distribution.⁵³

Cellular disorganization is a common histologic finding in HCM. Morphologic abnormalities are found at the gross, microscopic, and ultrastructural levels. The disarray of myocytes may contribute to diastolic and systolic dysfunction, as well as serving as a nidus for ventricular arrhythmias. The degree of LVH is associated with a worse clinical course. The presence of hypertrophy correlates directly with myocardial infarction, HF, stroke, and ventricular arrhythmias. Spirito and Autore⁵¹ found that the magnitude of LVH was directly related to the risk of sudden cardiac death.

Diastolic Dysfunction Diastolic dysfunction is the most common abnormality found in patients with HCM. Approximately 80% of patients exhibit symptoms associated with diastolic dysfunction. Studies of the LV led to the realization that diastolic dysfunction is the result of abnormalities in relaxation, distensibility (compliance), and filling. The abnormalities of diastolic function can be both regional and global and lead to an incoordination of contraction and relaxation. β -Adrenergic stimulation can aggravate these abnormalities, whereas β -receptor blockade may diminish them.⁵²

Abnormalities in filling are also associated with changes in chamber stiffness that occur in HCM. This stiffness may be the result of myocardial fibrosis, cellular disorganization, or increased myocardial mass. The decreased distensibility leads to an abnormally steep slope of the diastolic pressure–volume curve such that an increase in LV volume results in a disproportionate increase in diastolic pressure.

Myocardial relaxation is an energy-dependent process that is sensitive to episodes of ischemia. Diastolic resequestration of calcium ions by the sarcoplasmic reticulum is an energy-dependent process. In the event of ischemia, the sequestration of calcium is inhibited, allowing the calcium to continue its interaction with the myofibrillar contractile proteins. Calcium channel blockers have been used with some success in patients with diastolic dysfunction.⁵⁴

Systolic Function and Outflow Tract Obstruction Abnormalities of systolic function also occur in patients with HCM. The hypertrophied LV may cause a powerful but sometimes uncoordinated contraction presumably as a result of the abnormal architecture of the myocardium. The increase in LV wall thickness results in decreased wall stress during systole. Therefore, the LV contracts against a decreased afterload so that the LV is described as being *hyperdynamic*. EF often is increased.

Considerable controversy has surrounded the issue of the importance of outflow tract obstruction in conjunction with HCM. The presence of a gradient (the systolic pressure difference between the body and the outflow tract of the LV) is indicative of a dynamic obstruction of the LV outflow tract. Outflow tract gradients occur in

TABLE 20-6 Factors Known to Affect Outflow Gradients in Hypertrophic Cardiomyopathy

Factors that diminish gradients

- Decreasing myocardial contractility
 - β -Blocking drugs
 - Verapamil
- Increasing ventricular volume
- Increasing arterial pressure

Factors that enhance gradients

- Increasing myocardial contractility
 - Exercise
 - Inotropic agents
- Decreasing ventricular volume
- Decreasing arterial pressure

approximately 25% of patients with HCM.⁵⁰ The obstruction that occurs usually shows spontaneous variability and may be reduced by interventions that decrease myocardial contractility. The gradient can be augmented by factors that increase contractility (Table 20–6).⁵⁴ LV outflow tract obstruction at rest has been found to be a predictor of progression to severe HF symptoms, stroke, and death.⁵⁵

Myocardial Ischemia Chest pain in the absence of CAD is a common symptom of patients with HCM. However, it is appropriate to consider typical CAD in any patient with HCM if they have the usual risk factors for atherosclerosis.^{50,54,56} Several mechanisms are proposed for the myocardial ischemia seen in this patient population. There may be inadequate capillary density in relation to the increased LV muscle mass. The small intramural coronary arteries may be abnormally narrowed or excessively compressed during systole. Impaired relaxation during diastole may inhibit blood flow to the subendocardium. Once myocardial ischemia develops, further increases in LV filling pressure may occur, which, in turn, lead to more ischemia. Repeated episodes of ischemia may be responsible for progressive myocyte loss and fibrosis. The subendocardium is at greatest risk for ischemic damage because of the lower capillary density and higher oxygen demand secondary to wall tension.⁵⁴

Diagnosis

Making the diagnosis of HCM may be difficult because the disorder may be confused with CAD, aortic stenosis, or mitral regurgitation. Patients with HCM can be young and physically active. The physical signs of the cardiac examination depend on the presence of a systolic pressure gradient within the LV. If a gradient is present, a late-onset systolic murmur is heard often. The murmur is intensified by standing and the Valsalva maneuver and lessened with squatting or handgrip. Very rarely, some patients develop an end-stage LV dilation and a declining LV EF, which often are confused with idiopathic dilated cardiomyopathy.

Echocardiography is used to confirm the diagnosis. The diagnosis of HCM is made with two-dimensional echocardiography, with the usual criterion of LV wall thickness ≥ 15 mm. Magnetic resonance imaging of the entire LV may add valuable information, especially if the echocardiogram is of suboptimal quality.^{50,56}

The development of or increase in a murmur suggests progression of disease, but disappearance of a murmur does not imply improvement. In fact, disappearance of a murmur may herald further impairment of systolic function. Some patients will progress to CHF a result of atrial fibrillation, mitral regurgitation, or myocardial infarction. If SHF develops, the patient has a poor prognosis.

Contemporary methods of diagnosis consist of genotype assessment. Genetic testing allows for a definitive diagnosis and precise identification of mutations in myocardial sarcomere proteins. Unfortunately, screening for more than 200 mutations in multiple genes is complex, time consuming, costly, and restricted to a small number of research laboratories. Furthermore, genetic screening

identifies gene variants in only 50% to 60% of patients. Based on these limitations, genotype assessment has not become a standard part of routine clinical evaluation.^{50,51}

CLINICAL PRESENTATION OF HYPERTROPHIC CARDIOMYOPATHY

General

- The clinical presentation varies widely, ranging from no symptoms to severe symptoms of angina, HF, and/or sudden death. The severity of symptoms corresponds to the degree of LVH, but this relationship is not absolute.

Symptoms

- The patient may complain of dyspnea, chest pain, fatigue, palpitations, presyncope, and syncope.

Signs

- Systolic murmur

Other Diagnostic Tests

- Echocardiography will show increased myocardial mass.
- Electrocardiography will reveal LVH with or without ST-segment and T-wave abnormalities.

Prognosis

The clinical course for a patient with HCM should be viewed in terms of the specific subtypes of the disease spectrum. Patients fall into one of several relatively discrete pathways: (a) high risk for sudden death; (b) symptoms of DHF, including syncope; (c) progression toward advanced end-stage HF; and (d) atrial fibrillation and its sequelae. Of major concern is the incidence of sudden cardiac death among patients with HCM. Approximately 10% to 20% of HCM patients are at increased risk for sudden death. The mechanism responsible for sudden cardiac death is thought to be related to an electrically unstable myocardium leading to complex ventricular arrhythmias. Less often, sudden death may be the result of hemodynamic changes. The onset of atrial fibrillation in the face of severe LV diastolic dysfunction may result in a significant decrease in stroke volume. This decrease in cardiac output could lead acute LV failure, MI, or sudden death. Sudden death can be a complication, especially in young athletes with HCM. It is recommended that young patients with HCM refrain from competitive athletics.^{50,56}

Quantification of the risk of sudden death remains elusive for patients with HCM. The clinical markers associated with an increased risk for sudden death (Table 20-7) have a high negative predictive value. The absence of all these markers can be used to develop a profile for a patient at low risk for sudden death. The magnitude of hypertrophy appears to be a strong predictor, with the

cumulative risk nearly zero for patients with a wall thickness ≤ 19 mm. Young patients with severe hypertrophy (wall thickness >30 mm) are at high risk for sudden death even if they are asymptomatic. A high LV outflow tract pressure gradient ≥ 30 mm Hg is a strong predictor for older patients.⁵⁷ Presentation of HCM in the latter decades of life is common. Patients who present with HCM at an advanced age of 65 years or older usually have a prognosis that is no different from that of age- and gender-matched controls. Elderly patients with HCM tend to have mild degrees of LVH, and their symptoms are not severe.⁵⁸ Because systolic hypertension and diastolic HF are common in the elderly, the diagnosis of HCM may be challenging. However, marked LVH out of proportion to blood pressure, unusual patterns of LVH, or an outflow obstruction at rest strongly suggests HCM.⁵⁰

TREATMENT

Hypertrophic Cardiomyopathy

■ DESIRED OUTCOMES

Because no known means are available for preventing HCM, the focus must be on methods to minimize the consequences of the disorder.

■ GENERAL APPROACH TO TREATMENT

- ⑧ The treatment of HCM is designed to reduce symptoms, improve exercise tolerance, retard disease progression, and improve prognosis. Agents that decrease contractility, improve diastolic dysfunction, reduce ischemia, and suppress arrhythmias have been used with some success (Fig. 20-2). In 2003, the ACC in conjunction with the ESC published a consensus document on HCM.⁵⁹

■ NONPHARMACOLOGIC THERAPY

Surgical treatment generally is reserved for patients who are refractory to medical management, have an outflow gradient ≥ 50 mm Hg, a very thick ventricular septum, and high LV pressures. Surgical intervention is designed to relieve the outflow obstruction and the elevated LV pressures. The surgeon accomplishes this by performing a myectomy (i.e., removal of excess tissue). The procedure results in a reduction in LV filling pressures and a long-term improvement in symptoms. However, early mortality rates of up to 5% have been reported.^{52,59} Other complications may include septal perforation and late occurrence of HF.

The results of uncontrolled studies suggested that dual-chamber pacing decreased LV outflow gradients and improved symptoms. Subsequent controlled trials were not able to replicate the initial findings but demonstrated more modest improvement. Consequently, the ACC/AHA and the North American Society of Pacing and Electrophysiology have issued guidelines suggesting pacing for severely symptomatic patients who have not responded to medical management (class IIb recommendation, or one in which the efficacy is less well established by evidence).⁶⁰

Ablation of the myocardium using alcohol is another alternative to surgery. Septal ablation with alcohol results in the same type of outcomes as seen with myectomy. Long-term followup is limited because this procedure has been used for less than a decade. Because it is a percutaneous procedure (similar to cardiac catheterizations), it is being performed more frequently than myectomy. There is some concern that the risk for arrhythmia-related cardiac events may increase following alcohol ablation. Long-term followup is needed to assess this risk. Complete heart block is a common complication of septal ablation (14% in one case series) and requires a permanent pacemaker if it occurs.^{52,59}

TABLE 20-7 Risk Factors Associated with Sudden Cardiac Death in Hypertrophic Cardiomyopathy

Major risk factors

Prior cardiac arrest
Spontaneous sustained ventricular tachycardia
Positive family history of premature death
Multiple syncope or near-syncope episodes, especially if associated with exertion
Multiple and repetitive or prolonged episodes of nonsustained ventricular tachycardia
Marked left ventricular hypertrophy ≥ 30 mm
Hypotensive blood pressure response to exercise

Potential individual risk factors

Atrial fibrillation
Myocardial ischemia
Left ventricular outflow obstruction
Identification of a malignant genotype
Intense (competitive) physical exertion

Data from Zipes et al.⁶²

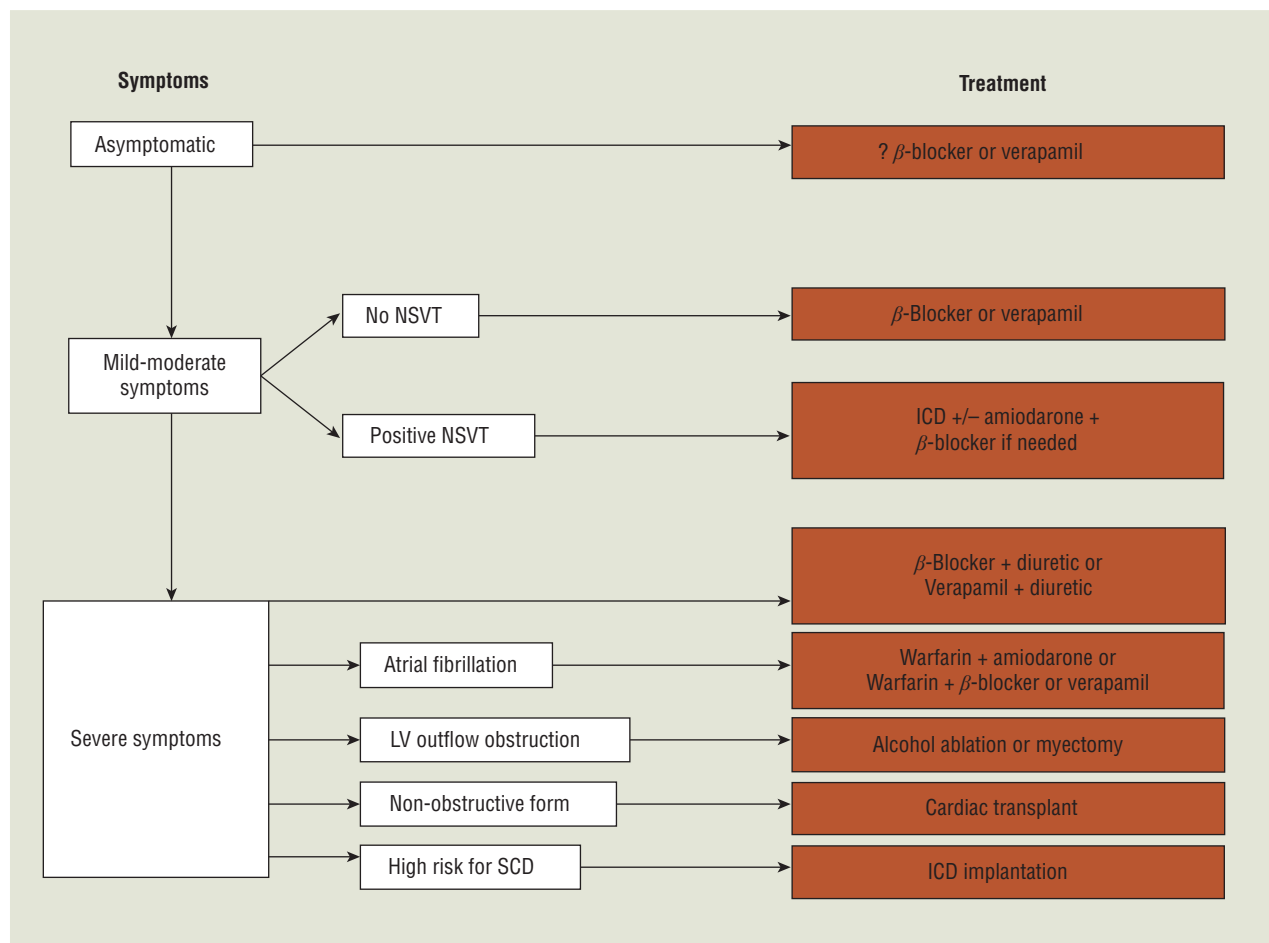

FIGURE 20-2. Treatment algorithm for hypertrophic cardiomyopathy. (ICD, implantable cardioverter-defibrillator; LV, left ventricular; NSVT, nonsustained ventricular tachycardia; SCD, sudden cardiac death; ?, questionable role.)

■ IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR

9 Sudden death is the most worrisome outcome of HCM, and the implantable cardioverter-defibrillator (ICD) is the most effective therapy for prevention of sudden death.⁶¹ It is difficult to know when to implant an ICD, especially in a young patient diagnosed with HCM. Patients who are candidates for an ICD for primary prevention will be young and relatively asymptomatic. In 2006, the ACC/AHA with the ESC published updated guidelines designating the ICD for primary prevention of sudden death (class IIa recommendation or one in which the weight of the evidence or opinion favors efficacy). These guidelines stipulate that patients should exhibit one or more major risk factors for sudden death (see Table 20–7), currently be receiving chronic medical therapy, and have a reasonable survival with good functional status at 1 year. For secondary prevention following cardiac arrest, ICD placement is considered a class I recommendation, where there is evidence or general agreement that the procedure is beneficial.⁶⁰ Conducting a clinical trial to provide evidence for a higher-level recommendation for primary prevention is unlikely to occur.⁶¹

■ PHARMACOLOGIC THERAPY

β-Adrenergic Blockers

10 β-Blocking agents have been used in obstructive and nonobstructive forms of HCM since the 1960s. Approximately one third to half of patients with angina, dyspnea, light-headedness, or syncope will have a favorable response to these agents.⁵⁴ Doses up to 480 mg/day

of propranolol or its equivalent are used. Resting heart rate should be 60 beats/min, and the maximum exercise heart rate should be <120 beats/min. The mechanism by which β-blockade is beneficial is by inhibiting sympathetic stimulation of the heart. Myocardial oxygen demand is reduced by decreasing heart rate, LV contractility, and myocardial wall stress during systole. Outflow tract obstruction may be minimized with β-blockade, especially under conditions of stress or exercise, when sympathetic stimulation is high.

Calcium Channel Blockers

Patients who have an inadequate response to β-blockade may respond to verapamil.⁵¹ Doses of verapamil up to 480 mg/day have beneficial effects on symptoms.⁵⁹ Calcium channel blockers may be of benefit to patients with HCM for several reasons. Increased calcium concentrations have been shown to play a role in prolonging ventricular depolarization, as well as the duration of isometric contraction and relaxation. Patients with HCM have a hyperdynamic ventricle in systole and delayed relaxation and decreased compliance during diastole. Calcium channel blockers decrease the myocardial oxygen demand, resulting in an improved balance between oxygen supply and demand; therefore, diastolic function may be improved.

Most patients with HCM who have been treated with a calcium channel blocker have received verapamil, although others also have been used. Intravenous verapamil has been noted to acutely reduce the outflow tract gradient in patients with obstructive HCM. The mechanism may be a decrease in systolic function as well as an increase in LV volumes as a result of enhanced LV diastolic filling.

The adverse effects associated with use of verapamil include constipation, sinus nodal blockade, prolongation of the PR interval,

AV dissociation, hypotension, and pulmonary congestion.⁵⁴ The risks may outweigh the benefits in patients with (a) a markedly elevated pulmonary capillary wedge pressure or pulmonary artery occlusion pressure, (b) a history of paroxysmal nocturnal dyspnea or orthopnea, (c) sick sinus syndrome or significant AV nodal disease in the absence of a permanent pacemaker, (d) low systolic blood pressure, and (e) a substantial outflow gradient. Verapamil should be avoided in patients with HF as a result of systolic dysfunction.⁵⁹ There is no evidence that either β -blockade or verapamil protects the patient from sudden cardiac death.

Studies using other calcium channel blockers are limited. Improvement in diastolic dysfunction may occur, but the dihydropyridines may cause a reflex increase in heart rate or hypotension or worsen the outflow tract gradient.

Antiarrhythmic Agents

Disopyramide has been used for treating both the supraventricular and ventricular arrhythmias occurring in patients with HCM. In addition, the negative inotropic effect and the ability to increase peripheral vascular resistance attributed to disopyramide have been used to reduce outflow tract obstruction. The anticholinergic side effects (blurred vision, dry mouth, and urinary retention) make disopyramide a problematic agent for long-term therapy in some patients. The QT interval on the ECG should be monitored in patients on disopyramide.⁵⁹

The role of amiodarone for the prevention of sudden death in patients with HCM has been questionable. A few nonrandomized studies have suggested a protective effect, whereas others demonstrate only symptomatic improvement. Nonetheless, the 2006 ACC/AHA/ESC give amiodarone a class IIb recommendation for primary prophylaxis against sudden death in patients with HCM when ICD placement is not feasible and who demonstrate one or more major risk factors for sudden death (see Table 20–7). Furthermore, in patients with HCM who are not candidates for ICD placement and have suffered a cardiac arrest, amiodarone therapy is considered the preferred treatment (class I recommendation).⁶²

A significant number of patients with HCM develop atrial fibrillation. Amiodarone is one of the most effective agents available to maintain normal sinus rhythm in these patients. For patients in chronic atrial fibrillation requiring rate control, a β -blocker or verapamil may be used. Anticoagulation should be considered because these patients are at risk for systemic embolization and stroke. If amiodarone is added to the therapy of a patient already receiving warfarin, the prothrombin time or international normalized ratio will be increased and should be monitored closely.⁵¹

Other Drugs

⑪ There is a small risk for bacterial endocarditis in HCM patients with LV outflow obstruction under resting conditions and in those with intrinsic mitral valve disease. Patients undergoing dental or selected surgical procedures that cause bloodborne bacteremia should receive appropriate antibiotic therapy. The administration of nitroglycerin and digoxin generally is discouraged in the presence of LV outflow obstruction.⁵⁹

CLINICAL CONTROVERSY

Some clinicians believe that ACE inhibitors have no role in the management of HCM with LV outflow obstruction. Others believe that ACE inhibitors may be beneficial by limiting hypertrophy.

Evaluation of Therapeutic Outcomes

The goal of treatment of patients with HCM is primarily to reduce their symptoms of dyspnea and exercise intolerance. Either β -

blocker or calcium channel blockers can be used. If a β -blocker is chosen, it is best to use an agent that does not have intrinsic sympathomimetic activity. The dose should be maximized. If the patient does not tolerate a β -blocker or has a contraindication to use of a β -blocker, then verapamil can be tried. Patients should be monitored for resolution of symptoms and an increase in exercise tolerance. Resolution of symptoms may take months to occur. In addition, both β -blockers and calcium channel blockers may cause hypotension and conduction abnormalities. β -Blockers may worsen pulmonary function. If dyspnea continues with maximal doses of a β -blocker or calcium channel blocker, a diuretic agent or a nitrate may be added with caution. Patients who are at high risk for sudden cardiac death should be considered candidates for an ICD.

For patients with significant obstruction to LV outflow who do not respond to medical management, a surgical approach may be necessary. Septal myectomy and alcohol ablation have been used. These approaches generally are reserved for patients who have an outflow gradient >50 mm Hg and/or severe symptoms and who have not responded to an adequate trial of medical therapy.

RESTRICTIVE CARDIOMYOPATHY

Restrictive cardiomyopathy is primarily an abnormality of diastolic function that results in impaired filling and increases in ventricular end-diastolic pressures with normal or decreased diastolic volume. It is associated with normal systolic function early in the course of the disease but a decrease in systolic function later in the disease process. Either one or both of the ventricles may be affected; therefore, restrictive cardiomyopathy may present as either left- or right-sided HF.⁵⁰

CLINICAL PRESENTATION OF RESTRICTIVE CARDIOMYOPATHY

General

- The majority of patients remain asymptomatic but experience symptoms during exercise or vigorous activity.

Symptoms

- The patient may complain of dyspnea, orthopnea, fatigue, edema, ascites, or chest pain.

Signs

- Significant jugular venous distension
- Mitral and/or tricuspid regurgitant murmurs
- Thromboembolic complications
- Kussmaul sign may be present

Laboratory Tests

- BNP and N-proBNP levels will be elevated.

Other Diagnostic Tests

- ECG may reflect atrial arrhythmias, tachybrady syndrome, or conduction abnormalities.
- Echocardiography may reveal small ventricles and dilated atria.

Epidemiology and Etiology

Restrictive cardiomyopathy is the type of cardiomyopathy encountered least frequently in western countries. Because restrictive cardiomyopathy is rare, the natural course of the disease is not well characterized, and reports on prognosis have been highly variable. Restrictive cardiomyopathies may be classified as either myocardial or endomyocardial. The myocardial types may be noninfiltrative, infiltrative, or storage diseases. The endomyocardial types are due to endomyocardial fibrosis, hypereosinophilic syndrome, carcinoid

heart disease, metastatic cancers, radiation, and anthracycline toxicity or secondary to drugs known to cause fibrosis.⁵⁴

Restrictive myocardial disease may result from several local or systemic disorders. Amyloidosis, hemochromatosis, scleroderma, carcinoid, sarcoidosis, diabetes, pseudoxanthoma elasticum, and endomyocardial fibrosis have been known to cause restrictive cardiomyopathy. The most common cause of restrictive cardiomyopathy in the industrialized world is amyloidosis, whereas endomyocardial fibrosis is a common cause in tropical areas of the world. There may be a genetic predisposition to idiopathic restrictive cardiomyopathy.⁵⁴

The cause of the disease, the severity of HF symptoms, and the presence of cardiac thrombi and arrhythmias are factors that affect long-term survival. Children diagnosed with restrictive cardiomyopathy have a worse prognosis than do adults and should be considered for early cardiac transplantation.⁶³

Pathophysiology

The major hemodynamic abnormality in restrictive cardiomyopathy is a limitation in ventricular filling leading to increased filling pressures. The cavity size and wall thickness of the ventricles usually are normal. Atrial dimensions often are increased. Thrombi are found frequently in the cardiac chambers. Patients have signs and symptoms consistent with HF. The abnormality is similar to that seen in pericardial disease causing constriction or tamponade.

Diagnosis

The diagnosis of restrictive cardiomyopathy should be considered in any patient who presents with signs and symptoms of HF but has only mild cardiomegaly. Differentiation from constrictive pericarditis is important because pericardectomy is an effective form of treatment of constrictive pericarditis. Recent studies have focused on using BNP as a potential noninvasive marker for differentiation of the two conditions.⁶⁴

TREATMENT

Restrictive Cardiomyopathy

The treatment of restrictive cardiomyopathy is complex because of the heterogeneity of the pathophysiologic abnormalities. Diuretics are used for the symptoms of venous congestion in the presence of restrictive cardiomyopathy, but caution is advised because these patients require high filling pressures to maintain an adequate stroke volume and cardiac output. Hypotension and hypoperfusion may occur as a result of excessive use of diuretics. Because systolic function often is normal, digoxin is of little benefit and may be proarrhythmic. Amiodarone can be used to maintain normal sinus rhythm in patients who have episodes of atrial fibrillation. Anticoagulation is needed to decrease the risk of systemic embolization, particularly in patients with atrial fibrillation, valvular regurgitation, and low cardiac output. In the case of hemochromatosis, chelation therapy and/or repeated phlebotomy may be of benefit. Treatment with corticosteroids and cytotoxic drugs has been used with some success in the early phase of endomyocardial fibrosis and eosinophilic cardiomyopathy.⁵⁴

Evaluation of Therapeutic Outcomes

The first step in assessing and treating a patient with restrictive cardiomyopathy is to rule out constrictive pericarditis because the two conditions have a similar presentation. Patients with constrictive pericarditis are treated easily with surgery, whereas patients with restrictive cardiomyopathy undergo a varied approach to therapy depending on the etiology of their disorder. The treatment is aimed at

relieving the symptoms associated with high filling pressures. This is achieved generally through the use of diuretics. Diuretic therapy should be initiated with low doses. Normalization of filling pressures is not possible or desirable. Patients' symptoms should be monitored for improvement. Excessive diuresis will result in inadequate cardiac output. Chelation therapy has been advocated for patients with hemochromatosis. Prednisone has been suggested for patients with sarcoidosis. There is no curative treatment for restrictive cardiomyopathy.

STUART T. HAINES, DANIEL M. WITT, AND EDITH A. NUTESCU

KEY CONCEPTS

- 1 The risk of venous thromboembolism (VTE) is related to several easily identifiable factors, including age, major surgery (particularly orthopedic procedures of the lower extremities), previous VTE, trauma, malignancy, and hypercoagulable states. These risks are additive.
- 2 The diagnosis of VTE must be confirmed by objective testing.
- 3 Antithrombotic therapies require meticulous and systematic monitoring as well as ongoing patient education. Well-organized anticoagulation management services improve the quality of patient care and reduce overall cost.
- 4 Bleeding is the most common adverse effect associated with anticoagulant drugs. A patient's risk of major hemorrhage is related to the intensity and stability of therapy, concurrent drug use, history of gastrointestinal bleeding, risk of falls, recent surgery or trauma, and age.
- 5 At the time of hospital admission, all patients should receive prophylaxis against venous thromboembolism that corresponds to their level of risk. Prophylaxis should be continued throughout the period of risk.
- 6 In the absence of contraindications, the treatment of VTE should initially include a rapid-acting anticoagulant (e.g., unfractionated heparin, low-molecular-weight heparin, or fondaparinux) overlapped with warfarin for at least 5 days and until the patient's international normalized ratio is greater than 2.0. Anticoagulation therapy should be continued for a minimum of 3 months. The duration of anticoagulation therapy should be based on the patient's risk of VTE recurrence and major bleeding.
- 7 Most patients with an uncomplicated deep vein thrombosis, with or without pulmonary embolism, can be safely treated as an outpatient.

Venous thromboembolism (VTE) is a potentially fatal disorder and a significant national health problem in our aging society.^{1,2} Although it can strike young, otherwise healthy adults, it most frequently occurs in patients who sustain multiple trauma, undergo major surgery, are immobile for a lengthy period of time, or have a hypercoagulable disorder. Resulting from clot formation within the

venous circulation (Fig. 21–1), VTE is manifested as deep vein thrombosis (DVT) and pulmonary embolism (PE). Death from PE can occur within minutes after the onset of symptoms, before effective treatment can be given.

Unfortunately, the disease is often clinically silent, and the first manifestation may be sudden death. In some case series, 80% of patients who died suddenly had some evidence of PE at the time of autopsy.³ Beyond the symptoms produced by the acute event, the long-term sequelae of VTE, such as the postthrombotic syndrome and recurrent thromboembolic events, also cause substantial pain and suffering.¹

The treatment of VTE is fraught with substantial risks.⁴ Antithrombotic drugs require precise dosing and meticulous monitoring.^{5–7} Systematic approaches to drug therapy management substantially reduce the risks, but bleeding remains an all too common and serious complication of administering antithrombotic drugs.^{7,8} Consequently, the prevention of VTE in at-risk patients is paramount to improving outcomes.³ When there is a suspicion of VTE, the rapid and accurate diagnosis of the disorder is critical to making appropriate treatment decisions.⁹ The optimal use of antithrombotic drugs requires not only an in-depth knowledge of their pharmacology and pharmacokinetic properties, but also a comprehensive approach to patient management.⁵

EPIDEMIOLOGY

The true incidence of VTE in the general population is unknown, because a substantial portion of patients, perhaps more than 50%, have clinically silent disease. An estimated 2 million people in the United States develop VTE each year; 600,000 are hospitalized, and 60,000 die.² The estimated annual direct medical costs of managing the disease are well over \$1 billion and growing. The best available data indicate the age-adjusted annual incidence of symptomatic VTE in whites to be 117 per 100,000 population.¹⁰ The incidence of VTE nearly doubles in each decade of life over the age of 50 years and is slightly higher in men. The age-adjusted incidence of PE has declined slightly in recent years, presumably because of heightened awareness of VTE, effective prevention strategies, early diagnosis, and prompt treatment. However, as the population ages, the total number of cases of DVT and PE continues to climb.

Relatively little is known about the risk of VTE in ethnic populations. African Americans appear to be at somewhat higher risk of VTE than are Americans of predominantly European ancestry, whereas Hispanic Americans may be at slightly lower risk.¹¹ Asian Americans and Pacific Islanders appear to have a strikingly low incidence of VTE.

The incidence of VTE in specific high-risk patient populations has been extensively studied.³ Patients who sustain multiple traumas or undergo an orthopedic procedure involving a lower extremity are at particularly high risk, with the incidence of VTE often exceeding

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

FIGURE 21-1. Venous circulation.

50% in the absence of effective prophylaxis. Among those undergoing major surgeries other than procedures involving the lower extremities, the incidence of VTE is 20% to 40% when one or more other risk factors are present, such as age older than 60 years. The long-term incidence of VTE among patients who have a prior history of VTE and who have metastatic cancer is extremely high.^{12,13} Likewise, the incidence of VTE after a myocardial infarction, stroke, and spinal cord injury is high.³ Several disorders of hypercoagulability have also been linked to a high lifetime incidence of VTE.^{3,14}

ETIOLOGY

1 A number of factors increase the risk of developing VTE (Table 21-1). These risk factors are additive and can be easily identified in clinical practice. A prior history of VTE is perhaps the strongest risk factor for recurrent VTE, presumably because of the destruction of venous valves and obstruction of blood flow caused by the initial event.¹⁵ Rapid blood flow has an inhibitory effect on thrombus formation, but a slow rate of flow reduces the clearance and dilution of activated clotting factors in the zone of injury and slows the influx of regulatory substances. Stasis of blood tips the delicate balance of procoagulation and anticoagulation in favor of thrombogenesis. The rate of blood flow in the venous circulation, particularly in the deep veins of the lower extremities, is relatively slow. Valves in the deep veins of the legs, as well as contraction of the calf and thigh muscles, facilitate the flow of blood back to the heart and lungs; thus, damage to the venous valves and prolonged periods of immobility result in venous stasis. Vessel obstruction, either from external compression or a thrombus, also promotes clot propagation. Reduced venous

blood flow explains, at least in part, why numerous medical conditions and surgical procedures are associated with an increased risk of VTE (Table 21-1). Greater-than-normal blood viscosity, seen in myeloproliferative disorders like polycythemia vera, for example, may also contribute to slowed blood flow and thrombus formation.

A growing list of hereditary deficiencies, gene mutations, and acquired diseases have been linked to hypercoagulability (see Table 21-1).¹²⁻¹⁴ Activated protein C resistance is the most common genetic disorder of hypercoagulability, with a prevalence rate approaching 5% among community-dwelling whites, and a rate as high as 40% among those who suffer an idiopathic DVT or who have a strong family history of VTE. Although these patients have normal plasma concentrations of protein C, they often have a mutation on factor V that renders it resistant to degradation by activated protein C. This mutation is known as factor V Leiden, named after the city of Leiden, Holland, where the defect was initially reported. The prothrombin G20210A mutation also appears to be a relatively common defect, occurring in as many as 3% of healthy individuals of southern European descent and 16% of those with an idiopathic DVT. Although less common, inherited deficiencies of the natural anticoagulants protein C, protein S, and antithrombin place patients at a high lifetime risk for VTE. Conversely, excessively high concentrations of factors VIII, IX, and XI also increase the risk of VTE. Given the prevalence of these inherited abnormalities in the general population, some patients have multiple genetic defects that have additive effects in terms of increasing the lifetime thrombotic risk.

Acquired disorders of hypercoagulability may result from malignancy, the presence of antiphospholipid antibodies, and estrogen use.¹²⁻¹⁵ The strong link between cancer and thrombosis has been recognized since the late 1800s.¹³ Tumor cells secrete a number of

TABLE 21-1 Risk Factors for Venous Thromboembolism

Risk Factor	Example
Age	Risk doubles with each decade after age 50 y
History of VTE	Strongest known risk factor of DVT and PE
Venous stasis	Major medical illness (e.g., CHF, status post-MI) Major surgery (e.g., general anesthesia >30 minutes) Paralysis (e.g., status post-stroke, spinal cord injury) Polycythemia vera
	Obesity Varicose veins
Vascular injury	Major orthopedic surgery (e.g., knee and hip replacement) Trauma (especially fractures of the pelvis, hip, or leg) Indwelling venous catheters

procoagulant substances that activate the coagulation cascade. Furthermore, patients with cancer often have suppressed levels of protein C, protein S, and antithrombin. It has been postulated that cancer cells use thrombotic mechanisms to recruit a blood supply (angiogenesis), metastasize, and create a barrier against host defense mechanisms. Antiphospholipid antibodies, most commonly found in patients with autoimmune disorders such as systemic lupus erythematosus and inflammatory bowel disease, can cause venous and arterial thrombosis.¹⁴ These antibodies are also associated with repeated pregnancy loss presumably caused by placental thrombosis. The precise mechanism by which the antiphospholipid antibodies provoke thrombosis is unclear, but they appear to activate the coagulation cascade and platelets, as well as to inhibit the anticoagulant activity of proteins C and S. Estrogen-containing contraception, estrogen replacement therapy, and the selective estrogen receptor modulators are all linked to venous thrombosis.¹⁶ Women with an underlying disorder of hypercoagulability are at particularly high risk of developing venous thrombosis while taking estrogens. Although the mechanisms are not clearly understood, estrogens increase serum clotting factor concentrations and induce activated protein C resistance. Increased serum estrogen concentrations may explain, in part, the increased risk of VTE observed during pregnancy and the immediate postpartum period.¹⁷

PATHOPHYSIOLOGY

The arrest of bleeding following vascular injury (hemostasis) is essential to life.^{18,19} Within the vascular system, blood remains in a fluid state, transporting oxygen, nutrients, plasma proteins, and

waste. With vascular injury, a dynamic series of reactions involving a complex interplay of thrombogenic and antithrombotic stimuli result in the local formation of a hemostatic plug that seals the vessel wall and prevents further blood loss (Figs. 21–2, 21–3, and 21–4). A disruption of this delicate system of checks and balances may lead to inappropriate clot formation within the blood vessel that subsequently obstructs blood flow or embolizes to a distant vascular bed. In the late 1800s, Dr. Rudolf Virchow, a German pathologist, recognized the role played by blood vessels, circulating elements in the blood, and the speed of blood flow in the regulation of clot formation (Table 21–2). Alterations in any one of these elements, known today as Virchow's triad, may lead to pathologic clot formation.

Under normal circumstances, the endothelial cells that form the intima of vessels maintain blood flow by producing a number of substances that inhibit platelet adherence, prevent the activation of the coagulation cascade, and facilitate fibrinolysis.^{18,19} Vascular injury can expose the subendothelium (see Fig. 21–3). Platelets readily adhere to the subendothelium, using glycoprotein Ib receptors found on their surfaces and facilitated by von Willebrand factor. This causes platelets to become activated, releasing a number of procoagulant substances into the local circulation that stimulate platelets to expose glycoprotein IIb/IIIa receptors. These receptors allow the platelets to adhere to one another, resulting in platelet aggregation. In addition, the damaged vascular tissue releases tissue factor, also known as tissue thromboplastin, which activates the extrinsic pathway of the coagulation cascade (see Fig. 21–4).

The coagulation cascade is a stepwise series of enzymatic reactions that result in the formation of a fibrin mesh.^{18,19} Clotting factors circulate in the blood in inactive forms. Specific stimuli convert an inactive precursor into an active form that, in turn, converts the next precursor in the sequence. It was once believed that all clotting factors were proteolytic enzymes, known as zymogens. It is now known that factors V and VIII have no enzymatic activity themselves, but rather serve as cofactors that greatly accelerate the enzymatic activity of their respective partners. The final steps in the cascade are the conversion of prothrombin to thrombin and fibrinogen to fibrin. Thrombin plays a key role in the coagulation cascade; it is responsible not only for the production of fibrin, but also for the conversion of factors V and VIII to their active forms, creating a positive feedback loop that greatly accelerates the production of more thrombin. Additionally, thrombin enhances platelet aggregation through its interactions with the glycoprotein IIb/IIIa receptor.

Traditionally, the coagulation cascade has been divided into three distinct parts: the intrinsic, extrinsic, and common pathways (see Fig. 21–4).^{18,19} This artificial division is somewhat misleading, as there are numerous interactions between the three pathways. The extrinsic pathway, sometimes referred to as the tissue factor pathway, appears to be the principal mechanism that triggers the coagulation cascade. Tissue factor, released from the subendothelium, forms a complex with factor VIIa. The factor VIIa–tissue factor complex activates factor X in the common pathway and factor IX in the intrinsic pathway. The intrinsic pathway plays a key role in the propagation of clot formation. The activation and inhibition of factor X in the common pathway is a key step in the regulation of clot formation. With its cofactor, factor Va, factor Xa converts prothrombin (II) to thrombin (IIa), which then cleaves fibrinogen to form fibrin monomers. Finally, as the fibrin monomers reach a critical concentration, they begin to precipitate and polymerize to form fibrin strands. Factor XIIIa covalently bonds these strands to one another.

Normally, a number of tempering mechanisms control coagulation (see Table 21–2 and Fig. 21–2).^{18,19} Without effective self-regulation, the coagulation cascade would proceed unabated until all the clotting factors and platelets were consumed. The intact endothelium adjacent to the damaged tissue actively secretes several anti-

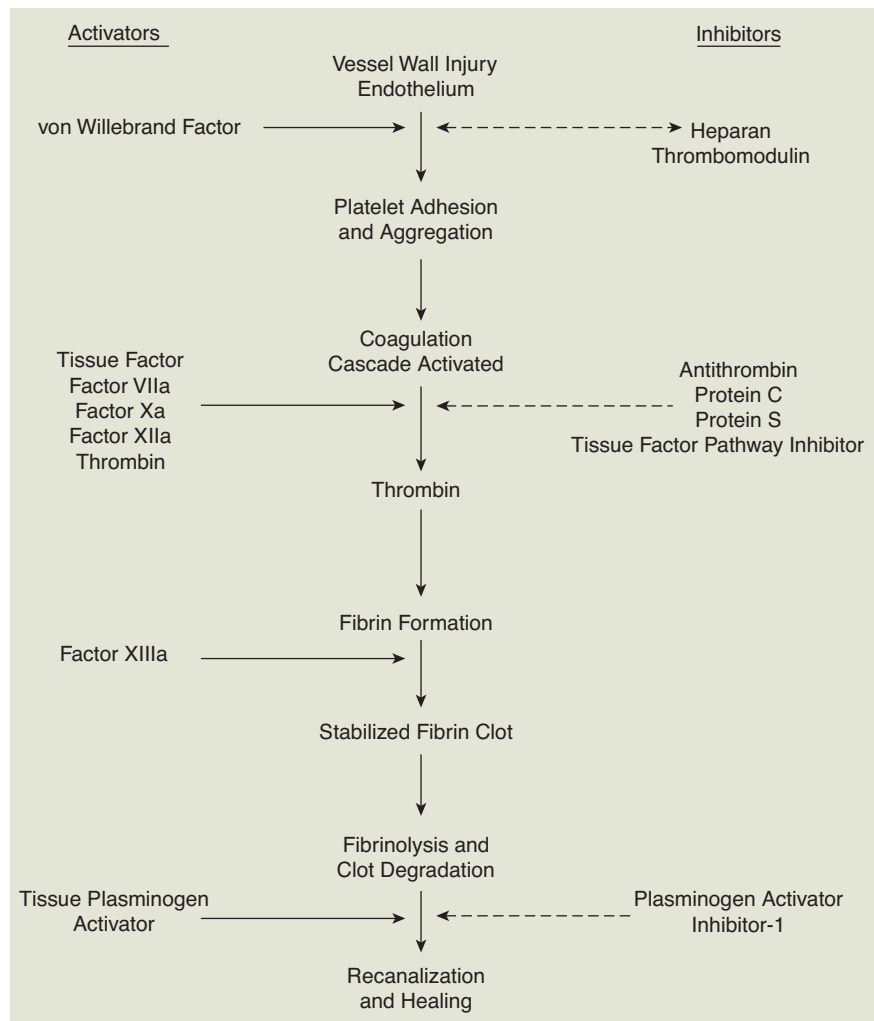

FIGURE 21-2. Hemostasis and thrombosis.

thrombotic substances. As its name implies, thrombomodulin modulates thrombin activity by converting protein C to its active form. When joined with its cofactor protein S, protein C enzymatically inactivates factors Va and VIIIa. Activated protein C also stimulates the release of tissue plasminogen activator. Antithrombin is a circulating protein that inhibits thrombin and factor Xa. Heparan sulfate, a heparin-like compound secreted by endothelial cells, exponentially accelerates antithrombin activity. By a similar mechanism, heparin cofactor II also inhibits thrombin. Tissue factor pathway inhibitor plays an important role by regulating the initiation of the coagulation cascade. When these self-regulatory mechanisms are intact, the formation of the fibrin clot is limited to the zone of tissue injury. However, disruptions in the system, so-called hypercoagulable states, often result in thrombosis.

The fibrinolytic protein plasmin degrades the fibrin mesh into soluble end products collectively known as fibrin split products or fibrin degradation products.^{18,19} The fibrinolytic system is also under the control of a series of stimulatory and inhibitory substances. Tissue plasminogen activator and urokinase plasminogen activator convert plasminogen to plasmin. Plasminogen activator inhibitor-1 inhibits the plasminogen activators, and α_2 -antiplasmin inhibits plasmin activity. Aberrations in the fibrinolytic system have also been linked to hypercoagulability.

CLINICAL PRESENTATION AND DIAGNOSIS

Although a thrombus can form in any part of the venous circulation, the majority begin in the lower extremities. Once formed, a venous

thrombus may either (a) remain asymptomatic, (b) spontaneously lyse, (c) obstruct the venous circulation, (d) propagate into more proximal veins, (e) embolize, or (f) act in any combination of these ways.²⁰ The majority of patients with VTE never develop symptoms from the acute event.²¹ However, even those who experience no symptoms may suffer long-term consequences, such as the post-thrombotic syndrome and recurrent VTE. Even when symptoms of DVT or PE are present (Tables 21-3 and 21-4), they are nonspecific.¹ It is extremely difficult to distinguish VTE from other disorders, and additional objective tests are required to confirm or exclude the diagnosis. Patients with DVT frequently present with unilateral leg pain and swelling. The postthrombotic syndrome, a long-term complication of DVT caused by damage to the venous valves, can produce symptoms very similar to those of an acute thrombotic event including chronic lower-extremity swelling, pain, tenderness, skin discoloration, and ulceration. Symptomatic PE often produces dyspnea, tachypnea, and tachycardia. Hemoptysis, while distressing, occurs in less than one-third of patients. Cardiovascular collapse, characterized by cyanosis, shock, and oliguria, is an ominous sign.

② Given that VTE can be debilitating or fatal, it is important to treat it quickly and aggressively.⁹ Conversely, because major bleeding induced by antithrombotic drugs can be equally harmful, it is important to avoid treatment when the diagnosis is not a reasonable certainty. Assessment of the patient's status should focus on the search for risk factors in the patient's medical history (see Table 21-1). Venous thrombosis is uncommon in the absence of risk factors, and the effects of these risks are additive. Even in the presence of mild, seemingly inconsequential symptoms, VTE should be strongly suspected in those with multiple risk factors.

Because radiographic contrast studies are the most accurate and reliable methods for the diagnosis of VTE, they are considered the gold standards in clinical trials.⁹ Contrast venography allows visualization of the entire venous system in the lower extremity and abdomen. Pulmonary angiography allows the visualization of the pulmonary arteries. The diagnosis of VTE can be made if there is a persistent intraluminal filling defect observed on multiple radiographic films. Contrast studies are expensive, invasive procedures that are technically difficult to perform and evaluate. Severely ill patients often are unable to tolerate the procedure, and many develop hypotension and cardiac arrhythmias. Furthermore, the contrast medium is irritating to vessel walls and toxic to the kidneys. For these reasons, noninvasive tests, such as ultrasonography, computed tomography scans, and the ventilation–perfusion scan, are frequently used in clinical practice for the initial evaluation of patients with suspected VTE.¹

D-dimer is a simple blood test frequently used in the diagnostic evaluation of patients suspected to have VTE.⁹ D-dimer is a degradation product of a fibrin blood clot and levels of D-dimer are significantly elevated in patients with acute thrombosis. Although the D-dimer test is a very sensitive marker of clot formation, it is not sufficiently specific. A variety of conditions can cause elevations of serum D-dimer, including recent surgery or trauma, pregnancy, and cancer. Therefore, a negative test can help to “rule out” a DVT or PE but a positive test should not be used to “rule in” the diagnosis.

Clinical assessment significantly improves the diagnostic accuracy of noninvasive tests such as ultrasonography, ventilation–perfusion

scanning, and D-dimer.^{1,9} Simple assessment checklists can be used to determine if a patient has a high, moderate, or low probability of a DVT or PE (Table 21–5). Patients with a high pretest probability of VTE have a greater than 60% chance of having VTE, compared with only 5% for the low pretest probability group. Clinical assessment can rule in or out the diagnosis of VTE with reasonable certainty when the results are consistent with those of a noninvasive test.⁹ For example, in patients with a high or moderate pretest probability of VTE and an abnormal lower-extremity ultrasonogram, the diagnosis of VTE can be reasonably concluded. In patients with a low pretest probability of VTE and a negative D-dimer test, the diagnosis of VTE can be excluded. However, if the results of the clinical assessment and the ultrasonogram are discordant, venography should be performed to make the definitive diagnosis.

PHARMACOLOGIC AGENTS USED IN THE MANAGEMENT OF VENOUS THROMBOEMBOLISM

UNFRACTIONATED HEPARIN

Unfractionated heparin (UFH) has been used for the prevention and treatment of thrombosis for decades. Commercially available UFH preparations are derived from bovine lung or porcine intestinal mucosa. Although some differences exist between the two sources, no differences in antithrombotic activity have been demon-

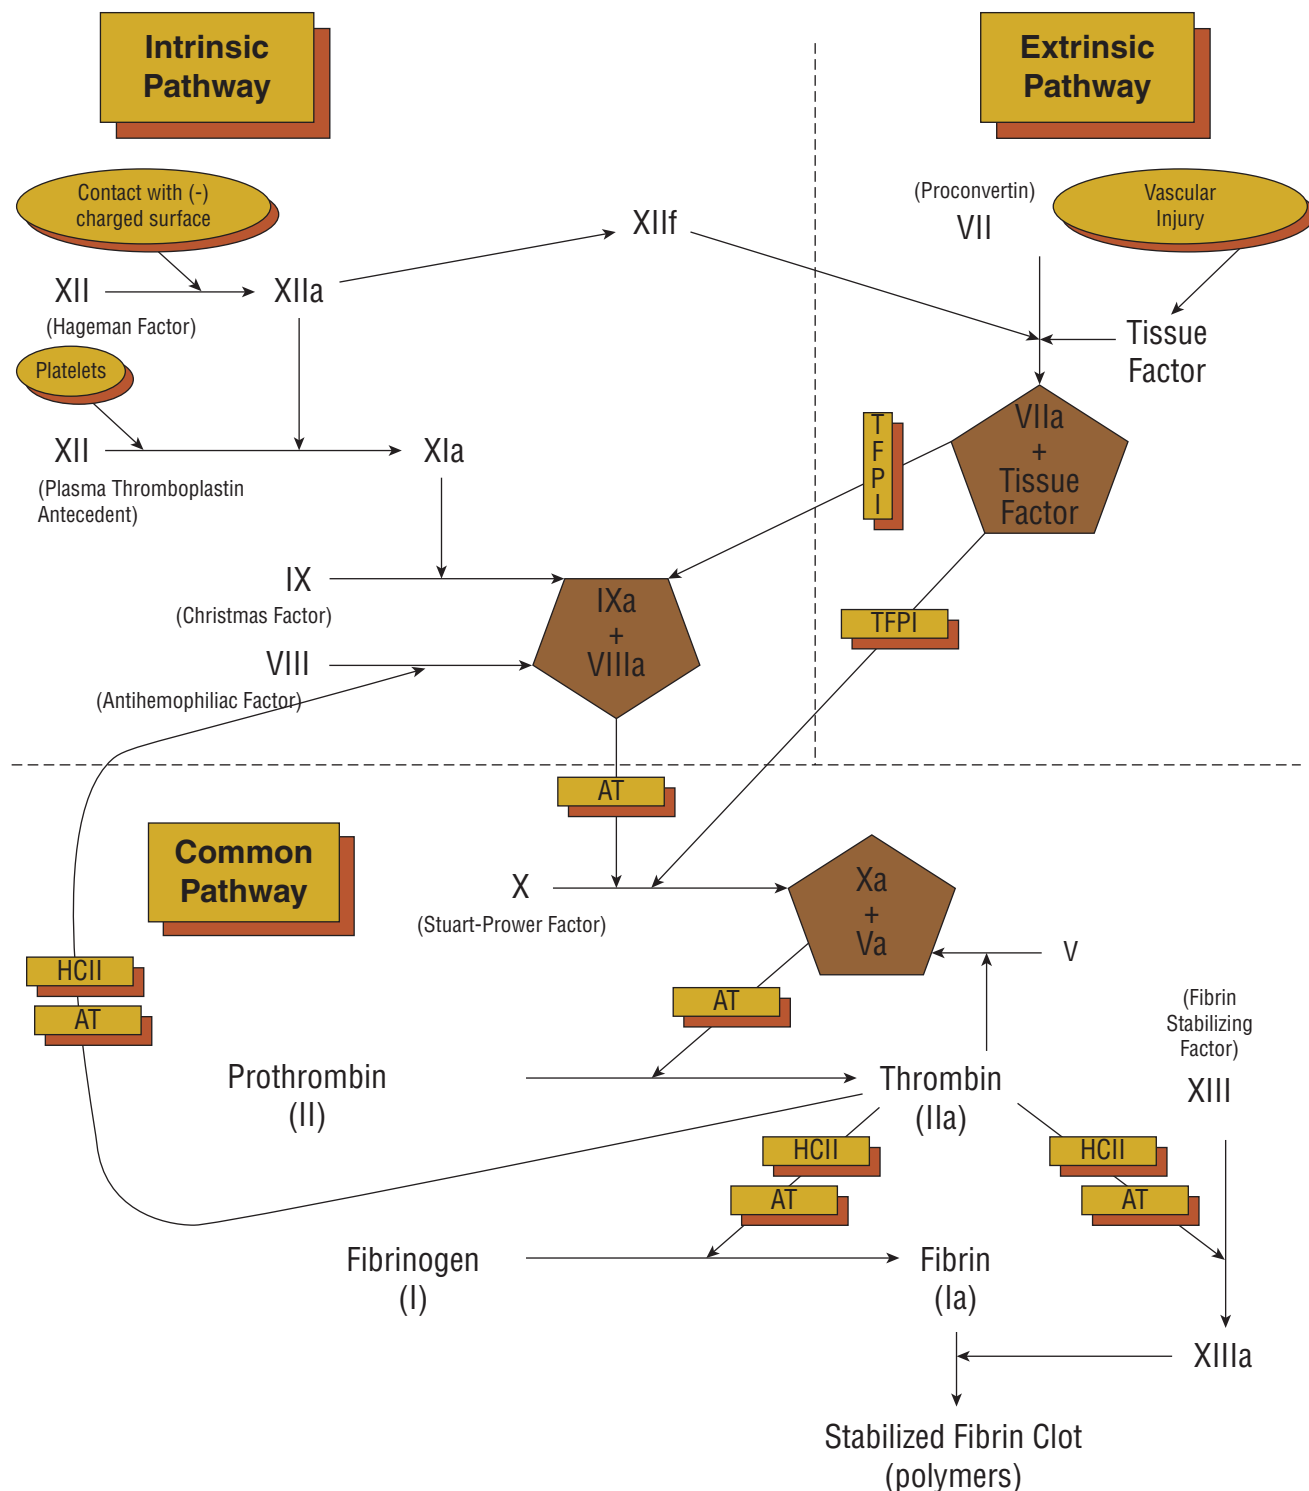

FIGURE 21-4. Coagulation cascade. (AT, antithrombin; HCII, heparin cofactor II; TFPI, tissue factor pathway inhibitor.)

strated. Today, UFH and the low-molecular-weight heparins (LMWHs) are the most commonly used therapies for the acute treatment of arterial and venous thrombosis.²²

Pharmacology

Unfractionated heparin is a heterogeneous mixture of sulfated glycosaminoglycans of variable lengths and pharmacologic properties (Table 21-6). Each heparin molecule is composed of repetitive units of D-glycosamine and uronic acid. The molecular weight of UFH molecules ranges from 3,000 to 30,000 daltons, with a mean of

15,000 daltons. The anticoagulant profile and clearance of each UFH molecule varies based on its length. The smaller chains are cleared less rapidly than their longer counterparts.²²

The anticoagulant effect of UFH is mediated through a specific pentasaccharide sequence on the heparin molecule that binds to antithrombin, provoking a conformational change (Fig. 21-5). Only one-third of the UFH molecules possess the unique pentasaccharide sequence with affinity for antithrombin. The UFH-antithrombin complex is 100 to 1,000 times more potent as an anticoagulant compared to antithrombin alone. Antithrombin inhibits the activity of several clotting factors including IXa, Xa,

XIIa, and thrombin (see Fig. 21–4). Through its action on thrombin, the UFH–antithrombin complex also inhibits the thrombin-induced activation of factors V and VIII.²² Unfractionated heparin prevents the growth and propagation of a formed thrombus and allows the patient's own thrombolytic system to degrade the clot.

Factors IIa (thrombin) and Xa are the most sensitive to inhibition by the UFH–antithrombin complex. To inactivate thrombin, the heparin molecule must form a ternary complex bridging between antithrombin and thrombin (see Fig. 21–5). Only molecules that contain more than 18 saccharides are able to bind to both antithrombin and thrombin simultaneously. Smaller heparin molecules cannot facilitate the interaction between antithrombin and thrombin. In contrast, the inactivation of factor Xa does not require UFH to form a bridge with antithrombin. It only requires that UFH bind to antithrombin using the specific pentasaccharide sequence. Heparin molecules with as few as 5 saccharide units are able to catalyze the

TABLE 21-3 Clinical Presentation of Deep Vein Thrombosis

General
Venous thromboembolism most commonly develops in patients with identifiable risk factors (see Table 21–2) during or following a hospitalization. Many, perhaps the majority, of patients have asymptomatic disease. Patients may die suddenly of pulmonary embolism.
Symptoms
The patient may complain of leg swelling, pain, or warmth. Symptoms are nonspecific and objective testing must be performed to establish the diagnosis.
Signs
The patient's superficial veins may be dilated and a "palpable cord" may be felt in the affected leg.
The patient may experience pain in back of the knee when the examiner dorsiflexes the foot of the affected leg (known as Homans sign).
Laboratory tests
Serum concentrations of D-dimer, a byproduct of thrombin generation, is usually elevated.
The patient may have an elevated erythrocyte sedimentation rate and white blood cell count.
Diagnostic tests
Duplex ultrasonography is the most commonly used test to diagnosis deep vein thrombosis. It is a noninvasive test that can measure the rate and direction of blood flow and visualize clot formation in proximal veins of the legs. It cannot reliably detect small blood clots in distal veins. Coupled with a careful clinical assessment, it can rule in or out the diagnosis in the majority of cases.
Venography (also known as phlebography) is the gold standard for the diagnosis of deep vein thrombosis. However, it is an invasive test that involves injection of radiopaque contrast dye into a foot vein. It is expensive and can cause anaphylaxis and nephrotoxicity.

TABLE 21-4 Clinical Presentation of Pulmonary Embolism

General
Pulmonary embolism (PE) most commonly develops in patients with risk factors for venous thromboembolism (see Table 21–2) during or following a hospitalization. Although many patients develop a symptomatic deep vein thrombosis prior to developing a PE, many do not. Patients may die suddenly before effective treatment can be initiated.
Symptoms
The patient may complain of cough, chest pain, chest tightness, shortness of breath, or palpitation. The patient may spit or cough up blood (hemoptysis). When PE is massive, the patient may complain of dizziness or lightheadedness. Symptoms may be confused for a myocardial infarction, requiring objective testing to establish the diagnosis.
Signs
The patient may have tachypnea (increased respiratory rate) and tachycardia (increased heart rate). The patient may appear diaphoretic (sweaty). The patient's neck veins may be distended. In massive PE, the patient may appear cyanotic and may become hypotensive. In such cases, oxygen saturation by pulse oximetry or arterial blood gas will likely indicate that the patient is hypoxic. In the worse cases, the patient may go into circulatory shock and die within minutes.
Laboratory tests
Serum concentrations of D-dimer, a byproduct of thrombin generation, is usually elevated.
The patient may have an elevated erythrocyte sedimentation rate and white blood cell count.
Diagnostic tests
Ventilation–perfusion (V/Q) and computerized tomography (CT) scans are the most commonly used tests to diagnosis PE. A V/Q scan measures the distribution of blood and air flow in the lungs. When there is a large mismatch between blood and air flow in one area of the lung, there is a high probability that the patient has a PE. Spiral CT scans can detect emboli in the pulmonary arteries. Pulmonary angiography is the gold standard for the diagnosis of PE. However, it is an invasive test that involves injection of radiopaque contrast dye into the pulmonary artery. The test is expensive and associated with a significant risk of mortality.

TABLE 21-5 Clinical Assessment Models for Deep Vein Thrombosis and Pulmonary Embolism

Pretest Probability of Deep Vein Thrombosis	
Clinical feature	Score
Tenderness along entire deep vein system	1.0
Swelling of the entire leg	1.0
Greater than 3 cm difference in calf circumference	1.0
Pitting edema	1.0
Collateral superficial veins	1.0
Risk factors present:	
Active cancer	1.0
Prolonged immobility or paralysis	1.0
Recent surgery or major medical illness	1.0
Alternative diagnosis likely (ruptured Baker cyst, rheumatoid arthritis, superficial thrombophlebitis, or infective cellulitis)	–2.0
Score ≥ 3 = high probability; 1–2 = moderate probability; ≤ 0 = low probability	
Pretest Probability of Pulmonary Embolism	
Clinical feature	Score
Deep vein thrombosis suspected	
Clinical features of deep vein thrombosis	3.0
Recent prolonged immobility or surgery	1.5
Active cancer	1.0
History of deep vein thrombosis or pulmonary embolism	1.5
Hemoptysis	1.0
Resting heart rate >100 beats/min	1.5
No alternative explanation for acute shortness of breath or chest pain	3.0

Score ≥ 6 = high probability; 2–6 = moderate probability; ≤ 1.5 = low probability

inhibition of factor Xa. Heparin uncouples from antithrombin after it has produced its effect and quickly recouples with another antithrombin molecule. Because of its relatively large size, the UFH–antithrombin complex is incapable of inactivating thrombin or factor Xa within a formed clot or bound to surfaces. At high doses, UFH also binds to heparin cofactor II, further inhibiting the activity of thrombin. UFH increases the release of tissue factor pathway inhibitor from vascular endothelium, augmenting its inhibitory effect on factor Xa. UFH, especially high-molecular-weight heparin fractions, also binds to platelets and inhibits platelet aggregation.²²

Pharmacokinetics

Unfractionated heparin is not reliably absorbed when taken orally as a result of its large molecular size and anionic structure. The bioavailability and biologic activity of UFH is limited by its propensity to bind to plasma proteins, platelet factor-4 (PF-4), macrophages, fibrinogen, lipoproteins, and endothelial cells.²² This may explain the substantial inter- and inpatient variability observed in the anticoagulation response to UFH.²²

The subcutaneous bioavailability of UFH is dose dependent and ranges from 30% at low doses to as much as 70% at high doses. Higher doses presumably saturate protein-binding sites, thereby permitting a larger proportion to reach the systemic circulation. The onset of anticoagulant effect is usually evident 1 to 2 hours after subcutaneous injection and peaks at 3 hours.²² When UFH is administered via the IV route, a continuous infusion is preferable. Intermittent IV boluses produce relatively high peaks in anticoagulation activity and have been associated with a greater risk of major bleeding.²² Intramuscular administration is discouraged because of erratic absorption and risk of large hematoma formation.

Unfractionated heparin has a dose-dependent half-life of approximately 30 to 90 minutes, but may be prolonged to as much as 150 minutes when given in high doses to some patients. There are two primary mechanisms for the elimination of UFH. The relative contribution of each mechanism to the total clearance of heparin is related to the dose and size of the UFH molecules. One mechanism is a rapid, but saturable zero-order process. Heparinases and desulfatases enzymatically inactivate heparin molecules bound to endothelial cells and macrophages, reducing them to smaller and less-sulfated molecules. Heparin is also eliminated renally. This first-order process is slower and nonsaturable. Low doses of UFH are cleared principally by the saturable, rapid, zero-order mechanism, whereas the renal route predominates at very high doses. With typical therapeutic regimens, a combination of the two mechanisms are used to eliminate UFH with the saturable mechanism predominating. Renal and hepatic dysfunction reduces the rate of clearance of UFH. Patients with active thrombosis may eliminate UFH more rapidly, possibly because of increased binding to acute phase reactants.²²

Dose and Administration

The dose and route of administration for UFH are based on the indication, the therapeutic goals, and the patient's individual response to therapy. The dose of UFH is expressed in units of activity. The number of units per milligram is variable and depends on the manufacturing process. For the prevention of VTE, UFH is given by subcutaneous injection in the abdominal fat layer over the iliac crest. The typical dose for prophylaxis is 5,000 units every 8 to 12 hours. When immediate and full anticoagulation is required, a weight-based IV bolus dose followed by a continuous infusion is preferred (Table 21-7).²² Subcutaneous UFH (initial dose of 333 units/kg followed by 250 units/kg every 12 hours) also provides adequate therapeutic anticoagulation for the treatment of acute VTE.²³

TABLE 21-7 Weight-Based^a Dosing for Unfractionated Heparin Administered by Continuous Intravenous Infusion

Indication	Initial Loading Dose	Initial Infusion Rate
Deep venous thrombosis/pulmonary embolism	80–100 units/kg	17–20 units/kg/h
	Maximum = 10,000 units	Maximum = 2,300 units/h
Activated Partial Thromboplastin Time (seconds)	Maintenance Infusion Rate	
	Dose adjustment	
<37 (or >12 s below institution-specific therapeutic range)	80 units/kg bolus then increase infusion by 4 units/kg/h	
37–47 (or 1–12 s below institution-specific therapeutic range)	40 units/kg bolus then increase infusion by 2 units/kg/h	
48–71 (within institution-specific therapeutic range)	No change	
72–93 (or 1–22 s above institution-specific therapeutic range)	Decrease infusion by 2 units/kg/h	
>93 (or >22 s above institution-specific therapeutic range)	Hold infusion for 1 h then decrease by 3 units/kg/h

Therapeutic Monitoring

3 Administration of UFH has traditionally required close monitoring because of the unpredictable anticoagulant patient response.²² Several tests are available to monitor UFH therapy including whole blood clotting time, activated partial thromboplastin time (aPTT), activated clotting time (ACT), antifactor Xa activity, and plasma heparin concentrations. The aPTT is the most widely used test to determine the degree of anticoagulation. The therapeutic range of aPTT has traditionally been considered to be 1.5 to 2.5 times the mean normal control value.²² Many currently available aPTT reagents do not accurately measure the response to heparin within this fixed therapeutic range; thus, the use of a fixed aPTT therapeutic range of 1.5 to 2.5 times the control represents a subtherapeutic dose of UFH in many instances.²² Because of substantial interlaboratory variability in the aPTT, an institution-specific aPTT therapeutic range that correlates with a plasma heparin concentration of 0.3 to 0.7 units/mL by an amidolytic antifactor Xa assay should be established.²²

Although most experts advocate using the aPTT to monitor UFH provided that institution-specific therapeutic ranges are defined, the use of aPTT has several limitations. First, preanalytical variables such as reagent sensitivity, temperature, phlebotomy methods, and hemodilution may result in aPTT results that do not correlate with the in vivo level of heparin anticoagulation present.²² Second, the aPTT response exhibits diurnal variation, with a peak response occurring around 3 AM during continuous IV infusion. Adjusting infusion rates in response to this diurnal variation could lead to subsequent over- or underdosing.²⁴ Third, the aPTT is prolonged beyond measurable limits when the heparin concentration exceeds 1 unit/mL; consequently, the aPTT is unsuitable for monitoring heparin therapy in patients who require doses of heparin that will produce serum concentrations >1 unit/mL. The ACT is the most suitable assay when high doses of heparin are used, especially during coronary angioplasty or coronary bypass surgery.²⁵ Fourth, the lower-weight heparin fragments accumulate but have little effect on the aPTT in vivo.²² Lastly, the data supporting the currently recommended heparin concentration therapeutic range is not derived from scientifically rigorous research.

The aPTT should be measured prior to the initiation of therapy to determine the patient's baseline. When administered by IV

Data from Levine MN, Raskob G, Beyth RJ, et al. Hemorrhagic complications of anticoagulant treatment: The Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy. *Chest* 2004;126:287S–310S.

infusion, the response to therapy should be measured 6 hours after the initiation of therapy or a dose change. This is usually sufficient time for heparin to reach steady state. The dose of heparin should be promptly adjusted based on the patient’s response and the institution-specific therapeutic range (see Table 21–7).²²

Some patients with acute VTE and myocardial infarction have a diminished response to UFH (so-called heparin resistance), presumably because of variations in the plasma concentrations of heparin-binding proteins. Some patients are reported to have acute elevations in factor VIII, preventing the prolongation of the aPTT by UFH. In some cases, antithrombin deficiency might be the culprit. The possibility of this phenomenon should be suspected in patients who require more than 40,000 units of UFH per 24-hour period. The recommended management of patients with “heparin resistance” is to adjust the UFH dose based on antifactor Xa concentrations.²²

Adverse Effects

4 Bleeding is the primary adverse effect associated with all anticoagulant drugs (Table 21–8).⁴ There is not solid evidence linking supratherapeutic aPTT values and the risk for bleeding in patients receiving UFH. The risk for bleeding is more closely related to underlying risk factors than to high aPTT values.²⁴ Therefore, UFH should not be administered to patients with contraindications to anticoagulation therapy (Table 21–9). Low-dose subcutaneous UFH is associated with a minimal risk of major bleeding. The rates of major bleeding for patients with VTE receiving full therapeutic doses of UFH via IV infusion for 5 to 10 days range from 2% to 4% and the rate of fatal bleeding ranges from approximately 0% to 2%.⁴ The presence of concomitant bleeding risks such as thrombocytopenia, the use other antithrombotic therapy, and a preexisting source of bleeding increase the risk of UFH-induced hemorrhage. The risk of bleeding also increases with age. Recent surgery, hemostatic defects, heavy alcohol consumption, renal failure, peptic ulcers, and neoplasms also increase the risk of major bleeding while receiving UFH.⁴

Anatomic sites commonly associated with UFH-related bleeding include the gastrointestinal and urinary tracts, as well as soft tissues. Minor bleeding, such as epistaxis, gingival bleeding, and prolonged bleeding from cuts and scrapes, is frequently reported. Bruising from minor trauma and at the sites of subcutaneous injections and venous access is also common. Local irritation, mild pain, erythema, histamine-like reactions, and hematoma can occur during UFH administration. Even small amounts of bleeding into critical sites such as the central nervous system (CNS) or the structures of the eye can cause catastrophic consequences.

Thrombocytopenia, defined as a platelet count less than 150,000, is common with UFH therapy.²⁶ Up to 30% of patients have some

TABLE 21-9	Contraindications to Anticoagulation Therapy
General	
Active bleeding	
Hemophilia or other hemorrhagic tendencies	
Severe liver disease with elevated baseline PT	
Severe thrombocytopenia (platelet count <20,000)	
Malignant hypertension	
Inability to meticulously supervise and monitor treatment	
Product-specific contraindications	
Argatroban	
Hypersensitivity to argatroban	
Bivalirudin	
Hypersensitivity to bivalirudin	
Fondaparinux	
Hypersensitivity to fondaparinux	
Severe renal insufficiency (creatinine clearance <30 mL/min)	
Body weight <50 kg	
Bacterial endocarditis	
Thrombocytopenia with a positive in vitro test for anti-platelet antibodies in the presence of fondaparinux	
Lepirudin	
Hypersensitivity to hirudins	
LMWHs	
Hypersensitivity to LMWH, UFH, pork products, methylparaben, or propylparaben	
History of HIT or suspected HIT	
UFH	
Hypersensitivity to UFH	
History of HIT	
Warfarin	
Hypersensitivity to warfarin

History of warfarin-induced skin necrosis	
Inability to obtain followup PT/INR measurements	
Inappropriate medication use or lifestyle behaviors	

HIT, heparin-induced thrombocytopenia; INR, international normalized ratio; LMWH, low-molecular-weight heparin; PT, prothrombin time; UFH, unfractionated heparin.

appreciable decline in their platelet count. Two distinct clinical presentations for thrombocytopenia can occur during heparin therapy. Heparin-associated thrombocytopenia (HAT) is a benign, transient, and mild phenomena, generally occurring within the first few days of treatment in the heparin-naïve patient. Platelet counts rarely drop below 100,000 in patients with HAT, and recover with continued therapy. Conversely, heparin-induced thrombocytopenia (HIT) is a serious drug-induced problem requiring immediate intervention (see Heparin-Induced Thrombocytopenia below). A baseline platelet count should be obtained before UFH therapy is initiated. If the patient has received UFH within the previous 100 days, or if previous UFH exposure is uncertain, a repeat platelet count should be performed within 24 hours.²⁶ Monitoring platelet counts every other day for 14 days or until UFH therapy is stopped, whichever occurs first, is recommended for patients who are receiving therapeutic doses of UFH.²⁶

Long-term UFH has been reported to cause alopecia, priapism, and suppressed aldosterone synthesis with subsequent hyperkalemia. The use of UFH in doses ≥20,000 units/day for more than 6 months, especially during pregnancy, is associated with significant bone loss and may lead to osteoporosis.²⁴ Few drug interactions are reported with UFH. Concurrent use with other antithrombotic drugs, thrombolytics, and antiplatelet agents increases the risk of bleeding, however.

Management of Bleeding and Excessive Anticoagulation

Hemorrhage can occur at any site in patients receiving UFH and close monitoring for signs and symptoms of bleeding is crucial.^{4,22}

In addition to an appropriate coagulation study to measure the response to UFH, it is necessary to regularly monitor hemoglobin, hematocrit, and blood pressure. Bleeding can produce a wide variety of symptoms, depending on the site of hemorrhage. Symptoms can include severe headache, joint pain, chest pain, abdominal pain, swelling, tarry stools, frank hematuria, or the passage of bright red blood through the rectum. Life-threatening bleeding, either as a consequence of a significant volume loss or because of the location (e.g., bleeding into a critical space), must be recognized swiftly and immediately treated. Critical areas include intracranial, pericardial, and intraocular sites, as well as the adrenal glands.

When major bleeding occurs, UFH should be immediately discontinued and the underlying source of bleeding should be identified and treated. Intravenous protamine sulfate, given in a dose of 1 mg per 100 units of UFH up to a maximum of 50 mg, can be administered to reverse the anticoagulant effects of UFH. Protamine sulfate has intrinsic anticoagulation activity, but when administered with UFH, it forms a stable salt that results in the loss of anticoagulation activity of both drugs. Protamine sulfate neutralizes UFH in 5 minutes, and its activity persists for 2 hours. It should be given by slow IV infusion over 10 minutes.²² In cases of large heparin overdoses or in patients with renal failure, a “rebound” effect may occur with a return of some anticoagulant activity several hours after the administration of protamine sulfate. Therefore, the patient’s coagulation status should be closely monitored. Multiple doses of protamine sulfate may be necessary if hemorrhage continues.

Use in Special Populations

Heparin-related compounds such as UFH or LMWH are the anticoagulants of choice during pregnancy.²⁷ Because UFH does not cross the placenta, it is not associated with teratogenicity or fetal bleeding complications.²⁷ UFH should be used cautiously during the last trimester of pregnancy and the peripartum period because of the risk of maternal hemorrhage. Induction of labor is advisable so that UFH can be discontinued prior to delivery to minimize the

risk for excessive bleeding during delivery. Long-term use of UFH during pregnancy may result in bone loss and increased risk for osteoporosis-related fractures.²⁷ Unfractionated heparin is not excreted in breast milk and is considered safe to use by women who are breast-feeding.²⁷

Advances in tertiary care for pediatric patients have resulted in increasing numbers of children requiring antithrombotic therapy, and UFH is commonly used in this setting.²⁸ For the treatment of acute thrombosis in children, the dosage of UFH is an initial loading dose of 75 to 100 units/kg over 10 minutes followed by a maintenance dose of 28 units/kg/h for infants up to 12 months of age and 20 units/kg/h for children 1 year old and older.²⁸

LOW-MOLECULAR-WEIGHT HEPARINS

Produced by either chemical or enzymatic depolymerization (see Table 21–6), LMWHs are fragments of UFH. They are heterogeneous mixtures of sulfated glycosaminoglycans with approximately one-third the molecular weight of UFH. Although all the LMWHs share similarities in their mechanisms of action with UFH, their molecular weight distributions vary, resulting in differences in their activity against factor Xa and thrombin, affinity for plasma proteins, propensity to release tissue factor pathway inhibitor, and duration of activity.²² The mean molecular weight of the LMWHs is product specific. These agents have several advantages over UFH, including (a) predictable anticoagulation dose response, (b) improved subcutaneous bioavailability, (c) dose-independent clearance, (d) longer biologic half-life, (e) lower incidence of thrombocytopenia, and (f) a reduced need for routine laboratory monitoring.²²

Currently, there are three LMWH products available in the United States. The usefulness of LMWHs has been extensively evaluated for a wide array of indications, including the treatment of acute coronary syndromes, DVT, and PE, as well as for the prevention of VTE in several high-risk populations. The FDA-approved indications and doses for the LMWHs are product specific (Table 21–10). The

TABLE 21-10 Indications and Doses for Low-Molecular-Weight Heparins

Indications	Enoxaparin	Dalteparin	Tinzaparin
Hip-replacement surgery (prophylaxis)	30 mg SC q 12 h initiated 12–24 h after surgery or 40 mg SC q 24 h initiated 12 h prior to surgery ^a Extended prophylaxis may be given for up to 3 weeks ^a	2,500 units SC given 2 h prior to surgery, followed by 2,500 international units the evening after surgery and at least 6 h after first dose, then 5,000 international units SC q 24 h ^a or 5,000 international units SC q 24 h initiated the evening prior to surgery ^a	75 units/kg SC q 24 h initiated the evening prior to surgery or 12 h after surgery or 4,500 unit SC q 24 h initiated 12 h prior to surgery
Knee-replacement surgery (prophylaxis)	30 mg SC q 12 h initiated 12–24 h prior to surgery ^a		75 units/kg SC q 24 h initiated the evening prior to surgery or 12 h after surgery
Abdominal surgery (prophylaxis)	40 mg SC q 24 h initiated 2 h prior to surgery ^a	2,500 units SC q 24 h initiated 1–2 h prior to surgery ^a Patients with malignancy: 5,000 units SC the evening prior surgery then 5,000 units SC q 24 h ^a or 2,500 units SC 1–2 h prior to surgery then 2,500 units 12 h after surgery followed by 5,000 units SC q 24 h ^a 2,500 units SC q 24 h	3,500 unit SC q 24 h initiated 1–2 h prior to surgery
Acute medical illness (prophylaxis)	40 mg SC q 24 h ^a		
Trauma (prophylaxis)	30 mg SC q 12 h starting 12–36 h after injury		
Deep vein thrombosis treatment (with or without pulmonary embolism)	1 mg/kg SC q 12 h ^a or 1.5 mg/kg SC q 24 h ^a	100 units/kg SC q 12 h or 200 units/kg SC q 24 h	175 units/kg SC q 24 h ^a
Unstable angina or non-Q-wave myocardial infarction	1 mg/kg SC q 12 h ^a	100 units/kg SC q 12 h ^a (maximum dose 10,000 units)	

^aFDA approved dose for indication.

LMWHs have largely replaced UFH for the prevention and treatment of VTE in some hospitals. However, institutional resources and individual patient needs should determine their precise role in the management of VTE.

Pharmacology

The LMWHs prevent the growth and propagation of formed thrombi. Like UFH, the LMWHs enhance and accelerate the activity of antithrombin through binding to a specific pentasaccharide sequence. Fewer than one-third of LMWH molecules contain the specific sequence necessary to interact with antithrombin. The principal difference in the pharmacologic activity of the LMWHs and UFH is their relative inhibition of factor Xa and thrombin. Because of their smaller chain length, the LMWHs have limited activity against thrombin (see Fig. 21–6). Fewer than 50% of the LMWH molecules have the requisite chain length to simultaneously bind antithrombin and thrombin. For this reason, the LMWHs have proportionally greater antifactor Xa activity. The ratio of antifactor Xa-to-IIa activity varies between 5.3:1 and 1.9:1. By comparison, UFH has an antifactor Xa-to-IIa activity ratio of 1:1. Like UFH, the LMWHs cause the endothelium to release tissue factor pathway inhibitor, which is believed to enhance the inhibition of factor Xa and to inactivate factor VIIa.²²

Pharmacokinetics

Compared with UFH, the LMWHs have a more predictable anticoagulation response. The improved pharmacokinetic profile of LMWHs is the result of reduced binding to proteins and cells.²² The bioavailability of LMWHs approaches 100% when administered subcutaneously, whereas the absorption of UFH is relatively poor and erratic. The subcutaneous bioavailability of the available LMWH products differs only slightly. The peak anticoagulation effect is seen in 3 to 5 hours.²²

The renal route is the predominant mode of elimination for the LMWHs. Consequently, their biologic half-life may be prolonged in patients with renal impairment. Longer heparin chains bind to macrophages and are rapidly degraded. Therefore, antifactor Xa activity, which is mediated by smaller heparin molecules, persists longer than antithrombin activity. The plasma half-life of the LMWH preparations is two to four times longer than UFH. The clearance of LMWHs is independent of dose.²²

Dosing and Administration

The LMWHs are given in fixed or weight-based doses based on the product and indication (see Table 21–10).²² Doses should be based on actual body weight and studies in obese patients indicate that full weight-based doses do not lead to elevated LMWH concentrations when compared with normal subjects; consequently, capping of the dose is not recommended.²⁴ The dose for enoxaparin is expressed in milligrams, whereas dalteparin and tinzaparin are expressed in units of antifactor Xa activity. Although they can be given by continuous intravenous infusion, the LMWHs are generally given by subcutaneous injection in the abdominal area or the upper outer part of the thigh while the patient is in a supine position. The clinician or patient pinches a layer of skin between the thumb and forefinger, and then introduces the entire length of the needle into a skin fold at a 90° angle. Injection sites should be alternated between right and left sides. Following subcutaneous administration, the drug is absorbed slowly, resulting in sustained antithrombotic activity over several hours.

The dosing interval for the LMWHs is every 12 or 24 hours depending on the indication and product. Larger doses are given once daily and produce significantly higher peak plasma concentrations. Given that the elimination half-life of the LMWHs is prolonged in patients with severe renal impairment, high doses may lead to a

significant accumulation in these patients. The enoxaparin dose should be reduced and the dosing interval extended to once daily in patients with creatinine clearance <30 mL/min.²⁹ The pharmacokinetics of dalteparin and tinzaparin are less-well characterized in patients with renal insufficiency, but some studies suggest that there is a lower degree of accumulation. Data on the use of LMWH in patients with end-stage renal disease receiving hemodialysis is very limited, thus UFH should be recommended for these patients. Given that few published data are available regarding the use of LMWHs in the setting of renal insufficiency, some experts recommend measuring antifactor Xa activity if therapy is continued for more than a few days.

For the prevention of VTE, the LMWHs have been studied in a variety of high-risk circumstances, including orthopedic surgery, abdominal surgery, acute spinal cord injury, neurosurgery, multiple trauma, and critical illness.³ The effectiveness of the LMWHs has been extensively evaluated for the treatment of VTE in hospitalized patients and used in the outpatient management of DVT.² They are also a reasonable alternative to warfarin therapy in circumstances when a prothrombin time (PT)/international normalized ratio (INR) can not be routinely obtained.

Therapeutic Monitoring

Because the LMWHs achieve predictable anticoagulant response when given subcutaneously, routine laboratory monitoring is unnecessary to guide the dosing of these agents. The PT, the ACT, and the aPTT are minimally affected by LMWHs.²² Prior to initiation of LMWH, a baseline PT/INR, aPTT, complete blood cell count with platelet count, and serum creatinine should be obtained. Most experts recommend monitoring the complete blood cell count every 5 to 10 days during the first 2 weeks of LMWH therapy and every 2 to 4 weeks thereafter.

Although several methods to monitor LMWHs have been explored, measurement of antifactor Xa activity has been the most widely used method in clinical practice. Routine antifactor Xa activity measurement is unnecessary in patients whose condition is stable and uncomplicated.²² Although very limited data support the use of laboratory monitoring to guide LMWH therapy, measuring antifactor Xa activity may be helpful in patients who have significant renal impairment (e.g., creatinine clearance <30 mL/min), weigh less than 50 kg, are morbidly obese, or require prolonged therapy (e.g., longer than 14 days). Periodic antifactor Xa activity monitoring may also be useful in women treated with a LMWH during pregnancy because of changing pharmacokinetic variables (e.g., volume of distribution and renal function).²⁷ Patients who are at very high risk of bleeding or thrombotic recurrence may also benefit from antifactor Xa monitoring to avoid periods of over- or underanticoagulation. Because newborns and pediatric patients have unpredictable pharmacokinetic profiles, they may require monitoring to ensure adequate therapy.

When antifactor Xa activity is used to monitor LMWH therapy, the sample should be drawn after steady state has been achieved (after the second or third dose) and approximately 4 hours after the subcutaneous injection, during the peak period of antifactor Xa activity.²² A calibrated LMWH heparin should be used to establish the standard curve for the assay. The therapeutic range for antifactor Xa activity is not well defined and as of this writing has not been clearly correlated with efficacy or the risk of bleeding.³⁰ For the treatment of VTE, an acceptable target range for the peak level is 0.5 to 1.0 units/mL and for the prevention of VTE an acceptable target range for the peak level is 0.2 to 0.4 units/mL.

Adverse Effects

As with UFH, bleeding is the most common adverse effect of the LMWHs.⁴ Although not consistently demonstrated in clinical trials,

the frequency of major bleeding is purported to be less with the LMWHs than with UFH.²² This difference may be partly a result of their reduced effects on platelet function, endothelial cells, and microvascular permeability. The incidence of major bleeding reported in clinical trials is less than 3% and varies among the LMWH preparations, their indication for use, patient population, and dose administered. Minor bleeding, particularly at the site of injection, occurs frequently with LMWH use. Several cases of epidural and spinal hematoma resulting in long-term or permanent paralysis have been reported with the use of enoxaparin during spinal and epidural anesthesia or spinal puncture.²⁹ The risk of these events is higher with the use of indwelling epidural catheters and concomitant use of drugs that affect hemostasis. Epidural catheters should be removed only after a minimum of 12 hours has elapsed after the last dose of the LMWH, and any subsequent dose should be given at least 2 hours later.

Although there is no proven method for reversing LMWH, if major bleeding does occur in a patient receiving an LMWH, it is recommended that IV protamine sulfate be administered.²² However, because of its limited binding to the shorter LMWH chains, protamine sulfate cannot completely neutralize the anticoagulant effects of LMWH. When given in equimolar concentrations, protamine sulfate neutralizes an estimated 60% to 75% of the antithrombotic activity of LMWH. The recommended dose of protamine sulfate is 1 mg/1 mg of enoxaparin or 1 mg/100 antifactor Xa units of dalteparin or tinzaparin administered in the previous 8 hours. If the LMWH dose was given in the previous 8 to 12 hours, a 0.5-mg dose of protamine should be given for every 100 antifactor Xa units. The use of protamine sulfate is not recommended if the LMWH was administered more than 12 hours earlier.²²

Although thrombocytopenia can occur with the use of a LMWH, the incidence of HIT is substantially lower than that observed with the use of UFH.^{22,26} The explanation may lie in the reduced propensity of the LMWHs to bind to platelets and PF-4. Because the LMWHs exhibit nearly 100% cross-reactivity with heparin antibodies in vitro, the LMWHs should be avoided in patients with an established diagnosis or history of HIT.²⁶ Platelet counts must be periodically monitored in all patients who are receiving a LMWH, and thrombocytopenia of any degree should be promptly evaluated.

The risk of osteoporosis appears to be substantially lower with the LMWHs than with UFH. The LMWHs have not caused appreciable changes in bone mineral density after several months of use.²⁷ They have been used in a limited number of patients with established heparin-induced osteoporosis. Although these reports are promising, it cannot be concluded that the LMWHs have no effect on bone formation until well-designed clinical trials are available.

Use in Special Populations

There is growing experience with the use of LMWHs during pregnancy.²⁷ The LMWHs do not cross the placenta. According to the results of a few large case series, the LMWH appear to be relatively safe to use during pregnancy and are an attractive alternative to UFH when long-term anticoagulation therapy is required. Furthermore, the LMWHs do not appear to affect bone formation.²⁷ Dalteparin, enoxaparin, and tinzaparin are classified as FDA pregnancy category B. The LMWHs are becoming the preferred agents in pediatric populations despite the fact that the safety and effectiveness of the LMWHs to treat VTE in children and infants has not been extensively studied.²⁸ Weight-based LMWH doses provide a less-predictable anticoagulant response in children compared to adults.²⁸ For enoxaparin, suggested therapeutic doses are 1.5 mg/kg every 12 hours for infants <2 months old and 1.0 mg/kg every 12 hours for those >2 months old. The suggested dose for dalteparin is 86 to 172 units/kg every 24 hours, keeping in mind that neonates appear to require higher doses/kg than older children or adults.²⁸ Until more

data are available, it is prudent to periodically monitor antifactor Xa activity in these special populations during long-term use.

FONDAPARINUX

Pharmacology

Fondaparinux, also known as pentasaccharide, is a synthetic molecule consisting of the five critical saccharide units that bind specifically, but reversibly, to antithrombin (see Fig. 21–5).¹⁹ Fondaparinux is the first in a class of anticoagulants that selectively inhibits factor Xa activity.³¹ Similar to UFH and the LMWHs, fondaparinux prevents thrombus generation and clot formation by indirectly inhibiting factor Xa activity through its interaction with antithrombin. When fondaparinux binds to antithrombin it causes a permanent conformational change in antithrombin's active site and catalyzes antifactor Xa activity by about 300-fold. Fondaparinux is not destroyed during this process and is released to bind many other antithrombin molecules.³¹ Unlike UFH and LMWH, fondaparinux has no direct effect on thrombin activity at therapeutic plasma concentrations.¹⁹ Selective inhibition of factor Xa may provide more efficient control over fibrin generation while preserving thrombin's regulatory functions in the control of hemostasis. Fondaparinux has no known effect on platelet function.¹⁹

Pharmacokinetics

Fondaparinux is rapidly and completely absorbed following subcutaneous administration (absolute bioavailability 100%). Peak plasma concentrations are achieved in approximately 2 hours after a single dose and 3 hours with repeated once-daily dosing. It is distributed primarily in blood. At therapeutic concentrations, fondaparinux is highly and specifically bound to antithrombin.³¹ It does not bind to red blood cells or other plasma proteins including albumin, glycoprotein, platelets, or PF-4.¹⁹ Fondaparinux is primarily eliminated unchanged in the urine. It is contraindicated in patients with severe renal function impairment (creatinine clearance <30 mL/min) because of an increased risk for bleeding. The terminal elimination half-life is 17 to 21 hours and is independent of the patient's age or sex.³² The anticoagulant effect of fondaparinux persists for 2 to 4 days following discontinuation of the drug in patients with normal renal function. Fondaparinux has no known pharmacokinetic drug interactions. However, concurrent use with other antithrombotic agents increases the risk of hemorrhage.

Dose and Administration

Fondaparinux is FDA-approved for the prevention of VTE following orthopedic (hip fracture, hip replacement, and knee replacement) surgery and for the treatment of DVT and PE.³² In the setting of VTE prevention, the dose of fondaparinux is 2.5 mg injected subcutaneously once daily starting 6 to 8 hours following surgery. It is important to avoid initiating fondaparinux too soon because there is a significant relationship between the timing of the first dose and the risk of major bleeding complications. Patients who weigh less than 50 kg should not be given fondaparinux for VTE prophylaxis. The usual duration of therapy is 5 to 9 days, but may be given as extended prophylaxis following hospital discharge for up to 21 days.³³ Fondaparinux has been evaluated for the treatment of DVT and PE in two phase III clinical trials.¹⁹ For the treatment of DVT or PE, the dose of fondaparinux is 7.5 mg given subcutaneously once daily. Patients who weigh more than 100 kg should be given 10 mg once daily and those who weigh less than 50 kg should receive only 5 mg daily.³²

Similar to the LMWHs, fondaparinux is administered into the fatty tissue of the abdominal wall. Patients should be instructed to pinch a fold of skin at the injection site and hold it throughout the

injection. The needle should be inserted at a 90° angle. Injection sites should be alternated from side to side.³²

Therapeutic Monitoring

A complete blood cell count should be measured at baseline and monitored periodically to detect the possibility of occult bleeding.³² Baseline kidney function should be determined and monitored closely in patients at risk of developing renal failure. Fondaparinux should be discontinued if the creatinine clearance drops below 30 mL/min. Signs and symptoms of bleeding should be monitored daily, particularly in patients with a baseline creatinine clearance between 30 and 50 mL/min. If neuraxial anesthesia has been used, patients should be closely monitored for signs and symptoms of neurologic impairment.

Fondaparinux does not alter coagulation tests such as the aPTT and PT. The role of antifactor Xa monitoring during fondaparinux is not well defined. Patients receiving fondaparinux therapy do not require routine coagulation testing.

Adverse Effects

The primary adverse effect associated with fondaparinux therapy is bleeding.³² The rate of major bleeding in the VTE prophylaxis trials was approximately 2% to 3%. Because the risk of major bleeding appears to be related to weight, in patients who weigh less than 50 kg, fondaparinux is contraindicated for VTE prophylaxis and the treatment dose is only 5 mg every 24 hours. Similar to UFH and the LMWHs, fondaparinux should be used with extreme caution in patients with neuraxial anesthesia or following a spinal puncture because of the risk for spinal or epidural hematoma formation. Unlike UFH and the LMWHs, fondaparinux does not cause heparin-induced thrombocytopenia and does not produce cross-sensitivity in vitro.¹⁹ A specific antidote to reverse the antithrombotic activity of fondaparinux is not currently available, but several potential products have been evaluated.³¹

Use in Special Populations

Fondaparinux has been used safely in elderly patients but the risk of major bleeding increases with age (1.8% in patients <65 years of age, 2.2% in patients age 65 to 74 years, and 2.7% in patients age 75 years or older).³² This is an important consideration because many

patients who undergo orthopedic surgery are elderly. Elderly patients are also more likely to have decreased renal function and careful assessment of renal status should be conducted prior to initiating therapy. Fondaparinux is contraindicated in patients with a creatinine clearance less than 30 mL/min.

Fondaparinux is a pregnancy category B drug.³² However, there is very limited information regarding fondaparinux use during pregnancy. The drug is excreted in the milk of lactating rats, but excretion in human milk is unknown. Until more data becomes available, UFH and LMWH should remain the agents of choice during pregnancy. Fondaparinux use in pediatric populations has not been studied.

IDRAPARINUX

Idraparinux is an analog of fondaparinux that has very long duration of effect (see Table 21–6) and was developed to be administered once weekly by subcutaneous injection. Idraparinux is currently undergoing phase III clinical trials evaluating its usefulness for both the acute and long-term management of VTE.³⁴

DIRECT THROMBIN INHIBITORS

In recent years, research has focused on the development of direct thrombin inhibitors (DTIs) that may offer benefits over traditional agents in the treatment and prevention of various thrombotic disorders. The DTIs have been studied for many indications such as HIT, prophylaxis and treatment of VTE, acute coronary syndromes with and without percutaneous transluminal coronary angioplasty, and nonvalvular atrial fibrillation. Currently four parenteral agents—lepirudin, desirudin, bivalirudin, and argatroban—are approved for use in the United States, and several oral compounds are in various phases of clinical development (Table 21–11).^{19,35,36}

Pharmacology and Pharmacokinetics

The direct thrombin inhibitors, as their name implies, directly interact with the thrombin molecule (Fig. 21–6). The agents in this class differ in terms of their molecular weight, chemical structure, and binding to the thrombin molecule. Unlike UFH, LMWH, and fondaparinux, DTIs do not require a cofactor (antithrombin) to exert their antithrombotic activity. They are capable of inhibiting

both circulating and clot-bound thrombin, a potential advantage over UFH and LMWH. Furthermore, DTIs do not induce immune-mediated thrombocytopenia and are widely used for the treatment of HIT.^{19,35,36}

Hirudin, the prototype of this class, is a 65-amino-acid polypeptide (7,000 Da) that was originally isolated from the salivary secretions of the medicinal leech (*Hirudo medicinalis*). Although not commercially available, the discovery of hirudin led to the development of derivatives such as lepirudin and desirudin via recombinant DNA technology. The hirudins (lepirudin, desirudin, and bivalirudin) form a stoichiometric and very slowly reversible complex by binding to both the active site and exosite-1 of the thrombin molecule (see Fig. 21-6). Because of this bivalent bond, hirudins are considered the most potent inhibitors of thrombin.^{19,35,36}

Lepirudin, a recombinant analogue of hirudin, is a 65-amino-acid polypeptide that is administered parenterally, either by continuous IV infusion or subcutaneous injection.^{19,37} It is indicated for anticoagulation in patients with HIT and associated thrombosis so as to prevent further thromboembolic complications. Research is also being conducted on the use of lepirudin for other indications, such as acute coronary syndromes and VTE. Because of the strong, almost irreversible bond between lepirudin and thrombin, lepirudin is associated with bleeding complications.³⁷ The primary route of elimination for lepirudin is through renal excretion, and systemic clearance is directly proportional to the glomerular filtration rate. Lepirudin has a terminal half-life of 1.3 hours in young healthy volunteers. In patients with marked renal insufficiency ($Cl_{cr} < 15$ mL/min) and on hemodialysis, elimination half-lives are prolonged up to 2 days.³⁶ Thus, dose adjustment is required in the setting of impaired renal function, a potential disadvantage of this agent (Table 21-12). Many patients develop antibodies to lepirudin. Up to 60% of patients treated with lepirudin for 10 days or more will develop antibodies. This may increase the anticoagulant effect of lepirudin, possibly as a result of delayed renal elimination of active lepirudin–antihirudin complexes. Consequently, strict monitoring of aPTT is necessary during prolonged therapy.^{19,35} Because fatal

anaphylaxis has been reported in patients who developed antibodies, patients should not be treated with lepirudin more than once.³⁸

Desirudin, also a recombinant hirudin analogue, is administered by subcutaneous injection and approved by the FDA in 2003 for the

TABLE 21-12 Dosing Considerations for Direct Thrombin Inhibitors in Patients with Renal and Hepatic Dysfunction

	Renal Impairment	Hepatic Impairment
Lepirudin	Bolus: 0.2 mg/kg (bolus dose should be avoided in patients with renal impairment) Infusion: Cl_{cr} 45–60 mL/min: 0.075 mg/kg/h Cl_{cr} 30–44 mL/min: 0.045 mg/kg/h Cl_{cr} 15–29 mL/min: 0.0225 mg/kg/h $Cl_{cr} < 15$ mL/min: no bolus; avoid or stop infusion HD: stop infusion & additional IV bolus doses of 0.1 mg/kg every other day should be considered if the aPTT ratio falls below 1.5	Dose adjustment not required
Desirudin	Cl_{cr} 31–60 mL/min: 5mg SC q 12 h $Cl_{cr} < 30$ mL/min: 1.7 mg SC q 12 h	Dose adjustment not required
Bivalirudin	Bolus: no dose adjustment Infusion: $Cl_{cr} < 30$: 1 mg/kg/h HD: 0.25 mg/kg/h	Dose adjustment not required
Argatroban	Dose adjustment not required	Initiate at 0.5 mcg/kg/min then titrate to aPTT 1.5–3.0 × baseline
Dabigatran	Dose adjustment will be required; degree of dose decrease not defined at this time.	Unclear at this time

aPTT, activated partial thromboplastin time; Cl_{cr} , creatinine clearance; HD, hemodialysis; SC, subcutaneous.

From Nutescu et al.³⁵

prevention of venous thrombosis in patients undergoing elective hip surgery.³⁹ Although approved for use, the agent is not currently commercially available in the United States. For acute myocardial infarction and unstable angina, desirudin has been given via continuous IV infusion.^{35,40} Desirudin has a terminal elimination half-life after subcutaneous dosing of approximately 2 hours, and 80% to 90% of the elimination is by renal clearance and metabolism. The total urinary excretion of unchanged drug amounts to 40% to 50% of the administered dose. Similar to lepirudin, in patients with moderate to severe renal impairment, the dosage should be reduced (see Table 21–12). Although antihirudin antibodies also have been documented with desirudin, the incidence appears to be lower than with lepirudin.^{35,41}

Bivalirudin, formerly known as Hirulog, is a semisynthetic 20-amino-acid polypeptide analogue of recombinant hirudin that is FDA approved for use in patients with unstable angina who are undergoing percutaneous transluminal coronary angioplasty and with provisional use of glycoprotein IIb/IIIa inhibitor for use as an anticoagulant in patients undergoing percutaneous coronary intervention.⁴² Recent reports also support the use of bivalirudin in patients with acute ST elevation myocardial infarction and in patients with HIT, although the agent is not currently FDA approved for these indications. Unlike lepirudin, bivalirudin is a reversible inhibitor of thrombin and provides transient antithrombotic activity with an estimated 20- to 30-minute half-life. This difference may reduce the risk of bleeding and antibody production.^{35,43} The ACT can be used to monitor the anticoagulant effect of bivalirudin. Therapeutic ACT levels are achieved within 5 minutes after initiating bivalirudin therapy, and ACT levels return to subtherapeutic levels within 1 hour of discontinuing the infusion. The aPTT test has also been used to monitor the anticoagulant effect of bivalirudin in patients with HIT. Bivalirudin is mostly cleared by proteolytic cleavage and by hepatic metabolism, with approximately 20% eliminated renally. The manufacturer recommends reducing the dose by 20% to 60% in patients with renal impairment and monitoring the ACT closely (see Table 21–12).^{35,43}

Argatroban differs from the hirudins in that it is a small, synthetic molecule derived from arginine that reversibly binds only to the active catalytic site of thrombin. Its small size relative to other DTIs enables it to inhibit both clot-bound and soluble thrombin, offering a potential therapeutic advantage over other agents in its class.^{26,44} Argatroban is primarily eliminated by hydroxylation and aromatization in the liver to inactive metabolites. A small percentage is excreted unchanged in the bile. The elimination half-life is 39 to 51 minutes, but extends to approximately 181 minutes in hepatic impairment. Dose adjustment is required in patients with hepatic impairment (see Table 21–12). The aPTT and ACT can be used to monitor the anticoagulant effect of argatroban. It is FDA approved for the prophylaxis or treatment of thrombosis in patients with HIT, and also as an anticoagulant in patients with HIT, or at risk of HIT, who are undergoing percutaneous coronary intervention.^{35,45}

Oral Direct Thrombin Inhibitors

Recent progress has also been made in the development of oral DTIs. These agents appear promising and offer various advantages such as oral administration, predictable pharmacokinetics and pharmacodynamics, a broad therapeutic window, no routine laboratory monitoring, no significant drug interactions, and fixed-dose administration. Several of these compounds are being investigated with dabigatran etexilate being in most advanced phases of clinical development. A previous agent of the class (ximelagatran) was denied FDA approval because of concerns of drug-induced liver toxicity. The first safe, oral DTI to make it to the U.S. market has the potential to revolutionize the provision of antithrombotic therapy.^{35,36}

Therapeutic Monitoring

Although the DTIs produce changes in the prothrombin time, the aPTT is used to monitor the patient's response to lepirudin, desirudin, and argatroban.^{19,35,40} After obtaining baseline coagulation studies, doses of lepirudin and argatroban should be titrated to achieve the institution-specific therapeutic range or an aPTT 1.5 to 3.0 times the mean normal control. Daily aPTT monitoring is also recommended for patients on desirudin, particularly those with impaired renal function.⁴¹ Although bivalirudin doses should be adjusted based on the ACT, some experience is also available using the aPTT.^{42,43} The ecarin clotting time is a potentially more suitable test to measure the antithrombotic activity of the direct thrombin inhibitors, but it is not readily available in most clinical labs in the United States. Oral DTIs appear to produce a predictable antithrombotic response in fixed doses and have a relatively large therapeutic window.³⁵ Consequently, routine anticoagulation monitoring may not be required for these agents. A complete blood count should be obtained at baseline and periodically thereafter to detect potential bleeding.

Adverse Effects

Contraindications for use of the DTIs and risk factors for bleeding are similar to other antithrombotic drugs (see Tables 21–8 and 21–9). Hemorrhage is the most serious and common adverse effect related to the DTIs.^{19,35,40} In studies evaluating the use of lepirudin for the treatment of patients with HIT, the incidence of major bleeding was relatively high (13% to 17%).³⁷ However, no fatal or intracranial bleeding events occurred. A slightly lower rate of major hemorrhage was reported in HIT trials using argatroban (approximately 5%) and, similarly, there were no reports of fatal or intracranial bleeding.⁴⁵ Bleeding complications with desirudin were similar to enoxaparin in a trial of patients undergoing elective hip surgery. Serious bleeding occurred in less than 1% of all patients in the trial.⁴¹ Minor bleeding and small reductions in red blood cell counts occurred relatively frequently but typically did not require drug discontinuation. There are no known agents that reverse the activity of the DTIs. Nonhemorrhagic effects such as fever, nausea, vomiting, and allergic reactions occur infrequently.

Drug–Drug and Drug–Food Interactions

The concurrent use of DTIs and thrombolytic agents substantially increases the bleeding risk, particularly intracranial hemorrhage, and should be undertaken with great caution. Warfarin and antiplatelet agents can be concurrently initiated with these agents. Because the DTIs prolong the PT and INR, close monitoring for bleeding complications is required. Few pharmacokinetic drug interactions with this class of agents are known. Drugs that alter renal function could prolong lepirudin, desirudin, and bivalirudin activity. Drugs that inhibit liver enzymes have the potential to interact with argatroban.⁴⁶

Use in Special Populations

Lepirudin, bivalirudin, and argatroban are classified by the FDA as pregnancy category B drugs but they should be used cautiously in women of child bearing age because experience is very limited.^{37,42,45} Desirudin is classified as pregnancy category C with no controlled trials in pregnant women.⁴¹ Lepirudin and argatroban have been evaluated in a very small number of children. Dosing requirements can vary widely in pediatric patients, thus product-specific dosing guidelines and monitoring should be followed.⁴⁷ Critically ill patients and patients with renal or hepatic impairment will require dosage adjustments according to the specific DTI used, and lower initiation doses are recommended (see Table 21–12).⁴⁸

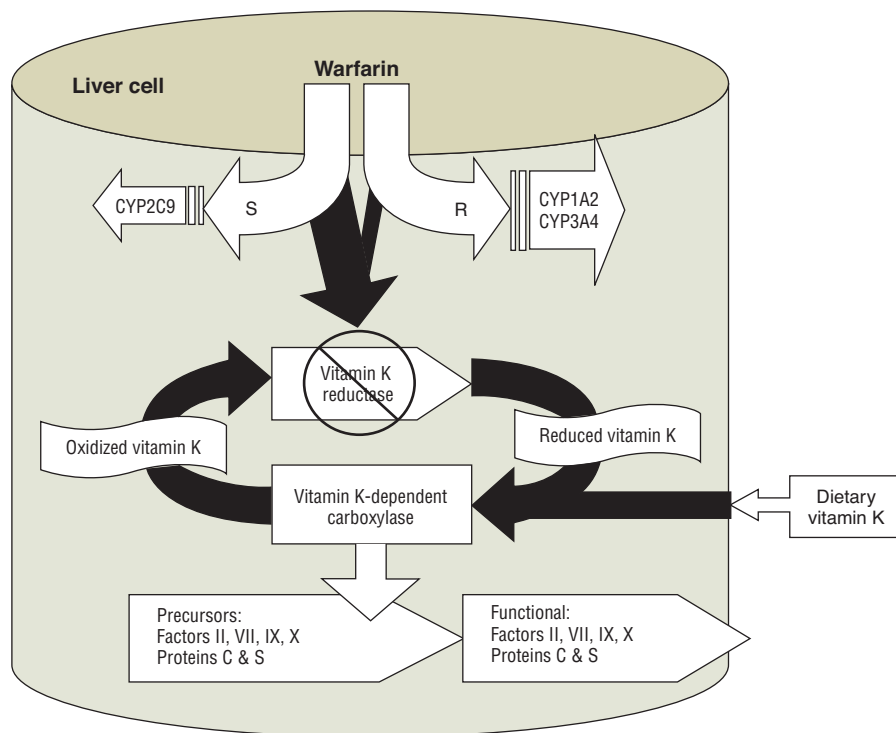

FIGURE 21-7. Pharmacologic activity and metabolism of warfarin.

WARFARIN

The most widely prescribed anticoagulant in North America is warfarin sodium (Coumadin). It was serendipitously discovered in the early 1940s at the University of Wisconsin after hemorrhagic deaths occurred in cattle eating spoiled sweet clover. Warfarin is the anticoagulant of choice when long-term or extended anticoagulation is indicated. Warfarin is FDA-approved for the prevention and treatment of VTE, as well as for the prevention of thromboembolic complications associated with atrial fibrillation, heart valve replacement, and myocardial infarction. Because of its narrow therapeutic index, predisposition to drug and food interactions, and propensity to cause hemorrhage, warfarin requires continuous patient monitoring and education to achieve optimal outcomes.⁵

Pharmacology

Warfarin exerts its anticoagulation effect by inhibiting the enzymes responsible for the cyclic interconversion of vitamin K in the liver (Fig. 21-7). Reduced vitamin K is a cofactor required for the carboxylation of the vitamin K-dependent coagulation proteins, namely factors II (prothrombin), VII, IX, and X, as well as the endogenous anticoagulant proteins C and S. Carboxylation of the N-terminal region of these proteins in the liver is required for biologic activity. By inhibiting the supply of vitamin K to serve as a cofactor in the production of these proteins, warfarin indirectly slows their rate of synthesis. Warfarin has no direct effect on previously circulating clotting factors or previously formed thrombus.^{5,6} The time required for warfarin to achieve its pharmacologic effect is dependant on the elimination half-lives of the coagulation proteins (Table 21-13). Given that prothrombin has a 2- to 3-day half-life, warfarin's full antithrombotic effect is not achieved for 8 to 15 days after the initiation of therapy. By suppressing the production of clotting factors, warfarin prevents the initial formation and propagation of thrombus.^{5,46}

Pharmacokinetics

Commercially available warfarin is a racemic mixture of R and S isomers. The S isomer is 2 to 5 times more potent than the R isomer.

Warfarin is rapidly and extensively absorbed from the gastrointestinal tract and reaches peak plasma concentration in approximately 90 minutes with a bioavailability of greater than 90% following oral administration. In plasma, both the R and S isomers are extensively (97% to 99%) bound to albumin.^{5,46} Warfarin undergoes stereoselective metabolism via cytochrome P450 (CYP) 1A2, 2C9, 2C19, 2C8, 2C18, and 3A4 isoenzymes in the liver (see Fig. 21-7). The pharmacokinetic parameters of warfarin, particularly hepatic metabolism, vary substantially between individuals leading to large interpatient differences in dose requirements. Genetic variations in the 2C9 isoenzyme and vitamin K epoxide reductase (VKOR) have been shown to correlate with warfarin dose requirements.^{49,50} Given the relatively greater potency of S-warfarin, coadministration of drugs that induce or inhibit the CYP2C isoenzymes are more likely to cause a clinically significant interaction.⁵ These and other pharmacokinetic variations in warfarin metabolism likely explain the large interpatient dose-response seen with warfarin in clinical practice.

Dosing and Administration

The dose of warfarin is patient-specific based on the desired intensity of anticoagulation and the patient's individual response.^{5,6} There is tremendous interpatient variability with regard to the pharmacodynamic response and pharmacokinetic disposition of warfarin. In addition, there is significant inpatient variability in these parameters over time. Therefore, the dose of warfarin must be based on continual clinical and laboratory monitoring. At the

initiation of therapy, it is difficult to predict the specific dose that an individual will require. Warfarin dosing algorithms that incorporate pharmacogenetic information regarding CYP2C9 and VKOR polymorphisms are currently being evaluated. The usefulness of pharmacogenetic information in managing patients is not yet known.

Although the average weekly dose of warfarin is between 25 mg and 55 mg, some patient-related variables are associated with lower than usual dose requirement including: advanced age (>65 years old), elevated baseline INR, poor nutritional status, liver disease, hyperthyroidism, genetic polymorphisms in CYP2C9 and VKOR, and concurrent use of medications known to enhance the effect of warfarin (Table 21-14).^{5,6} Prior to initiating therapy, the clinician should screen for the presence of contraindications to anticoagulation therapy and risk factors for major bleeding (see Tables 21-8 and 21-9). It is essential to collect a complete medication history, including the use of herbal and nutritional products (Tables 21-15 and 21-16).

TABLE 21-15 Warfarin Dietary Supplements Interactions Involving Cytochrome P450 Metabolism

Dietary Supplement	Mechanism
Bergamottin (component of grapefruit juice)	2C9 inhibitor
Bishop's weed (Bergapten)	3A4 inhibitor
Bitter orange	3A4 inhibitor
Cat's claw	3A4 inhibitor
Chrysin	1A2 inhibitor
Cranberry	2C9 inhibitor
Devil's claw	2C9 inhibitor
Dehydroepiandrosterone (DHEA)	3A4 inhibitor
Diindolymethane	1A2 inducer
Echinacea	3A4 inhibitor
Eucalyptus	3A4, 2C9, 2C19, 1A2 inhibitor
Feverfew	1A2, 2C9, 2C19, 3A4 inhibitor
Fo-ti	1A2, 2C9, 2C19, 3A4 inhibitor
Garlic	2C9, 2C19, and 3A4 inhibitor
Ginseng	CYP P450 inducer
Goldenseal	3A4 inhibitor
Guggul	3A4 inducer
Grape	1A2 inducer
Grapefruit juice	1A2, 2A6, and 3A4 inhibitor
Indole-3-carbinol	1A2 inducer
Ipriflavone	2C9, 1A2 inhibitor
Kava	1A2, 2C9, 2C19, 2D6, 3A4 inhibitor
Licorice	3A4 inhibitor
Lime	3A4 inhibitor
Limonene	2C9, 2C19 substrate, and 2C9 inducer
Lycium (Chinese wolfberry)	2C9 inhibitor
Milk thistle	2C9 and 3A4 inhibitor
Peppermint	1A2, 2C9, 2C19, 3A4 inhibitor
Red clover	1A2, 2C9, 2C19, 3A4 inhibitor
Resveratrol	1A, 2E1 3A4 inhibitor
St. John's wort	1A2, 2C9, 3A4 inducer
Sulforaphane	1A2 inhibitor
Valerian	3A4 inhibitor
Wild cherry	3A4 inhibitor

CLINICAL CONTROVERSY

Some clinicians recommend that warfarin therapy be started using no more than 5 mg daily based on evidence that the majority of patients will achieve a therapeutic INR by day 5. Furthermore, some patients become excessively anticoagulated when higher doses are used. However, some clinicians recommend initiating warfarin therapy with 10 mg daily because a therapeutic INR is achieved 1 day sooner, thereby facilitating earlier hospital discharge and more rapid discontinuation of LMWH therapy. In addition, they argue, there is no evidence that bleeding complications occur more frequently when a higher initial dose is used.

There is some controversy regarding the optimal dosing regimen when initiating warfarin therapy.^{5,51,52} To achieve a therapeutic INR in the least amount of time, some clinicians have used relatively high doses of warfarin (10 or 15 mg) and then adjusted the dose based on the patient's response. Studies in patients with atrial fibrillation that compared a 5-mg initial dose to a 10-mg dose questioned this practice.⁵³ Although a 10-mg dose produced a more rapid response in the INR, many patients subsequently became excessively anticoagulated. However, a more recent study in patients with acute venous thrombosis demonstrated that 10-mg initial doses can be used safely when the subsequent INR response is monitored appropriately.⁵¹

Although data on the optimal induction regimen is conflicting, there is a pharmacodynamic rationale for avoiding doses larger than

TABLE 21-16 Dietary Supplements That Can Affect Platelet Function and Anticoagulation Status

Agent	Mechanism	Comments
Bladderwrack	Has anticoagulant effects	Increased risk of bleeding or bruising
Boldo	Constituents may have antiplatelet effects	Increased risk of bleeding or bruising
Bromelain	Decreased platelet aggregation	Increased risk of bleeding or bruising
Burdock	Decreased platelet aggregation by inhibiting platelet activation factor	Increased risk of bleeding or bruising
Caffeine	May have antiplatelet activity; not reported in humans	Increased risk of bleeding or bruising; found in black tea, green tea, guarana, mate, oolong tea
Clove	Eugenol has antiplatelet activity	Increased risk of bleeding or bruising
Cod liver oil	May inhibit platelet aggregation	Increased risk of bleeding or bruising; avoid concomitant use
Coltsfoot	May inhibit platelet aggregation	Increased risk of bleeding or bruising; avoid concomitant use
Danshen	Decreased platelet aggregation; may also have antithrombotic effects	Increased risk of bleeding or bruising; avoid concomitant use
Dong quai	May inhibit platelet aggregation	Increased risk of bleeding or bruising
Fenugreek	Constituents may have antiplatelet effects; concentration may not be clinically significant	Increased risk of bleeding or bruising
Fish oil	Has antiplatelet effects	Increased risk of bleeding or bruising
Flax seed	Decreased platelet aggregation and increased bleeding time	Increased risk of bleeding or bruising
Gamma linolenic acid (GLA)	Has anticoagulant effects	Increased risk of bleeding or bruising; found in borage and evening primrose oil
Garlic	Has anticoagulant effects and may inhibit platelet aggregation	Increased risk of bleeding or bruising
Ginger	Inhibit thromboxane synthetase and decrease platelet aggregation	Increased risk of bleeding or bruising
Ginkgo	Decreased platelet aggregation; ginkgolide B, a component of ginkgo, is a potent inhibitor of PAF	Increased risk of bleeding or bruising
Ginseng, panax	Components may decrease platelet aggregation through PAF antagonism; not shown in humans	Increased risk of bleeding or bruising; use with caution until more is known.
Ginseng, Siberian	A component, dihydroxybenzoic acid, may inhibit platelet aggregation	Increased risk of bleeding or bruising
Melatonin	Unknown; might increase the anticoagulant or antiplatelet effect; decreased prothrombin activity observed	Increased risk of bleeding or bruising
Nattokinase	Has thrombolytic activity	Increased risk of bleeding or bruising
Onion	Decreased platelet aggregation	Increased risk of bleeding or bruising
Pantethine	Decreased platelet aggregation	Increased risk of bleeding or bruising
Policosanol	Inhibits platelet aggregation	Increased risk of bleeding or bruising
Poplar	Contains salicylates and may cause decreased platelet aggregation	Increased risk of bleeding or bruising
Resveratrol	Has antiplatelet effects	Increased risk of bleeding or bruising
Sea buckthorn	Inhibits platelet aggregation	Increased risk of bleeding or bruising
Turmeric	Decreased platelet aggregation; has antiplatelet effects	Increased risk of bleeding or bruising
Vinpocetine	Has antiplatelet effects	Increased risk of bleeding or bruising
Vitamin E	Inhibits platelet aggregation and antagonizes the effects of vitamin K-dependent clotting factors	Dose dependent and significant with doses greater than 800 units per day; advise patients to avoid high doses of vitamin E; increased risk of bleeding or bruising
Willow bark	Decreased platelet aggregation; has antiplatelet effects but less than aspirin	Increased risk of bleeding or bruising

PAF, platelet activating factor.

From Nutescu et al.⁶⁴

10 mg.⁵ Large doses result in a more rapid depression in factor VII concentrations.⁵³ This early response to therapy may give the clinician a false impression that a therapeutic INR has been achieved after only 2 or 3 days. It is important to remember that patients are not truly anticoagulated at this point because a significant reduction in prothrombin concentrations requires at least 5 days to occur. Large doses may also increase the theoretical risk for early thrombotic complications, such as warfarin-induced skin necrosis. After the initiation of warfarin therapy protein C becomes rapidly depleted, but prothrombin concentrations will remain near normal for several days. If protein C concentrations are severely suppressed relative to prothrombin, there is a potential for inducing a hypercoagulable state.

For most patients, initiating therapy with 5 mg daily and adjusting the dose based on the INR response will produce therapeutic INRs in 4 to 5 days (Fig. 21–8). Lower or higher starting doses may be acceptable based on patient-related factors and how quickly followup laboratory monitoring can be performed. Several dosing nomograms have been developed and prospectively evaluated.^{5,51,54} For patients with acute venous thrombosis, UFH, LMWH, or fondaparinux should be overlapped with warfarin therapy for at least 5 days regardless of whether the target INR has been achieved earlier.²

Warfarin therapy can be safely initiated on an outpatient basis provided there is no urgent need for anticoagulation (i.e., prevention of venous thrombosis). Given that laboratory monitoring is performed less frequently in the outpatient setting, warfarin therapy should be undertaken a bit more cautiously. In most circumstances, the initial dose should not exceed the anticipated maintenance dose. The response to therapy should be measured every 3 to 5 days until stabilized. The full antithrombotic effect may require up to 15 days to be achieved.^{5,46}

When adjusting the dose of warfarin, the clinician should allow sufficient time for changes in the INR to occur. In general, dose changes should not be made more frequently than every 3 days. Doses should be adjusted by calculating the weekly dose and reducing or increasing the weekly dose by 5% to 25%. The effect of a small dose change may not become evident for 5 to 7 days. Patients should not have followup INR tests sooner than anticipated changes are likely to occur.⁵

Therapeutic Monitoring

Warfarin requires frequent laboratory monitoring to ensure optimal therapeutic outcomes and minimize bleeding complications.

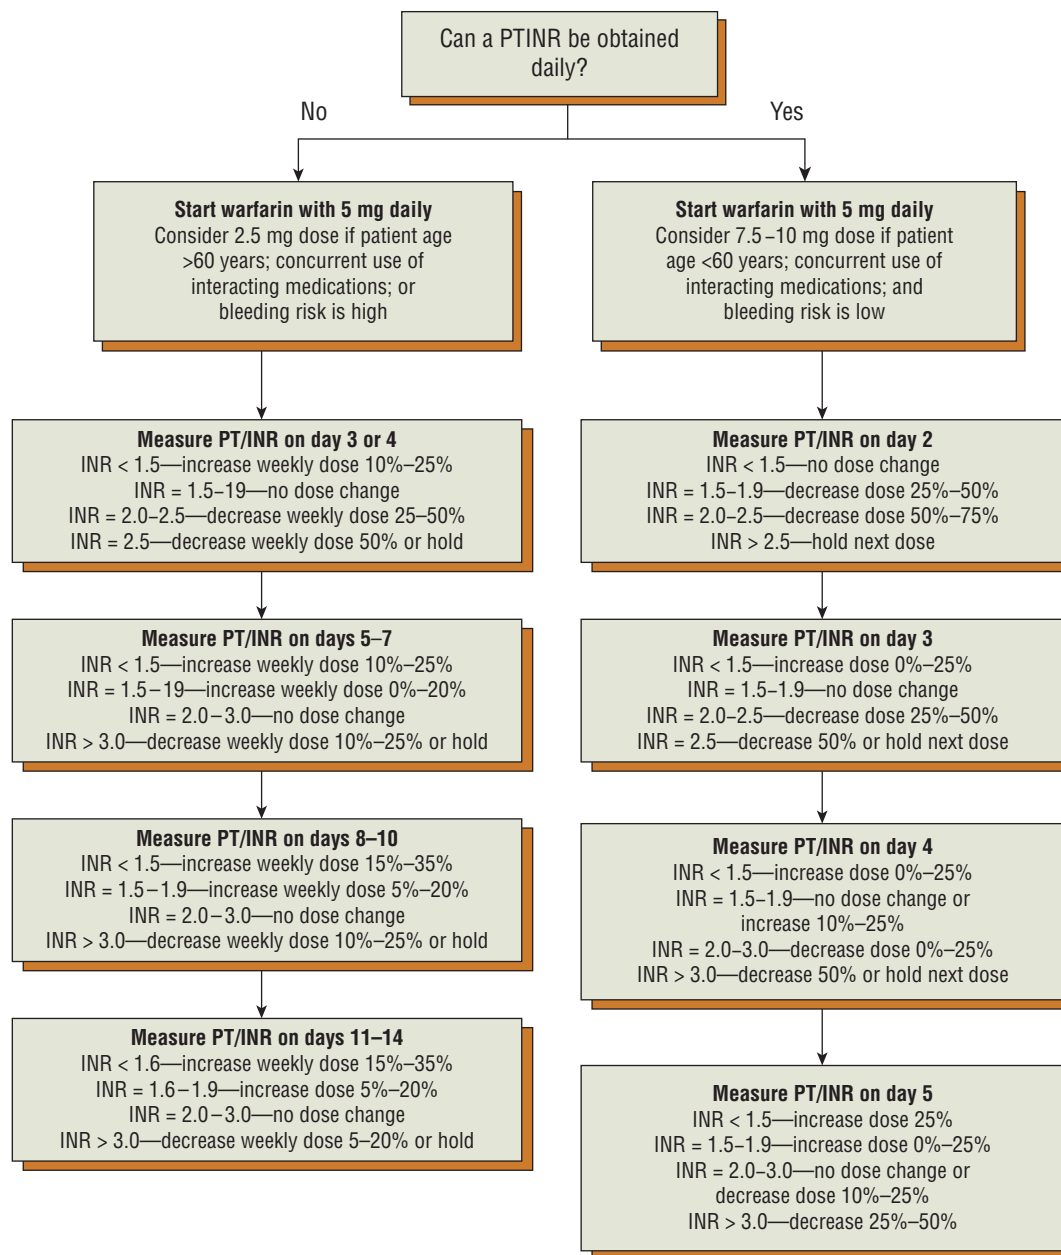

FIGURE 21-8. Initiation of warfarin therapy. (INR, international normalized ratio; PT, prothrombin time.)

The prothrombin time (PT), also known as the protime and one-step Quick test, has been used for decades to monitor the anticoagulation effects of warfarin.^{5,55} The PT measures the biologic activity of factors II, VII, and X activity and correlates well to warfarin's anticoagulation effect. The test is performed by measuring the time required for clot formation after adding calcium and thromboplastin to citrated plasma. Several thromboplastins are commercially available and are extracted from mammalian tissue rich in tissue factor (e.g., rabbit brain) or produced from recombinant human tissue factor. Although an effective tool for monitoring warfarin therapy, the PT is problematic to interpret because there is wide variability in the sensitivity of thromboplastin reagents. Given the same blood sample, different thromboplastins will produce substantially different results that may prompt clinicians to make potentially inappropriate dosing decisions. The World Health Organization (WHO) addressed the need for standardization in the late 1970s by developing a reference thromboplastin and recommending the use of the INR to monitor warfarin therapy. The INR corrects for differences in thromboplastin reagents through the following formula:

$$\text{INR} = \left(\frac{\text{PT}^{\text{Patient}}}{\text{PT}^{\text{Control}}} \right)^{\text{ISI}}$$

The International Sensitivity Index (ISI) is a measure of the thromboplastin's responsiveness compared to the WHO reference standard. Each thromboplastin reagent manufactured has an ISI value that should be used to calculate the INR. Although the INR system has a number of potential problems, it is currently the best means available to interpret the PT and the preferred method for monitoring oral anticoagulation therapy.

The recommended target INR and goal range is based on the therapeutic indication.^{5,55} For most indications, the target INR is 2.5 with an acceptable range of 2.0 to 3.0. The target INR is higher for some patients with mechanical prosthetic heart valves (target INR = 3.0, range 2.5 to 3.5). A baseline PT and complete blood cell count should be obtained prior to initiating warfarin therapy. In patients with an acute thromboembolic event, a PT should be measured minimally every 3 days during the first week of therapy. In this situation, UFH or LMWH therapy should be continued for at least

TABLE 21-17 Vitamin K Content of Select Foods^a

From Booth and Centurelli.¹¹²

5 days and until the INR is greater than 2.0 and stable. The concurrent use of antithrombotic drugs with warfarin may prolong the prothrombin time slightly. Once the patient's dose-response is established, an INR should be determined every 7 to 14 days until it stabilizes and optimally every 4 weeks thereafter.^{2,5,6}

At each encounter, patients should be meticulously questioned regarding their medication use and symptoms related to bleeding and thromboembolic complications. Any changes in medications, including changes in dose as well as non-prescription drug and dietary supplement use, should be carefully explored (see Tables 21–14, 21–15, and 21–16). Dietary intake of vitamin K rich foods should also be evaluated (Table 21–17).

Anticoagulation therapy management services can improve the care of patients who take warfarin therapy by providing structured, comprehensive patient education and evaluation.⁵ When staffed by experienced and knowledgeable practitioners, anticoagulation management services improve the safety and effectiveness of warfarin therapy compared to “usual” medical care. Anticoagulation patient management services lower the overall cost of care by reducing the frequency of major bleeding and recurrent thromboembolic events.^{7,56}

Portable prothrombin time monitoring devices have enhanced patient management. Not only do these devices permit clinicians to do “real-time” therapeutic drug monitoring, but they enable patients to engage in self-testing at home.^{57,58} Self-monitoring, in its simplest form, requires the patient to report their test results to a healthcare professional. In such arrangements, the clinician continues to make warfarin dosing decisions. Highly motivated and sophisticated patients can be trained to manage themselves, independently altering the dose of warfarin therapy based on their INR results. Patients who engage in INR self-monitoring and warfarin self-management report high levels of satisfaction with care and maintain the INR within the therapeutic range more frequently than those managed by “usual care.” Home INR testing and self-management are clearly not for everyone, however. It requires careful patient selection and considerable education. Unfortunately, PT monitoring systems remain relatively expensive and are rarely covered by medical insurance.

Adverse Effects

Warfarin's primary adverse effect is bleeding.⁴ Hemorrhagic complications, ranging from mild to life-threatening, can occur at any site in the body. Although warfarin is not believed to cause bleeding per se, it can “unmask” an existing lesion or enable a massive hemorrhage from an ordinarily minor bleeding source. The gastrointestinal tract is the most frequent site of bleeding. Bruising on the arms and legs is commonplace, but a painful hematoma may necessitate the temporary discontinuation of therapy. Intracranial hemorrhage is the most serious and feared complication related to warfarin therapy, often resulting in permanent disability or death.

The annual incidence of major bleeding ranges from 1% in highly selected patient populations who are carefully managed, to greater than 10% in patients managed in less-structured environments, according to some studies.^{4,5} There are no universally accepted criteria for defining a bleeding event as major or minor. Most studies have defined major bleeding as any bleeding event that required hospitalization, transfusion of 2 or more units of blood or plasma, or that led to a greater than 2 g/dL drop in hemoglobin concentration. Bleeding that does not meet the criteria for a major hemorrhage is generally considered to be a minor. Minor bleeding is very common. Few studies have prospectively evaluated the incidence of minor bleeding but it is likely to be greater than 15% annually even in the most expertly managed patients.^{4,5}

Several risk factors for bleeding while taking anticoagulation therapy have been identified (see Table 21–8). Intensity of anticoagulation therapy appears to be the most powerful risk factor. Patients whose target INR is greater than 3.0 have twice the incidence of major bleeding compared to those with a target of 2.5. The risk of intracranial hemorrhage increases significantly when the INR remains greater than 4.0 for prolonged periods of time especially in the elderly. Patients given low-intensity warfarin therapy (goal INR 1.3 to 1.9) may have a lower incidence of bleeding, but this level of anticoagulation is insufficient protection against thrombosis for most indications. Wide variability in the anticoagulation response, as seen in patients with very unstable INR values, also appears to be associated with an increased risk of bleeding. The risk of hemor-

rhage is greatest during the first few weeks of therapy; however, bleeding can occur at any time and the cumulative incidence steadily increases over time.^{4,5}

Nonhemorrhagic adverse effects associated with warfarin are uncommon, but can be serious when they do occur.^{5,6} The “purple toe syndrome,” manifested as a purplish discoloration of the toes, is an extremely rare event reported in a small percentage of patients receiving warfarin. The etiology of this unusual phenomenon is unknown, but is thought to be the result of cholesterol microembolization into the arterial circulation of the toes.

Warfarin-induced skin necrosis is an uncommon but very serious dermatologic reaction that is manifested by a painful maculopapular rash and ecchymosis or purpura that subsequently progresses to necrotic gangrene.⁵⁹ It most frequently appears in areas of the body rich in subcutaneous fat, such as the breasts, thighs, buttocks, and abdomen. The incidence of warfarin-induced skin necrosis is less than 0.1%. It occurs most commonly in middle-aged women who are being treated for acute venous thrombosis. Although symptoms generally appear during the first week of therapy, it has been reported in a small number of patients who had taken warfarin for months and even years. The pathogenesis of warfarin-induced skin necrosis is not clearly understood. Many believe imbalances between procoagulant and anticoagulant proteins that occur early in the course of warfarin therapy resulting in capillary thrombosis and secondary hemorrhages. The observation that patients with proteins C or S deficiency appear to be at greater risk for warfarin-induced skin necrosis supports this theory. Warfarin-induced skin necrosis has also been reported in patients with other disorders of hypercoagulability, such as antithrombin deficiency and antiphospholipid antibodies. Patients who receive large “loading” doses of warfarin may also be at greater risk. It is recommended that heparin therapy be overlapped for a minimum of 7 days when initiating therapy in any patient suspected to have a hypercoagulable state or who has a strong family history of venous thrombosis. If the diagnosis of skin necrosis is suspected, warfarin therapy should be immediately discontinued, vitamin K administered, and full-dose UFH or LMWH therapy initiated. Warfarin therapy should be restarted with extreme caution in patients with a history of skin necrosis, if at all.

Gastrointestinal side effects of warfarin therapy are uncommon and usually self-limited. Because warfarin interferes with vitamin K metabolism, there has been some theoretical concern that it may adversely affect bone formation and cause osteoporosis with long-term use. In one recent analysis, long-term use of warfarin was associated with osteoporotic fractures, in men with atrial fibrillation.⁶⁰

Management of Bleeding and Excessive Anticoagulation

Specific recommendations for the management of patients with an elevated INR are published by the American College of Chest Physicians (ACCP) Consensus Conference on Antithrombotic Therapy (Fig. 21–9).⁵ Patients with a mildly elevated INR (3.5 to 5.0) should be examined for signs and symptoms of bleeding, as well as factors that increase bleeding risk. In this circumstance, either reducing the dose of warfarin or holding one or two doses will safely manage most patients. When a swift reduction in an elevated INR is required, oral or intravenous vitamin K₁ (phytonadione) can be given.^{5,61} In the absence of major bleeding, the oral route of administration is preferred. While the IV route produces a more rapid reversal, it is associated with rare but serious anaphylactoid reactions. If the INR is between 5 and 9, doses of warfarin should be withheld and may be combined with a low dose of oral vitamin K (≤ 5 mg). Low doses of oral vitamin K will consistently reduce the INR within 24 hours without making the patient refractory to warfarin therapy. Overcorrection of the INR in the patient who is not bleeding is unnecessary but common. Simply withholding warfarin will result in correction of

INRs between 5 and 9 within 48 to 72 hours in most patients.⁶² The decision to administer vitamin K should be individualized based on the patient’s bleeding risk and the underlying indication for anticoagulation therapy. Vitamin K should be used with caution in patients at high risk of recurrent thromboembolism because of the possibility of INR overcorrection. Conversely, simply withholding warfarin therapy may not lower a high INR quickly enough in patients at high risk for developing bleeding complications. If the INR is greater than 9, a 5-mg oral dose of vitamin K is recommended. High doses of vitamin K (e.g., 10 mg) are associated with prolonged resistance to warfarin and the occurrence of thromboembolic complications. In the event of a serious or life-threatening bleed, intravenous vitamin K should be administered as well as fresh-frozen plasma, clotting factor concentrates, or recombinant FVII.

Drug–Drug and Drug–Food Interactions

The pharmacokinetic and pharmacodynamic properties of warfarin, coupled with its narrow therapeutic index, predispose this agent to numerous clinically important food and drug interactions (see Tables 21–14, 21–15, 21–16, and 21–17).^{5,63,64} Vitamin K can reverse warfarin’s pharmacologic activity, and many foods contain sufficient vitamin K to reduce the anticoagulation effect of warfarin if a patient consumes them in large portions or repetitively within a short period of time.⁶⁴ Patients should be given a list of vitamin K-rich foods and instructed to maintain a relatively consistent intake. It is important to stress consistency and moderation rather than absolute abstinence. Abrupt changes in vitamin K intake should be considered when unexplained changes in the INR occur. Alternative sources of vitamin K, such as multivitamins and nutritional supplements (e.g., Sustacal and Ensure) should also be considered. Patients who require parenteral nutrition should not receive a weekly bolus dose of vitamin K if they are taking warfarin therapy.

Pharmacokinetic drug interactions with warfarin are primarily a result of alterations in hepatic metabolism or binding to plasma proteins. Drugs that inhibit or induce the CYP2C9, CYP1A2, and CYP3A4 isoenzymes have the greatest potential to significantly alter the response to warfarin therapy. Protein-binding displacement interactions can also occur. However, in the absence of hepatic disease or a diminished capacity to metabolize warfarin, changes in protein binding result in only transient changes in the INR. Drugs that alter hemostasis, platelet function, or the clearance of clotting factors (e.g., thyroid hormone replacement) can alter the response to warfarin therapy or increase the risk of bleeding by pharmacodynamic mechanisms.^{5,63}

The explosive increase in the use of herbal and alternative therapies in North America has raised concern regarding their potential to interact with warfarin therapy.⁶⁴ All patients on warfarin therapy should be questioned regarding the use of herbal drugs and dietary supplements. Clinicians should advise patients on warfarin therapy to seek information about potential interactions with warfarin whenever they start to take a new drug product, whether it is prescribed or purchased over the counter. If there is a known drug interaction or doubt about its potential to alter the response to warfarin, more frequent INR testing following the initiation of the new agent is prudent.

Use in Special Populations

In the absence of a clear and compelling indication, warfarin should not be used during pregnancy because of the potential for fetal hemorrhage and teratogenic complications.²⁷ Warfarin crosses the placenta and is associated with several embryopathies, particularly CNS abnormalities, that have occurred throughout gestation. The FDA has designated warfarin a pregnancy category X agent. As UFH and the LMWHs are large molecules that do not cross the placental

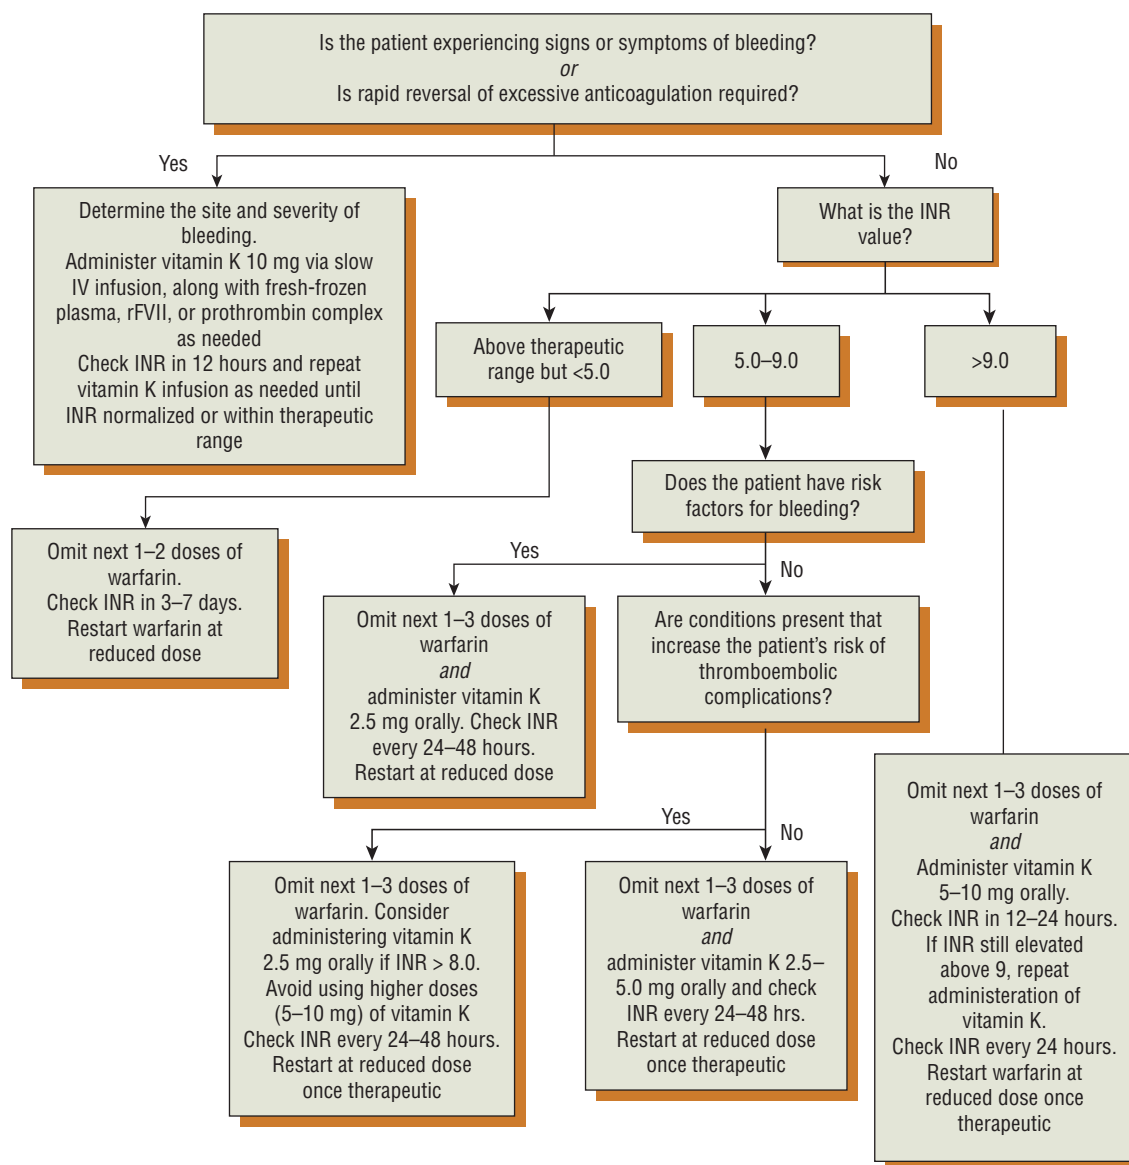

FIGURE 21-9. Management of an elevated international normalized ratio (INR) in patients taking warfarin. Dose reductions should be made by determining the weekly warfarin dose and reducing the weekly dose by 10% to 25% based on degree of INR elevation. Conditions that increase the risk of thromboembolic complications include history of hypercoagulability disorders (e.g., protein C or S deficiency, presence of antiphospholipid antibodies, antithrombin deficiency, activated protein C resistance), arterial or venous thrombosis within the previous month, thromboembolism associated with malignancy, and mechanical mitral valve in conjunction with atrial fibrillation, previous stroke, poor ventricular function, or coexisting mechanical aortic valve. (INR, international normalized ratio; rFVII, recombinant factor VII.)

barrier, they are considered the drugs of choice for anticoagulation during pregnancy. Warfarin is excreted into the breast milk in very low concentrations and is generally considered safe to use by women who are breast-feeding.

Patients scheduled to undergo major surgery or other invasive procedures often require temporary discontinuation of warfarin therapy.⁵ The decision to withhold warfarin therapy should be based on the type of surgical procedure being performed and the patient's risk of bleeding and thromboembolism. Warfarin therapy should generally not be discontinued in patients undergoing minimally invasive procedures such as dental work.^{5,65} If the bleeding risk from the procedure is considerable, warfarin should be stopped 4 to 5 days prior to the procedure in order to allow the INR to return to near-normal values. Alternatively, warfarin can be stopped and a low dose (2.5 mg) of oral vitamin K may be given 2 days prior to the procedure.⁵ Patients at moderate or high risk of thromboem-

bolism (i.e., DVT or PE in the previous month) should be given so-called bridge therapy with UFH or a LMWH before and/or after the procedure (Table 21-18).

Warfarin use among elderly patients is increasingly common. Although the drug has been extensively studied in this population, some debate still remains regarding the relative risks of warfarin therapy in the elderly.^{5,6} Data supporting the notion that age increases hemorrhagic risk are somewhat conflicting. Age greater than 75 years is associated with an increased risk of intracranial hemorrhage, but the overall incidence of major bleeding is similar to younger users. Elderly patients may be more prone to excessive anticoagulation as a consequence of nutritional deficiencies, comorbidities, and multiple-drug interactions. Furthermore, they are often at greater risk of falls. Although they often derive the greatest benefit from anticoagulation therapy, elderly patients should be monitored with greater vigilance, and warfarin dose changes should be made more cautiously.

TABLE 21-18 General Approach to Periprocedural Anticoagulation Therapy Management

Days Relative to Procedure	Anticoagulation Management
-7 to -10	Assess thrombosis and bleeding risk Determine appropriate bridging plan Obtain INR
-7	Stop aspirin or other antiplatelet therapy
-6 or -5	Stop Warfarin ^a
-4 or -3	Start LMWH ^b
-2	LMWH
-1	Give last dose of LMWH 12–24 hours before procedure Obtain INR
0 = Surgery	Resume warfarin ^c at usual maintenance dose on evening after procedure
+1	Resume LMWH ^d Warfarin
+2 to +3	LMWH ^d Warfarin
+4 to +5	Obtain INR and CBC LMWH Warfarin
+6	Obtain INR and CBC Stop LMWH once INR is therapeutic

CBC, complete blood count; INR, international normalized ratio; LMWH, low-molecular-weight heparin.

^aWarfarin stopped on day -5 if INR drawn on day -7 to -10 is 2.0 to 3.0 or day -6 if INR drawn on day -7 to -10 is 2.5 to 3.5.

^bLMWH is initiated 2 days (36 to 48 hours) after warfarin is discontinued.

^cProphylactic dose LMWH may be used in low bleeding-risk procedures.

^dFull (treatment) doses of LMWH can be resumed on days 1, 2, and 3 once hemostasis is adequate.

From Ansell et al.⁵

GENERAL APPROACH TO THE PREVENTION OF VENOUS THROMBOEMBOLISM

Given that VTE is often clinically silent and potentially fatal, strategies to prevent DVT in at-risk populations will have the greatest impact

on patient outcomes.³ To rely on the early diagnosis and treatment of VTE is unacceptable because many patients will die before treatment can be initiated. Furthermore, even clinically silent disease is associated with long-term morbidity from the postthrombotic syndrome and predisposes the patient to future thromboembolic events. Despite an immense body of literature that overwhelmingly supports the widespread use of pharmacologic and nonpharmacologic strategies to prevent VTE, prophylaxis is underused in most hospitals. Even when prophylaxis is given, many patients receive prophylaxis that is less than optimal. Educational programs and clinical decision support systems have been shown to improve the appropriate use of VTE prevention methods.³

5 The goal of an effective VTE prophylaxis program is to identify all patients at risk, determine each patient's level of risk, select and implement regimens that provide sufficient protection for the level of risk, and avoid or limit complications from the selected regimens. As hospitalized patients are frequently at high risk for VTE, screening all patients prior to or at the time of admission to determine their level of risk is the first step in an effective prophylaxis program. The risk classification criteria and recommended prophylaxis strategies promulgated by the ACCP Conference on Antithrombotic Therapy is widely used in North America (Table 21-19).³ Several pharmacologic and nonpharmacologic methods are effective for preventing VTE, and these can be used alone or in combination. Nonpharmacologic methods improve venous blood flow by mechanical means, whereas drug therapy counteracts the propensity for thrombus formation by dampening the coagulation cascade.

Nonpharmacologic Strategies

Resumption of ambulation as soon as possible following surgery reduces the incidence of VTE in low-risk patients.³ Walking increases venous blood flow and promotes the flow of natural antithrombotic factors into the lower extremities. During prolonged surgeries, electrical calf muscle stimulation devices that mimic the pumping action produced during ambulation can be beneficial. Although these

TABLE 21-19 Risk Classification and Consensus Guidelines for Venous Thromboembolism Prevention

From Geerts et al.³

devices can reduce the risk of DVT by more than 50%, their use is painful, and they can be used only when the patient is under general anesthesia. Continuous passive motion devices and plantar compression systems are also available but their effectiveness is uncertain.

Graduated compression stockings reduce the incidence of VTE by approximately 60% following general surgery, neurosurgery, and stroke.^{3,66} Compression stockings work by increasing the velocity of venous blood flow. They apply a graded amount of pressure, with the greatest amount of pressure applied at the ankle. Inexpensive and safe, they are an excellent choice when pharmacologic interventions are either contraindicated or difficult to monitor adequately. When combined with pharmacologic interventions, graduated compression stockings have an additive effect. Some patients are unable to wear compression stockings because of the size or shape of their legs, however.

Similar to graduated compression stockings, intermittent pneumatic compression (IPC) devices increase the velocity of blood flow in the lower extremities.^{3,67} The technique involves the sequential inflation of a series of cuffs wrapped around the patient's legs. Using graded pressure, the cuffs inflate in 1- to 2-minute cycles continually throughout the day from the ankles to the thighs. IPC reduces the risk of VTE by more than 60% following general surgery, neurosurgery, and orthopedic surgery.³ There is some theoretical concern that external compression may dislodge a previously formed clot.⁶⁸ Although IPC is well tolerated and safe to use in patients who have contraindications to pharmacologic therapies, it does have a few drawbacks. It is more expensive than the use of graduated compression stockings, it is a relatively cumbersome technique, and some patients may have difficulty sleeping while using it.³ Like graduated compression hose, IPC can increase the effectiveness of pharmacologic prophylaxis.

Inferior vena cava (IVC) filters, also known as Greenfield filters, provide short-term protection against PE in very-high-risk patients by preventing the embolization of a thrombus formed in the lower extremities into the pulmonary circulation.^{3,69,70} Percutaneous insertion of a filter into the IVC is a minimally invasive procedure performed via fluoroscopy. Despite the widespread use of IVC filters, there are very limited data regarding their effectiveness and long-term safety. The evidence suggests that IVC filters, particularly in the absence of effective antithrombotic therapy, increase the long-term risk of recurrent DVT. In the only randomized clinical trial examining the short- and long-term effectiveness of the filters in patients with a documented proximal DVT, treatment with IVC filters in combination with anticoagulation therapy reduced the risk of pulmonary embolism by more than 75% during the first 12 days following insertion.⁷⁰ However, this benefit was not sustained during 2 years of followup and the long-term risk of recurrent deep vein thrombosis was nearly twofold higher in those who received a filter. Although IVC filters can reduce the short-term risk of PE in patients who are at highest risk, they should be reserved for patients in whom other prophylactic strategies cannot be used. Furthermore, to reduce the long-term risk of VTE in association with IVC filters, pharmacologic prophylaxis is necessary, and warfarin therapy should begin as soon as the patient is able to tolerate it.

Pharmacologic Strategies

Several pharmacologic interventions have been extensively evaluated in numerous randomized clinical trials.³ Appropriately selected drug therapies can dramatically reduce the incidence of VTE following hip replacement, knee replacement, general surgery, myocardial infarction, and ischemic stroke (see Table 21–19). The choice of agent and dose to use for VTE prevention must be based on the patient's level of risk for thrombosis and bleeding complications, as well as cost and the availability of an adequate drug therapy monitoring system.

Most randomized controlled trials fail to show a significant benefit from aspirin therapy in the prevention of VTE.³ The ACCP Consensus Conference continues to recommend against the use of aspirin as the primary method of VTE prophylaxis. Antiplatelet drugs clearly reduce the risk of coronary artery and cerebrovascular events in patients with arterial disease, but aspirin produces a very modest reduction in VTE following orthopedic surgeries of the lower extremities. The relative contribution of platelets in the pathogenesis of venous thrombosis compared with that of arterial thrombosis can explain the reason for this difference. Venous thrombosis results primarily from venous stasis, while arterial thrombosis is most often the result of vascular wall injury.

CLINICAL CONTROVERSY

In a series of large, well-designed phase III clinical trials, fondaparinux was superior to enoxaparin for the prevention of VTE in patients who were undergoing lower-extremity orthopedic surgery. However, the rate of symptomatic pulmonary embolism and death was not different between the two treatments in any of these studies. Furthermore, fondaparinux has not been compared to warfarin for the prevention of VTE in high-risk patients. Based on these findings, some experts contend that fondaparinux offers no clinical advantages over enoxaparin or warfarin. In addition, although there was no difference in the risk of major hemorrhage seen in the clinical trials when compared to enoxaparin, some clinicians worry about the potential for bleeding with fondaparinux because it has a long half-life and it cannot be reversed with protamine sulfate. Despite these concerns, some experts believe fondaparinux should be used preferentially because asymptomatic DVTs and PEs may increase the future risk of recurrent thrombotic events and the postthrombotic syndrome.

The most extensively studied agents for the prevention of VTE are UFH, the LMWHs, and fondaparinux.^{3,71} The LMWHs and fondaparinux provide superior protection against VTE when compared to low-dose UFH.^{3,71} Their more predictable absorption when given by subcutaneous injection may be the explanation. Even so, UFH remains a highly effective, cost-conscious choice for many patient populations, provided that it is given in the appropriate dose (see Table 21–19). Low-dose UFH (5,000 units every 12 hours or every 8 hours) given subcutaneously reduces the risk of VTE by 55% to 70% in patients undergoing a wide range of general surgical procedures and following a myocardial infarction or stroke. For the prevention of VTE following hip and knee replacement surgery, the effectiveness of low-dose UFH is considerably lower.³ Adjusted-dose UFH therapy provided subcutaneously, which requires dose adjustments to maintain the aPTT at the high end of the normal range, appears to be substantially more effective than low-dose UFH in the highest-risk patient populations. However, adjusted-dose UFH has been studied in only a few relatively small clinical trials and requires frequent laboratory monitoring. The LMWHs and fondaparinux appear to provide a high degree of protection against VTE in most high-risk populations. The appropriate prophylactic dose for each LMWH product is indication specific (see Table 21–10). There is no evidence that one LMWH is superior to another for the prevention of VTE. Fondaparinux was significantly more effective than enoxaparin in several clinical trials that enrolled patients undergoing high risk orthopedic procedures but has not been shown to reduce the incidence of symptomatic PE or mortality.⁷¹ To provide optimal protection, some experts believe that the LMWHs should be initiated prior to surgery.^{3,72}

Warfarin is a commonly used option for the prevention of VTE following orthopedic surgeries of the lower extremities.³ The evi-

dence is equivocal regarding the relative effectiveness of warfarin compared to the LMWHs for the prevention of clinically important VTE events in the highest risk populations. When used to prevent VTE, the dose of warfarin should be adjusted to maintain an INR between 2.0 and 3.0; however, some orthopedic surgeons favor lower initial INR goal ranges (e.g., 1.5 to 2.5) because of fear of bleeding at the surgical site. Oral administration and low drug cost give warfarin some advantages over the LMWHs and fondaparinux. However, warfarin does not achieve its full antithrombotic effect for several days, requires frequent monitoring and periodic dosage adjustments, and carries a substantial risk of major bleeding. For these reasons, warfarin is reserved for the highest-risk patients. Furthermore, warfarin should be recommended only when a well-developed monitoring system is available.⁵

The optimal duration for VTE prophylaxis following surgery is not well established.^{3,73} Prophylaxis should be given throughout the period of risk. For general surgical procedures and medical conditions, once the patient is able to ambulate regularly and other risk factors are no longer present, prophylaxis can be discontinued. Because of the relatively high incidence of VTE in the first month following hospital discharge among patients who have undergone a lower extremity orthopedic procedure, extended prophylaxis following hospital discharge with either a LMWH, fondaparinux, or warfarin appears to be beneficial. Most clinical trials support the use of antithrombotic therapy for 21 to 35 days following total hip replacement and hip fracture repair surgeries.^{33,74,75}

Pharmacoeconomic Considerations

Only a handful of studies have formally evaluated the cost-effectiveness of VTE prevention strategies. The acquisition costs of graduated compression stockings, heparin, and warfarin are considerably less than those of the LMWHs and fondaparinux. However, the acquisition cost for drug therapy is relatively small when compared with the overall cost of care.⁷⁶ Economic analyses must take into account the efficacy of the strategy, treatment complications, and monitoring costs.

The determination of the cost-effectiveness of VTE prophylaxis is based on the premise that a reduction in future VTE events will reduce overall healthcare costs.⁷⁷ Furthermore, the incremental cost per patient will decrease proportionally with an increase in the frequency of VTE in the population. Stated another way, the cost of providing prophylaxis to 1,000 patients will decline as the incidence of VTE in the given population increases. Consequently, more expensive and effective strategies become more cost-effective in higher-risk populations. In populations at low risk for VTE, early ambulation appears to be the most cost-effective strategy. In populations at moderate risk, the use of graduated compression stockings, the least expensive intervention, results in a lower overall cost of care, whereas low-dose UFH is estimated to increase the cost \$50 (in 1990 dollars) per patient when compared with no prophylaxis.⁷⁸ This compares favorably with the incremental costs associated with other routinely employed preventative measures. Although LMWH provides slightly greater reductions in the risk of VTE in patients who are at moderate risk of VTE, the additional cost is estimated to be \$107 (in 1999 dollars) per patient when compared to low-dose UFH.⁷⁹ Whether universal use of LMWH in moderate-risk patients is a cost-effective strategy remains controversial.

In high-risk patients, the cost-effectiveness of prevention is far greater because the incidence of VTE is higher. Following hip replacement surgery, regardless of the strategy selected, prophylaxis saves money when compared with no prophylaxis.⁷⁷ The LMWHs and fondaparinux slightly increase the total mean cost of care after total hip and knee replacement when compared with low-dose UFH and warfarin.^{80,81} However, because of their superior effectiveness, the LMWHs have a significantly lower cost per DVT and PE

avoided.⁷⁷ Based on typical drug-acquisition costs, LMWH and fondaparinux appear to be cost-effective choices in the highest-risk patient populations.⁸²

GENERAL APPROACH TO THE TREATMENT OF VENOUS THROMBOEMBOLISM

6 Before initiating anticoagulation therapy for the treatment of VTE, it is imperative to establish an accurate diagnosis; thus preventing unnecessary risk and expense to the patient.⁸³ Anticoagulation therapy remains the mainstay of treatment for VTE. DVT and PE are manifestations of the same disease process and are treated similarly.² Full “therapeutic” doses of antithrombotic drugs prevent thrombus extension and embolization as well as reduce the risk of long-term sequelae such as the postthrombotic syndrome, pulmonary hypertension, and recurrent thromboembolism.^{2,84} The standard approach is to initiate therapy with UFH by continuous IV infusion or a LMWH or fondaparinux by subcutaneous injection and to make the transition to warfarin for maintenance therapy (Table 21–20 and Fig. 21–10). In rare circumstances, elimination of the obstructing thrombus is warranted and the use of venous thrombectomy or thrombolysis can be considered.² Inferior vena

TABLE 21-20 Consensus Guidelines for Venous Thromboembolism Treatment

	Recommendation	Grade ^a
Acute anticoagulation	Acute treatment of DVT or PE should be with LMWH, fondaparinux, intravenous UFH, or adjusted-dose subcutaneous UFH	1A
	The dose of UFH should be sufficient to prolong the aPTT to a range that corresponds to a plasma heparin level of 0.2 to 0.4 international units/mL by protamine titration or an anti-Xa level of 0.3 to 0.6 international units/mL	1C+
	LMWH and fondaparinux are preferred over UFH	2B
Duration of acute treatment	A LMWH is preferred in patients with cancer	1A
	Treatment with UFH, LMWH, or fondaparinux should be overlapped with warfarin for at least 5 days and can be stopped when the INR is >2.0; most patients should have warfarin started at the same time as UFH, LMWH, or fondaparinux	1A
	Patients with cancer should be treated with a LMWH for at least 6 months	1A
	A longer period of heparin therapy (approximately 10 days) is recommended for massive PE or severe iliofemoral thrombosis	1C
Long-term anticoagulation	Oral anticoagulation therapy (target INR 2.5, range: 2.0 to 3.0) should be continued for at least 3 months; if oral anticoagulation therapy is contraindicated (e.g., pregnancy), a treatment dose of LMWH or adjusted-dose UFH should be used	1A
	Patients with an idiopathic VTE, an inherited disorder of hypercoagulability, or antiphospholipid antibodies should be treated indefinitely (at least 2.5 years)	1A
	Patients with continuing risk factors (e.g., malignancy, immobility) should be treated for at least 12 months	1C

aPTT, activated partial thromboplastin time; DVT, deep vein thrombosis; INR, international normalized ratio; LMWH, low-molecular-weight heparin; PE, pulmonary embolism; UFH, unfractionated heparin; VTE, venous thromboembolism.

^aRefers to grade of recommendation (1A, strong recommendation applying to most patients without reservation; 1C, intermediate-strength recommendation that may change when stronger evidence becomes available; 1C+, strong recommendation that applies to most patients in most circumstances; 2B, weak recommendation where alternative approaches likely to be better for some patients under some circumstances).

From Buller et al.²

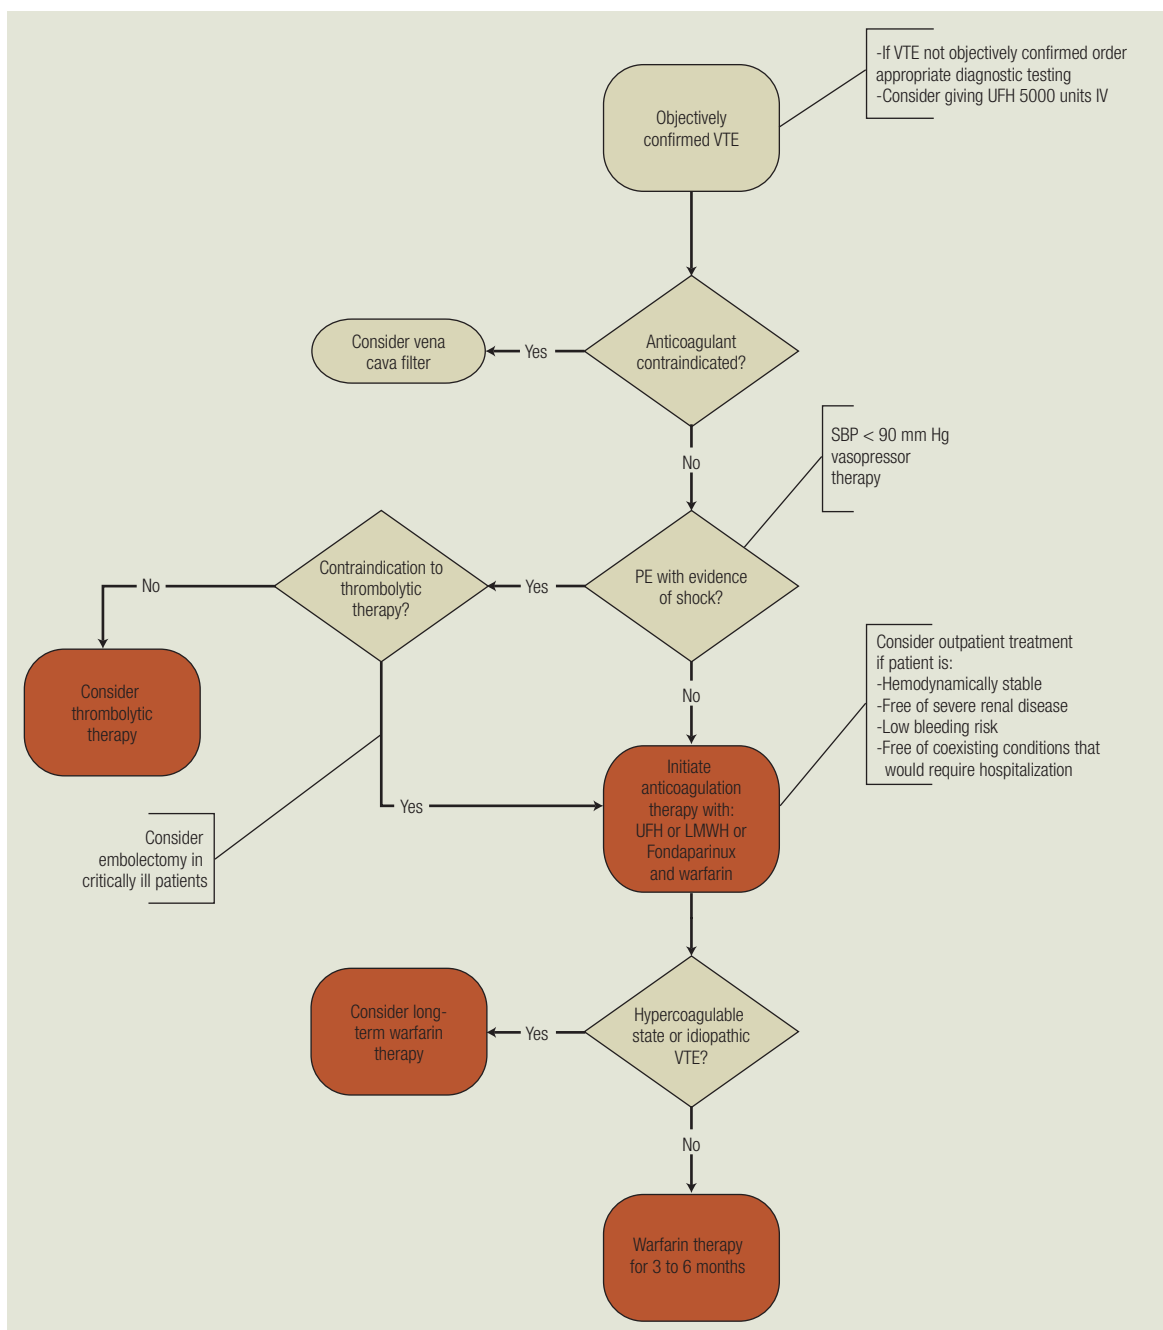

FIGURE 21-10. Treatment of venous thromboembolism (VTE). (LMWH, low-molecular-weight heparin; PE, pulmonary embolism; SBP, systolic blood pressure; UFH, unfractionated heparin.)

cava interruption with a filter is also an option in those with contraindications to anticoagulation therapy or in whom anticoagulant therapy has failed.

Once the diagnosis of VTE has been objectively confirmed (see Clinical Presentation and Diagnosis below), anticoagulant therapy with either UFH, LMWH, or fondaparinux should be instituted as soon as possible. LMWHs and fondaparinux are highly effective and can be administered in the outpatient setting. The decision to initiate therapy with a LMWH or fondaparinux on an outpatient basis should be based on institutional resources and patient specific variables (Table 21–21). **7**

UNFRACTIONATED HEPARIN

The parenteral administration of UFH followed by warfarin has been the conventional treatment of patients with VTE for decades.

Although UFH can be given by either subcutaneous or IV injection, continuous IV infusion has been preferred because of improved dosing precision (see Table 21–7).² When UFH is administered by IV infusion, the aPTT or a suitable coagulation study should be used to monitor the anticoagulant effect.²⁴ The infusion rate should be adjusted to maintain an appropriate range corresponding to a heparin concentration of 0.3 to 0.7 international units/mL anti-Xa activity by the amidolytic assay. Weight-based dosing of UFH achieves a therapeutic aPTT in the vast majority of patients in the first 24 hours (see Table 21–7).²² Failure to give a sufficient dose of IV UFH has been shown to increase the risk of VTE recurrence not only during the initial treatment but also during long-term therapy.²⁴ Intravenous UFH requires hospitalization with frequent monitoring and dose adjustment. Well organized inpatient anticoagulation management services have been shown to improve patient care by increasing the proportion of aPTT values in the therapeutic

TABLE 21-21 Outpatient Treatment Protocol for Deep Venous Thrombosis

Target Population:	Inclusion/exclusion criteria for outpatient venous thromboembolism (VTE) treatment
Inclusion:	Patients with objectively diagnosed VTE
Relative exclusion:	Patients with clinical evidence of pulmonary embolus or suspected embolism who are hemodynamically stable
Exclusion:	Arterial thromboembolism or patients who are currently receiving dialysis, actively bleeding, have had recent (within 2 weeks) major surgery/trauma, or have other severe uncompensated comorbid conditions
Recommended Procedure:	May vary depending on the patient's clinical condition
A. Confirm diagnosis of VTE by objective testing	
1. Venous ultrasonogram	
2. Ventilation-perfusion (V/Q) scan	
3. Computed tomography (CT) scan	
B. Day 1	
1. Baseline laboratory evaluation	
a. Prothrombin time (PT) and calculated international normalized ration (INR)	
b. Activated partial thromboplastin time (aPTT)	
c. Serum creatinine (Scr)	
d. Complete blood count (CBC) with platelets	
2. Medication	
a. Low-molecular-weight heparin (LMWH) or fondaparinux injections	
i. Enoxaparin 1 mg/kg subcutaneously (SC) q 12 h or	
ii. Enoxaparin 1.5 mg/kg SC q 24 h (not recommended for patients with cancer or for obese patients)	
iii. Dalteparin 100 units/kg SC q 12 h or	
iv. Dalteparin 200 units/kg SC q 24 h or	
v. Tinzaparin 175 units/kg SC q 24 h or	
vi. Fondaparinux 7.5 mg SC q 24 h (5 mg if <50 kg and 10 mg if >100 kg)	
b. Warfarin sodium 5–10 mg orally every evening	
c. Pain medication if necessary (avoid nonsteroidal antiinflammatory drugs [NSAIDs])	
3. Patient education	
a. Clinical pharmacy/nursing	
i. Educate patient regarding the importance of proper monitoring of anticoagulation therapy and indications for additional medical evaluation; document activities in the medical record	
ii. Teach patient how to self-administer LMWH (if patient or family member unwilling or unable to self-administer LMWH injection, visiting nurse services should be arranged); initial LMWH injection should be administered in the medical office or hospital	
iii. Instruct patient regarding local therapy: elevation of affected extremity; localized heat, antiembolic exercises (flexion–extension of ankle for lower-extremity VTE, or hand squeezing–relaxation for upper-extremity VTE)	
b. Pharmacy operations	
i. Provide backup for clinical pharmacy/nursing; reinforce patient education regarding indication, use, monitoring, side effects, and drug interactions with antithrombotic therapy	
ii. Repackage LMWH syringes (if indicated) in patient-specific doses and dispense 5 to 7 days of therapy	
iii. Screen patient's pharmacy profile for potential drug–drug interactions with anticoagulation therapy	
c. Clinical pharmacy anticoagulation service enrollment	
i. The physician should forward outpatient VTE treatment orders to the anticoagulation service	
C. Day 2	
1. Laboratory evaluation: not required on day 2 of therapy	
2. Medications: continue LMWH and warfarin as directed	
3. Anticoagulation service	
a. Contact patient and evaluate for symptoms of pulmonary embolism (PE), clot extension, and/or bleeding	
b. Arrange for visiting nursing service if family or family member is having difficulty with outpatient therapy	
c. Continue reduced activity as long as pain persists (when possible, elevate extremity); increase activity as tolerated	
d. Document activities in medical record	
D. Day 3	
1. Laboratory evaluation: check INR	
2. Medications: continue LMWH and warfarin directed	
3. Anticoagulation service	
a. Contact patient and evaluate for symptoms of PE, clot extension, and/or bleeding	
b. Interpret results of INR and adjust dose of warfarin to achieve a target INR of 2.5	
c. Patient activity: continue reduced activity as long as pain persists (when possible, elevate extremity); increase activity as tolerated	
d. Document activities in medical record	
E. Day 4

F. Day 5

1. Laboratory evaluation: check INR and CBC with platelets
2. Medications: continue LMWH if indicated and warfarin as directed
3. Anticoagulation service
 - a. Contact patient and evaluate for symptoms of PE, clot extension, and/or bleeding
 - b. Interpret results of INR and adjust doses of warfarin to achieve a target INR of 2.5
 - c. Patient activity: no restriction; if pain increases, contact primary care provider
 - d. Document activities in medical record

range, reducing the length of hospital stay, and lowering total hospital costs when compared to usual care.⁸ However, despite the widespread use of weight-based dosing protocols, some patients still fail to achieve an adequate response to UFH therapy.²⁴ There is also evidence that UFH does not prevent thrombus progression in some patients with DVT, and rebound thrombin generation has been observed when UFH is discontinued abruptly.²⁴ These limitations of traditional IV UFH in the acute treatment of VTE have led to the investigation of alternative approaches.

LOW-MOLECULAR-WEIGHT HEPARIN

Because of their improved pharmacokinetic and pharmacodynamic profile as well as ease of use, the LMWHs have replaced UFH for the treatment of VTE in many institutions. The LMWHs given subcutaneously in fixed, weight-based doses (see Table 21-10) are at least as effective as UFH given IV for the treatment of VTE.² A number of meta-analyses comparing LMWH to UFH in the treatment of venous thromboembolism have been conducted. These analyses demonstrate no differences in clinically important end points, including recurrent DVT, PE, major or minor bleeding, and thrombocytopenia.² Surprisingly, patients who received LMWH had a significantly lower mortality rate. The reduction in mortality was primarily seen in patients with cancer.² The explanation for this survival advantage is unknown. There appears to be no difference in the risk of recurrent VTE between patients who are treated on an inpatient or outpatient basis with a LMWH for DVT.⁸⁵ However, outpatient treatment was associated with a slightly greater risk of major bleeding indicating the need for close monitoring when LMWH is given in this setting. There appears to be no difference in the efficacy or safety of once-daily versus twice-daily dosing regimens.² However, a subgroup analysis in one study suggested that patients with cancer and obese patients have higher recurrence rates with once-daily enoxaparin.⁸⁶

Given the predictable response and the reduced need for laboratory monitoring with LMWH, stable patients with DVT who have normal vital signs, low bleeding risk and no other comorbid conditions requiring hospitalization can be discharged early or treated entirely on an outpatient basis (see Table 21-21).⁸⁷ The efficacy and safety of LMWH in the home-based treatment of proximal DVT was initially established in large clinical studies.^{87,88} The results of randomized controlled clinical trials, as well as the experience of several successful outpatient DVT treatment programs in a variety of health-care settings, have led to an increased acceptance for outpatient management. Indeed, surveys of patients who received outpatient DVT treatment indicate a high degree of satisfaction and comfort, with 91% expressing satisfaction with home treatment.⁸⁷

Patients presenting with PE and no evidence of hemodynamic instability are at low risk of subsequent morbidity and mortality. Evidence exists suggesting that patients with submassive PE who are hemodynamically stable can be managed safely as outpatients with LMWH or fondaparinux.²⁴ However, hemodynamically unstable patients with PE should generally be admitted and treated with either intravenous UFH, LMWH, or fondaparinux. If thrombolytic

therapy or embolectomy is anticipated, UFH, which can be rapidly reversed, is preferred.⁸⁹ Patients with PE who present with shock have the highest risk of mortality and require aggressive interventions such as volume expansion, vasopressor therapy, intubation and mechanical ventilation in addition to antithrombotic therapy.⁹⁰

Not all patients are appropriate candidates for outpatient DVT treatment. At a minimum, patients with objectively diagnosed DVT must be reliable or have adequate caregiver support.⁸⁷ Patients and their caregivers must be willing and active participants in the outpatient management of DVT (Table 21-22). Patients who are unable to manage or who decline at-home treatment should be admitted to the hospital. These patients may subsequently opt for early discharge on LMWH. Daily patient contact either in person or via telephone is essential to identify potential complications and to address questions and concerns promptly. During daily contacts patients must be asked about symptoms that may indicate bleeding, thrombus extension, and PE.⁸⁷ Once acute treatment with a LMWH or fondaparinux has been transitioned to long-term warfarin therapy (approximately 5 to 10 days), patient contact can occur less frequently.

FONDAPARINUX

Two clinical trials have shown fondaparinux to be a safe and effective alternative to enoxaparin and intravenous UFH for the treatment of VTE.^{91,92} In the Mondial Assessment of Thromboembolism Treatment Initiated by Synthetic Pentasaccharide with Symptomatic End-points-Deep Venous Thrombosis (MATISSE-DVT) trial, a fixed-dose regimen of fondaparinux (7.5 mg q 24 h) given by subcutaneous injection was compared to the standard weight-adjusted dosing of enoxaparin (1 mg/kg q 12 h) for the acute treatment DVT followed by 3 months of warfarin therapy.⁹¹ In the MATISSE-PE trial, fondaparinux (7.5 mg subcutaneously [SC] q 24 h) was compared to UFH administered by IV infusion.⁹² In both trials, the dose of fondaparinux was increased to 10 mg SC every 24 hours for patients who weighed more than 100 kg and reduced to 5 mg SC every 24 hours for those who weighed less than 50 kg. Fondaparinux received FDA approval for the acute treatment of DVT and PE in 2004.³²

WARFARIN

Warfarin monotherapy is an unacceptable choice for the acute treatment of VTE because it does not produce a rapid anticoagulation effect and is associated high incidence of recurrent thromboembolism. However, warfarin is very effective in the long-term management of VTE and should be started concurrently with rapid acting injectable anticoagulant therapy.² The rapid acting injectable anticoagulant should overlap with warfarin therapy for at least 5 days and until a therapeutic INR has been achieved. The initial dose of warfarin should be 5 to 10 mg (see Fig. 21-8) and periodically adjusted to achieve and maintain an INR between 2.0 and 3.0.

The appropriate duration of warfarin maintenance therapy requires careful consideration of the circumstances surrounding the initial thromboembolic event, the presence of ongoing thromboembolic risk factors, and the risk of bleeding.^{2,93} A major consideration

TABLE 21-22 Patient Education for Outpatient Deep Vein Thrombosis Therapy

General information regarding DVT and the goals of treatment

- Anticoagulant medications (injections and warfarin tablets) have been prescribed to prevent the blood clot from growing larger so that the body can begin to dissolve the clot
- Your body may be able to completely dissolve the clot, but in some cases the clot never goes completely away; even with adequate anticoagulation therapy, some people will have chronic pain and swelling in the affected extremity; people who have had one clot are at increased risk of having future clots
- Warfarin tablets take several days to begin to work; LMWH injections work right away so at first LMWH injections and warfarin tablets are used together
- When the warfarin has become effective, you will be able to stop the LMWH injections; you will continue to take warfarin tablets for 3 to 6 months or longer to prevent blood clots from returning
- It is important for you to administer your LMWH or fondaparinux and warfarin exactly as directed

Subcutaneous injection technique

- You must learn to give yourself a subcutaneous injection of LMWH or fondaparinux; alternatively, you may have a family member or visiting nurse give it to you
- If your LMWH or fondaparinux syringes were filled by the manufacturer, they can be stored at room temperature; if your syringes were filled by the pharmacy, they should be stored in the refrigerator; if you were instructed to fill your own syringes, you should prepare the syringe immediately prior to injecting its contents
- If you see a bubble in the syringe, do not try to get it out, you may accidentally squirt out part of your dose
- Choose an injection site on your abdomen; clean the area with alcohol, then position an uncapped syringe at a 90-degree angle; pinch the skin, stick the needle in as far as it will go and gently but firmly push the plunger down; this will inject the medicine into the skin; when all the medication has been injected, remove the needle and dispose of it in an appropriate container
- You will likely experience a burning sensation when the medication is injected; this will go away after a few minutes
- Rotate injection sites from side to side, do not inject into the same site more than once; avoid the area around your navel; do not inject into any bruises

Blood test monitoring

- Regular blood tests are required to make sure your medication is working properly
- The prothrombin time tells how quickly your blood forms a clot; it is used to tell how well warfarin is working
- The INR is a way to standardize the prothrombin time between laboratories; your goal INR range is between 2.0 and 3.0; if your INR is less than 2.0, you are at higher risk for clotting, if your INR is greater than 3.0, you are at higher risk for bleeding; your dose of warfarin will be adjusted based on the results of this test
- You need to have a complete blood count test both before you begin therapy and after you have been on LMWH or fondaparinux for about 5 days; this will help detect internal bleeding and the occurrence of a rare side effect of heparin therapy that can decrease a component of your blood called platelets

Warfarin information

- Each strength of warfarin has a unique color; each time you refill your prescription, make sure your new tablets are the same color you have been taking; if they are not the same color, ask your pharmacist why
- Warfarin should be taken at approximately the same time each day
- The most common and serious side effect of warfarin is bleeding; you should be careful to avoid situations or activities that increase your risk of injury; apply direct pressure to control bleeding from superficial cuts
- Warfarin has many drug interactions; always check with your provider before taking any new medications (including over-the-counter medications and dietary supplements)
- Foods rich in vitamin K (green leafy vegetables, etc.) may interfere with warfarin; you do not need to avoid foods rich in vitamin K, but you should try to maintain consistent dietary habits
- Alcohol can increase your risk for bleeding and interfere with warfarin therapy; drink alcohol in moderation (1 to 2 drinks per day); avoid binge drinking

Contact your provider if you experience

- Persistent bleeding from a cut or scrape
- Blood in your urine
- Blood in your stool
- Persistent nose bleeding
- Increased swelling or pain in your affected extremity

Go to the emergency department if you experience

- Shortness of breath
- Chest pain
- Coughing up blood
- Black tarry-appearing stool
- Severe headache of sudden onset
- Slurred speech

DVT, deep vein thrombosis; INR, international normalized ratio; LMWH, low-molecular-weight heparin.

in determining the risk of recurrent VTE once anticoagulation therapy is stopped is whether the initial thrombotic event was associated with a major transient or reversible risk factor (e.g., within 3 months of surgery with general anesthesia, plaster cast immobilization of a leg, or hospitalization). For patients in this situation, the risk of recurrence is relatively small, approximately 3% in the first year and approximately 10% over 5 years, and only 3 months of oral anticoagulation treatment is warranted.⁹³ For VTE associated with a minor transient or reversible risk factor (e.g., within 6 weeks of initiation of estrogen therapy, air travel lasting >10 hours, pregnancy, or less marked leg injuries or immobilization) 3 months of oral anticoagulation therapy is reasonable, but some experts prefer 6 months of treatment.⁹³

Patients with unprovoked (idiopathic) VTE have a recurrence risk of approximately 10% in the first year and approximately 30% over 5 years. These patients should be considered for indefinite oral anticoagulation therapy if possible, but should receive at least 6 to

12 months of therapy.² Factors that may lead to the decision to stop oral anticoagulation therapy after 6 to 12 months include noncompliance with warfarin therapy, initial clot although idiopathic was isolated in calf veins, or a moderate to high risk of bleeding.⁹³ Risk factors for bleeding include age >65 years, previous stroke, history of bleeding (e.g., gastrointestinal), active peptic ulcer disease, renal impairment, anemia, thrombocytopenia, liver disease, diabetes mellitus, concurrent antiplatelet use, noncompliance, and the presence of a structural lesion (e.g., tumor, recent surgery) expected to be associated with bleeding. Presence of one to two bleeding risk factors suggests moderate bleeding risk while three or more risk factors suggest a high bleeding risk.⁹³

Increasingly, patients with VTE are being tested for hereditary and acquired hypercoagulable states (thrombophilia). With the exception of individuals with the antiphospholipid antibody syndrome, homozygotes for the factor V Leiden mutation, and heterozygotes with both the factor V Leiden and prothrombin 20210 gene

mutations, the presence of thrombophilia does not appear to confer a clinically important risk for VTE recurrence.⁹³ Indefinite or life-long anticoagulation therapy should be considered for those patients with recurrent VTE events or one of the thrombophilias known to impart a high life-time risk of thrombosis. Otherwise decisions regarding duration of therapy should be guided by the presence or absence of transient VTE risk factors.⁹³ The decision to continue anticoagulation therapy indefinitely should be reassessed annually. Patients should be involved in any decision to continue anticoagulation therapy with consideration given to the patient's long-term prognosis, risk of bleeding, ability to adhere to anticoagulation therapy instructions, financial resources, lifestyle, and quality of life. When the benefits of continued anticoagulation therapy no longer outweigh the risks, therapy should be discontinued.⁹³

THROMBOLYSIS AND THROMBECTOMY

Most cases of VTE require only anticoagulation therapy. In some cases, however, removal of the occluding thrombus by either pharmacologic or surgical means may be warranted.² There is a relative paucity of data supporting either thrombolysis or thrombectomy in the routine management of VTE, and more study is clearly needed to clarify their precise role.

Thrombolytic agents are proteolytic enzymes that enhance the conversion of plasminogen to plasmin which subsequently degrades the fibrin matrix. Thrombolytic therapy for DVT was once believed to improve long-term outcomes by preventing the postthrombotic syndrome. Indeed, thrombolytic therapy improves venous patency. However, clinical trials have failed to demonstrate any sustained benefit from the routine use of thrombolytic therapy and the evidence that thrombolytic therapy is superior to anticoagulation therapy alone in preventing the postthrombotic syndrome is uncertain.² Patients who present with massive DVT and limb gangrene despite anticoagulation therapy are candidates for thrombolysis (Table 21–23).² Some authorities recommend thrombolytic treatment for patients with massive iliofemoral VTE who are at low risk for bleeding. Catheter-directed instillation of a thrombolytic agent directly into the clot is increasingly being used. The risk of bleeding associated with catheter-directed drug administration appears to be less than systemic administration. Prospective clinical trials are necessary to clarify the clinical utility of catheter-directed thrombolysis in the treatment of DVT but most experts recommend against its routine use.²

In the management of acute PE, alteplase, streptokinase, and urokinase have all been shown to restore pulmonary artery patency more rapidly than UFH alone. However, this early benefit does not improve long-term patient outcomes. One week following acute treatment, clot lysis and vessel patency are similar with or without thrombolytic therapy. Thrombolytic therapy has never been shown to improve morbidity or mortality, but is associated with a substantial risk of hemorrhage.² For this reason, patients being considered for thrombolytic therapy should be screened carefully for contraindications relating to bleeding risk.⁸⁹ Admittedly, clinical trials to date have been underpowered to detect a benefit from thrombolytic therapy. The association of thrombolytic therapy with hemorrhage is particularly problematic because PE frequently occurs following a surgical procedure when the risk of bleeding is high. Given the relative lack of data to support their routine use, thrombolytic agents should be reserved for those patients with PE who are most likely to benefit (see Table 21–23). Patients who have hemodynamic compromise as evidenced by significant hypotension (systolic blood pressure 90 mm Hg or less) or severe right ventricular strain because of a large clot burden may benefit from thrombolytic therapy.² Five percent to 10% of patients diagnosed with a PE present with shock. Mortality among these patients is as high as 50%, thus justifying the risks

TABLE 21-23 Thrombolysis for the Treatment of Venous Thromboembolism

- Thrombolytic therapy should be reserved for patients who present with shock, hypotension, right ventricular strain, or massive DVT with limb gangrene
- Diagnosis must be objectively confirmed before initiating thrombolytic therapy
- Thrombolytic therapy is most effective when administered as soon as possible after PE diagnosis, but benefit may extend up to 14 days after symptom onset
- Approved PE thrombolytic regimens
 - Streptokinase 250,000 units intravenously over 30 minutes followed by 100,000 units/h for 24 hours^a
 - Urokinase 4,400 units/kg intravenously over 10 minutes followed by 4,400 units/kg/h for 12 to 24 hours^a
 - Alteplase 100 mg intravenously over 2 hours
- Factors that increase the risk of bleeding must be evaluated before thrombolytic therapy is initiated (i.e., recent surgery, trauma or internal bleeding, uncontrolled hypertension, recent stroke or intracranial hemorrhage)
- Baseline labs should include CBC and blood typing in case transfusion is needed
- UFH should not be used during thrombolytic therapy; the aPTT nor any other anticoagulation parameter should not be monitored during the thrombolytic infusion
- aPTT should be measured following the completion of thrombolytic therapy
 - If aPTT less than 2.5 times control value, UFH infusion should be started and adjusted to maintain aPTT in therapeutic range
 - If aPTT greater than 2.5 times control value, remeasure every 2 to 4 hours and start UFH infusion when aPTT is less than 2.5
- Avoid phlebotomy, arterial puncture, and other invasive procedures during thrombolytic therapy to minimize the risk of bleeding

aPTT, activated partial thromboplastin time; CBC, complete blood cell count; DVT, deep vein thrombosis; PE, pulmonary embolism; UFH, unfractionated heparin.

^aTwo hour infusions of streptokinase and urokinase are as effective and safe as alteplase.

associated with thrombolytic therapy. Although thrombolytic therapy for patients with massive PE manifested by shock and cardiovascular collapse is considered the standard of care, only one trial has demonstrated a mortality benefit.⁹⁰

A significant number of hemodynamically stable patients with PE have evidence of right ventricular dysfunction and appear to be at higher risk for recurrent PE and death when treated with heparin alone. Some experts believe that thrombolytic therapy is beneficial in patients with evidence of right ventricular dysfunction because it restores pulmonary blood flow and reduces pulmonary artery pressure. However, convincing data are lacking.⁸⁹

Although it is an uncommon choice, venous thrombectomy is a reasonable approach to remove a massive obstructive thrombus in a patient with significant iliofemoral venous thrombosis, particularly if the patient is either not a candidate for or has not responded to thrombolysis.² In cases of chronic PE—where persistent emboli produce progressive pulmonary hypertension, hypoxemia, and right-sided heart failure—surgical embolectomy offers greater benefit than anticoagulants and may be the treatment of choice if performed by an experienced surgical team.² The surgical technique has been refined over the past 20 years. The procedure uses a balloon catheter to extract the thrombus while the patient is under general anesthesia. Fluoroscopy and venography guide the procedure. Balloon angioplasty, with or without stent placement, can be used if a focal iliac vein stenosis is discovered. Full-dose anticoagulation therapy is essential during the entire operative and postoperative period. These patients need indefinite oral anticoagulation therapy targeted to an INR of 2.5 (range 2.0 to 3.0).²

VENA CAVA INTERRUPTION

Anticoagulation therapy is the accepted standard for treating DVT and PE. However, an IVC filter may be indicated in special situations when anticoagulants are ineffective or unsafe, including in (a) patients with an absolute contraindication to anticoagulation

therapy because of active bleeding or anticipated bleeding from a predisposing lesion; (b) patients with a massive PE who survives but in whom recurrent embolism might be fatal; and (c) patients who have recurrent VTE despite adequate anticoagulation therapy.² Interruption of the IVC can be accomplished with an occlusive filter, often called a Greenfield filter, inserted percutaneously through the femoral or jugular vein and advanced into place using fluoroscopic guidance, usually below the renal veins. There is little evidence to support the widespread use of vena cava filters. Vena cava filters reduce the risk of PE in the short-term, but also appear to increase the long-term risk for recurrent DVT presumably as a consequence of the accumulation of thrombus on the filter, which may partially occlude the vena cava, resulting in venous stasis.² Data from the International Cooperative Pulmonary Embolism Registry have documented a reduction in 90-day mortality associated with IVC filters, but this observation was not confirmed in a randomized study of filter placement where all patients were treated with anticoagulants.^{2,89} Whether patients with permanent IVC filters should receive anticoagulant therapy remains unresolved but many clinicians opt to resume warfarin therapy as soon as possible and continue it indefinitely.² Given these concerns, retrievable filters that can be removed after the period of greatest risk for PE have been developed and have been suggested for use in patients with transient contraindications to anticoagulation therapy.⁸⁹

ANCILLARY THERAPY

In addition to anticoagulant therapy for patients with proximal DVT, wearing graduated compression stockings can reduce the risk of developing the postthrombotic syndrome by as much as 50%.⁹⁴ To be effective, graduated compression stockings must fit properly and provide adequate pressure at the ankle (30 to 40 mm Hg). The discomfort associated with wearing properly fitted stockings along with the expense and unflattering cosmetic appeal makes routine use of compression stockings undesirable for many patients.

During the acute phase of DVT, antiembolic leg exercise may also be useful. To perform the exercise, patients should elevate the legs above the hips (7° to 10°) with feet supported. The patient then flexes one foot at a time back and forth for 3 to 5 minutes or until the calf muscle group is fatigued. This exercise should be repeated 4 to 6 times daily. Patients should also be instructed not to remain in a sitting position for more than 20 minutes without ambulating briefly or stretching the leg for a few minutes.

Strict bedrest was traditionally recommended following acute DVT based on the assumption that leg movement would dislodge the clot, resulting in PE. However, the evidence contradicts this assumption. Ambulation in conjunction with graduated compression stockings results in faster reduction in pain and swelling with no apparent increase in the rate of clot embolization.⁹⁵ Patients should be encouraged to ambulate as much as their symptoms permit. If pain and swelling increase with ambulation, the patient should be instructed to lie down and elevate the affected leg until symptoms subside.

TREATMENT OF VENOUS THROMBOEMBOLISM IN SPECIAL POPULATIONS

Pregnancy

The use of anticoagulation therapy for the treatment of DVT or PE in pregnant women is common.²⁷ UFH and LMWH are the preferred anticoagulants for use during pregnancy (Table 21–24). They do not cross the placenta and evidence suggests they are safe for the fetus.²⁷ Warfarin should be avoided because it crosses the placenta and can produce fetal bleeding, central nervous system abnormalities, and embryopathy. The direct thrombin inhibitors also cross the

TABLE 21-24 Unfractionated and Low-Molecular-Weight Heparin Use during Pregnancy

Acute treatment	LMWH
	<ul style="list-style-type: none"> • Enoxaparin 1 mg/kg SC q 12 h or 1.5 mg/kg q 24 h or • Dalteparin 100 U/kg SC q 12 h or 200 U/kg q 24 h or • Tinzaparin 175 U/kg SC q 24 h
Long-term treatment ^b	or UFH
	<ul style="list-style-type: none"> • Initiate using weight-based intravenous therapy and adjust dose to achieve therapeutic anti-Xa level for at least 5 days • Transition to SC adjusted-dose UFH administered q 8–12 h with midinterval anti-Xa activity in the therapeutic range^a
	LMWH
	Maintain initial LMWH dose regimen throughout pregnancy or Alter LMWH dose in proportion to any weight change (usually gain) or Obtain monthly anti-Xa level measurements 4 to 6 hours after morning dose and adjust LMWH dose based on anti-Xa level (target = 0.5 to 1.2 units/mL if twice daily dosing; 1.0 to 2.0 units/mL if once-daily dosing)
Issues at time of delivery	or UFH
	Obtain monthly anti-Xa level at the midpoint of the dosing interval and adjust UFH dose to achieve an anti-Xa level of 0.3 to 0.7 units/mL
	Elective induction of labor
	<ul style="list-style-type: none"> • Discontinue UFH or LMWH 24 hours prior to induction • Initiate therapeutic doses of UFH by IV infusion and discontinue 4 to 6 hours prior to expected time of delivery if risk of recurrent VTE is deemed high
	Spontaneous labor
	<ul style="list-style-type: none"> • For LMWH, if there is a reasonable expectation that significant anticoagulant effect will be present at time of delivery (a) epidural should be avoided, and (b) reversal with protamine sulfate may be considered • For UFH, monitor the aPTT and reverse with protamine sulfate if aPTT is prolonged near the time of delivery
	Postpartum
	<ul style="list-style-type: none"> • Commence UFH or LMWH as soon as safely possible (usually 12 hours following delivery) • Concurrently initiate warfarin therapy and discontinue UFH or LMWH when the INR is 2.0 or greater • Continue anticoagulants for at least 4 weeks following delivery • Warfarin can be safely used by women who are breast-feeding

placenta. To date, fondaparinux has not been formally evaluated in pregnant patients.

Long-term UFH therapy has been linked to significant bone loss and osteoporosis, requires multiple daily injections, and must be monitored frequently (every 1 to 2 weeks) throughout pregnancy. Because of these limitations, many experts recommend the use of LMWH over UFH throughout pregnancy.²⁷

Pediatric Patients

Although seen far more frequently in adults, VTE in children has become increasing common secondary to prematurity, cancer, trauma,

surgery, congenital heart disease, and systemic lupus erythematosus. Children often develop DVTs associated with an indwelling central venous catheter. In contrast to adults, children rarely develop idiopathic VTE.²⁸

Anticoagulation with UFH and warfarin remains the most frequently used approach for the treatment of VTE in pediatric patients. The recommended target aPTT and INR ranges as well as the duration of therapy are extrapolated from clinical trials in adults. The recommended initial bolus dose of UFH is 75 to 100 units/kg given intravenously over 10 minutes followed by a maintenance infusion of 28 units/kg/h for infants 2 to 12 months of age and 20 unit/kg/h for children age 1 year or older. Subsequent adjustments should be made every 4 to 6 hours to maintain the aPTT within the institution-specific therapeutic range. The usual warfarin starting dose is 0.2 mg/kg with a maximum of 10 mg.²⁸ Infants require higher doses of warfarin per kg to maintain a target INR of 2.0 to 3.0 compared to teenagers and adults (mean dose 0.33 mg/kg, 0.09 mg/g, and 0.04 to 0.08 mg/kg, respectively). The INR target range is 2.0 to 3.0. Frequent INR monitoring and warfarin dose adjustments are typically required. When compared to adults, only 10% to 20% of pediatric patients can be safely monitored once monthly. Obtaining coagulation monitoring tests in pediatric patients is problematic because many have poor or nonexistent venous access. To address this problem, many clinicians recommend using fingerstick blood samples with a portable point-of-care monitor. Because LMWHs have low drug-interaction potential, are less likely to cause HIT or osteoporosis, and require less-frequent laboratory testing, they are an attractive alternative in pediatric patients.²⁸ Enoxaparin, dalteparin, tinzaparin, and reviparin have been evaluated in pediatric patients. Most experts recommend that anti-Xa activity be monitored and the dose adjusted to maintain antifactor Xa levels between 0.5 and 1.0 units/mL. Compared to adults, children younger than 2 to 3 years of age or who weigh less than 5 kg have higher perikilogram dose requirements to achieve a “therapeutic” response. The doses of LMWH for older children are generally similar to the weight-adjusted doses used in adults.²⁸ Warfarin can be initiated concurrently with UFH or LMWH therapy. Therapy should be overlapped for a minimum of 5 days and until the INR is therapeutic. Warfarin should be continued for at least 3 months. Thrombolysis and thrombectomy have been successfully employed in pediatric patients but published data are very limited.

Patients with Cancer

VTE is a frequent complication of malignancy. Furthermore, compared to patients without cancer, the rate of recurrent VTE in patients with cancer is threefold higher and the risk of bleeding is two- to sixfold higher.³⁴ Warfarin therapy in cancer patients is often complicated by drug interactions (e.g., chemotherapy and antibiotics) and the need to frequently interrupt therapy for invasive procedures (e.g., thoracentesis, percutaneous biopsies, and abdominal paracentesis). Maintaining stable INR control is more difficult in this patient population because of nausea, anorexia, and vomiting.³⁴

CLINICAL CONTROVERSY

Evidence suggests that LMWH administered for 3 to 6 months after a DVT or PE is more effective than warfarin in preventing recurrent VTE events in patients with cancer. Despite the fact that current consensus guidelines recommend the use of a LMWH over warfarin for the long-term treatment of VTE in cancer patients, many practitioners still prefer the use of warfarin in these patients.

Randomized trials provide evidence that long-term LMWH therapy for VTE in cancer patients significantly decreases the rate of

recurrent VTE without increasing bleeding risks compared to traditional therapy with oral anticoagulants.³⁴ In one relatively small study in cancer patients with VTE, fixed-dose SC enoxaparin for 3 months appeared to be more effective than conventional warfarin therapy, with only 10.5% of enoxaparin-treated patient compared to 21% of warfarin-treated patients reaching the composite outcome of major bleeding and recurrent VTE ($p = 0.09$).³⁶ In the Comparison of LMWH versus Oral Anticoagulation Therapy for the Prevention of Recurrent Venous Thrombosis (CLOT) trial, continuous treatment with dalteparin for 6 months (200 units/kg SC every day for 1 month followed by 150 units/kg every day thereafter) was compared to conventional therapy with dalteparin followed by warfarin in cancer patients following an acute VTE.⁹⁷ The probability of recurrent VTE was reduced by nearly 50% in the long-term dalteparin treatment group, from 17.4% to 8.8% ($p = 0.0017$). There was no difference in the rate of major bleeding. Although this provides compelling data that cancer patients should be given LMWH instead of warfarin for the long-term treatment of VTE, the economic implications of this strategy have not yet been evaluated. In the absence of insurance coverage to offset the relatively high cost of long-term LMWH therapy, most patients are unable to afford it.

For patients with VTE and cancer who do receive LMWH, therapy should continue for at least the first 3 to 6 months of long-term treatment, at which time further LMWH can be considered or warfarin therapy can be substituted.² Anticoagulation therapy should continue for as long as the cancer is “active” and while the patient is receiving antitumor therapy.³⁴ A risk-to-benefit assessment should be performed on a regular basis and the overall clinical status of the patient should be considered, along with the risk for bleeding, quality of life, and life expectancy.³⁴ Many patients with terminal cancer receiving palliative care prefer LMWH over warfarin.⁹⁸ Consideration should be given to stopping anticoagulant therapy even in the presence of active cancer for patients who are at very high risk of bleeding complications.⁹³

PHARMACOECONOMIC CONSIDERATIONS

Hospitalization is the main cost driver in the management of VTE.⁸⁸ Although the drug acquisition cost for the LMWHs and fondaparinux are substantially higher than UFH, avoiding hospitalization dramatically decreases the overall costs of DVT treatment. A number of cost-effectiveness analyses using decision modeling suggest that the treatment of DVT with LMWHs is more cost effective than the treatment with UFH in both inpatient and outpatient settings.⁹⁹ Based on this decision model, the LMWHs will reduce overall healthcare cost if as few as 8% of patients are treated entirely on an outpatients basis or 13% of patients are discharged from hospital early.

Despite the substantial cost savings stemming from outpatient DVT treatment from the perspective of the insurer, the reality is that some patients are unable to afford LMWH or fondaparinux prescriptions and are therefore denied outpatient treatment. The results of a recent study may provide a therapeutic option for patients in this situation. The objective of this trial was to determine if fixed-dose, weight-adjusted, subcutaneous UFH is as effective and safe as LMWH for the treatment of VTE.²³ Eligible patients were randomized to receive either UFH administered subcutaneously as an initial dose of 333 units/kg, followed by a fixed dose of 250 units/kg every 12 hours or a weight-based dose of LMWH. Both treatments could be administered at home and both were overlapped with warfarin therapy in the traditional manner. End points included recurrent VTE within 3 months and major bleeding within 10 days of study entry. The groups did not differ significantly in either of the study end points and treatment was administered completely at home in 72% of the UFH group and in 68% of the LMWH group. Further evidence is required to confirm these results; however, this lower cost

option may facilitate the outpatient treatment of VTE for selected patients who otherwise would not have been able to afford it.

HEPARIN-INDUCED THROMBOCYTOPENIA

HIT is an uncommon but extremely serious adverse effect associated with heparin use.²⁶ The immune-mediated platelet activation and thrombin generation seen during HIT can lead to severe and unusual thrombotic complications. Morbidity and mortality associated with HIT is disturbingly high—up to 50% of patients who develop the disorder will suffer a thrombotic complication or die within 30 days in the absence of treatment. The diagnosis of HIT is based on laboratory findings that confirm heparin antibody formation and platelet activation (Table 21–25). To prevent the thrombotic complications associated with HIT, prompt discontinuation of heparin and initiation of an alternative anticoagulant therapy is imperative.

ETIOLOGY AND PATHOPHYSIOLOGY OF HIT

Two types of thrombocytopenia associated with heparin use have been described.¹⁰⁰ As many as 25% of patients receiving heparin therapy develop a benign, mild reduction in platelet counts referred to as non-immune-mediated heparin-associated thrombocytopenia (previously called HIT type 1). HAT produces a transient fall in platelet count that occurs early, typically between days 2 and 4, during the course of therapy. The degree of thrombocytopenia is usually mild, with platelet counts rarely going below 100,000. It is not necessary to discontinue heparin therapy in these patients as platelet counts generally rebound to baseline values despite continued use. The exact mechanism of HAT is unknown; however, it may be the result of platelet aggregation, a dilutional effect, or diminished platelet production often seen in acutely ill patients. No clinical sequelae are associated with this benign phenomenon.

The second type of thrombocytopenia associated with heparin use is known as immune-mediated HIT (formally known as HIT type 2).^{38,100} HIT is a severe pathologic adverse effect of heparin with a significant potential to cause thrombotic complications (see Table 21–25). The time course and magnitude of thrombocytopenia associated with HIT differs from that of HAT. Platelets counts typically begin to fall days 5 to 10 following initiation of heparin and reach a nadir by days 7 to 14. The development of thrombocytopenia

can be delayed (delayed-onset HIT) up to 20 days, and begin several days after heparin has been stopped in patients naive to heparin therapy. Conversely, so-called rapid-onset HIT can occur rapidly and abruptly (within 24 hours following heparin initiation) in patients with a recent exposure to heparin (i.e., previous 3 months).²⁶ Platelet counts commonly fall below 150,000 mm³ but rarely nadir as low as 20,000 mm.³ In some cases, overt thrombocytopenia may not occur, but a drop in platelet count greater than 50% from baseline is considered indicative of HIT.

The frequency of immune-mediated HIT is most powerfully related to the duration and type of heparin used and to a lesser extent the dose and route of administration.^{26,38} The incidence of HIT associated with intravenous full dose UFH given for prolonged periods is significantly higher than that of low-dose subcutaneous UFH or LMWHs. The estimated overall incidence of HIT after 5 days of UFH use is 1% to 3% but the cumulative incidence may be as high as 6% after 14 days of continuous intravenous use. The incidence of HIT with low dose subcutaneous UFH in medical patients has been reported to be approximately 1%.¹⁰¹ Low-molecular-weight heparins are associated with a significantly lower risk of HIT (<1%).²⁶ The incidence of HIT is higher with bovine UFH versus porcine UFH. In addition, the HIT risk varies with the exposed patient population: surgical patients > medical patients > pregnant patients.^{26,102}

The pathogenesis of HIT involves an immunoglobulin mediated response to the heparin molecule leading to platelet activation and thrombin generation (Fig. 21–11).^{38,100} With platelet activation there is release of PF-4 from platelet granules. Heparin binds to PF-4 forming a negatively charged polysaccharide molecule that is highly antigenic and stimulates the production of immunoglobulin (Ig) G antibodies. Although heparin-induced antibody formation occurs in 10% to 20% of patients treated with heparin, the vast majority of these patients never develop HIT. In patients who develop HIT, the heparin–PF-4–IgG complexes bind to the Fc receptor on platelets, leading to further platelet activation and the release of PF-4 and procoagulant microparticles from platelet granules. In addition, PF-4 and heparin-like molecules bind to the surface of endothelial cells resulting in antibody-induced endothelial cell damage and the release of tissue factor. The net result of this cascade of events is an increased risk of thrombotic events secondary to platelet activation, endothelial damage, and thrombin generation despite moderate to severe thrombocytopenia. Antibodies to the heparin/PF-4 complex are transient, and they have been reported to disappear from the circulation within a median of 85 days.^{26,38}

CLINICAL PRESENTATION AND DIAGNOSIS OF HIT

Thrombotic complications are the most common clinical sequelae of HIT (see Table 21–25).^{26,38} The incidence of thrombosis can be as high as 50% in those patients with laboratory-confirmed immune-mediated thrombocytopenia. Thrombosis may occur in patients with seemingly mild thrombocytopenia but platelet counts invariably have dropped more than 50% from baseline. This syndrome is poorly recognized and many, perhaps most, patients diagnosed with HIT initially presented with thrombosis. Even among those who are diagnosed prior to the development of thrombosis, the prognosis is poor. In patients diagnosed with HIT without thrombosis and managed only by discontinuation of UFH, the risk of symptomatic thrombosis is 25% to 50%, and fatal thrombosis is 5%.^{26,38}

The thrombotic risk is 30 times higher in patients with HIT as compared to control populations.¹⁰¹ Venous thrombosis is the most common thrombotic complication associated with HIT and the majority of patients develop proximal DVT. PE occurs in 25% of patients with thrombotic complications and contributes signifi-

TABLE 21-25 Presentation of Heparin-Induced Thrombocytopenia

General

Venous thromboembolism is the most common presentation of heparin-induced thrombocytopenia (HIT), although arterial events (e.g., myocardial infarction, stroke) can occur. HIT should be suspected if a patient develops a deep vein thrombosis or pulmonary embolism while or soon after receiving unfractionated heparin.

Symptoms and signs

Thromboembolic events secondary to HIT produce the same signs and symptoms as those of other etiologies (see Presentation of Deep Venous Thrombosis and Pulmonary Embolism).

Laboratory tests

The patient's platelets count will typically be below 150,000/mm³ or drop more than 50% from baseline. The platelet count usually drops after 5 to 10 days of unfractionated heparin therapy, but may drop sooner if the patient has received heparin in the past 3 months.

Other diagnostic tests

An enzyme-linked immunoabsorbent assay (ELISA) for the presence of antibodies to the heparin–PF4 complex should be performed to confirm the diagnosis. Functional assays, including the heparin-induced platelet activation assay (HIPAA), the serotonin release assay (SRA), or the platelet-aggregation assay (PAA), may also be performed to confirm the diagnosis.

FIGURE 21-11. Pathogenesis of heparin-induced thrombocytopenia. (IgG, immunoglobulin G; PF4, platelet factor-4.)

cantly to mortality. Arterial thrombosis occurs less commonly.^{26,100} Limb artery occlusion, stroke, and myocardial infarction are the most commonly reported arterial events. HIT has also been linked with atypical manifestations such as skin necrosis, venous limb gangrene, and anaphylactic-type reactions after IV bolus of UFH. Heparin-induced skin lesions occur in 10% to 20% of patients with HIT. Lesions range from painful, localized erythematous plaques to widespread dermal necrosis. Amputation in such cases is frequently required. Mortality from HIT may be as high as 50% in patients with acute thrombosis. The relatively high frequency of thrombotic complications and poor outcomes associated with HIT emphasize the need for prompt recognition and diagnosis.^{26,38}

The diagnosis of immune-mediated HIT is made based on clinical findings supplemented by laboratory tests confirming the presence of antibodies to heparin or platelet activation induced by heparin.^{26,38} While thrombocytopenia is the most common initial event suggesting the diagnosis of HIT, clinicians should evaluate all the potential causes. New thrombosis shortly after the development of thrombocytopenia is a distinguishing feature in nearly half of all patients with HIT. The time course and magnitude of thrombocytopenia are the features distinguishing immune-mediated HIT from HAT. Acute thrombosis and skin lesions may also occur prior to the development of overt thrombocytopenia. HIT should immediately be suspected when these events occur in any patient on UFH or LMWH therapy.^{26,38}

Laboratory testing must be performed to confirm the diagnosis of HIT.^{26,100,103} Laboratory testing is very helpful in patients with only mild to moderate thrombocytopenia in whom HIT is suspected. Two types of assays are available to detect the presence of heparin antibodies. Platelet activation assays, also known as functional assays, confirm *in vitro* platelet activation in the presence of therapeutic heparin levels. Functional assays include the heparin-induced platelet-activation assay, the serotonin release assay, and the platelet-aggregation assay. The heparin-induced platelet-activation assay and serotonin release assay tests have higher sensitivity and specificity

than the platelet-aggregation assay but are technically more difficult to perform. Antigen assays that detect the presence of specific antibodies against the heparin–PF-4 complex using enzyme-linked immunosorbent assays are also available. These tests have reasonably high sensitivity and specificity. The optimal test for laboratory confirmation of immune-mediated HIT is unclear. The most readily available test with the greatest sensitivity and specificity should be used. The combined use of functional and enzyme-linked immunosorbent assays may reduce false-negative results. When results of one test are negative or indeterminate in patients suspected of HIT, another test should be considered.

GENERAL APPROACHES TO THE TREATMENT OF HIT

The goal of therapy in patients with HIT is to reduce the thrombosis risk by decreasing thrombin generation and platelet activation. The ACCP Consensus Conference on Antithrombotic Therapy has established recommendations for the treatment of HIT.²⁶ Once the diagnosis of HIT is established or strongly suspected, *all* sources of heparin, including heparin flushes, should be discontinued and an alternative anticoagulant agent should be initiated (Fig. 21-12).^{26,38} Even in the absence of thrombosis, patients with HIT are at extremely high risk for developing serious thrombotic complications without treatment. Because the time required for diagnostic laboratory results to be reported can be prolonged, it is crucial that alternate anticoagulant agents be initiated in a timely fashion to prevent new thrombosis. Anticoagulant agents that rapidly inhibit thrombin activity and are devoid of significant cross-reactivity with heparin–PF-4 antibodies are the drugs of choice for the management of HIT (Table 21-26).^{26,38} In cases of severe or life-threatening thrombosis, surgical extraction of thrombi may be required. Limited data exists regarding the use of thrombolytic therapy (see Table 21-23) in severe HIT with thrombosis. The use of warfarin for long-term anticoagulation in patients with HIT and thrombosis

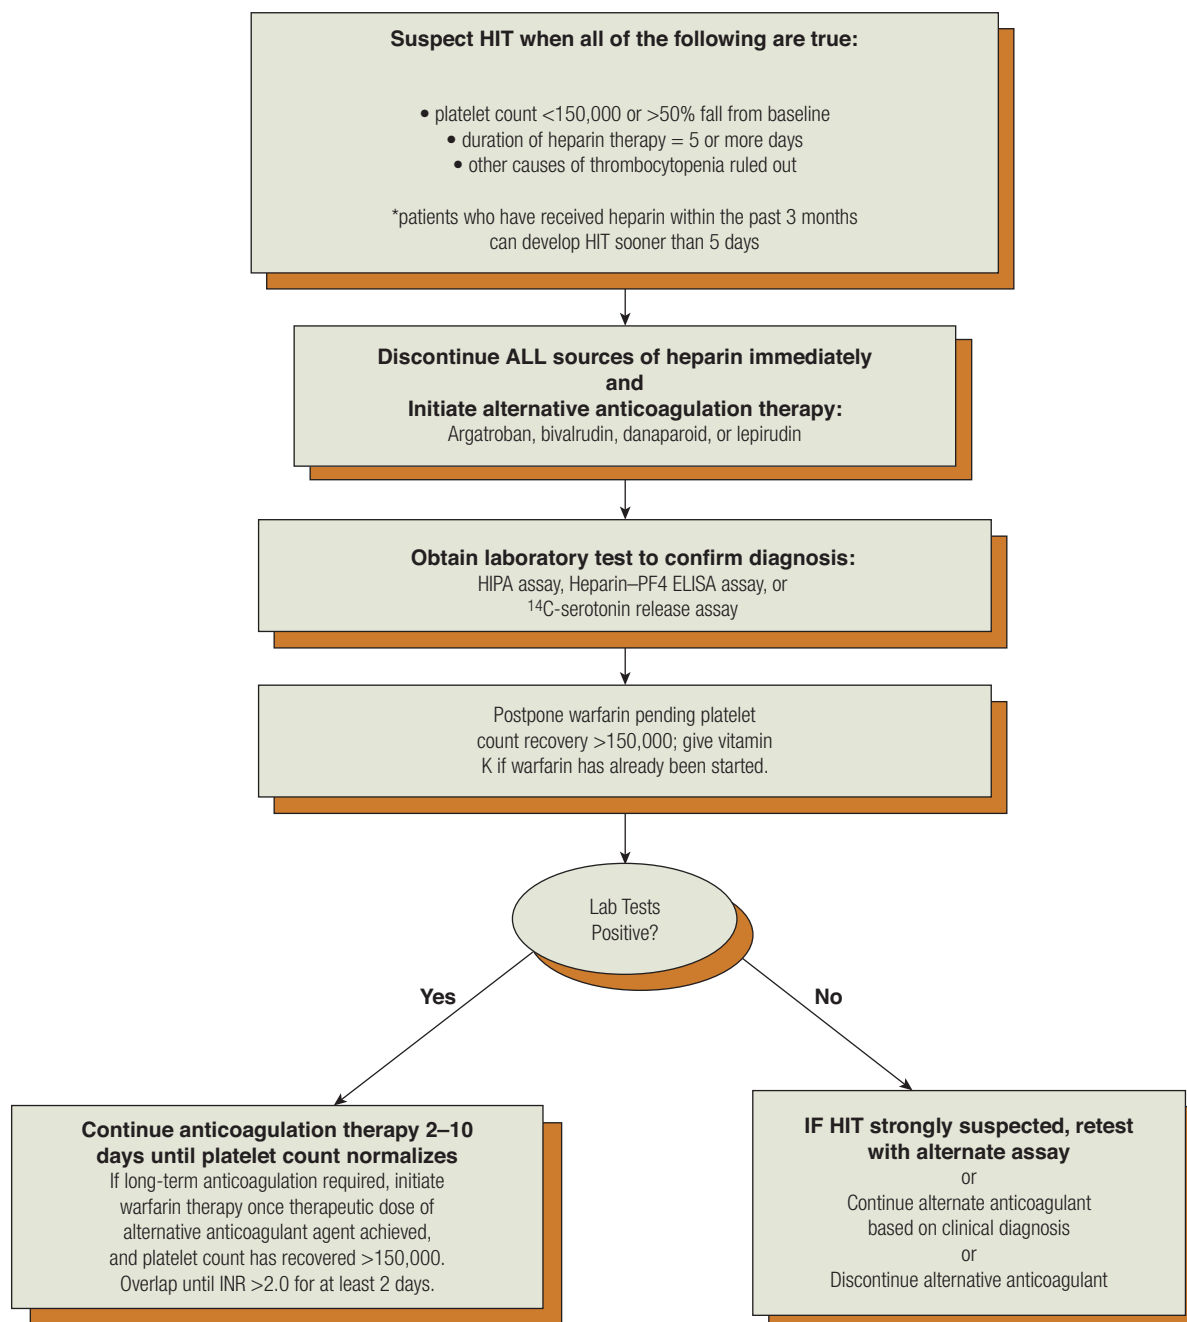

FIGURE 21-12. Treatment of heparin-induced thrombocytopenia (HIT). (HIPA assay, heparin-induced platelet activation assay; ELISA, enzyme-linked immunosorbent assay; INR, international normalized ratio.)

is recommended, but warfarin should only be initiated after substantial platelet count recovery has been documented (e.g., >150,000/mm³). In addition, great care with dosing must be taken when initiating warfarin in these patients, as the risk of inducing further thrombosis secondary to inhibition of proteins C and S is possible.²⁶

PHARMACOLOGIC TREATMENT OPTIONS

DTIs are the drugs of choice for the treatment of HIT with or without thrombosis (see Table 21–26).²⁶ Three DTIs are currently available in the United States for the treatment of patients with HIT—lepirudin, argatroban, and bivalirudin—but only the first two are FDA approved for this indication. For the treatment of HIT, lepirudin and argatroban are administered by intravenous infusion and should be titrated based on aPTT testing. The comparative efficacy of these agents has not been formally evaluated, and they are considered

equally suitable for the initial treatment of HIT. Some clinicians prefer argatroban because it has a shorter half-life, modest bleeding risk, and lower cost when compared to lepirudin.¹⁰⁴ Because of a short-half life, low immunogenicity, minimal effect on INR, and enzymatic metabolism, bivalirudin appears to be a promising alternative for treatment of HIT. However, to date efficacy data is only based on case series.⁴³ Given fondaparinux is devoid of in vitro cross-reactivity to HIT antibodies, does not interfere with PT/INR measurement, and has enjoyed favorable experience in HIT in a few case reports, it is a promising alternative for the management of HIT.¹⁰⁵ Patient-related factors, such as the presence of renal or hepatic dysfunction, drug-specific features such as prior exposure to lepirudin, as well as institutional preference, availability, and cost should be used to determine the most appropriate agent. The LMWHs are not recommended for use in HIT because they have nearly 100% cross reactivity with heparin-antibodies by in vitro testing.^{26,38}

TABLE 21-26 Recommended Dose and Monitoring Parameters for Direct Thrombin Inhibitors to Treat Heparin-Induced Thrombocytopenia

Agent	Dose	Monitoring Parameters	Clinical Considerations
Lepirudin	0.4 mg/kg (up to 110 kg) slow IV bolus ^a (can also be given without bolus), followed by 0.15 mg/kg/h (up to 110 kg) IV infusion ^b	Obtain baseline PT, aPTT, CBC, S _{cr} . Check aPTT 2 hours after initiation and each dose change and adjust dose to achieve aPTT 1.5–2.5 times control. Once stable, monitor aPTT q 12 h.	Dose must be reduced in patients with renal impairment; avoiding the bolus dose may reduce the risk of accumulation and may reduce the risk of anaphylaxis; antithrombin antibodies can occur in 40%–60% of patients and can lead to reduced clearance. Concomitant warfarin requires dose adjustment.
Argatroban	2 mcg/kg/min continuous IV infusion (no bolus); maximum infusion 10 mcg/kg/min	Obtain baseline PT, aPTT, CBC. Monitor aPTT 2 hours after initiation and each dose change and adjust dose to achieve aPTT of 1.5–3 times control (maximum 100 s).	Dose reduction is necessary for those patients with hepatic impairment and in critically ill; will cause significant elevation in PT/INR; concurrent warfarin therapy requires special management (when INR >4, argatroban therapy should be withheld and the INR rechecked to determine if it is therapeutic).
Bivalirudin	0.15–0.20 mg/kg/h IV infusion (no bolus); approved dose for PCI: 0.75 mg IV bolus, followed by 1.75 mg/kg/h infusion up to 4 hours	Obtain baseline PT, aPTT, CBC, S _{cr} . Check aPTT 2 hours after initiation and adjust dose to achieve aPTT 1.5–2.5 times control.	Not FDA approved for treatment of HIT.

aPTT, activated partial thromboplastin time; CBC, complete blood cell count; HIT, heparin-induced thrombocytopenia; INR, international normalized ratio; IV, intravenous; PCI, percutaneous coronary intervention; PT, prothrombin time; S_{cr}, serum creatinine.

^aBolus dose is not advised in patients with renal impairment.

^bDose in isolated HIT: no bolus, 0.1 mg/kg/h infusion with aPTT adjusted to 1.5–2.0 times control.

The use of warfarin during the initial treatment of HIT is potentially dangerous.^{26,38} The rapid reduction in protein C concentrations induced early in the course of warfarin therapy further increases the risk thrombosis in patients with HIT. This concern is supported by the observation that several patients with HIT have developed venous limb gangrene and warfarin-induced skin necrosis when treated with warfarin. Patients with venous limb gangrene had relatively high INRs after the initiation of warfarin therapy and presumably had rapid depletion of protein C but persisting thrombin generation. Therefore, warfarin is contraindicated as monotherapy for the initial treatment of patients diagnosed with HIT. However, patients with HIT and thrombosis requiring long-term anticoagulation can be treated with warfarin if therapy is appropriately timed and carefully initiated. A conservative approach is to withhold warfarin until the patient is stabilized and platelet counts have substantially recovered at least above 100,000 mm³, and preferably above 150,000 mm³. If warfarin has already been initiated when HIT is diagnosed, reversing therapy with vitamin K (5 to 10 mg either IV or oral) is recommended. This may prevent the development of further thrombotic adverse events caused by protein C depletion. Warfarin can be reinitiated once platelet counts have been recovered (>150,000 mm³) but it should be overlapped with a direct thrombin inhibitor for a minimum of 5 days and until the full anticoagulant effect of warfarin has been achieved (i.e., INR within the therapeutic range for at least 2 consecutive days). Initial doses of warfarin greater than 5 mg should be strictly avoided in these patients.^{26,38}

The management of pregnant patients with a history of HIT whom requires anticoagulation therapy presents a challenge. Both UFH and LMWH are the anticoagulants of choice for pregnant patients requiring anticoagulation therapy.²⁷ Women who develop HIT during pregnancy or who have a recent history of HIT (e.g., less than 3 months) cannot use UFH or LMWH safely. Limited evidence exists for the use of DTIs in pregnancy. Lepirudin is known to cross the placenta, however case reports suggest it may be safe for the management of HIT with thrombosis in pregnancy.¹⁰⁶ Danaparoid, a low-molecular-weight heparinoid not available in the United States, does not cross the placenta and it has also been investigated as a potential anticoagulant option in pregnant patients with HIT.²⁷ Limited case reports suggest that fondaparinux may also be a future potential alternative in pregnant patients.¹⁰⁷

EVALUATION OF THERAPEUTIC OUTCOMES

The appropriate duration of therapy in patients with HIT will depend on whether the patient had a thrombotic event. Patients with HIT without thrombosis should be continued on therapeutic doses of an alternative anticoagulant agent until the platelet counts have normalized. Platelet counts should be monitored frequently, and patients should be watched closely for the development of new thrombosis after starting an alternate anticoagulant. Patients with thrombosis, either at the time of presentation or following the diagnosis of HIT, should receive therapy with an alternative anticoagulant such as lepirudin or argatroban followed by a transition to warfarin after the platelet count has recovered to >150,000 mm³. Warfarin therapy is usually continued for at least 6 months, or longer if indicated. The initial anticoagulant used should be continued until the INR is stable and therapeutic for more than two consecutive days. In addition, it is important to clearly document the occurrence of immune-mediated HIT in the patient's medical record and educate the patient regarding this adverse effect. Future use of UFH, particularly in the next 3 to 6 months, should be strictly avoided. As PF-4–heparin antibodies are transient and usually cleared within 3 months, patients with a history of HIT should be tested for HIT antibodies prior to any future use of UFH. Although there are few data regarding the use of UFH in patients with a remote history of HIT, these patients should receive alternative anticoagulant agents for most indications until more rigorous data are available.^{26,38}

NATIONAL QUALITY INITIATIVES

Venous thromboembolism is the most common preventable cause of hospital death in the United States and nearly two-thirds of all VTE events are related to hospitalization.² Furthermore, PE is the third most common cause of hospital-related deaths in the United States (300,000 fatalities annually). Survivors of VTE are at-risk for recurrence and other serious long-term complications, including post-thrombotic syndrome and chronic pulmonary hypertension. The estimated annual direct medical costs of managing the disease are well over \$1 billion. Although VTE is often clinically silent, with as many as 25% of cases presenting as sudden death from PE, needless mortality and morbidity occur as a result of underdiagnosis and underuse of

TABLE 21-27 Organizations Monitoring Quality Care

The Joint Commission <i>www.jointcommission.org</i> A not-for-profit healthcare accreditation organization that issues performance-based standards and assesses organizational compliance to improve patient safety and quality of care.
Leapfrog Group <i>www.leapfroggroup.org</i> An initiative of healthcare purchasing organizations seeking improvements in safety, quality, and affordability of healthcare, with funding from the Business Roundtable, Robert Wood Johnson Foundation, and member organizations.
National Quality Forum <i>www.qualityforum.org</i> A not-for-profit that develops and implements national strategies for healthcare quality measurement and reporting.

prophylaxis. Despite the fact that several clinical interventions are known to be effective in preventing and treating VTE, only one-third of all patients who are at risk for VTE and who are appropriate candidates actually receive prophylaxis.¹⁰⁸ Although preventing VTE is a significant patient safety issue, there is little public awareness of the life-threatening nature of DVT and PE. A survey conducted on behalf of the American Public Health Association suggests that 75% of Americans have little or no awareness of DVT, and less than one-half of respondents could identify any risk factors associated with its development.¹⁰⁹ Recognizing the lack of public awareness, several organizations have focused on increasing consumer knowledge of the risks, signs, and symptoms of VTE through increased media visibility.

Given the number and variety of clinical conditions or circumstances that place individuals at risk for VTE, improvements in VTE prevention and care have the potential to benefit many patients. Over the past decade, the focus on quality health care has been emphasized by the call to accountability through the Joint Commission’s Agenda for Change, the Institute of Medicine’s report on medical errors, the National Quality Forum’s endorsed safe practices, the Leapfrog Group, and the demand for value by healthcare consumers (Table 21–27).^{108,110} Despite widespread national efforts to educate healthcare professionals about VTE prevention and treatment and the publication of numerous clinical guidelines, VTE prevention measures are not widely or consistently used. Therefore, wide variation in the prevention and treatment of VTE persists. Given the mortality and morbidity attributed to VTE, the need for standards of care is compelling. The National Quality Forum (NQF) is developing national consensus standards for VTE prevention and treatment that will be applicable to a variety of healthcare settings.¹⁰⁸ The outcomes of this effort will provide a framework for measuring the effective screening, prevention, and treatment of VTE. NQF’s recommendations include developing organizational policies that address staff education, treatment protocols, and adherence measurements to improve VTE prevention in the hospital. The ultimate goal of the NQF consensus standards is to facilitate early promulgation of VTE policies, risk assessment, prophylaxis, diagnosis and treatment services as well as patient education and organizational accountability. To that end, the Joint Commission is developing performance measures to enforce the NQF’s recommendations.^{108,110} Four major domains have been identified: risk assessment, prevention, diagnosis, and treatment. Ten proposed measures have been selected for testing using a multiphased testing approach (Table 21–28).

Hopefully, through the concerted efforts of government and accrediting agencies working with hospitals and other healthcare institutions, the incidence of DVT and PE will begin to fall. Systematic approaches to this problem are needed at every level, starting with increased public and health practitioner awareness, continuing with the uniform use of effective prophylactic strategies in patients at risk, and concluding with greater accountability with precise quality measurements.

TABLE 21-28 The Joint Commission’s Proposed Performance Measures for the Prevention and Treatment of Venous Thrombosis

Number	Description of Proposed Performance Measure
1	Documentation of Venous Thromboembolism Risk Assessment/Prophylaxis within 24 Hours of Hospital Admission
2	Documentation of Venous Thromboembolism Risk Assessment/Prophylaxis within 24 Hours of Transfer to ICU
3	Documentation of Inferior Vena Cava Filter Indication
4	Venous Thromboembolism Patients with Overlap of Parenteral and Warfarin Anticoagulation Therapy
5	Venous Thromboembolism Patients Receiving Unfractionated Heparin with Platelet Count Monitoring
6	Venous Thromboembolism Patients with Renal Insufficiency that Received Reduced/Discontinued Anticoagulation Therapy
7	Venous Thromboembolism Patients Receiving Unfractionated Heparin Management by Nomogram/Protocol
8	Venous Thromboembolism Discharge Instructions
9	Venous Thromboembolism Patients with International Normalized Ratio >6 After Initiation of Warfarin Therapy
10	Incidence of Potentially Preventable Hospital-Acquired Venous Thromboembolism

From The Joint Commission.¹¹⁰

CLINICAL CONTROVERSY

For the treatment of an acute VTE, LMWHs should be dosed based on the patient’s actual (or total) body weight. Efficacy and safety data from clinical trials indicate that obese patients should be given full therapeutic doses based on the patient’s actual (or total) body weight are used. Dose adjustments or dosing “caps” are not recommended in obese patients. Despite these data, some clinicians only use LMWH doses up to 150 mg (or 150 international units) per dose even if the patient’s actual body weight is higher than 150 kg.

ABBREVIATIONS

SUSAN C. FAGAN AND DAVID C. HESS

KEY CONCEPTS

- 1 Stroke is one of the leading killers of individuals worldwide.
- 2 Stroke can be either ischemic (88%) or hemorrhagic (12%).
- 3 Transient ischemic attacks (TIAs) require urgent intervention to reduce the risk of stroke, which is known to be highest in the first few days after TIA.
- 4 Carotid endarterectomy should be performed in ischemic stroke patients with 70% to 99% stenosis of the ipsilateral carotid artery, provided that it is done in an experienced center.
- 5 Early reperfusion (<3 hours from onset) with tissue plasminogen activator (t-PA) has been shown to reduce the ultimate disability caused by ischemic stroke.
- 6 Antiplatelet therapy is the cornerstone of antithrombotic therapy for the secondary prevention of ischemic stroke.
- 7 Warfarin is the drug of choice for secondary prevention of cardioembolic stroke.
- 8 Blood pressure lowering is effective in both the primary and secondary prevention of both ischemic and hemorrhagic stroke regardless of blood pressure.
- 9 Blood pressure lowering in the acute stroke period (first 7 days) can result in decreased cerebral blood flow and worsened symptoms.
- 10 Statin therapy is recommended for all ischemic stroke patients, regardless of baseline cholesterol, to reduce recurrent vascular events.

1 Stroke is the second leading killer worldwide and the third leading cause of death in the United States, behind cardiovascular disease and all cancers. Despite improvements in the stroke mortality rates in the second half of the 20th century, stroke occurs in more than 700,000 individuals per year and results in 150,000 deaths.¹ Recent advances in our knowledge of the pathophysiology of stroke and efforts to organize stroke care have led to evidence-based recommendations on the management of the stroke patient.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

EPIDEMIOLOGY

There are currently 4.6 million stroke survivors in the United States, and stroke is the leading cause of adult disability.¹ Approximately 20% of patients in nursing homes have had a stroke,² and stroke is also a leading diagnosis in inpatient rehabilitation. Owing in part to the need for these expensive posthospitalization care environments, stroke is also one of the most expensive diseases in the United States, with annual costs greater than \$50 billion.¹ Current projections are that death caused by stroke will increase exponentially in the next 30 years owing to aging of the population and our inability to control risk factors.³

Stroke risk is increased above that of the general population in elderly male individuals and in African Americans.¹ In addition, geographic disparity in stroke incidence exists, such that several areas of the southeastern United States have stroke mortality rates more than twice that of the national average.⁴ This phenomenon, originally describing areas of the coastal Carolinas and Georgia, has been named the “Stroke Belt.”

ETIOLOGY AND CLASSIFICATION

2 Stroke can be either ischemic or hemorrhagic (88% and 12%, respectively, of all strokes in the 2006 American Heart Association report).¹ A classification of stroke by mechanism is given in Fig. 22–1. Hemorrhagic strokes include subarachnoid hemorrhage, intracerebral hemorrhage, and subdural hematomas. Subarachnoid hemorrhage occurs when blood enters the subarachnoid space (where cerebrospinal fluid is housed) owing to either trauma, rupture of an intracranial aneurysm, or rupture of an arteriovenous malformation (AVM). By contrast, intracerebral hemorrhage occurs when a blood vessel ruptures within the brain parenchyma itself, resulting in the formation of a hematoma. These types of hemorrhages very often are associated with uncontrolled high blood pressure and sometimes antithrombotic or thrombolytic therapy. Subdural hematomas refer to collections of blood below the dura (covering of the brain), and they are caused most often by trauma. Hemorrhagic stroke, although less common, is significantly more lethal than ischemic stroke, with 30-day case-fatality rates that are two to six times higher.^{5,6}

Ischemic strokes are caused either by local thrombus formation or by embolic phenomenon, resulting in occlusion of a cerebral artery. Atherosclerosis, particularly of the cerebral vasculature, is a causative factor in most cases of ischemic stroke, although 30% are cryptogenic. Emboli can arise either from intra- or extracranial arteries (including the aortic arch) or, as is the case in 20% of all ischemic strokes, the heart. Cardiogenic embolism is presumed to have occurred if the patient has concomitant atrial fibrillation, valvular heart disease, or any other condition of the heart that can lead to clot formation.⁷ Distinguishing between cardiogenic embolism and other causes of ischemic stroke is important in determining long-term pharmacotherapy in a given patient.

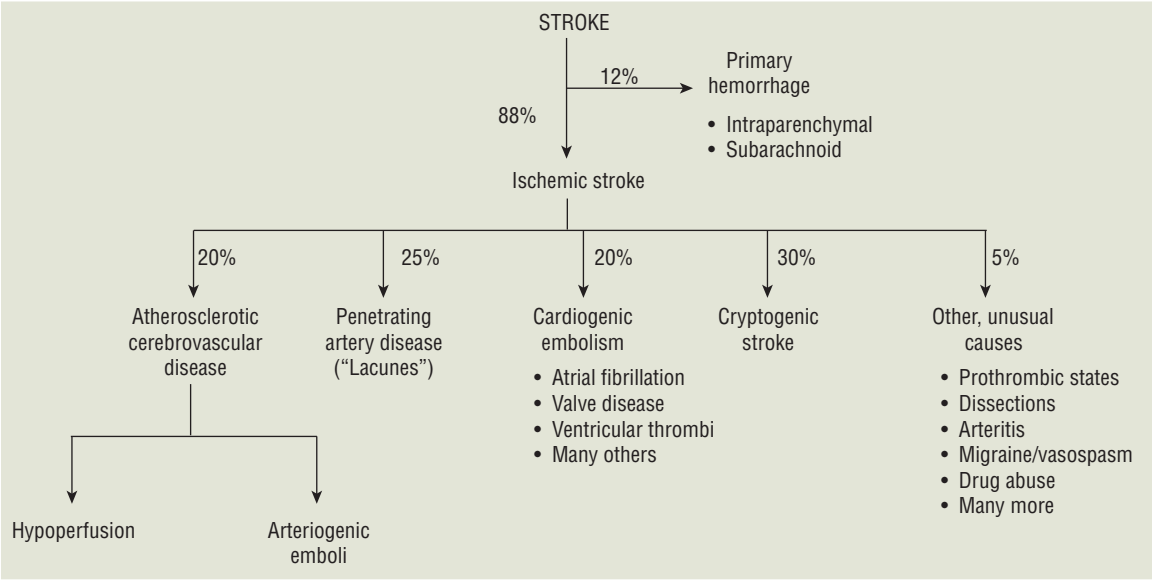

FIGURE 22-1. A classification of stroke by mechanism with estimates of the frequency of various categories of abnormalities. Approximately 30% of ischemic strokes are cryptogenic.

RISK FACTORS

Risk factors for stroke can be subdivided into nonmodifiable, modifiable, and potentially modifiable. In addition, risk factors can be either well documented or less well documented.⁸ The main risk factors of stroke are listed in Table 22–1. Recommendations for risk factor reduction aggressively target the modifiable, well-documented risk factors, even in individuals with nonmodifiable risk.⁸ The nonmodifiable risk factors are age, race, sex, low birth weight, and family history.

TABLE 22-1 Risk Factors for Ischemic Stroke
Nonmodifiable risk factors or risk markers
Age
Gender
Race
Family history of stroke
Low birth weight
Modifiable, well-documented
Hypertension—single most important risk factor for ischemic stroke
Atrial fibrillation—most important and treatable cardiac cause of stroke
Other cardiac diseases
Diabetes—independent risk factor
Dyslipidemia
Cigarette smoking
Alcohol
Sickle cell disease
Asymptomatic carotid stenosis
Postmenopausal hormone therapy
Lifestyle factors—associated with stroke risk
Obesity
Physical inactivity
Diet
Potentially modifiable, less-well documented
Oral contraceptives
Migraine
Drug and alcohol abuse
Hemostatic and inflammatory factors—fibrinogen linked to increased risk
Homocysteine
Sleep disordered breathing

Adapted from Goldstein LB, Adams R, Alberts MJ, et al. Primary prevention of ischemic stroke: A guideline from the American Heart Association/American Stroke Association Stroke Council: Cosponsored by the Atherosclerotic Peripheral Vascular Disease Interdisciplinary Working Group; Cardiovascular Nursing Council; Clinical Cardiology Council; Nutrition, Physical Activity, and Metabolism Council; and the Quality of Care and Outcomes Research Interdisciplinary Working Group. *Stroke* 2006;37:1583–1633.

An individual’s risk of having a stroke increases substantially as he or she ages, with a doubling of risk for each decade older than 55 years of age. African Americans, Asian-Pacific Islanders, and Hispanics experience higher death rates than their Caucasian counterparts.^{1,4} Men are at a higher risk of stroke than women when matched for age, but women who suffer from a stroke are more likely to die from it.¹

The most common modifiable, well-documented risk factors for stroke include hypertension, cigarette smoking, diabetes, atrial fibrillation, and dyslipidemia. The treatment of hypertension, beginning in the mid-20th century, is thought to be primarily responsible for the drastic reduction in stroke death rates between 1950 and 1980 in the United States.⁴ A second very important risk factor for stroke is cardiac disease. Patients with coronary artery disease, congestive heart failure, left ventricular hypertrophy, and especially atrial fibrillation are at increased risk of stroke.^{8,9} In fact, the presence of atrial fibrillation is one of the most potent risk factors for ischemic stroke, with stroke rates from 5% to 20% per year depending on the patient’s comorbid conditions.^{10,11} Other known risk factors for atherosclerosis are also known to place patients at risk of stroke. Diabetes mellitus, dyslipidemia, and cigarette smoking are known atherogenic states that lead to cerebrovascular disease and ischemic stroke.^{8,9,12}

PATHOPHYSIOLOGY

ISCHEMIC STROKE

In carotid atherosclerosis, progressive accumulation of lipids and inflammatory cells in the intima of the affected arteries, combined with hypertrophy of arterial smooth muscle cells, results in plaque formation. Eventually, sheer stress may result in plaque rupture, collagen exposure, platelet aggregation, and clot formation. The clot can remain in the vessel, causing local occlusion, or travel distally as an embolism, eventually lodging downstream in a cerebral vessel. In the case of cardiogenic embolism, stasis of blood in the atria or ventricles of the heart leads to the formation of local clots that can become dislodged and travel directly through the aorta to the cerebral circulation. The final result of both thrombus formation and embolism is an arterial occlusion, decreasing cerebral blood flow and causing ischemia distal to the occlusion.¹³

Normal cerebral blood flow averages 50 mL/100 g per minute, and this is maintained over a wide range of blood pressures (mean arterial pressures of 50 to 150 mm Hg) by a process called *cerebral autoregu-*

FIGURE 22-2. Main arterial blood supply to the brain.

lation. Cerebral blood vessels dilate and constrict in response to changes in blood pressure, but this process can be impaired by atherosclerosis and acute injury, such as stroke. When local cerebral blood flow decreases below 20 mL/100 g per minute, ischemia ensues, and when further reductions below 12 mL/100 g per minute persist, irreversible damage to the brain occurs, and this is called *infarction*. Tissue that is ischemic but maintains membrane integrity is referred to as the ischemic *penumbra* because it usually surrounds the infarct core. This penumbra is potentially salvageable through therapeutic intervention.

Reduction in the provision of nutrients to the ischemic cell eventually leads to depletion of the high-energy phosphates (e.g., adenosine triphosphate [ATP]) necessary for the maintenance of membrane integrity. Subsequently, extracellular potassium accumulates at the same time that sodium and water are sequestered intracellularly, leading to cell swelling and eventual lysis. Electrolyte imbalance also leads to depolarization of the cell and influx of calcium into the cell. The increase in intracellular calcium results in the activation of lipases, proteases, and endonucleases and the release of free fatty acids from membrane phospholipids. The depolarization of the neuron leads to the release of excitatory amino acids, such as glutamate and aspartate, that perpetuate the neuronal damage when released in excess. The accumulation of free fatty acids, including arachidonic acid, results in the formation of prostaglandins, leukotrienes, and free radicals. In ischemia, the magnitude of free-radical production overwhelms normal scavenging systems, leaving these reactive molecules to attack cell membranes and contribute to the mounting intracellular acidosis. All these events occur within 2 to 3 hours of the onset of ischemia and contribute to the ultimate cell death.¹³

Later targets for intervention in the pathophysiologic process involved after cerebral ischemia include the influx of activated inflammatory cells, starting from 2 hours after the onset of ischemia and lasting for several days. Also, the initiation of apoptosis, or programmed cell death, is thought to occur many hours after the acute insult and can interfere with recovery and repair of brain tissue.¹⁴

HEMORRHAGIC STROKE

The pathophysiology of hemorrhagic stroke is not as well studied as that of ischemic stroke. However, it is known that the presence of blood in the brain parenchyma causes damage to the surrounding tissue through the mechanical effect it produces (mass effect) and the neurotoxicity of the blood components and their degradation prod-

ucts.⁵ Approximately 30% of intracerebral hemorrhages continue to enlarge over the first 24 hours, most within 4 hours, and clot volume is the most important predictor of outcome, regardless of location.¹⁵ Hemorrhage volumes >60 mL are associated with 71% to 93% mortality at 30 days.^{5,6} Much of the early mortality of hemorrhagic stroke (up to 50% at 30 days) is caused by the abrupt increase in intracranial pressure that can lead to herniation and death.¹ There is also evidence to support that both early and late edema contributes to worsened outcome after intracerebral hemorrhage.⁶

CLINICAL PRESENTATION (INCLUDING DIAGNOSTIC CONSIDERATIONS)

Stroke is a term used to describe an abrupt-onset focal neurologic deficit that lasts at least 24 hours and is of presumed vascular origin. A TIA is the same but lasts less than 24 hours and usually less than 30 minutes. The abrupt onset and the duration of the symptoms are determined through the history. The use of sensitive imaging techniques (magnetic resonance imaging [MRI]) has revealed that symptoms lasting more than 1 hour and less than 24 hours, although technically TIAs, are associated with infarction, making TIA and minor stroke clinically indistinguishable. The location of the central nervous system injury and its reference to a specific arterial distribution in the brain are determined through the neurologic examination and confirmed by imaging studies such as computed tomography (CT) scanning and MRI. The main arterial supply to the brain is illustrated in Fig. 22–2. Further diagnostic tests are performed to identify the cause of the patient's stroke and to design appropriate therapeutic strategies to prevent further events.¹⁶

CLINICAL PRESENTATION OF STROKE

General

- The patient may not be able to reliably report the history owing to cognitive or language deficits. A reliable history may have to come from a family member or another witness.

Symptoms

- The patient may complain of weakness on one side of the body, inability to speak, loss of vision, vertigo, or falling. Ischemic stroke is not usually painful, but patients may complain of headache, and with hemorrhagic stroke, it can be very severe.

Signs

- Patients usually have multiple signs of neurologic dysfunction, and the specific deficits are determined by the area of the brain involved.
- Hemi- or monoparesis occurs commonly, as does a hemisensory deficit.
- Patients with vertigo and double vision are likely to have posterior circulation involvement.
- Aphasia is seen commonly in patients with anterior circulation strokes.
- Patients also may suffer from dysarthria, visual field defects, and altered levels of consciousness.

Laboratory Tests

- Tests for hypercoagulable states (protein C deficiency, antiphospholipid antibody) should be done only when the cause of the stroke cannot be determined based on the presence of well-known risk factors for stroke. Protein C, protein S, and antithrombin III are best measured in the “steady state,” not in the acute stage. Antiphospholipid antibodies as measured by anticardiolipin antibodies, β_2 -glycoprotein I, and lupus anticoagulant screen are of higher yield than protein C, protein S, and antithrombin III but should be reserved for patients who are young (<50 years of age), have had multiple venous/arterial thrombotic events, or have livedo reticularis (a skin rash).

Other Diagnostic Tests

- CT scan of the head will reveal an area of hyperintensity (white) in the area of hemorrhage and will be normal or hypointense (dark) in the area of infarction. The CT scan may take 24 hours (and rarely longer) to reveal the area of infarction.
- MRI of the head will reveal areas of ischemia with higher resolution and earlier than the CT scan. Diffusion-weighted imaging (DWI) will reveal an evolving infarct within minutes.
- Carotid Doppler (CD) studies will determine whether the patient has a high degree of stenosis in the carotid arteries supplying blood to the brain (extracranial disease).
- An electrocardiogram (ECG) will determine whether the patient has atrial fibrillation, a potent etiologic factor for stroke.
- Transthoracic echocardiography (TTE) will determine whether valve abnormalities or wall-motion abnormalities are sources of emboli to the brain. A “bubble test” can be done to look for an intraatrial shunt indicating an atrial septal defect or a patent foramen ovale.
- Transesophageal echocardiography (TEE) is a more sensitive test for thrombus in the left atrium. It is effective at examining the aortic arch for atheroma, a potential source of emboli.
- Transcranial Doppler (TCD) will determine whether the patient is likely to have intracranial stenosis (e.g., middle cerebral artery stenosis).

TREATMENT**Stroke****■ DESIRED OUTCOME**

The goals of treatment of acute stroke are (1) to reduce the ongoing neurologic injury and decrease mortality and long-term disability, (2) prevent complications secondary to immobility and neurologic dysfunction, and (3) prevent stroke recurrence.^{17–19} Primary prevention of stroke is reviewed elsewhere.⁸

■ GENERAL APPROACH TO TREATMENT

The initial approach to the patient with a presumed acute stroke is to ensure that the patient is supported from a respiratory and cardiac standpoint and to quickly determine whether the lesion is ischemic or hemorrhagic-based on a CT scan. Ischemic stroke patients presenting within hours of the onset of their symptoms should be evaluated for reperfusion therapy. **3** TIAs also require urgent intervention to reduce the risk of stroke, which is known to be highest in the first few days after TIA.²⁰ Patients with elevated blood pressure should remain untreated unless their blood pressure exceeds 220/120 mm Hg, or they have evidence of aortic dissection, acute myocardial infarction (AMI), pulmonary edema, or hypertensive encephalopathy. If blood pressure is treated, short-acting parenteral agents, such as labetalol, nicardipine, and nitroprusside, are favored. Current recommendations regarding management of arterial hypertension in stroke patients is given in Table 22–2.^{17–19}

In patients with subarachnoid hemorrhage, an immediate assessment of whether the patient has a berry or saccular aneurysm should be made. If an aneurysm is found by angiography, endovascular coiling or clipping via a craniotomy should be performed to reduce the risk of rebleeding. In intracerebral hemorrhage, patients may require external ventricular drainage (EVD) if there is intraventricular blood and evolving hydrocephalus (enlargement of the ventricles). Once the patient is out of the hyperacute phase, attention is placed on preventing worsening, minimizing complications, and instituting appropriate secondary prevention strategies. The acute phase of the stroke includes the first week after the event.¹⁷

■ NONPHARMACOLOGIC THERAPY**Ischemic Stroke**

Surgical interventions in the acute ischemic stroke patient are limited. In certain cases of ischemic cerebral edema owing to a large infarction, craniectomy to release some of the rising pressure has been tried. In cases of significant swelling associated with a cerebellar infarction, surgical decompression can be lifesaving. Beyond surgical intervention, however, the use of an organized, multidisciplinary approach to stroke care that includes early rehabilitation has been shown to be very effective in reducing the ultimate disability owing to ischemic stroke. In fact, the use of “stroke units” has been associated with outcomes similar to those achieved with early thrombolysis when compared with usual care.¹⁷

4 In secondary prevention, carotid endarterectomy of an ulcerated and/or stenotic carotid artery is a very effective way to reduce stroke incidence and recurrence in appropriate patients and in centers where the operative morbidity and mortality are low. In fact, in ischemic stroke patients with 70% to 99% stenosis of an ipsilateral internal carotid artery, recurrent stroke risk can be reduced by up to 48% compared with medical therapy alone when combined

TABLE 22-2 Blood Pressure Treatment Guidelines in Acute Ischemic Stroke Patients

Treatment	Received t-PA	Did Not Receive t-PA
None	<180/105	<220/120
Labetalol IV ^a or Nicardipine IV ^b	180–230/105–120	>220/121–140
Nitroprusside ^c	Diastolic >140	Diastolic >140

t-PA, tissue plasminogen activator.

^aLabetalol IV = 10–20 mg, doubled every 10–20 minutes, to a maximum of 300 mg. Also can use an infusion of 2–8 mg/min.

^bNicardipine IV = infusion starting at 5 mg/h up to 15 mg/h.

^cNitroprusside IV = infusion starting at 0.5 mcg/kg/min, with continuous arterial blood pressure monitoring.

Adapted from Adams HP, del Zoppo G, Alberts MJ, et al. *Stroke* 2007;38:1655–1711.

with aspirin 325 mg daily.²¹ In patients in whom the risk of endarterectomy is thought to be excessive, carotid stenting can be effective in reducing recurrent stroke risk but is less invasive.²² Carotid stenting is still considered investigational, however, and issues remain regarding the optimal methods and patients for this procedure.

Hemorrhagic Stroke

In patients with subarachnoid hemorrhage owing to a ruptured intracranial aneurysm or an AVM, surgical intervention to either clip or ablate the offending vascular abnormality substantially reduces mortality owing to rebleeding.²³ In the case of primary intracerebral hemorrhage, however, the benefits of surgery are less well documented. Although many patients undergo surgical treatment of intracerebral hematomas, the procedures have not been studied adequately in clinical trials.^{5,15} Insertion of EVD for hydrocephalus and subsequent monitoring of intracranial pressure are done commonly and are the least invasive of the procedures done in these patients. Surgical decompression of a hematoma is more controversial, except when it is a last option in a life-threatening situation. Guidelines have been developed for the use of surgical intervention in the treatment of intracerebral hemorrhage, but they are limited in their impact by the lack of clinical trial data to support them.¹⁵

■ PHARMACOLOGIC THERAPY

Ischemic Stroke

Drug Treatments of First Choice: Published Guidelines

The Stroke Council of the American Stroke Association has created and published guidelines that address the management of acute ischemic stroke.¹⁷ In general, the only two pharmacologic agents recommended with a grade A recommendation are intravenous t-PA within 3 hours of onset and aspirin within 48 hours of onset.

5 Early reperfusion (<3 hours from onset) with intravenous t-PA has been shown to reduce the ultimate disability caused by ischemic stroke.²⁴ Caution must be exercised when using this therapy, and adherence to a strict protocol is essential to achieving positive outcomes.¹⁷ The essentials of the treatment protocol can be summarized as (1) stroke team activation, (2) onset of symptoms within 3 hours, (3) CT scan to rule out hemorrhage, (4) meet inclusion and exclusion criteria (Table 22-3), (5) administer t-PA 0.9 mg/kg over 1 hour, with 10% given as initial bolus over 1 minute, (6) avoid antithrombotic (anticoagulant or antiplatelet) therapy for 24 hours, and (7) monitor the patient closely for response and hemorrhage.¹⁷

Early aspirin therapy also has been shown to reduce long-term death and disability^{25,26} but should never be given within 24 hours of the administration of t-PA because it can increase the risk of bleeding in such patients.¹⁷

The American Heart Association/American Stroke Association (AHA/ASA) guidelines address all pharmacotherapy used in the secondary prevention of ischemic stroke and are updated every 3 years.²⁷ It is clear that antiplatelet therapy is the cornerstone of antithrombotic therapy for the secondary prevention of ischemic stroke and should be used in noncardioembolic strokes. All three currently used agents, aspirin, clopidogrel, and extended-release dipyridamole plus aspirin (ERDP-ASA), are considered first-line antiplatelet agents by the American College of Chest Physicians (ACCP). In patients with atrial fibrillation and a presumed cardiac source of embolism, warfarin is the antithrombotic agent of first choice. Other pharmacotherapy recommended for secondary prevention of stroke include blood pressure lowering and statin therapy. Current recommendations regarding the acute treatment and secondary prevention of stroke are given in Table 22-4.

TABLE 22-3 Inclusion and Exclusion Criteria for Alteplase Use in Acute Ischemic Stroke

Inclusion criteria (all YES boxes must be checked before treatment)

YES

- ☐ Age 18 years or older
- ☐ Clinical diagnosis of ischemic stroke causing a measurable neurologic deficit
- ☐ Time of symptom onset well established to be less than 180 minutes before treatment would begin

Exclusion criteria (all NO boxes must be checked before treatment)

NO

- ☐ Evidence of intracranial hemorrhage on noncontrast head CT
- ☐ Only minor or rapidly improving stroke symptoms
- ☐ High clinical suspicion of subarachnoid hemorrhage even with normal CT
- ☐ Active internal bleeding (e.g., GI/GU bleeding within 21 days)
- ☐ Known bleeding diathesis, including but not limited to platelet count <100,000/mm³
- ☐ Patient has received heparin within 48 hours and had an elevated APTT
- ☐ Recent use of anticoagulant (e.g., warfarin) and elevated PT (>15 second)/INR
- ☐ Intracranial surgery, serious head trauma, or previous stroke within 3 months
- ☐ Major surgery or serious trauma within 14 days
- ☐ Recent arterial puncture at noncompressible site
- ☐ Lumbar puncture within 7 days
- ☐ History of intracranial hemorrhage, arteriovenous malformation, or aneurysm
- ☐ Witnessed seizure at stroke onset
- ☐ Recent acute myocardial infarction
- ☐ SBP >185 mm Hg or DBP >110 mm Hg at time of treatment

APTT, activated partial thromboplastin time; CT, computed tomography; DBP, diastolic blood pressure; GI, gastrointestinal; GU, genitourinary; INR, international normalized ratio; PT, prothrombin time; SBP, systolic blood pressure.

TABLE 22-4 Recommendations for Pharmacotherapy of Ischemic Stroke

	Recommendation	Evidence ^a
Acute treatment	t-PA 0.9 mg/kg IV ^{7,17} (maximum 90 kg) over 1 hour in selected patients within 3 hours of onset	IA
	ASA 160–325 mg daily ^{7,17} started within 48 hours of onset	IA
Secondary prevention		
Noncardioembolic	Antiplatelet therapy	IA
	Aspirin 50–325 mg daily ^{7,27}	Ila A (all three as initial options)
	Clopidogrel 75 mg daily ^{7,27}	Ilb B (over aspirin)
	Aspirin 25 mg + extended-release dipyridamole 200 mg twice daily ^{7,27}	Ila A (over aspirin)
Cardioembolic (esp. atrial fibrillation)	Warfarin (INR = 2.5) ^{7,27}	IA
All	Antihypertensive treatment ²⁷	IA
Previously hypertensive	ACE inhibitor + diuretic ²⁷	IA
Previously normotensive	ACE inhibitor + diuretic ²⁷	Ila B
Dyslipidemic	Statin ²⁷	IA
Normal lipids	Statin ²⁷	Ila B

ACE, angiotensin-converting enzymes; ASA, aspirin; INR, international normalized ratio; t-PA, tissue plasminogen activator.

^aClasses and levels of evidence: I—evidence or general agreement that useful and effective; II—conflicting evidence about the usefulness; Ila—weight of evidence in favor of the treatment; Ilb—usefulness less well established; III—not useful and maybe harmful. Levels of evidence: A—multiple randomized clinical trials; B—a single randomized trial or nonrandomized studies; C—expert opinion or case studies.²³ (Level A in reference 7—t-PA recommendation—does not require multiple trials, just randomized, well-controlled clinical trial.)

Data from Albers et al.,⁷ Adams et al.,¹⁷ and Sacco et al.²⁷

■ GENERAL INFORMATION REGARDING SAFETY AND EFFICACY (INCLUDING PIVOTAL CLINICAL TRIALS)

t-PA

The effectiveness of IV t-PA in the treatment of ischemic stroke was demonstrated in the National Institutes of Neurologic Disorders and Stroke (NINDS) Recombinant Tissue-Type Plasminogen Activator (rt-PA) Stroke Trial, published in 1995.²⁴ In 624 patients treated in equal numbers with either t-PA 0.9 mg/kg IV or placebo within 3 hours of the onset of their neurologic symptoms, 39% of the treated patients achieved an “excellent outcome” at 3 months compared with 26% of the placebo patients. An “excellent outcome” was defined as minimal or no disability by several different neurologic scales. This beneficial effect was reported despite a 10-fold increase in the risk of symptomatic intracerebral hemorrhage in the t-PA-treated patients (0.6% vs. 6.4%). Overall mortality was not different between the two groups (17% with t-PA and 21% with placebo). Patients with very severe symptoms at baseline (National Institutes of Health Stroke Scale [NIHSS] >20) and early ischemic changes on CT scan were shown to be at highest risk for the development of symptomatic intracranial hemorrhage. Even in patients at highest risk for bleeding, however, those receiving t-PA had better outcomes at 90 days than those who received placebo.²⁴ The publication of the NINDS trial results significantly changed the way in which acute stroke is managed in the community, promoting the development of acute stroke teams and emphasis on the early diagnosis and treatment of acute stroke. Prospectively collected data, even from the best centers, report between 3% and 8.5% of ischemic stroke patients in the United States receive t-PA, primarily owing to failure of patients to present in time to facilities equipped to administer the therapy safely.²⁸ Hemorrhage rates associated with t-PA use in the community have been reported to be similar to those reported in the NINDS trial (5%),²⁹ but significantly higher rates (up to 15%) have been reported when a strict protocol is not followed.³⁰

Aspirin

The use of early aspirin to reduce long-term death and disability owing to ischemic stroke is supported by two large, randomized clinical trials. In the International Stroke Trial (IST),²⁶ aspirin 300 mg/day significantly reduced stroke recurrence within the first 2 weeks without effect on early mortality, resulting in a significant decrease in death and dependency at 6 months. In the Chinese Acute Stroke Trial (CAST),²⁵ aspirin 160 mg/day reduced the risk of recurrence and death in the first 28 days, but long-term death and disability were not different than with placebo. In both trials, a small but significant increase in hemorrhagic transformation of the infarction was demonstrated. Overall, the beneficial effects of early aspirin have been embraced and adopted into clinical guidelines.

Antiplatelet Agents

All patients who have had an acute ischemic stroke or TIA should receive long-term antithrombotic therapy for secondary prevention.²⁷ **6** In patients with noncardioembolic stroke, this will be some form of antiplatelet therapy. In a recent meta-analysis, the overall benefit of antiplatelet therapy in patients with atherothrombotic disorders was estimated to be 22%.³¹ Aspirin is the best-studied of the available agents and, until recently, was considered the sole first-line agent. However, published literature has supported the use of clopidogrel and the combination product ERDP-ASA as additional first-line agents in secondary stroke prevention.

The efficacy of clopidogrel as an antiplatelet agent in atherothrombotic disorders was demonstrated in the Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events (CAPRIE) trial.³² In

this study of more than 19,000 patients with a history of either myocardial infarction (MI), stroke, or peripheral arterial disease (PAD), clopidogrel 75 mg/day was compared with aspirin 325 mg/day for its ability to decrease MI, stroke, or cardiovascular death. In the final analysis, clopidogrel was slightly (8% relative risk reduction [RRR]) more effective than aspirin ($P = 0.043$) and had a similar incidence of adverse effects. It is not associated with the blood dyscrasias (neutropenia) common with its congener, ticlopidine, and is used widely in patients with atherosclerosis.

In the European Stroke Prevention Study 2 (ESPS-2), aspirin 25 mg and extended-release dipyridamole (ERDP) 200 mg twice daily were compared alone and in combination with placebo for their ability to reduce recurrent stroke over a 2-year period.³³ In a total of more than 6,600 patients, all three treatment groups were shown to be superior to placebo—aspirin alone, 18% RRR; ERDP alone, 16% RRR; and the combination, 37% RRR. Importantly, this study was the first to show a significant benefit of combination antiplatelet therapy in stroke prevention, with the combination demonstrating a significant advantage over the aspirin-alone group (23% RRR; $P = 0.006$) and the ERDP-alone group (24% RRR; $P = 0.002$). Headache resulting in discontinuation occurred in approximately 15% of the ERDP groups (four times more common than in the placebo group), and the aspirin-treated patients, even at the low dose of 50 mg/day, experienced significantly more bleeding than the other groups. The combination of aspirin 25 mg and ERDP 200 mg twice daily is a highly effective treatment to prevent recurrence in patients with stroke or TIA. The European/Australasian Stroke Prevention in Reversible Ischemia Trial (ESPRIT) confirmed the results of ESPS-2, in that the combination of dipyridamole (83% extended release) and aspirin (30–325 mg daily) was more effective than aspirin alone in reducing recurrent stroke.³⁴ Headache was an important cause of discontinuation in the ESPRIT trial, further stressing the importance of monitoring and education in these patients. No data exist on the ability of this combination to reduce MI and/or cardiovascular death in patients with other indications for antiplatelet therapy.

Warfarin

7 Warfarin is the most effective treatment for the prevention of stroke in patients with atrial fibrillation.^{10,11,35,36} In patients with atrial fibrillation and a recent history of stroke or TIA, the risk of recurrence places these patients in one of the highest risk categories known. In the European Atrial Fibrillation Trial (EAFT), 669 patients with nonvalvular atrial fibrillation (NVAf) and a prior stroke or TIA were randomized to either warfarin (international normalized ratio [INR] = 2.5–4), aspirin 300 mg/day, or placebo. Patients in the placebo group experienced stroke, MI, or vascular death at a rate of 17% per year compared with 8% per year in the warfarin group and 15% per year in the aspirin group. This represents a 53% reduction in risk with anticoagulation.¹⁰ Subsequent studies in the primary prevention of stroke in patients with NVAf have demonstrated that targeting an international normalization ratio (INR) of 2.5 prevents stroke with the lowest bleeding risk (Stroke Prevention in Atrial Fibrillation [SPAF III]); therefore, a target INR of 2.5 is recommended in the secondary prevention of stroke.^{11,35,36}

Use of warfarin in the secondary prevention of noncardioembolic stroke was addressed in the Warfarin Aspirin Recurrent Stroke Study.³⁷ In 2,206 patients with recent stroke, warfarin (INR = 1.4–2.8) was not superior to aspirin 325 mg/day in the prevention of recurrent events. Further data from the Warfarin-Aspirin in Intracranial Disease (WASID) trial demonstrated that aspirin therapy was as effective and safer than warfarin in patients with intracranial stenosis.³⁸ These studies led most clinicians to abandon the practice of using warfarin in all but patients with cardioembolic sources of emboli, mainly atrial fibrillation.

Blood Pressure Lowering

8 Elevated blood pressure is very common in ischemic stroke patients, and treatment of hypertension in these patients is associated with a decreased risk of stroke recurrence.³⁹ In the Perindopril pROtection aGainst REcurrent Stroke Study (PROGRESS), a multinational stroke population (40% Asian) was randomized to receive either blood pressure lowering with the angiotensin-converting enzyme (ACE) inhibitor perindopril (with or without the thiazide diuretic indapamide) or placebo.⁴⁰ Treated patients achieved an overall 9 points systolic and 4 points diastolic mm Hg blood pressure reduction, and this was associated with a 28% reduction in stroke recurrence. In the patients who received the combination treatment (clinician's discretion), the average blood pressure lowering achieved was 12 systolic and 5 diastolic mm Hg, and this was associated with an even larger reduction in stroke recurrence (43%). Similar results were achieved in patients with and without hypertension. Based on the results of this study and other evidence of the tolerability and vascular protective properties of the ACE inhibitors, the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC7) and the AHA/ASA guidelines recommend an ACE inhibitor and a diuretic for the reduction of blood pressure in patients with stroke or TIA.^{27,41} **9** Blood pressure lowering in the acute stroke period (first 7 days) can result in decreased cerebral blood flow and worsened symptoms; therefore, recommendations are limited to patients out of the acute stroke period.²⁷

Statins

10 The statins have been shown to reduce the risk of stroke by approximately 30% in patients with coronary artery disease and elevated plasma lipids.^{42–44} The National Cholesterol Education Program (NCEP) considers ischemic stroke or TIA to be a coronary “equivalent” and has recommended the use of statins to achieve a low-density lipoprotein (LDL) concentration of less than 100 mg/dL.⁴⁵ When the Heart Protection Study was published, it provided evidence that simvastatin 40 mg/day reduced stroke risk in high-risk individuals (including patients with prior stroke) by 25% ($P < 0.0001$), even in patients with LDL concentrations of less than 116 mg/dL.⁴⁶ The investigators also showed that this practice is extremely safe, with an excess incidence of myopathy of 0.01%. The Stroke Prevention by Aggressive Reduction in Cholesterol (SPARCL) study went one step further by demonstrating, in stroke patients, that atorvastatin 80 mg daily reduced the risk of recurrent stroke by 16% and coronary events by 42% while causing an increase in liver enzymes, but no increase in myopathy.⁴⁷ Statin therapy is an effective way to reduce stroke risk and should be considered in all ischemic stroke patients. Whether high-dose statin therapy is prescribed should be determined in the individual patient by a careful weighing of the benefits against the potential increase in adverse events.

Heparin for Prophylaxis of Deep-Vein Thrombosis (DVT)

The use of low-molecular-weight heparins or low-dose subcutaneous unfractionated heparin (5,000 units twice daily) can be recommended for the prevention of DVT in hospitalized patients with decreased mobility owing to their stroke and should be used in all but the most minor strokes.^{7,17}

■ ALTERNATIVE DRUG TREATMENTS

Aspirin Plus Clopidogrel

In the Management of ATherothrombosis with Clopidogrel in High-risk patients (MATCH) study, clopidogrel in combination with aspi-

rin 75 mg daily was no better than clopidogrel alone in secondary stroke prevention.⁴⁸ However, the combination has been studied in patients with acute coronary syndromes and patients undergoing percutaneous coronary interventions and shown to be significantly more effective than aspirin alone in reducing MI, stroke, and cardiovascular death.^{49,50} Also, when clopidogrel was used with aspirin, the risk of life-threatening bleeding increased from 1.3% to 2.6%.⁴⁸ In the Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management and Avoidance (CHARISMA) trial, the combination was again found to significantly increase serious bleeding in a high risk atherosclerosis population (clinically evident disease or multiple risk factors) with no consistent benefit in terms of preventing vascular events, when compared to aspirin alone.⁵¹ This combination can only be recommended in patients with a recent history of MI or coronary stent placement and only with ultra-low-dose aspirin to minimize bleeding risk.⁵²

Angiotensin II Receptor Blockers

Angiotensin II receptor blockers (ARBs) also have been shown to reduce the risk of stroke. In the Losartan Intervention For Endpoint Reduction in Hypertension (LIFE) study, losartan and metoprolol were compared for their ability to reduce blood pressure and prevent cardiovascular events in a group of severely hypertensive patients.⁵³ Despite similar reductions in blood pressure of approximately 30/16 mm Hg, the losartan group experienced a 24% reduction in the risk of stroke. In a similar study comparing eprosartan to nitrendipine, the ARB eprosartan was superior to the calcium channel blocker in reducing recurrent stroke risk, when equal blood pressure lowering was achieved.⁵⁴ The ARBs should be considered in patients unable to tolerate ACE inhibitors for blood pressure lowering after acute ischemic stroke.

Heparins

The use of full-dose unfractionated heparin in the acute stroke period has never been proven to positively affect stroke outcome, and it significantly increases the risk of intracerebral hemorrhage.^{7,17} Trials of low-molecular-weight heparins or heparinoids have been largely negative and do not support their routine use in stroke patients.^{55–57} Other potential but unproven uses for treatment doses of either unfractionated or low-molecular-weight heparins include bridge therapy in patients being initiated on warfarin, carotid dissection, or continuous worsening of ischemia despite adequate antiplatelet therapy.⁷

■ DRUG CLASS INFORMATION

Aspirin

Aspirin exerts its antiplatelet effect by irreversibly inhibiting cyclooxygenase, which, in platelets, prevents conversion of arachidonic acid to thromboxane A₂ (TXA₂), which is a powerful vasoconstrictor and stimulator of platelet aggregation. Platelets remain impaired for their life span (5 to 7 days) after exposure to aspirin. Aspirin also inhibits prostacyclin (PGI₂) activity in the smooth muscle of vascular walls. PGI₂ inhibits platelet aggregation, and the vascular endothelium can synthesize prostacyclin such that the platelet antiaggregating effect is maintained. The suppression of PGI₂ production by aspirin has been found to be dose- and duration-related; the higher the dose, the longer the cyclooxygenase production is suppressed. Therefore, the lower the aspirin dose, the less effect on PGI₂.⁷ The optimal dose of aspirin is still under study, but it should be the dose that inhibits TXA₂ with the least amount of PGI₂ inhibition. It has been shown that an aspirin dose of 325 mg/day will inhibit TXA₂ but will not significantly inhibit PGI₂ production. There is probably a point at which lower doses of aspirin do not completely block TXA₂, and recent studies indicate that the lowest effective dose may be in the range of 50 mg/day.⁵⁸ Upper

gastrointestinal (GI) discomfort and bleeding are the most common adverse effects of aspirin and have been shown to be dose-related. The highest rates of GI bleeding (5%) have been reported in patients receiving 1,200 mg/day as compared with rates of 2% in patients taking the more commonly prescribed, 300 mg/day. Upper GI symptoms are much more common than frank bleeding, however, with 40% of patients affected at 1,200 mg/day and 25% at 300 mg/day.⁵⁹ In the ESPS-2 study, even 50 mg/day of aspirin was associated with a twofold increase in bleeding over the placebo group.³³

Low doses (<100 mg) of aspirin quickly inhibit cyclooxygenase in all the platelets in the circulation. Therefore, the onset of the antiplatelet effect of aspirin is less than 60 minutes.⁶⁰ It has been reported, however, that some patients either have or develop “aspirin resistance” and can require higher doses to achieve the desired antiplatelet effect.⁶¹ Despite this, routine testing for aspirin resistance is not recommended. It was observed recently that administration of ibuprofen prior to the administration of a daily aspirin dose prohibits the aspirin from binding irreversibly to the cyclooxygenase and can decrease its antiplatelet effect.⁶² Current recommendations are to administer aspirin at least 2 hours before ibuprofen or to wait at least 4 hours after an ibuprofen dose.

Extended-Release Dipyridamole Plus Aspirin

Early studies of the role of dipyridamole in stroke prevention failed to show a benefit over that realized by aspirin alone. Dipyridamole, in high doses, is thought to inhibit platelet aggregation by inhibiting phosphodiesterase, leading to accumulation of cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) intracellularly, which prevent platelet activation. In addition, dipyridamole also enhances the antithrombotic potential of the vascular wall.⁶³ The ESPS-2 demonstrated the efficacy of high-dose extended-release dipyridamole alone and in combination with aspirin in secondary stroke prevention.³³ This was the first study to demonstrate the benefits of combination antiplatelet therapy in stroke prevention (the combination was significantly more effective than either agent alone). The extended-release formulation of dipyridamole is important in that it allows twice-daily administration and higher doses to be tolerated in patients. The use of immediate-release generic dipyridamole in combination with regular aspirin, in order to reduce costs, is unproven and should be discouraged.

In the ESPS-2, 25% of the patients who received combination dipyridamole and aspirin discontinued the therapy early, and the rate of discontinuation owing to headache was more than three times as common (10%) as in the aspirin-alone group (3%). Other reasons for discontinuation were GI problems. Slow initiation of ERDP-ASA at one capsule at bedtime daily for 2 or 3 days can be tried in order to lessen headache symptoms. The headache caused by ERDP-ASA is mostly self-limiting and decreases after several days.⁶⁴

Clopidogrel

Clopidogrel has a unique platelet antiaggregatory effect in that it is an inhibitor of the adenosine diphosphate (ADP) pathway of platelet aggregation and inhibits known stimuli to platelet aggregation.^{7,32} This effect causes an alteration of the platelet membrane and interference with the membrane-fibrinogenic interaction leading to a blocking of the platelet glycoprotein IIb/IIIa receptor. A time lag of 3 to 7 days before the antiplatelet effect is maximal should be expected. The tolerability of clopidogrel 75 mg/day is at least as good as medium-dose (325 mg/day) aspirin, and GI bleeding is less.³² Clopidogrel is associated with an increased risk of diarrhea and rash, but discontinuation rates owing to adverse effects are similar to those with aspirin 325 mg/day (5.3% to 6%, respectively).³² There is no excess neutropenia in patients taking clopidogrel, and rates of thrombotic thrombocytopenic purpura probably are no greater than background rates.⁶⁵

Clopidogrel is a thienopyridine prodrug and needs to be biotransformed by the liver to an active metabolite. Evidence suggests that the enzyme responsible for the conversion is human cytochrome P450 3A4 (CYP3A4) and that the platelet effects of clopidogrel can be diminished in patients receiving agents that inhibit this enzyme.⁶⁶ Although high doses of the lipophilic statins atorvastatin and simvastatin can diminish the effectiveness of clopidogrel to inhibit platelet aggregation *in vitro*, there does not appear to be any adverse effect on atherothrombotic event rates.⁶⁷ Concomitant administration of clopidogrel with lipophilic statins is often recommended.

■ INVESTIGATIONAL STRATEGIES

Reperfusion

Various investigations aimed at shortening the time required to open the occluded cerebral artery and preserve its patency are underway in acute ischemic stroke patients.⁶⁸ Strategies being tried include longer-acting fibrinolytic agents, intraarterial fibrinolysis with t-PA and other agents, and endovascular clot removal using mechanical and laser-guided approaches. In addition, investigators are trying to identify, using sensitive MRI techniques, which patients benefit from reperfusion at time points outside the approved 3-hour time window. Undoubtedly, efforts to reperfuse the ischemic brain will continue to be explored, so more patients will be eligible for this therapy.

Neuroprotection and Neurorestoration

Although many different neuroprotective agents have been studied in clinical trials of acute ischemic stroke, most have been unsuccessful.⁶⁹ A promising nonpharmacologic strategy that has been shown to provide neuroprotection in patients has been hypothermia.⁷⁰ Currently, clinical trials are underway to optimize the mechanism of cooling the ischemic brain (intravascular coils versus surface cooling) and rewarming the patient after hypothermia. Despite discouraging results in previous attempts, however, there is still great interest in developing pharmacologic agents that provide neuroprotection. Some of the most promising agents include free-radical scavengers (NXY-059),⁷¹ anti-inflammatory agents, and agents with multiple proposed mechanisms of protection (e.g., albumin infusions).⁷² In addition, hope still exists that clinicians will be able to enhance the reparative process of the brain (neurorestoration) through targeted neurorehabilitation and the use of neural and cell transplantation.⁷³

HEMORRHAGIC STROKE

There are currently no standard pharmacologic strategies for treating intracerebral hemorrhage (ICH).¹⁵ The use of hemostatic agents (e.g., factor VII) in the hyperacute phase (<4 hours from onset) can reduce hematoma growth, but no improvement in outcomes has been demonstrated.⁷⁴ Medical guidelines for the management of blood pressure, raised intracranial pressure, and other medical complications of ICH are those required for the management of any acutely ill patient in a neurointensive care unit.

Subarachnoid hemorrhage (SAH) owing to aneurysm rupture is associated with a high incidence of delayed cerebral ischemia (DCI) in the 2 weeks following the bleeding episode. Vasospasm of the cerebral vasculature is thought to be responsible for DCI and occurs between 4 and 21 days after the bleed, peaking at days 5 through 9.²³ The calcium channel blocker nimodipine is recommended to reduce the incidence and severity of neurologic deficits owing to DCI. Nimodipine at a dose of 60 mg every 4 hours should be initiated on diagnosis and continued for 21 days in all SAH patients. Administration of nimodipine therapy is complicated by a fairly high incidence of hypotension. This can be managed by reducing

the dosing interval to 30 mg every 2 hours (same daily dose), reducing the total daily dose (30 mg every 4 hours), and maintaining intravascular volume and pressor therapy.²³

PHARMACOECONOMIC CONSIDERATIONS

Although t-PA is expensive, when the total healthcare costs are factored in, savings can accrue to the healthcare system as a direct result of appropriate t-PA therapy.⁷⁵ It has been estimated that, at a rate of \$600 per patient treated, annual cost savings of \$15 and \$22 million could be realized by increasing national t-PA use to 4% and 6%, respectively (from the current 2%).⁷⁶

In antithrombotic prophylaxis for atrial fibrillation, warfarin therapy was evaluated using quality-adjusted life-years (QALYs) saved.⁷⁷ It was found that in patients with atrial fibrillation and one additional risk factor, warfarin therapy cost \$8,000 per QALY saved. In high-risk patients, those with atrial fibrillation and two or more risk factors, warfarin use was estimated to save \$6,200 in costs from stroke and TIA. Costs of monitoring and hemorrhages from warfarin were estimated to be \$5,500, thus showing a positive savings from warfarin use. Those without risk factors were much more costly to treat at an estimated \$370,000 per QALY saved when compared with aspirin treatment. Warfarin is cost-effective in high-risk patients, particularly if the hemorrhagic side effects are lower relative to the stroke risk. For comparison purposes, hypertension screening is estimated to cost \$10,000 to \$50,000 per QALY saved. A Swedish study reported the cost-effectiveness of primary stroke prevention in atrial fibrillation patients with oral anticoagulants or aspirin based on four published clinical trials.⁷⁸ The authors found that the total cost per stroke prevented was a \$16 savings if the intracerebral bleeding was 0.3% and \$43 if the bleeding rate was 2%. At a bleeding complication rate of 1.3%, warfarin would prevent 1,000 strokes per year and save approximately \$29 million. The cost-effectiveness of the various first-line antiplatelet agents have been compared as well.⁷⁹ Without a doubt, aspirin, owing to its extremely low acquisition cost (pennies daily), is cost saving. In other words, it reduces costs at the same time as saving QALYs. The use of clopidogrel or ERDP-ASA is associated with higher efficacy but significantly greater costs as well (up to \$3 daily). Despite this, both options have been deemed “cost-effective” when administered to a 65-year-old patient with a history of stroke or TIA for the prevention of recurrence. In a recent analysis, ERDP-ASA was associated with \$5,000 to \$15,000 per

QALY (adjusted for the acquisition cost) and clopidogrel was \$26,580 per QALY. Any cost per QALY less than \$50,000 is thought to be “cost-effective.”⁷⁹ These estimates are extremely dependent on the assumptions made in the model. Cost-effectiveness in an individual patient is much more difficult to discern.

Primary prevention strategies that address the risk factors for ischemic stroke can be powerful in reducing the costs of stroke. Many of the stroke risk factors can be modified and some eliminated at very low costs (lifestyle changes), therefore developing risk-factor-reduction strategies can be the most cost-effective measure of all. More research is needed in identifying the cost-effectiveness of other forms of acute stroke treatment.

CLINICAL CONTROVERSIES

The use of full-dose unfractionated heparin in the management of acute ischemic stroke remains controversial despite years of debate and a lack of evidence supporting its use. Proponents of the therapy cite strong anecdotal evidence of positive responses in selected patients who have never been studied in clinical trials.

The use of intracranial angioplasty and stenting is strongly supported in the few institutions where the technology exists. Whether these procedures should be attempted in patients outside clinical trials remains controversial.

The use of surgical evacuation of intracranial hemorrhage with and without instillation of fibrinolytic agents is controversial. Although fervently pursued in select centers and countries, indications and outcomes are not known. Results of ongoing clinical trials can assist in settling this controversy.

EVALUATION OF THERAPEUTIC OUTCOMES

MONITORING OF THE PHARMACEUTICAL CARE PLAN

Patients with acute stroke should be monitored intensely for the development of neurologic worsening (recurrence or extension), complications (thromboembolism or infection), or adverse effects from pharmacologic or nonpharmacologic interventions. The most common reasons for deterioration in a stroke patient are (1) exten-

TABLE 22-5 Monitoring the Hospitalized Acute Stroke Patient

	Treatment	Parameter(s)	Frequency	Comments
Ischemic stroke	t-PA	BP, neurologic function, bleeding	Every 15 minutes \times 1 hour; every 0.5 h \times 6 h; every 1 hour \times 17 hour; every shift after	
	Aspirin	Bleeding	Daily	
	Clopidogrel	Bleeding	Daily	
	ERDP/ASA	Headache, bleeding	Daily	Headache usually transient (2–3 days) and may respond to simple analgesics
	Warfarin	Bleeding, INR, Hb/Hct	INR daily \times 3 days; weekly until stable; monthly	
Hemorrhagic stroke		BP, neurologic function, ICP	Every 2 hours in ICU	Many patients require intervention with short-acting agents to reduce BP to <180 mm Hg systolic
All	Nimodipine (for SAH)	BP, neurologic function, fluid status	Every 2 hours in ICU	
		Temperature, CBC	Temp. every 8 hours; CBC daily	For infectious complications such as UTI or pneumonia
		Pain (calf or chest)	Every 8 hours	For DVT, MI, acute headache
		Electrolytes and ECG	Up to daily	For fluid and electrolyte imbalances, cardiac rhythm abnormalities
	Heparins for DVT prophylaxis	Bleeding, platelets	Bleeding daily, platelets if suspected thrombocytopenia	

BP, blood pressure; CBC, complete blood count; DVT, deep-vein thrombosis; ECG, electrocardiography, ERDP-ASA, extended-release dipyridamole plus aspirin; Hb/Hct, hemoglobin/hematocrit; ICP, intracranial pressure; ICU, intensive care unit; MI, myocardial infarction; SAH, subarachnoid hemorrhage.

sion of the original lesion—ischemic or hemorrhagic—in the brain, (2) development of cerebral edema and raised intracranial pressure, (3) hypertensive emergency, (4) infection (urinary and respiratory most common), (5) venous thromboembolism (deep venous thrombosis and pulmonary embolism), (6) electrolyte abnormalities and cardiac rhythm disturbances (can be associated with brain injury), and (7) recurrent stroke.

The approach to monitoring the stroke patient is summarized in Table 22–5. Customization of the plan should be made for each patient based on his or her comorbidities and ongoing disease processes.

ABBREVIATIONS

ACE: angiotensin-converting enzyme
 ADP: adenosine diphosphate
 ARB: angiotensin II receptor blocker
 ATP: adenosine triphosphate
 AVM: arteriovenous malformation
 cAMP: cyclic adenosine monophosphate
 CAST: Chinese Acute Stroke Trial
 CD: carotid Doppler
 cGMP: cyclic guanosine monophosphate
 CT scan: computed tomographic scan
 CYP3A4: cytochrome P450 3A4
 DCI: delayed cerebral ischemia
 EAFT: European Atrial Fibrillation Trial
 ECG: electrocardiogram
 ERDP-ASA: extended-release dipyridamole plus aspirin
 GI: gastrointestinal
 ICH: intracerebral hemorrhage
 INR: international normalized ratio
 IST: International Stroke Trial
 JNC: Joint National Committee
 LDL: low-density lipoprotein
 MI: myocardial infarction
 MRI: magnetic resonance imaging
 NCEP: National Cholesterol Education Program
 NIHSS: National Institutes of Health Stroke Scale
 NINDS: National Institute of Neurological Disorders and Stroke
 NVAf: nonvalvular atrial fibrillation
 PAD: peripheral arterial disease
 PGI₂: prostacyclin
 QALY: quality-adjusted life-year
 RRR: relative risk reduction
 SAH: subarachnoid hemorrhage
 TCD: transcranial Doppler
 TIA: transient ischemic attack
 TXA₂: thromboxane A₂
 t-PA: tissue plasminogen activator

ROBERT L. TALBERT

KEY CONCEPTS

- 1 Hypercholesterolemia, elevated low-density lipoprotein (LDL) levels, and low high-density lipoprotein (HDL) levels are unequivocally linked to increased risk for coronary heart disease and cerebrovascular morbidity and mortality. LDL is the primary target.
- 2 Multiple genetic abnormalities and environmental factors are involved in clinical lipid abnormalities, and routinely used clinical laboratory measurements do not define the underlying abnormalities.
- 3 Initial therapy for any lipoprotein disorder is therapeutic lifestyle changes with restricted intake of total and saturated fat and cholesterol and a modest increase in polyunsaturated fat intake along with a program of regular exercise and weight reduction if needed.
- 4 If pharmacologic therapy is insufficient after therapeutic lifestyle changes, lipid-lowering agents should be chosen based on the specific lipoprotein disorder presentation and the severity of the lipid abnormality.
- 5 Considering compliance, adverse effects, and effectiveness, for patients with hypercholesterolemia statins are the drugs of choice because they are the most potent form of monotherapy and are cost effective in patients with known coronary artery disease or multiple risk factors and in high-risk primary prevention patients.
- 6 Patients who do not respond to statin monotherapy can be treated with combination therapy for hypercholesterolemia but should be monitored closely because of an increased risk for adverse effects and drug interactions.
- 7 Hypertriglyceridemia usually responds well to niacin, gemfibrozil, and fenofibrate. High-dose niacin should be used cautiously in diabetics because of worsening glycemic control. Statins lower triglycerides to a variable extent depending on baseline triglyceride concentration and statin potency.
- 8 Low high-density lipoprotein-cholesterol (HDL-C) levels are addressed with lifestyle modifications, such as smoking cessation and increased exercise. Niacin, gemfibrozil, and fenofibrate can significantly increase HDL-C.
- 9 Lipid-lowering therapy is generally considered cost effective, particularly in secondary intervention and high-risk patients.
- 10 Decreasing elevated total cholesterol and low-density lipoprotein cholesterol (LDL-C) levels reduce coronary heart disease mortality and total mortality; increasing HDL reduces coronary heart disease events as well. Aggressive treatment of hypercholesterolemia results in fewer patients progressing to myocardial infarction, angina, and stroke and reduces the need for interventions such as coronary artery bypass graft and percutaneous transluminal coronary angioplasty.

Cholesterol, triglycerides, and phospholipids are the major lipids in the body. They are transported as complexes of lipid and proteins known as *lipoproteins*. Plasma lipoproteins are spherical particles with surfaces that consist largely of phospholipid, free cholesterol, and protein and cores composed mostly of triglyceride and cholesterol ester (Fig. 23–1). The three major classes of lipoproteins in serum are low-density lipoproteins (LDLs), high-density lipoproteins (HDLs), and very-low-density lipoproteins (VLDLs). VLDL is carried in the circulation as triglyceride and can be estimated by dividing the triglyceride concentration by five. Intermediate-density lipoprotein (IDL) resides between VLDL and LDL and is included in the LDL measurement in routine clinical measurement. Abnormalities of plasma lipoproteins can result in a predisposition to coronary, cerebrovascular, and peripheral vascular arterial disease and constitutes one of the major risk factors for coronary heart disease (CHD). Accumulating evidence over the last decades had linked elevated total cholesterol and low-density lipoprotein-cholesterol (LDL-C) levels and reduced HDL levels to the development of CHD. Premature coronary atherosclerosis, leading to the manifestations of ischemic heart disease (see Chap. 17), is the most common and significant consequence of dyslipidemia. The National Cholesterol Education Program (NCEP) Adult Treatment Panel III (ATP III) published its third report summarizing these data and giving recommendations for the management of hypercholesterolemia in adults.^{1,2} This report and the later update modify earlier recommendations and provide a new way of risk-stratifying patients based on multiple risk factors, the presence of diabetes, and the metabolic syndrome. The American Heart Association (AHA) also provides guidelines for primary and secondary prevention of CHD.^{3,4}

Total cholesterol and LDL-C increase throughout life in men and women, representing an atherogenic pattern characteristic of westernized society diets.⁵ Based on the National Health and Nutrition Examination Survey (NHANES 1999–2004) and ATP III guidelines, slightly more than 50% or nearly 105 million American adults older than 20 years have total cholesterol levels ≥ 200 mg/dL.⁶ More than half of individuals at borderline to high risk remain unaware that they have hypercholesterolemia, and fewer than half of highest-risk persons (those with symptomatic CHD) are receiving lipid-lowering

FIGURE 23-1. Diagrammatic representation of the structure of low-density lipoprotein (LDL), the LDL receptor, and the binding of LDL to the receptor via apolipoprotein B-100. (From Ganong WF. *Review of Medical Physiology*, 22nd ed. New York: McGraw-Hill, 2005:303.)

treatment. Approximately one third of treated patients are achieving their LDL goal; fewer than 20% of CHD patients are at their LDL goal.^{6,7} Changes in the NCEP guidelines have increased the number of persons eligible for therapeutic lifestyle changes (TLC) or lipid-lowering therapy by millions. NCEP estimates that only 26% of patients have an optimal LDL-C (<100 mg/dL) and that large numbers of patients either are untreated or undertreated.¹ Unfortunately, those patients at highest risk are less likely to be treated to desirable levels of LDL.⁸ Although these numbers seem staggering in their enormity, substantial progress has been made, and the number of Americans with a desirable blood cholesterol level (<200 mg/dL) has risen to 49% from 45% from the earlier survey (1976–1980), whereas the average total cholesterol in the United States has fallen from 220 mg/dL in 1960–1962 to 203 mg/dL in 2002.⁹ Patients who are at risk but who have not yet experienced their first cardiovascular or cerebrovascular event (e.g., myocardial infarction [MI]) are termed *primary prevention* patients, whereas those with manifest vascular disease are termed *secondary intervention* patients.

① Data from the Framingham study and from other studies demonstrate that the risk for developing cardiovascular disease is related to the degree of total cholesterol and LDL elevation in a graded, continuous fashion.^{10,11} Hypercholesterolemia is additive to the other nonlipid risk factors for CHD, including cigarette smoking, hypertension, diabetes, low HDL levels, and electrocardiographic abnormalities. The presence of established CHD or prior MI increases the risk of MI five to seven times that seen in men or women without CHD, and LDL level is a significant predictor of subsequent morbidity and mortality. Approximately 50% of all MIs and at least 70% of CHD deaths occur in patients with known CHD; therefore, these patients should be targeted for screening, identification, and treatment. Unfortunately, the identification of patients at high risk because of hypercholesterolemia or other lipid disorders is too frequently overlooked because blood lipid levels are not always evaluated in this population even after an event such as MI.

A comparison of the United States to other countries shows similar relationships between total cholesterol, LDL, and an inverse relationship with HDL to coronary artery disease (CAD) mortality.¹⁰

On a positive note, the U.S. mortality rate is midway among the countries studied. The United States has shown the greatest decline in CAD mortality (35%–40%) in men and women over the last 10 years compared to other countries. A decline in the prevalence of hypercholesterolemia in certain segments of the U.S. population parallels these trends in mortality.¹ LDL and the ratio of LDL to HDL also have been used to assess risk, but their use adds little information to total cholesterol alone unless HDL is abnormally high or low. HDL transports cholesterol from lipid-laden foam cells to the liver. HDL has been shown to be protective for the occurrence of CHD, and an inverse relationship exists between CHD and HDL levels.¹²

VLDL, the major lipoprotein associated with triglycerides, is enriched with cholesterol esters. It is smaller, denser, and more atherogenic than less-dense VLDL. Routine measurement of triglycerides cannot distinguish between the types of VLDL present in plasma. Elevation of triglyceride-rich lipoproteins is associated with low HDL, and this ratio predicts increased risk. The 8-year follow-up of the Copenhagen male study found a clear gradient of risk for ischemic heart disease with increasing triglyceride levels within each level of high-density lipoprotein-cholesterol (HDL-C). Compared to the lowest tertile of triglyceride concentrations, the highest tertile had 2.2 relative risk for ischemic heart disease, and the relationship extended across all concentrations of HDL.¹³ The Helsinki Heart Study showed that hypertriglyceridemia and low HDL are associated with obesity (body mass index [BMI] >26 kg/m²), smoking, sedentary lifestyle, blood pressure ≥140/90 mm Hg, and blood glucose >4.4 mmol/L, and that the benefit of gemfibrozil (risk reduction 68%, *P* <0.03) was largely confined to overweight subjects.¹⁴ Hypertriglyceridemia in certain instances (e.g., diabetes mellitus, nephrotic syndrome, chronic renal disease, and perhaps in women) is associated with increased cardiovascular risk. This is thought to be a consequence of the presence of atherogenic lipoproteins and of hypertriglyceridemia being a marker for them, as triglycerides usually are not independently predictive for CHD.¹⁵

LIPOPROTEIN METABOLISM AND TRANSPORT

As the major plasma lipids, cholesterol and triglycerides are essential substrates for cell membrane formation and hormone synthesis, and they provide a source of free fatty acids.¹⁶ Dyslipidemia can be defined as elevated total cholesterol, LDL-C, or triglycerides level, low HDL-C concentration, or some combination of these abnormalities. Lipids, which are water immiscible, are not present in free form in the plasma but rather circulate as lipoproteins. Hyperlipoproteinemia refers to an increased concentration of the lipoprotein macromolecules that transport lipids in the plasma. The density of plasma lipoproteins is determined by their relative content of protein and lipid. Density, composition, size, and electrophoretic mobility divide lipoproteins into four classes (Table 23–1).

LDL is further divided into LDL₁ (or IDL; density 1.006–1.019 g/mL) and LDL₂ (1.019–1.063 g/mL). LDL₂ is the major LDL component in plasma; it carries 60% to 70% of the total serum cholesterol. HDL has been subdivided into HDL₂ (density 1.063–1.125 g/mL) and HDL₃ (1.125–1.21 g/mL). Fluctuations in HDL usually are caused by alterations in the levels of HDL₂. HDL normally carries approximately 20% to 30% of the total cholesterol. VLDL also has been subdivided into three classes, and it carries approximately 10% to 15% of serum cholesterol and most of the triglyceride in the fasting state. VLDL is the precursor for LDL, and VLDL remnants also may be atherogenic. Table 23–2 lists the characteristics of the protein constituent of lipoproteins known as *apolipoproteins*. The structure of LDL, the LDL receptor, and the binding of LDL to the receptor via apolipoprotein B-100 is shown in Fig. 23–1.

TABLE 23-1 Composition of Lipoprotein Isolated from Normal Subjects

Lipoprotein Class	Density Range (g/mL)	Diameter (nm)	Protein	Composition (Weight %)			
				Triglyceride	Free Cholesterol	Ester	Phospholipid
Chylomicrons	<0.94	75–1200	1–2	80–95	1–3	2–4	3–9
VLDL	0.94–1.006	30–80	6–10	55–80	4–8	16–22	10–20
LDL	1.006–1.063	18–25	18–22	5–15	6–8	45–50	18–24
HDL	1.063–1.21	5–12	45–55	5–10	3–5	15–20	20–30

HDL, high-density lipoprotein; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein.

Chylomicrons are large triglyceride-rich particles that contain apolipoproteins B-48, B-100, and E. They are formed from dietary fat solubilized by bile salts in intestinal mucosal cells. Chylomicrons normally are not present in the plasma after a fast of 12 to 14 hours. They are catabolized by lipoprotein lipase (LPL), which is activated by apolipoprotein C-II and in the vascular endothelium and hepatic lipase to form chylomicron remnants. The remnants that contain apolipoprotein E (Fig. 23–2) are taken up by the “remnant receptor,” which may be an LDL receptor–related protein, in the liver. Free cholesterol is liberated intracellularly after attachment to the remnant receptor. Chylomicrons also function to deliver dietary triglyceride to skeletal muscle and adipose tissue. During the catabolism of nascent chylomicrons to remnants, triglyceride is converted to free fatty acids and apolipoproteins A-I, A-II, A-IV (free in plasma), C-I, C-II, and C-III, and phospholipids are transferred to HDL. Apolipoproteins E and C-II are transferred to chylomicrons from HDL and eventually back through these metabolic events. Hepatic VLDL synthesis is regulated in part by diet and hormones and is inhibited by uptake of chylomicron remnants in the liver. VLDL is secreted from the liver and serially converted via LPL to IDL and finally to LDL. VLDL receptors are found in adipose tissue and muscle and bear close homology to the structure of LDL receptors.

LDL, the major cholesterol transport lipoprotein, basically has only apolipoprotein B-100. It is mostly derived from VLDL catabolism and cellular synthesis. When normal subjects fast and consume a low-fat diet, most cholesterol is synthesized and used in the extrahepatic organs; most of the cholesterol carried by LDL is taken

up by the liver for catabolism. In patients with homozygous familial hypercholesterolemia, enhanced synthesis of LDL may occur because LDL clearance is reduced as a consequence of the lack of LDL receptors. LDL is catabolized through interaction of cell surface receptors found on liver, adrenal, and peripheral cells (including fibroblasts and smooth muscle cells). These cells recognize apolipoprotein B-100 on LDL, and, after binding to a receptor on the cell membrane, LDL is internalized and degraded. In the normal fasting state, approximately 70% of LDL is cleared through the receptor-dependent mechanism, although this is highly dependent on the availability and type of saturated and monosaturated or polyunsaturated fat from dietary sources. Ingestion of cholesterol and saturated fatty acids such as C12:0, C14:0, and C16:0 is associated with reduced LDL receptor activity, increased LDL production rate, and elevated LDL plasma concentration. Receptor-independent mechanisms are also involved to a lesser extent in the catabolism of LDL, and these receptors are present in many tissues but are most active in animals in the adrenals and ovary. Increased intracellular cholesterol resulting from LDL catabolism inhibits the activity of 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase, the rate-limiting enzyme for intracellular cholesterol biosynthesis (Fig. 23–3). Additional consequences of increased intracellular cholesterol include reduced synthesis of LDL receptors, which limits subsequent cholesterol uptake from the plasma, and accelerated activity of acyl-coenzyme A:cholesterol acyltransferase (ACAT) to facilitate cholesterol storage within cells. LDL-C also may be excreted into bile and become part of the enterohepatic pool or may be lost in the stool.

TABLE 23-2 Characteristics and Functions of Apolipoproteins

Apolipoprotein	Lipoprotein Density Class	Approximate Plasma Concentration (mg/dL)	Approximate Molecular Weight (kDa)	Reported Functions	Major Site of Synthesis
A-I	Chylomicrons, HDL	120	28	Cofactor with LCAT, structural protein on HDL, ligand for HDL receptor	Liver, intestine
A-II	Chylomicrons, HDL	35	17	Structural protein for HDL, ligand for HDL receptor	Liver
A-IV	Chylomicrons, 1.21B	15	46	Possibly facilitates transfer of other apolipoproteins between HDL and chylomicrons	Intestine
Lp(a)	LDL, HDL	10	500±	Bound to B-100, high homology with plasminogen, may prevent LDL uptake by B, E receptor	Liver
B-100	VLDL, LDL, IDL	100	540	Necessary for assembly and secretion of VLDL from liver, structural protein of VLDL, IDL, LDL, ligand for LDL receptor	Liver
B-48	Chylomicrons	Trace	264	Necessary for assembly and secretion of chylomicrons from small intestine	Intestine
C-I	Chylomicrons, VLDL, HDL	7	6.6	Cofactor with LCAT; may inhibit hepatic uptake of chylomicron and VLDL remnants	Liver
C-II	Chylomicrons, VLDL, HDL	4	8.9	Activator of LPL	Liver
C-III	Chylomicrons, VLDL, HDL	13	8.8	Inhibitor with LPL; may inhibit hepatic uptake of chylomicron and VLDL remnants	Liver
D	HDL	6	32	?	?
E2-E4	Chylomicrons, VLDL, HDL	5	34	Ligand for several lipoproteins to LDL receptor, LRP and possibly to a separate hepatic apolipoprotein E receptor	Liver

IDL, intermediate-density lipoprotein; LCAT, lecithin-cholesterol acyltransferase; LRP, LDL receptor–related protein. Other abbreviations are in Table 23–1.

FIGURE 23-2. Simplified diagram of lipoprotein systems for transporting lipids in humans. In the exogenous system, chylomicrons rich in triglycerides of dietary origin are converted to chylomicron remnants rich in cholesteryl esters by the action of lipoprotein lipase (LPL). In the endogenous system, very-low-density lipoproteins (VLDL) rich in triglycerides are secreted by the liver and converted to intermediate-density lipoproteins (IDL) and then to low-density lipoproteins (LDL) rich in cholesteryl esters. Some of the LDLs enter the subendothelial space of arteries, are oxidized, and then are taken up by macrophages, which become foam cells. The letters on the chylomicrons, chylomicron remnants, VLDL, IDL, and LDL identify the primary apoproteins (ApoB, ApoC, ApoE) found in them. (LDLR, low-density lipoprotein receptor.) (From Kasper DL, Braunwald E, Fauci AS, et al., eds. *Harrison's Principles of Internal Medicine*, 16th ed. New York, McGraw-Hill, 2005, p. 2289.)

Lipoprotein(a) is a cholesterol-rich lipoprotein similar in composition and density to LDL and with close homology to fibrinogen. It is reported to be an important independent risk factor for the development of premature cardiovascular disease.

Nascent HDL is derived from liver and gut synthesis primarily in the form of apolipoprotein A-I phospholipid discs.¹² Esterification of free cholesterol in nascent HDL and from peripheral tissues to cholesteryl esters by lecithin-cholesterol acyltransferase (LCAT) results in the production of HDL₃. Further addition of tissue cholesterol to HDL₃ results in the formation of HDL₂. HDL₂ can also be formed from remodeling of chylomicrons and VLDL catabolism. HDL₂ can be converted back to HDL₃ by the action of hepatic lipase and by the transfer of cholesteryl esters to the liver, LDL, and VLDL. Apolipoprotein A-I production is increased by estrogens, leading to higher HDL levels in women and in individuals receiving estrogen. Transfer of excess cholesterol from peripheral tissues by HDL is called *reverse cholesterol transport*. Putative HDL receptors in peripheral cells facilitate the uptake of cholesterol by HDL, which transfers cholesterol to either VLDL and LDL or to the liver for secretion into bile or conversion into bile acids. These processes rid peripheral tissue (e.g., coronary arteries) of excessive amounts of cholesterol and account for some of the protective effects noted with increasing HDL in women and other factors that elevate HDL levels. Variants of the cholesterol ester transfer protein (CETP) have been demonstrated in humans, and the B1B1 genotype is associated with lower HDL and progression of coronary atherosclerosis. Inhibition of CETP leads to elevations in HDL. However, CETP inhibitors tested in clinical trials did not induce regression of atherosclerotic plaque and were associated with higher blood pressure and CHD events.^{17–19}

The “response-to-injury” hypothesis states that risk factors such as oxidized LDL, mechanical injury to the endothelium (e.g., percutaneous transluminal angioplasty), excessive homocysteine, immunologic attack, and infection-induced (e.g., *Chlamydia*, herpes simplex virus 1) changes in endothelial and intimal function lead to endothelial dysfunction and a series of cellular interactions that culminate in atherosclerosis. C-reactive protein is an acute phase reactant and a

marker for inflammation; it may be useful in identifying patients at risk for developing CAD.²⁰ The eventual outcomes of this atherogenic cascade are clinical events such as angina, MI, arrhythmias, stroke, peripheral arterial disease, abdominal aortic aneurysm, and sudden death. Atherosclerotic lesions are thought to arise from transport and retention of plasma LDL-C through the endothelial cell layer into the extracellular matrix of the subendothelial space. Once in the artery wall, LDL is chemically modified through oxidation and nonenzymatic glycation. Mildly oxidized LDL then recruits monocytes into the artery wall, and the monocytes become transformed into macrophages. Macrophages have tremendous potential for accelerating LDL oxidation and apolipoprotein B accumulation and altering the receptor-mediated uptake of LDL into the artery wall from the usual LDL receptor to a “scavenger receptor” not regulated by cell content of cholesterol. Oxidized LDL increases plasminogen inhibitor levels (promotion of coagulation), induces expression of endothelin (vasoconstrictive substance), inhibits expression of nitric oxide (a vasodilator and platelet inhibitor), and is toxic to macrophages if highly oxidized. As oxidation of biologically active lipids proceeds, other lipids such as lysophosphatidylcholine, hydroperoxides, aldehydic breakdown products of fatty acids, and oxysterol are formed and continue the reaction within the tissue. These events lead to a massive accumulation of cholesterol. The cholesterol-laden cells are called *foam cells*, which are the earliest recognized cells of the arterial fatty streak.

Oxidized LDL provokes an inflammatory response that is mediated by a number of chemoattractants and cytokines. Examples that appear to be involved at different stages of lesion development include monocyte chemoattractant protein 1 (MCP-1); monocyte colony stimulating factor (M-CSF); *gro*; vascular cell adhesion molecule (VCAM-1); E-selectin (endothelial-leukocyte adhesion molecule [ELAM]-1); intercellular adhesion molecule (ICAM-1); platelet-derived growth factor (PDGF); vascular endothelial growth factor (VEGF); transforming growth factors (TGF- α and TGF- β); interleukin (IL)-1 and IL-6; and the ratio of IL-10 and IL-12. Some of these factors (e.g., MCP-1 and M-CSF) appear to participate early in the

FIGURE 23-3. Biosynthetic pathway for cholesterol. The rate-limiting enzyme in this pathway is 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG-CoA reductase). (CETP, cholesterol ester transfer protein; HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; LPL, lipoprotein lipase; VLDL, very-low-density lipoprotein.) (Modified from Breslow JL. Genetic basis of lipoprotein disorders. *J Clin Invest* 1989; 84:373.)

process of monocyte-macrophage attachment and transmigration across the endothelium, whereas others (PDGF and VCAM-1) promote later lesion growth.¹⁸ Based on murine model studies, the extent of oxidation and the inflammatory response is under genetic control of a major gene termed *Ath-1*. The process of aging may lead to lipoproteins that are more susceptible to oxidation and have longer resident time in the vascular compartment. Two proteins associated with HDL (apolipoprotein J and paraoxonase) appear to play important roles in minimizing oxidation of LDL-C.^{21,22} Increased recognition of the role of these growth regulatory molecules provides the possibility of future directions for antagonists to regulatory molecules such as PDGF, TGF- β , and the interleukins. Repeated injury and repair within an atherosclerotic plaque eventually leads to the formation of a fibrous cap that protects the underlying core of lipids, collagen, calcium, and inflammatory cells such as T-lymphocytes. Maintenance of the fibrous plaque is critical to preventing plaque rupture and subsequent coronary thrombosis. An imbalance between plaque synthesis and degradation may lead to a weakened or vulnerable plaque prone to rupture. The fibrous cap may become weakened through decreased synthesis of the extracellular matrix or increased degradation of the matrix. The cytokine interferon- γ , produced by T lymphocytes, inhibits the ability of smooth muscle cells to synthesize collagen, a structurally important component of the fibrous cap. A family of enzymes known as *matrix*

TABLE 23-3 Fredrickson-Levy-Lees Classification of Hyperlipoproteinemia

Type	Lipoprotein Elevation
I	Chylomicrons
IIa	LDL
IIb	LDL + VLDL
III	IDL (LDL ₁)

V	VLDL + Chylomicrons

IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein.

metalloproteinases can degrade all major constituents of the vascular extracellular matrix: collagen, elastin, and proteoglycans.²³

Lipoprotein disorders are classified into six categories, which are commonly used for phenotypical description of dyslipidemia (Table 23-3). **2** Specific genetic defects with disrupted protein, cell, and organ function give rise to several disorders within each family of lipoproteins (Table 23-4). An elevated cholesterol level does not necessarily equate with familial hypercholesterolemia or type IIa, as cholesterol may be elevated in other lipoprotein disorders and the lipoprotein pattern does not describe the underlying genetic defect. The preceding discussion focused on primary or genetic dyslipoproteinemia; however, secondary forms exist, and several drugs may elevate lipid levels (Table 23-5). The secondary forms of hyperlipidemia initially should be managed by correcting the underlying abnormality, including modification of drug therapy when appropriate.

Familial hypercholesterolemia is characterized by (a) selective elevation in the plasma level of LDL, (b) deposition of LDL-derived cholesterol in tendons (xanthomas) and arteries (atheromas), and (c) inheritance as an autosomal dominant trait with homozygotes more severely affected than heterozygotes. Homozygotes (prevalence 1:1,000,000) have severe hypercholesterolemia (650–1,000 mg/dL), with early appearance of cutaneous xanthomas and fatal CHD generally before age 20 years. The primary defect in familial hypercholesterolemia is the inability to bind LDL to the LDL receptor or, rarely, a defect of internalizing the LDL receptor complex into the cell after normal binding. Homozygotes have essentially no functional LDL receptors. This leads to lack of LDL degradation by cells and unregulated biosynthesis of cholesterol, with total cholesterol and LDL-C inversely proportional to the deficit in LDL receptors. Heterozygotes have only about half the normal number of LDL receptors, total cholesterol levels in the range from 300 to 600 mg/dL and cardiovascular events beginning in the third and fourth decades of life.

Familial LPL deficiency is a rare, autosomal recessive trait characterized by massive accumulation of chylomicrons and corresponding increase in plasma triglycerides or a type I lipoprotein pattern. VLDL concentration is normal. Presenting manifestations include repeated attacks of pancreatitis and abdominal pain, eruptive cutaneous xanthomatosis, and hepatosplenomegaly beginning in childhood. Symptom severity is proportional to dietary fat intake and consequently to the elevation of chylomicrons. LPL is normally released from vascular endothelium or by heparin and hydrolyzes chylomicrons and VLDL (see Fig. 23-2). Diagnosis is based on low or absent enzyme activity with normal human plasma or apolipoprotein C-II, a cofactor of the enzyme. Accelerated atherosclerosis is not associated with the disease. Abdominal pain, pancreatitis, eruptive xanthomas, and peripheral polyneuropathy characterize type V (VLDL and chylomicrons). Symptoms may occur in childhood, but usually the disorder is expressed at a later age. The risk of atherosclerosis is increased with the disorder. Patients commonly are obese, hyperuricemic, and diabetic, and alcohol intake, exogenous estrogens, and renal insufficiency tend to be exacerbating factors.

Patients with familial type III hyperlipoproteinemia (also called *dysbetalipoproteinemia*, *broad-band*, or β -VLDL) develop the fol-

TABLE 23-4 Lipoprotein Disorders

Lipid Phenotype	Plasma Lipid Levels [mmol/L (mg/dL)]	Lipoproteins		Clinical Signs
		Elevated	Phenotype	
Isolated hypercholesterolemia				
Familial hypercholesterolemia	Heterozygotes TC = 7–13 (275–500)	LDL	IIa	Usually develop xanthomas in adulthood and vascular disease at 30–50 years
	Homozygotes TC >13 (>500)	LDL	IIa	Usually develop xanthomas in adulthood and vascular disease in childhood
Familial defective Apo B-100	Heterozygotes TC = 7–13 (275–500)	LDL	IIa	
Polygenic hypercholesterolemia	TC = 6.5–9 (250–350)	LDL	IIa	Usually asymptomatic until vascular disease develops; no xanthomas
Isolated hypertriglyceridemia				
Familial hypertriglyceridemia	TG = 2.8–8.5 (250–750)	VLDL	IV	Asymptomatic; may be associated with increased risk of vascular disease
Familial LPL deficiency	TG >8.5 (750)	Chylomicrons, VLDL	I, V	May be asymptomatic; may be associated with pancreatitis, abdominal pain, hepatosplenomegaly
Familial Apo C-II deficiency	TG >8.5 (>750)	Chylomicrons, VLDL	I, V	As above
Hypertriglyceridemia and hypercholesterolemia				
Combined hyperlipidemia	TG = 2.8–8.5 (250–750) TC = 6.5–13 (250–500)	VLDL, LDL	IIb	Usually asymptomatic until vascular disease develops; familial form may present as isolated high TG or isolated high LDL cholesterol
Dysbetalipoproteinemia	TG = 2.8–8.5 (250–750); TC = 6.5–13 (250–500)	VLDL, IDL; LDL normal	III	Usually asymptomatic until vascular disease develops; may have palmar or tuberous xanthomas

Apo, apolipoprotein; LPL, lipoprotein lipase; TC, total cholesterol; TG, triglycerides. Other abbreviations as in Table 23-1.

lowing clinical features after age 20 years: xanthoma striata palmaris (yellow discolorations of the palmar and digital creases); tuberous or tuberous xanthomas (bulbous cutaneous xanthomas); and severe atherosclerosis involving the coronary arteries, internal carotids, and abdominal aorta. A defective structure of apolipoprotein E does not allow normal hepatic surface receptor binding of remnant particles derived from chylomicrons and VLDL (known as IDL). Aggravating factors such as obesity, diabetes, and pregnancy may promote overproduction of apolipoprotein B-containing lipoproteins. Although homozygosity for the defective allele (E_2/E_2) is common (1:100), only 1 in 10,000 express the full-blown picture, and interaction with other genetic or environmental factors, or both, is needed to produce clinical disease.

Familial combined hyperlipidemia is characterized by elevations in total cholesterol and triglycerides, decreased HDL, increased apolipoprotein B, and small, dense LDL.²⁴ It is associated with premature CHD and may be difficult to diagnose because lipid levels do not consistently display the same pattern.

Type IV hyperlipoproteinemia is common and occurs in adults, primarily in patients who are obese, diabetic, and hyperuricemic and do not have xanthomas. It may be secondary to alcohol ingestion and can be aggravated by stress, progestins, oral contraceptives, thiazides, or β -blockers. Two genetic patterns that occur in type IV hyperlipoproteinemia are familial hypertriglyceridemia, which does not carry a great risk for premature CAD, and familial combined hyperlipidemia, which is associated with increased risk for cardiovascular disease.

Rare forms of lipoprotein disorders include hypobetalipoproteinemia, abetalipoproteinemia, Tangier disease, LCAT deficiency (fish eye disease), cerebrotendinous xanthomatosis, and sitosterolemia. Most of these rare lipoprotein disorders do not result in premature atherosclerosis, with the exceptions of familial LCAT deficiency, cerebrotendinous xanthomatosis, and sitosterolemia with xanthomatosis. Treatment consists of dietary restriction of plant sterols (sitosterolemia with xanthomatosis) and chenodeoxycholic acid (cerebrotendinous xanthomatosis), or, potentially, blood transfusion (LCAT deficiency).

TABLE 23-5 Secondary Causes of Lipoprotein Abnormalities

Hypercholesterolemia	Hypothyroidism Obstructive liver disease Nephrotic syndrome Anorexia nervosa Acute intermittent porphyria Drugs: progestins, thiazide diuretics, glucocorticoids, β -blockers, isotretinoin, protease inhibitors, cyclosporine, mirtazapine, sirolimus
Hypertriglyceridemia	Obesity Diabetes mellitus Lipodystrophy Glycogen storage disease Ileal bypass surgery Sepsis Pregnancy Acute hepatitis Systemic lupus erythematosus Monoclonal gammopathy: multiple myeloma, lymphoma Drugs: Alcohol, estrogens, isotretinoin, β -blockers, glucocorticoids, bile acid resins, thiazides; asparaginase, interferons, azole antifungals, mirtazapine, anabolic steroids, sirolimus, bexarotene
Hypocholesterolemia	Malnutrition Malabsorption Myeloproliferative diseases Chronic infectious diseases: acquired immune deficiency syndrome, tuberculosis Monoclonal gammopathy Chronic liver disease
Low high-density lipoprotein	Malnutrition Obesity Drugs: non-ISA β -blockers, anabolic steroids, probucol, isotretinoin, progestins

ISA, intrinsic sympathomimic activity.

CLINICAL PRESENTATION

General

- Most patients are asymptomatic for many years before disease is clinically evident
- Patients with the metabolic syndrome may have three or more of the following: abdominal obesity, atherogenic dyslipidemia, increased blood pressure, insulin resistance with or without glucose intolerance, prothrombotic state, or proinflammatory state

Symptoms

- None to severe chest pain, palpitations, sweating, anxiety, shortness of breath, loss of consciousness or difficulty with speech or movement, abdominal pain, sudden death

Signs

- None to severe abdominal pain, pancreatitis, eruptive xanthomas, peripheral polyneuropathy, high blood pressure, body mass index >30 kg/m² or waist size >40 inches in men (35 inches in women)

Laboratory Tests

- Elevations in total cholesterol, LDL, triglycerides, apolipoprotein B, C-reactive protein
- Low HDL

Other Diagnostic Tests

- Lipoprotein(a), homocysteine, serum amyloid A, small dense LDL (pattern B), HDL subclassification, apolipoprotein E isoforms, apolipoprotein A-1, fibrinogen, folate, *Chlamydia pneumoniae* titer, lipoprotein-associated phospholipase A₂, omega-3 index²⁵
- Various screening tests for manifestations of vascular disease (ankle-brachial index, exercise testing, magnetic resonance imaging) and diabetes (fasting glucose, oral glucose tolerance test)

PATIENT EVALUATION

A fasting lipoprotein profile including total cholesterol, LDL-C, HDL-C, and triglycerides should be measured in all adults 20 years and older at least once every 5 years.¹ If the profile is obtained in the nonfasted state, only total cholesterol and HDL-C will be usable because LDL-C usually is a calculated value. If total cholesterol is ≥ 200 mg/dL or HDL-C is <40 mg/dL, a followup fasting lipoprotein profile should be obtained. After a lipid abnormality is confirmed (Table 23-6), major components of the evaluation are the history (including age, gender, and, if female, menstrual and hormone replacement status), physical examination, and laboratory investigations. A complete history and physical examination should assess (a) presence or absence of cardiovascular risk factors (Table 23-7) or definite cardiovascular disease in the individual; (b) family history of premature cardiovascular disease or lipid disorders; (c) presence or absence of secondary causes of lipid abnormalities, including concurrent medications (see Table 23-5); and (d) presence or absence of xanthomas or abdominal pain, or history of pancreatitis, renal or hepatic disease, peripheral vascular disease, abdominal aortic aneurysm, or cerebral vascular disease (carotid bruits, stroke, or transient ischemic attack). In an important change in the ATP III guidelines, diabetes mellitus is regarded as a CHD risk equivalent.¹ The presence of diabetes in patients without known CHD is associated with the same level of risk as in patients without diabetes but with confirmed CHD.^{26,27} ATP III identifies four categories of risk that modify the goals and modalities of LDL-lowering therapy (Table 23-8).² The

TABLE 23-6 Classification of Total, LDL, and HDL Cholesterol, and Triglycerides

Total cholesterol	
<200	Desirable
200–239	Borderline high
≥ 240	High
LDL cholesterol	
<100	Optimal
100–129	Near or above optimal
130–159	Borderline high
160–189	High
≥ 190	Very high
HDL cholesterol	
<40	Low
≥ 60 mg/dL	High
Triglycerides	
<150	Normal
150–199	Borderline high
200–499	High
≥ 500	Very high

All values are given in milligrams per deciliters.

HDL, high-density lipoprotein; LDL, low-density lipoprotein.

highest category is known CHD or CHD risk equivalents, which is defined as the risk for major coronary events equal to or greater than established CHD, that is, $>20\%$ per 10 years (2% per year). The next category is moderately high risk, consisting of patients with multiple (2+) risk factors in which 10-year risk for CHD is 10% to 20%. Moderate risk is defined as ≥ 2 risk factors and a 10-year risk of $\geq 10\%$. The lowest risk category is persons with a risk factor of 0 to 1. Risk is estimated from Framingham risk scores²⁸ and is estimated based on the patient's age, LDL-C or total cholesterol level, blood pressure, presence of diabetes, and smoking status (Table 23-7). This approach for a single patient is referred to as a *case finding* or *patient-based approach*, whereas large-scale screening and recommendations for the general populace, health care providers, and the food industry are called a *population-based approach*.

Measurement of plasma cholesterol (which is approximately 3% lower than serum determinations), triglyceride, and HDL-C levels after a fast of 12 hour or longer is important, as triglycerides may be elevated in nonfasted individuals; total cholesterol is only modestly affected by fasting. Analytic and biologic variability can have a major impact on the measurement and interpretation of cholesterol level (or any other laboratory test). Analytic variability can be minimized through the use of adequate quality control procedures, including internal training, routine calibration and monitoring, and external proficiency testing. Even with these measures, the coefficient of variability in the best procedures can acceptably be up to 5%, and,

TABLE 23-7 Major Risk Factors (Exclusive of LDL Cholesterol) That Modify LDL Goals^a

Age
Men: ≥ 45 years
Women: ≥ 55 years or premature menopause without estrogen replacement therapy
Family history of premature CHD (definite myocardial infarction or sudden death before age 55 years in father or other male first-degree relative, or before age 65 years in mother or other female first-degree relative)
Cigarette smoking
Hypertension ($\geq 140/90$ mm Hg or taking antihypertensive medication)
Low HDL cholesterol (<40 mg/dL) ^b

HDL, high-density lipoprotein; LDL, low-density lipoprotein.

^aDiabetes is regarded as a coronary heart disease (CHD) risk equivalent.

^bHDL cholesterol ≥ 60 mg/dL counts as a "negative" risk factor; its presence removes one risk factor from the total count.

TABLE 23-8 LDL Cholesterol Goals and Cutpoints for Therapeutic Lifestyle Changes and Drug Therapy in Different Risk Categories

Risk Category	LDL Goal (mg/dL)	LDL Level at Which to Initiate TLC (mg/dL)	LDL Level at Which to Consider Drug Therapy (mg/dL)
High risk: CHD or CHD risk equivalents (10-year risk >20%)	<100 (optional goal: <70)	≥100	≥100 (<100 mg/dL; consider drug options) ^a
Moderately high risk: 2+ risk factors (10-year risk >10%–20%)	<130	≥130	≥130 (100–129: consider drug options)
Moderate risk: 2+ risk factors (10-year risk <10%)	<130	≥130	≥160
Lower risk: 0–1 risk factor ^b	<160	≥160	≥190 (160–189: LDL-lowering drug optional)

CHD, coronary heart disease; LDL, low-density lipoprotein.

^aSome authorities recommend use of LDL-lowering drugs in this category if LDL cholesterol <100 mg/dL cannot be achieved by therapeutic lifestyle changes (TLC). Others prefer to use drugs that primarily modify triglycerides and high-density lipoprotein, e.g., nicotinic acid or fibrates. Clinical judgement also may call for deferring drug therapy in this subcategory.

^bAlmost all people with 0–1 risk factor have a 10-year risk <10%; thus, 10-year risk assessment in people with 0–1 risk factor is not necessary.

when combined with average biologic variability, total variability may be as high as approximately 22%. Analytic variability with desktop equipment generally is greater in the fingerstick capillary blood methods, usually yielding measurements less than those from a clinical laboratory; this technology should be considered for use only as a screening method. Reliance on desktop methods can result in misclassification of 7% to 14% of patients if capillary blood is used. Two determinations, 1 to 8 weeks apart, with the patient on a stable diet and weight and in the absence of acute illness, are recommended to minimize variability and obtain a reliable baseline.¹ If total cholesterol is >200 mg/dL, a second determination is recommended, and if the values are more than 30 mg/dL apart, the average of three values should be used. Familiarity with the method and quality control procedures used by local laboratories are essential for interpretation of reported values. If the physical examination and history are insufficient to diagnose a familial disorder, then agarose-gel lipoprotein electrophoresis is useful to determine which class of lipoproteins is affected. If triglyceride levels are <400 mg/dL and neither type III hyperlipidemia nor chylomicrons are detected by electrophoresis, then VLDL and LDL concentrations can be calculated as follows: VLDL = Triglycerides/5; LDL = Total cholesterol – (VLDL + HDL).

Because total cholesterol is composed of cholesterol derived from LDL, VLDL, and HDL, determination of HDL is useful when total plasma cholesterol is elevated. HDL may be elevated by moderate alcohol ingestion (fewer than two drinks per day), physical exercise, smoking cessation, weight loss, oral contraceptives, phenytoin, and terbutaline. Smoking, obesity, a sedentary lifestyle, and use of drugs such as β -blockers lower HDL. Only exercise and smoking cessation can be recommended as interventions for low HDL concentrations. Niacin and gemfibrozil increase HDL concentrations.

The range of lipid concentrations represents a population mean ± 2 SD and does not define the risk of disease. Reference values for plasma total, LDL, and HDL-C concentrations for men and women, as well as various ethnic groups, are available from the NHANES III.⁵ Levels of Cholesterol and triglycerides increase throughout life until about the fifth decade for men and the sixth decade for women. Past these ages, total cholesterol and LDL plateau and fall slightly. HDL tends to fall slightly with time and more rapidly after menopause in women. Institution of a population-based approach for cholesterol reduction should shift the entire curve to the left, and the potential reduction in cardiovascular mortality would be proportional to mean reductions at any cholesterol concentration.

Based on a careful review of the experimental pathologic, genetic, and epidemiologic evidence relating to the relationship between blood cholesterol levels and CHD, the adult treatment panel III of the NCEP recommends use of a fasting lipoprotein profile and risk factor assessment in the initial classification of adults.^{1,29} If total cholesterol is <200 mg/dL, then the patient has a *desirable blood cholesterol level* (Table 23–6). Cholesterol levels between 200 and 239

mg/dL are classified as *borderline–high blood cholesterol levels*, and assessment of risk factors (Table 23–7) is needed to more clearly define disease risk. Blood cholesterol levels ≥ 240 mg/dL are classified as *high blood cholesterol levels*. If total cholesterol is <200 mg/dL and HDL is >40 mg/dL, no further followup is recommended for patients without known CHD who have fewer than two risk factors. In patients with evidence of CHD or other clinical atherosclerotic disease, the LDL goal is <100 mg/dL, and most patients will require diet and/or drug intervention. In patients with very high risk (known CHD and multiple risk factors), the LDL goal may be set <70 mg/dL based on evidence from newer studies.²⁹ Decisions regarding classification and management are based on the LDL-C levels listed in Table 23–8. An increasing number of persons have the metabolic syndrome, which is characterized by abdominal obesity, atherogenic dyslipidemia (elevated triglycerides, small LDL particles, low HDL-C), increased blood pressure, insulin resistance (with or without glucose intolerance), and prothrombotic and proinflammatory states. ATP III recognizes the metabolic syndrome as a secondary target of risk reduction therapy after LDL-C has been addressed, and, if the metabolic syndrome is present, the patient is considered to have a CHD risk equivalent. Other lipid targets include non-HDL goals for patients with triglycerides >200 mg/dL. Non-HDL is calculated by subtracting HDL from total cholesterol, and the targets are 30 mg/dL greater than for LDL at each risk stratum. Non-HDL takes into consideration atherogenic particles such as remnant lipoproteins and IDL, which are not measured in routine clinical laboratory testing.³⁰ HDL raising has potential benefit, but the current guidelines do not set any specific goals, and evidence in support of aggressively increasing HDL levels is modest.³¹

The Expert Panel on Children and Adolescents of the NCEP recommends screening of higher-risk children (positive family history or parental high blood cholesterol ≥ 240 mg/dL).^{32,33} The rationale for this approach is based partly on the recognition that atherosclerosis begins in the childhood and adolescent years, as documented in the Pathobiologic Determinants of Atherosclerosis in Youth (PDAY) and the Bogalusa studies.³⁴ Similarly, if children with high blood lipids or lipoprotein levels are identified but the levels in the parents are unknown, the parents should be screened because they likely are at high risk. Racial and gender differences do exist in the determination of lipoprotein fractions and should be considered in screening. Use of the serum cholesterol level alone may be of insufficient specificity or sensitivity, depending on the cut points used in screening, and other discretionary factors, such as hypertension, smoking, obesity, high-fat diet, and use of cholesterol-raising medication, may be needed to correctly identify children at risk. Presently, children older than 10 years are candidates for drug therapy if a trial of diet (6 months to 1 year) proves to be inadequate and LDL-C remains >190 mg/dL, or >160 mg/dL if two or more risk factors or CHD is present in the child or adolescent, or if patient has a history of premature CHD. The Dietary Intervention Study in

Children (DISC) found that a fat-restricted diet in pubertal children modestly lowered LDL-C and maintained psychologic well-being, and that dietary changes are acceptable to children.^{35,36} Although bile acid sequestrants have been the recommended drugs for this population, clinical trials now demonstrate that statin therapy is effective and well tolerated in pediatric populations.^{37,38} The long-term consequences of drug therapy in this population are unknown. In special instances, familial hypercholesterolemia (particularly the homozygous form) or the existence of CHD or two or more risk factors in the child prompts earlier institution of drug therapy after a trial of dietary intervention.

TREATMENT

■ DESIRED OUTCOMES

The goals of therapy expressed as LDL-C levels and the level of initiation of TLC and drug therapy are given in Tables 23–8 and 23–9 for adults and children, respectively. Although these goals are surrogate end points, the primary reason for instituting TLC and drug therapy is to reduce the risk of first events or recurrent events such as MI, angina, heart failure, ischemic stroke, and other forms of peripheral arterial disease, such as carotid stenosis and abdominal aortic aneurysm.

■ GENERAL APPROACH¹

Establishing targeted changes and outcomes with consistent reinforcement of goals and measures at followup visits to attain goals are important to reduce barriers for optimizing TLC and pharmacologic therapy. **3** TLC should be implemented in all patients prior to considering drug therapy. The components of TLC include reduced intake of saturated fats and cholesterol, dietary options to reduce LDL, such as consumption of plant stanols and sterols and soluble fiber, weight reduction, and increased physical activity. In general, physical activity of moderate intensity 30 minutes per day for most days of the week should be encouraged.^{39,40} Patients with known CAD or who are at high risk should be evaluated before they undertake vigorous exercise. Weight and BMI should be determined at each visit, and lifestyle patterns to induce a weight loss of 10% should be discussed with persons who are overweight. All patients should be counseled to stop smoking and to meet the Joint National Committee VII guidelines for control of hypertension.

■ NONPHARMACOLOGIC THERAPY

Individualized dietary counseling that provides acceptable substitutions for unhealthy foods and ongoing reinforcement by a registered dietitian are necessary for maximal effect. The objectives of dietary therapy are to progressively decrease the intake of total fat, saturated fatty acids (i.e., saturated fat), and cholesterol and to achieve a desirable body weight. Typical American diets now include 13% to 20% of total calories from saturated fat and cholesterol intake of 350

to 450 mg/day, both in excess of a “heart healthy” diet for normal Americans, let alone patients with a lipid disorder. Excessive dietary intake of cholesterol and saturated fatty acids leads to decreased hepatic clearance of LDL and deposition of LDL and oxidized LDL in peripheral tissues. The targeted saturated fatty acids have carbon chain lengths of 12 (lauric acid), 14 (myristic acid), and 16 (palmitic acid). The rationale for using a nutritionally balanced, low-fat, low-cholesterol diet for treatment of hypercholesterolemia is based on the following principles: (a) it represents a reasonable extension of the diet recommended for the general public; (b) it progressively decreases the major cholesterol-raising constituent of the diet; (c) it precludes large intakes of polyunsaturated fats; and (d) it facilitates weight reduction by removing foods of high caloric density.^{41–44}

Dietary expertise in providing a wide range of options and suggestions in food preparation can make the difference between a good and an inadequate response to diet. Information on eating out in a healthy fashion and advice for shopping are important factors for success in diet therapy. An example is awareness of products with misleading labels, such as coffee creamers that state they contain “no cholesterol” when they may contain hydrogenated (saturated) fats or oils (e.g., palmitic acid, palm kernel oil, or coconut oil), which makes them undesirable because of their saturated fat content. Variations in polyunsaturated and saturated fat and cholesterol intake influence the LDL concentration, but the amount of cholesterol has been found to have a greater effect than the proportion of polyunsaturated or saturated fat. There were racial differences in elevation of LDL, with diets high in saturated fat consumed more by whites than by other racial groups. The isomeric form of fatty acids is important.⁴¹ Fatty acids with the *cis* configuration are the preferred substrate for the ACAT reaction and significantly increase hepatic LDL receptor clearance while reducing LDL-C production rate. The *trans* isomeric form cannot be used by ACAT and is biologically inactive, with no effect on LDL concentration.

Ideally, therapeutic TLC, including reduced intake of saturated fats and cholesterol, increased stanol/sterol and fiber intake, weight reduction, and increased physical activity, should be used to attain lower LDL-C and to achieve reductions in CHD risk (Table 23–10). TLC may obviate the need for drug therapy, augment LDL-lowering drug therapy, and allow for lower doses. Weight control plus increased physical activity reduce risk beyond LDL-C lowering, are the primary management approach for the metabolic syndrome, raise HDL, and reduce non-HDL-C.^{45,46} Many persons should be given a 3-month trial (two visits 6 weeks apart) of dietary therapy and TLC before advancing to drug therapy unless patients are at very high risk (severe hypercholesterolemia, known CHD, CHD risk equivalents, multiple risk factors, strong family history). Although changes in blood lipid levels may change before 3 months, adoption

TABLE 23-9 Classification of Lipid Levels in Children and Adolescents (Age <20 Years)

	Desirable (mg/dL)	Borderline (mg/dL)	Undesirable (mg/dL)
Total cholesterol	<170	170–199	≥200
LDL cholesterol	<110	110–129	≥130
HDL cholesterol	>45	25–45	<35
Triglycerides	<125	NA	≥125

HDL, high-density lipoprotein; LDL, low-density lipoprotein; NA, not applicable.

TABLE 23-10 Macronutrient Recommendations for the Therapeutic Lifestyle Changes Diet

Component ^a	Recommended Intake
Total fat	25%–35% of total calories
Saturated fat	Less than 7% of total calories
Polyunsaturated fat	Up to 10% of total calories
Monounsaturated fat	Up to 20% of total calories
Carbohydrates ^b	50%–60% of total calories
Cholesterol	<200 mg/day
Dietary fiber	20–30 g/day
Plant sterols	2 g/day
Protein	Approximately 15% of total calories
Total calories	To achieve and maintain desirable body weight

^aCalories from alcohol not included.

^bCarbohydrates should derive from foods rich in complex carbohydrates, such as whole grains, fruits, and vegetables.

of a different eating pattern may require a longer period of time. It is important to involve all family members, especially if the patient is not the primary person preparing food. The NCEP and AHA both have excellent Internet-based resources to aid patients in altering their diet in a culturally sensitive manner (<http://www.americanheart.org/presenter.jhtml?identifier=1200009>; <http://www.nhlbi.nih.gov/health/index.htm>). If all of the recommended dietary changes from NCEP were made, the estimated reduction, on average, in LDL would range from 20% to 30%.¹ Adherence to diet and interindividual variability in macronutrient intake influence the eventual LDL level achieved. Based on the NHANES data, less than half of patients who should be instructed on heart healthy diet receive any dietary instructions.

Other dietary interventions or diet supplements may be useful in certain patients with lipid disorders. Increased intake of soluble fiber in the form of oat bran, pectins, certain gums, and psyllium products can result in useful adjunctive reductions in total cholesterol and LDL-C, but these dietary alterations or supplements should not be substituted for more active forms of treatment. Total daily fiber intake should be about 20–30 g/day, with about 25% or 6 g/day, being soluble fiber.¹ Studies with psyllium seed in doses of 10 to 15 g/day show reductions in total cholesterol and LDL-C ranging from approximately 5% to 20%.^{47,48} They have little or no effect on HDL-C or triglyceride concentrations. These products also may be useful in managing constipation associated with the bile acid sequestrants. Psyllium binds cholesterol in the gut but also reduces hepatic production and clearance. Fish oil supplementation provides an increased amount of the omega-3 polyunsaturated fatty acids, such as eicosapentaenoic acid and docosahexaenoic acid. In epidemiologic studies, ingestion of large amounts of cold-water oily fish was associated with a reduction in CHD risk, but whether the same advantage is conferred with commercially prepared fish oil products is unclear. Each 20 g/day ingestion of fish lowers CHD risk by 7%, and eating fish at least once weekly should reduce CHD mortality.⁴⁹ Fish oil supplementation has a fairly large effect in reducing triglycerides and VLDL-C, but it either has no effect on total cholesterol and LDL-C or may cause elevations in these fractions. Other actions of fish oil may account for their protective effects. These effects include quantitative and qualitative alterations in the synthesis of prostanoid substances, changes in immune function and cellular proliferation, and potential antioxidative actions.⁵⁰ Responses noted with fish oil are discussed in Pharmacologic Therapy below.⁵¹

Fat substitutes such as olestra (sucrose polyester, Olean, Procter and Gamble), a mixture of hexa-esters, hepta-esters, and octa-esters formed from the reaction of sucrose with long-chain fatty acids, are approved by the Food and Drug Administration (FDA) as a nondigestible, nonabsorbable, noncaloric fat substitute for snack foods. Olestra is heat stable, so it can be used in the preparation of fried and baked foods, an advantage over several other fat substitutes. It is similar in composition to triglycerides, but olestra is not hydrolyzed in the gastrointestinal tract by pancreatic lipase and, consequently, is not taken up by the intestinal mucosa. The principal adverse effects associated with olestra use are bloating, flatulence, diarrhea, and “anal leakage.” Because of the ability of olestra to solubilize lipophilic substances, there has been concern over potential drug interactions in which lipophilic drugs (e.g., digitoxin, cyclosporine, or colchicine) or vitamins (A, D, E, and K) are solubilized in olestra and excreted in the feces.

Studies have demonstrated the LDL-lowering effect of plant sterols, which are isolated from soybean and tall pine-tree oils. Ingestion of 2 to 3 g/day will reduce LDL by 6% to 15%.¹ Plant sterols can be esterified to unsaturated fatty acids (creating sterol esters) to increase lipid solubility. Hydrogenating sterols produces plant stanols and, with esterification, stanol esters. The efficacies of plant sterols and stanols are considered comparable. Because lipids are needed to

solubilize stanol/sterol esters, they usually are available in commercial margarines. The presence of plant stanols/sterols is listed on the food label. When margarine products are used, persons must be advised to adjust caloric intake to account for the calories contained in the products. For example, Benecol (McNeil) is a butter-like spread that contains a plant stanol ester, an ingredient that can lower cholesterol, which is derived from plant stanols found naturally in small amounts in foods such as wheat, rye, and corn.⁵² In August 2007, the FDA issued a warning about the consumption of red yeast rice and products containing red yeast rice/policosonal. These products contained lovastatin, which could interact with other drugs and would have the same toxicity of statins but would not be recognized by the consumer. The reduction in LDL with their use is minimal.⁵³

Drug therapy is indicated after an adequate trial of TLC changes as outlined in Tables 23–8 and 23–9.

■ PHARMACOLOGIC THERAPY

Numerous randomized, double-blinded clinical trials have demonstrated that reduction of LDL reduces CHD event rates in primary prevention, secondary intervention, and angiographic trials.⁵⁴ Generally speaking, for every 1% reduction in LDL, there is a 1% reduction in CHD event rates.¹ However, if treatment extends beyond the typical duration of a clinical trial (2–5 years), the accumulated benefit could be greater. A 1% elevation of HDL results in an approximately 2% reduction in CHD events.^{12,55} Of interest, angiographic trials, which typically cause small changes in luminal diameter (i.e., approximately 0.04-mm difference in change between placebo and active treatment), result in fewer clinical events, such as MI, and a decreased need for revascularization. These unexpected findings suggest that plaque size and luminal encroachment by plaque may be less important than the effects of cholesterol lowering on activity in the plaque and endothelial dysfunction. These studies provide a strong rationale for attempting to lower plasma cholesterol and LDL in patients with hypercholesterolemia.

4 Although many efficacious lipid-lowering drugs exist, none is effective for all lipoprotein disorders, and all such agents are associated with some adverse effects.⁵⁶ Lipid-lowering drugs can be broadly divided into agents that decrease the synthesis of VLDL and LDL, agents that enhance VLDL clearance, agents that enhance LDL catabolism, agents that decrease cholesterol absorption, agents that elevate HDL, or some combination of these characteristics (Table 23–11). Table 23–12 lists recommended drugs of choice for each lipoprotein phenotype and alternate agents. Table 23–13 lists available products and their doses.

Treatment of type I hyperlipoproteinemia is directed toward reducing the levels of chylomicrons derived from dietary fat, with subsequent reduction in plasma triglycerides. Total daily fat intake should be no more than 10–25 g/day, or approximately 15% of total calories. Secondary causes of hypertriglyceridemia (see Table 23–5) should be excluded. Any underlying disorder should be treated appropriately. Type V hyperlipoproteinemia also requires stringent restriction of the fat component of dietary intake; in addition, drug therapy is indicated (as outlined in Table 23–12) if the response to diet alone is inadequate. Medium-chain triglycerides, which are absorbed without chylomicron formation, can be used as a dietary supplement for caloric intake if needed for types I and V. Hepatic fibrosis has been reported with medium-chain triglycerides. Omega-3 fatty acids may be useful for patients with LPL deficiency. In patients with apolipoprotein C-II deficiency, infusion of plasma may normalize plasma triglyceride levels.

Primary hypercholesterolemia (familial hypercholesterolemia, familial combined hyperlipidemia, type IIa hyperlipoproteinemia) is treated with bile acid resins (BARs) or sequestrants (colestipol, cholestyramine, and colestevlam), HMG-CoA reductase inhibitors

TABLE 23-11 Effects of Drug Therapy on Lipids and Lipoproteins

Drug	Mechanism of Action	Effects on Lipids	Effects on Lipoproteins	Comment
Cholestyramine, colestipol, colesevelam	↑ LDL catabolism ↓ Cholesterol absorption	↓ Cholesterol	↓ LDL ↑ VLDL	Problem with compliance; binds many coadministered acidic drugs
Niacin	↓ LDL and VLDL synthesis	↓ Triglyceride ↓ Cholesterol	↓ VLDL ↓ LDL ↑ HDL	Problems with patient acceptance; good in combination with bile acid resins; extended-release niacin causes less flushing and is less hepatotoxic than sustained-release form
Gemfibrozil, fenofibrate, clofibrate	↑ VLDL clearance ↓ VLDL synthesis	↓ Triglyceride ↓ Cholesterol	↓ VLDL ↓ LDL ↑ HDL	Clofibrate causes cholesterol gallstones; modest LDL lowering; raises HDL; gemfibrozil inhibits glucuronidation of simvastatin, lovastatin, atorvastatin
Lovastatin, pravastatin, simvastatin, fluvastatin, atorvastatin, rosuvastatin	↑ LDL catabolism; inhibit LDL synthesis	↓ Cholesterol	↓ LDL	Highly effective in heterozygous familial hypercholesterolemia and in combination with other agents
Ezetimibe	Blocks cholesterol absorption across the intestinal border	↓ Cholesterol	↓ LDL	Few adverse effects; effects additive to other drugs

HDL, high-density lipoprotein; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein.

(statins), niacin, or ezetimibe. ⁵ Of these choices, statins are first choice because they are the most potent LDL-lowering agents. Statins interrupt the conversion of HMG-CoA to mevalonate, the rate-limiting step in de novo cholesterol biosynthesis, by inhibiting HMG-CoA reductase (see Fig. 23-3). Currently available products include lovastatin, pravastatin, simvastatin, fluvastatin, and atorvastatin. Rosuvastatin is the most potent statin currently on the market. Table 23-14 lists the pharmacokinetic properties of the statins.⁵⁷ The plasma half-lives of all the statins are reported to be short, except for atorvastatin and rosuvastatin, which may account for their potency. In the Comparative Dose Efficacy Study of Atorvastatin Versus Simvastatin, Pravastatin, Lovastatin, and Fluvastatin in Patients with Hypercholesterolemia (CURVES), the largest head-to-head comparison of statins, atorvastatin was found to be the most potent drug for lowering total cholesterol and LDL-C, with reductions in LDL-C of 38%, 46%, 51%, and 54% for the 10-, 20-, 40-, and 80-mg doses, respectively.⁵⁸ Metabolic studies of statin use in normal volunteers and patients with hypercholesterolemia suggest reduced synthesis of LDL-C as well as enhanced catabolism of LDL mediated through LDL receptors as the principal mechanisms for lipid-lowering effects. Total cholesterol and LDL-C are reduced in a dose-related fashion by at least 30% on average when added to dietary therapy, with the

effects more pronounced in nonfamilial than in familial hypercholesterolemia. ⁶ Combination therapy with bile acid sequestrants and lovastatin is rational: LDL receptor numbers are increased, leading to greater degradation of LDL-C; intracellular synthesis of cholesterol is inhibited; and enterohepatic recycling of bile acids is interrupted. Combination therapy with a statin plus ezetimibe also is rational because ezetimibe inhibits cholesterol absorption across the gut border and adds 12% to 20% further reduction when combined with a statin or other drugs.⁵⁹ Elevation of serum transaminase levels (primarily alanine aminotransferase) to more than three times the upper limit of normal occurs in approximately 1.3% of patients taking moderate to high doses of statins; serious muscle toxicity occurs in <0.6% of patients.⁶⁰ Meta-analysis of placebo-controlled studies with statins demonstrated a low risk of abnormal alanine aminotransferase or creatine kinase (CK) and a low risk of myopathy without or with rhabdomyolysis.⁶¹ Lens opacities have been reported with lovastatin. However, in the age groups studied, these abnormalities are common and tend to wax and wane with time irrespective of drug therapy, and no statistical association is known to exist. As a category of monotherapy, the HMG-CoA reductase inhibitors are the most potent total cholesterol and LDL-C-lowering agents and are among the best tolerated.^{60,61} In an analysis of more than 75,000 patients allocated to statins in clinical trials, Alsheikh-Ali et al.⁶² found that risk of statin-associated elevated liver enzymes or rhabdomyolysis was not related to the magnitude of LDL-C lowering. A highly significant inverse relationship between achieved LDL-C levels and rates of newly diagnosed cancer was observed ($R^2 = 0.43$, $P = 0.009$).⁶² The WHO Foundation Collaborating Centre for International Drug Monitoring has issued a report suggesting that a rare relationship may exist between statin use and the onset of upper motor neuron diseases such as amyotrophic lateral sclerosis, but this association remains uncertain.⁶³ Numerous pharmacokinetic and pharmacodynamic differences among statins and patients give rise to variable responses to therapy.⁶⁴

The primary action of BAR is binding bile acids in the intestinal lumen, with concurrent interruption of enterohepatic circulation of bile acids and markedly increased excretion of acidic steroids in the feces. This action decreases the bile acid pool size and stimulates hepatic synthesis of bile acids from cholesterol. Depletion of the hepatic pool of cholesterol results in increased cholesterol biosynthesis and increased number of LDL receptors on the hepatocyte membrane. The increased number of receptors stimulates catabolism from plasma and lowers LDL levels. BAR also reduces CETP, which correlates with total cholesterol and LDL-C concentrations, perhaps by interfering with hepatic microsomal cholesterol content; however,

TABLE 23-12 Lipoprotein Phenotype and Recommended Drug Treatment

Lipoprotein Type	Drug of Choice	Combination Therapy
I	Not indicated	—
IIa	Statins	Niacin or BAR
	Cholestyramine or colestipol	Statins or niacin
	Niacin	Statins or BAR
IIb	Statins	Ezetimibe
	Fibrates	BAR, fibrates, ^b or niacin
	Niacin	Statins, niacin, BAR ^a
III	Fibrates	Statins or fibrates
	Niacin	Ezetimibe
IV	Fibrates	Statins or niacin
	Niacin	Statins or fibrates
V	Fibrates	Ezetimibe
	Niacin	Niacin
		Fish oils

^aBile acid resins (BARs) are not used as first-line therapy if triglycerides are elevated at baseline because hypertriglyceridemia may worsen with BAR alone.

^bFibrates includes gemfibrozil or fenofibrate.

TABLE 23-13 Comparison of Drugs Used in the Treatment of Hyperlipidemia

Drug	Manufacturer	Dosage Forms	Usual Daily Dose	Maximum Daily Dose
Cholestyramine (Questran)	BMS	Bulk powder/4-g packets	8 g tid	32 g
Cholestyramine (Questran Light)	BMS	Bulk powder/4-g packets		
Cholestyramine (Cholybar)	Parke-Davis	4-g resin per bar		
Colestipol hydrochloride (Colestid)	Upjohn	Bulk powder/5-g packets	10 g bid	30 g
Colesevelam (WelChol)	Sankyo	625-mg tablets	1,875 mg bid	4,375 mg
Niacin	Various	50-, 100-, 250-, 500-mg tablets; 125-, 250-, 500-mg capsules	2 g tid	9 g
Extended-release niacin (Niaspan)	Kos	500, 750, 1,000 mg tablets	500 mg	2,000 mg
Extended-release niacin + lovastatin (Advicor) ^a	Kos	Niacin/lovastatin 500-mg/20-mg tablets Niacin/lovastatin 750-mg/20-mg tablets Niacin/lovastatin 1,000-mg/20-mg	Niacin/lovastatin 500 mg/20 mg	Niacin/lovastatin 1,000 mg/20 mg tablets
Clofibrate	Banner Pharmacaps, USL Pharma	500-mg capsules	1 g bid	2 g
Fenofibrate (TriCor and others)	Abbott, various	67-, 134-, 200-mg capsules (micronized); 54-, 160-mg tablets; 40-, 120-mg tablets; 50-, 160-mg tablets	54 mg or 67 mg	201 mg
Gemfibrozil (Lopid)	Parke-Davis	300-mg capsules	600 mg bid	1.5 g
Lovastatin (Mevacor)	MSD	20-, 40-mg tablets	20–40 mg	80 mg
Pravastatin (Pravachol)	Bristol-Myers Squibb	10-, 20-mg tablets	10–20 mg	40 mg

ω-3 Acid ethyl esters (Lovaza)	Reliant	Eicosapentaenoic acid (EPA) 465 mg, docosahexaenoic acid (DHA) 375 mg	Four 1-g capsules QD or two 1-g capsules bid	Four 1-g capsules QD or two 1-g capsules bid

BMS, Bristol-Myers Squibb; MSD, Merck Sharp & Dohme.

Probuco is no longer on the market in the United States. Gemfibrozil, fenofibrate, and lovastatin are available as generic products.

^aManufacturer does not recommend use of the fixed combination as initial therapy for primary hypercholesterolemia or mixed dyslipidemia. It is specifically indicated for patients receiving lovastatin alone plus diet who require an additional reduction in triglyceride levels or increase in HDL-cholesterol levels; it also is indicated for those treated with niacin alone who require additional decreases in LDL cholesterol.

this effect is not as great as with statins.⁶⁵ BARs are generally ineffective in patients with homozygous familial hypercholesterolemia because these individuals genetically lack the ability to increase synthesis of LDL receptors. The increase in hepatic cholesterol biosynthesis may be paralleled by increased hepatic VLDL production; consequently, BARs may aggravate hypertriglyceridemia in patients with combined hyperlipidemia. Gastrointestinal complaints of con-

stipation, bloating, epigastric fullness, nausea, and flatulence are most commonly reported.¹ With intensive education, patients can learn to tolerate resins on a long-term basis, as evidenced in clinical trials by adherence to active drug regimens. In routine clinical practice, at least 40% of patients discontinue therapy within 1 year, but adherence rates can be improved with pharmacist interventions.^{66,67} Adverse effects can be managed by increasing fluid intake, modifying the diet

TABLE 23-14 Pharmacokinetics of the Statins

Parameter	Lovastatin	Simvastatin	Pravastatin	Fluvastatin	Atorvastatin	Rosuvastatin
Isoenzyme	3A4	3A4	None	2C9	3A4	2C9/2C19
Lipophilic	Yes	Yes	No	Yes	Yes	No
Protein binding (%)	>95	95–98	~50	>90	96	88
Active metabolites	Yes	Yes	No	No	Yes	Yes
Elimination half-life (h)	3	2	1.8	1.2	7–14	13–20

Isoenzyme refers to the specific isoenzyme in the cytochrome P450 system, which is responsible for the metabolism of each drug. Pharmacokinetic parameters in this table are based on studies and reviews presented in the literature.

to increase bulk, and using stool softeners. The other major limiting complaint with BARs is their gritty texture and bulk. This problem can be minimized by mixing the powder with orange drink or juice. Tablet forms of bile acid sequestrants should help to improve compliance with this form of therapy, whereas the bar does not improve compliance.⁶⁸ Other potential adverse effects include impaired absorption of fat-soluble vitamins A, D, E, and K; hypernatremia and hyperchloremia; gastrointestinal obstruction; and reduced bioavailability of acidic drugs such as coumarin anticoagulants, digitoxin, nicotinic acid, thyroxine, acetaminophen, hydrocortisone, hydrochlorothiazide, loperamide, and possibly iron. Hyperchloremic metabolic acidosis, hypernatremia, and gastrointestinal obstruction have been reported to occur almost exclusively in children, and malabsorption of fat-soluble vitamins probably is most common with high doses (e.g., 30 g/day of cholestyramine) of the BARs. Drug interactions can be avoided by alternating administration times, with an interval of at least 6 hours between the BAR and other drugs. Colestipol and cholestyramine have comparable side effects; however, colestipol may have better palatability because it is odorless and tasteless. Colesevelam is the newest BAR, and total and LDL-C reduction are dose related. Adverse effects are qualitatively similar to those occurring with the older BARs but may occur less often. Because of adverse effects that occur commonly with BARs at higher doses, BARs are increasingly used in combination with other drugs because low doses are tolerated well, and the BARs work in complementary fashion with other agents.

Niacin (nicotinic acid) can be used for treatment of primary hypercholesterolemia in combination with bile acid sequestrants or as monotherapy for this and other disorders (Table 23–12). Niacin reduces hepatic synthesis of VLDL, which in turn leads to reduced synthesis of LDL. Factors responsible for decreased VLDL production include inhibition of lipolysis with decreased free fatty acids in plasma, decreased hepatic esterification of triglycerides, and a possible direct effect on hepatic production of apolipoprotein B.⁶⁹ The complementary action of niacin and bile acid sequestrants in increasing catabolism and decreasing LDL synthesis may account for the additive effects of this combination in patients with hyperlipidemia. Niacin also increases HDL by reducing its catabolism. Niacin selectively decreases hepatic removal of HDL apolipoprotein A-I but not removal of cholesterol esters, thereby increasing the capacity of retained apolipoprotein A-I to augment reverse cholesterol transport in isolated hepatic cells. Niacin is used principally for treatment of mixed hyperlipidemia or as a second-line agent in combination therapy for hypercholesterolemia. It is considered the first-line agent or an alternative for treatment of hypertriglyceridemia and diabetic dyslipidemia.^{70,71} Numerous smaller trials suggest that lower doses of niacin can be combined with statins or gemfibrozil to minimize adverse effects and maximize response. These combinations require careful monitoring because interactions occur.

Many adverse drug reactions occur commonly with niacin use, but most of the symptoms and biochemical abnormalities do not require discontinuation of therapy. Cutaneous flushing and itching appear to be prostaglandin mediated and can be reduced by aspirin 325 mg given shortly before niacin ingestion.^{1,72} Flushing seems to be related to rising plasma concentrations of niacin; taking the dose with meals and slowly titrating the dose upward may minimize these effects. Laropiprant is a selective antagonist of the prostaglandin D₂ receptor subtype 1 (DP1), which may mediate niacin-induced vasodilation. Coadministration of laropiprant 30, 100, and 300 mg with extended-release (ER) niacin significantly lowered flushing symptom scores (by at least 50%) and significantly reduced malar skin blood flow measured by laser Doppler perfusion imaging.⁷³ Gastrointestinal intolerance and flushing are common problems. Acanthosis nigricans, a darkening of the skin in skinfold areas and an external marker of insulin resistance, may be seen with high doses of niacin. Sustained-

release products may minimize these complaints in some patients, but controlled trials with regular-release products do not demonstrate much difference between sustained- and regular-release products. The only legend form of niacin, Niaspan (Kos), is an extended-release form of niacin with pharmacokinetics intermediate between instant and sustained-release products, which are sold as food supplements rather than legend products. In controlled trials, Niaspan is reported to have fewer dermatologic reactions and a low risk for hepatotoxicity. Niaspan in combination with statins produces large reductions in LDL and increases in HDL.⁷⁴ Potentially important laboratory abnormalities occurring with niacin therapy include elevated liver function tests, hyperuricemia, and hyperglycemia. Experience with niacin in diabetes suggests that some diabetic patients do not have worsened glycemic control with dose-titration and sustained-release products.⁷⁵ With doses less than 3 g/day, the degree of liver function test elevation generally is not marked and often is transient, and a temporary reduction in dosage frequently corrects the problem. Niacin-associated hepatitis is more common with sustained-release preparations, and their use should be restricted to patients intolerant of regular-release products.^{75,76} Sustained-release products often are more expensive and, given the lack of data on reduced adverse effects and increased incidence of hepatitis, regular-release products should always be used first. Preexisting gout and diabetes may be exacerbated by niacin; patients with these conditions should be monitored more closely and their medication titrated appropriately. Patients with well-controlled diabetes mellitus type 2 do not have significant changes in glycemic control with niacin doses up to 2 g/day.⁷⁶ Niacin is contraindicated in patients with active liver disease. Dry eyes and other ophthalmologic complaints are occasionally noted. Concomitant alcohol and hot drinks may magnify flushing and pruritus with niacin and should be avoided at the time of ingestion. Nicotinamide should not be used for treatment of hyperlipidemia because it does not effectively lower cholesterol or triglyceride levels.

Combined hyperlipoproteinemia (type IIb) can be treated with statins, niacin, or gemfibrozil to lower LDL-C without elevating VLDL and triglycerides. Niacin is the most effective agent and can be combined with a bile acid sequestrant. BARs alone for treatment of this disorder may elevate VLDL and triglycerides, and their use as single agents for treatment of combined hyperlipoproteinemia should be avoided. Fibric acid (gemfibrozil, fenofibrate) monotherapy is effective in reducing VLDL, but a reciprocal rise in LDL may occur, and total cholesterol values may remain relatively unchanged. Gemfibrozil reduces synthesis of VLDL and, to a lesser extent, apolipoprotein B, with a concurrent increase in the rate of removal of triglyceride-rich lipoproteins from plasma. Plasma HDL concentrations may rise 10% to 15% or more with fibrates. Ezetimibe also can be used in combination therapy for type IIb disease. Gastrointestinal complaints with fibric acid derivatives occur in 3% to 5% of patients, rash in 2%, dizziness in 2.4%, and transient elevations in transaminase levels and alkaline phosphatase in 4.5% and 1.3%, respectively.⁷⁷ Gemfibrozil and fenofibrate may enhance the formation of gallstones associated with an increase in the lithogenic index; however, the rate is low (0.5%–7%) and similar to that seen with placebo in the Helsinki Heart Study.⁷⁷ Fibric acid derivatives may potentiate the effects of oral anticoagulants, so prothrombin time and international normalized ratio should be monitored very closely when this combination is used.

Type III hyperlipoproteinemia can be treated with fibric acid derivatives or niacin. Although fibric acid derivatives have been suggested as the drugs of choice for treatment of this disorder, the lack of data from major studies on hypercholesterolemia supporting their efficacy in altering cardiovascular mortality and the numerous, well-documented serious adverse effects occurring with their use make niacin a reasonable consideration. Gemfibrozil increases the

activity of LPL and reduces the synthesis or secretion of VLDL from the liver into the plasma. A myositis syndrome of myalgia, weakness, stiffness, malaise, and elevations in creatinine phosphokinase and aspartate aminotransaminase is seen with the fibric acid derivatives and seems to be more common in patients with renal insufficiency.⁷⁷ Enhanced hypoglycemic effects are reported to occur when fibric acid derivative are given to patients taking sulfonylurea compounds, but the mechanisms for these interactions are not well understood.

Three fibric acid derivatives (clofibrate, gemfibrozil, and fenofibrate) are approved for use in the United States. Gemfibrozil and fenofibrate are used much more commonly than clofibrate. All reduce LDL-C by 20% to 25% in patients with heterozygous familial hypercholesterolemia. The response of LDL-C, HDL-C, and triglycerides to this category of drug is highly dependent on the specific lipoprotein type (e.g., type IIa vs IIb) and the baseline triglyceride concentration.⁷⁸

As a potential alternative therapy for this phenotype, numerous epidemiologic and normal volunteer studies have found that diets high in omega-3 polyunsaturated fatty acids (from fish oil), mostly commonly eicosapentaenoic acid, reduce cholesterol, triglycerides, LDL-C, and very-low-density lipoprotein cholesterol (VLDLC) and may elevate HDL-C.⁵¹ The effects of fish oil on lipoprotein metabolism are mediated by a reduction in VLDL production and suppression of VLDL apolipoprotein B. In patients with hypertriglyceridemia (either phenotype type IIb or V), a diet high in omega-3 fatty acids given for 4 weeks reduced cholesterol 27% and 45% and triglyceride 64% and 79% in the type IIb and type V patients, respectively.⁴⁹ A diet high in eicosapentaenoic acid given to hyperlipidemic hemodialysis patients resulted in significant decreases in cholesterol and triglycerides for as long as 13 weeks. Fish oil supplementation may be most useful in patients with hypertriglyceridemia; however, its role in treatment is not well defined. Potential complications of fish oil supplementation, such as thrombocytopenia and bleeding disorders, have been noted, especially with high doses (eicosapentaenoic acid 15–30 g/day). Well-controlled trials are needed to determine if fish oils are safe and effective before their use can be broadly recommended. Based a meta-analysis, fish consumption lowers the risk of CHD, but nutraceuticals have not been adequately tested.⁴⁹ A prescription form of concentrated fish oil, Lovaza, has become available.⁵¹ This product lowers triglycerides by 14% to 30% and raises HDL by approximately 10%, depending on baseline values.

Combination drug therapy may be considered after adequate trials of monotherapy and for patients who are documented as compliant to the prescribed regimen. Two or three lipoprotein profiles at 6-week intervals should confirm lack of response prior to initiation of combination therapy. Cholestyramine can be added for patients with fasting hypertriglyceridemia but should not be used as the initial drug because triglycerides are likely to increase. Contraindications to, and drug interactions with, combined therapy should be carefully screened. Consideration should be given to the extra cost of drug product and monitoring that may be required. In general, a statin and a BAR or niacin with a BAR provide the greatest reduction in total cholesterol and LDL-C. Regimens intended to increase HDL levels should include either gemfibrozil or niacin, bearing in mind that statins combined with either of these drugs may result in a greater incidence of hepatotoxicity or myositis. This is particularly important for statins that are eliminated via cytochrome 3A4 or through glucuronidation.⁵⁷ Familial combined hyperlipidemia may respond better to a fibric acid and a statin than to a fibric acid and a BAR.⁷⁹

Severe forms of hypercholesterolemia, such as familial hypercholesterolemia, familial defective apolipoprotein B-100, severe polygenic hypercholesterolemia, familial combined hyperlipidemia, and familial dysbetalipoproteinemia (type III), may require more intensive therapy. In particular, patients with familial hypercholesterol-

emia often require combination therapy (two or three drugs) and are managed with surgical therapy (partial ileal bypass), plasmapheresis (LDL apheresis), and liver transplantation (to replace LDL receptors).

■ HYPERTRIGLYCERIDEMIA

It is important to remember that lipoprotein pattern types I, III, IV, and V are associated with hypertriglyceridemia, and that these primary lipoprotein disorders and underlying diseases should be excluded prior to implementing therapy (see Table 23–5). A family history positive for CHD is important in identifying patients at risk for premature atherosclerosis.^{80,81} If a patient with CHD has elevated triglycerides, the associated abnormality probably is a contributing factor to CHD and should be treated.²⁹

High serum triglycerides (see Tables 21–6 and 21–12) should be treated by achieving desirable body weight, consumption of a diet low in saturated fat and cholesterol, regular exercise, smoking cessation, and restriction of alcohol (in selected patients). ATP III identifies the sum of LDL and VLDL (termed *non-HDL* [total cholesterol – HDL]) as a secondary target of therapy in persons with high triglycerides (≥ 200 mg/dL).^{1,29} This approach is used when triglycerides are >200 mg/dL and accounts for atherogenic particles carried in VLDL and remnant particles. The goal for non-HDL in persons with high serum triglycerides can be set 30 mg/dL higher than that for LDL on the premise that VLDL ≤ 30 mg/dL is normal. **7** In patients with borderline-high triglycerides but accompanying risk factors for established CHD disease, family history of premature CHD, concomitant LDL elevation or low HDL, and genetic forms of hypertriglyceridemia associated with CHD (familial dysbetalipoproteinemia, familial combined hyperlipidemia), drug therapy with niacin should be considered. Niacin can be used cautiously in diabetics based on the results of the Arterial Disease Multiple Intervention Trial (ADMIT), which found triglycerides were reduced by 23%, HDL-C increased by 29%, glucose increased only slightly (mean 8.7 mg/dL), and hemoglobin A_{1c} did not change.⁸² Alternative therapies include gemfibrozil, statins, and fish oil.^{81,83,84} Fibrates may increase LDL, and their use in borderline-high triglyceridemia requires careful monitoring to detect this deleterious change in lipid profile. Statins also can be used because they provide modest reductions in triglycerides and modest elevations in HDL. Higher doses of statins may reduce HDL as well as LDL and triglycerides, with the amount of reduction related to the baseline concentration and dose.^{81,84} In this situation, the goal of therapy is to lower triglycerides and VLDL particles that may be atherogenic, increase HDL, and reduce LDL.

Very high triglycerides are associated with pancreatitis and other consequences of the chylomicron syndrome. At this level of triglycerides elevation, a genetic form of hypertriglyceridemia often coexists with other causes of elevated triglycerides, such as diabetes. Dietary fat restriction (10%–20% of calories as fat), weight loss, alcohol restriction, and treatment of the coexisting disorder are the basic elements of management. Drugs useful for treatment of hypertriglyceridemia include gemfibrozil, niacin, and higher-potency statins (atorvastatin, rosuvastatin, and simvastatin). Gemfibrozil is the preferred drug in diabetics because of the effect of niacin on glycemic control unless the newer extended-release forms are used. Fenofibrate may be preferred in combination with statin therapy because it does not impair glucuronidation and minimizes potential drug interactions. Successful treatment is defined as a reduction in triglycerides <500 mg/dL.¹

■ LOW HDL-C

Low HDL is a strong independent risk predictor of CHD. ATP III redefined low HDL-C as <40 mg/dL but specified no goal for HDL-C

raising.¹ Low HDL may be a consequence of insulin resistance, physical inactivity, type 2 diabetes mellitus, cigarette smoking, very high carbohydrate intake, and certain drugs (see Table 23–5).⁸ In low HDL, the primary target remains LDL according to ATP III, but emphasis shifts to weight reduction, increased physical activity, smoking cessation, and, if drug therapy is required, fibric acid derivatives and niacin. Niacin has the potential for the greatest increase in HDL, and the effect is more pronounced with regular or immediate-release forms than with sustained-release forms.⁸⁵

■ DIABETIC DYSLIPIDEMIA

Diabetic dyslipidemia is characterized by hypertriglyceridemia, low HDL, and LDL that is minimally elevated. Small, dense LDL (pattern B) in diabetes is more atherogenic than larger, more buoyant forms of LDL (pattern A). Routine lipoprotein profiles do not differentiate between pattern A and pattern B.^{86–88} Diabetes in ATP III is a CHD risk equivalent. The primary target is LDL, and the goal of treatment is to lower LDL-C to <100 mg/dL.¹ When LDL is >130 mg/dL, most patients require simultaneous therapeutic lifestyle changes and drug therapy. When LDL-C is between 100 and 129 mg/dL, intensifying glycemic control, options include adding drugs for the atherogenic dyslipidemia (fibrates, niacin), and intensifying LDL-C-lowering therapy. Because the primary target is LDL-C in patients with diabetic dyslipidemia, statins are considered by many to be the initial drugs of choice.^{1,29} The relative risk reduction for CHD in diabetics versus nondiabetics was greater in several trials, including the West of Scotland Coronary Prevention Study (37% vs 20%),⁸⁹ Air Force/Texas Coronary Atherosclerosis Prevention Study (AFCAPS/TexCAPS; 43% vs 36%),⁹⁰ Cholesterol and Recurrent Events (CARE) trial (25% vs 23%),⁹¹ and Scandinavian Simvastatin Survival Study (4S; 55% vs 32%).⁹² All statins are fairly comparable in triglyceride lowering, and because statins differ in potency for LDL reduction, a ratio of LDL reduction to triglyceride reduction can be applied. Statin therapy may protect against the development of diabetes.²⁶ The most recent trial of LDL lowering in type 2 diabetes mellitus is the Collaborative Atorvastatin Diabetes Study (CARDS).⁹³ This was a randomized, double-blinded placebo comparison of atorvastatin 10 mg/day versus placebo in 2,838 diabetes to reduce first CHD events. Baseline LDL was 118 mg/dL, and with atorvastatin LDL fell by 46 mg/dL. The primary end point, a composite of acute CHD death, nonfatal MI, hospitalized unstable angina, resuscitated cardiac arrest, coronary revascularization, or stroke, was reduced by 37%. This study suggests that all diabetics should have LDL much lower than 100 mg/dL, and these results are consistent with the Heart Protection Study analysis of diabetic patients.⁹⁴

According to the Diabetes Atherosclerosis Intervention Study (DAIS), fenofibrate reduced angiographic progression of CAD in type 2 diabetics.⁹⁵ Fewer CHD events were seen with fenofibrate compared with placebo, but the difference was not significant. Fibrates principally lower VLDL and triglycerides while increasing HDL, with only modest lowering of total cholesterol and LDL-C. Fibrates may increase LDL levels. In contrast to niacin, fibrates tend to improve glucose tolerance, with the greatest effect seen with bezafibrate. The Helsinki Heart Study found gemfibrozil was most effective for diabetic dyslipidemia.⁹⁶ Although the effect of statins on triglycerides and HDL abnormalities commonly seen in patients with diabetes is less than with fibrates, the subgroup analyses cited earlier suggest that these drugs significantly reduce CHD risk. Cholestyramine in diabetic patients may result in lower LDL levels but may increase VLDL and triglyceride levels, which already are commonly elevated in diabetes. Resins may aggravate constipation, which is common in diabetics. As demonstrated in ADMIT and in the Assessment of Diabetes Control and Evaluation of the Efficacy of Niaspan Trial (ADVENT), immediate-release and extended-release niacin are highly effective in raising HDL and lowering triglycerides and LDL.^{82,97}

■ SPECIAL CONSIDERATIONS

Elderly

Hypercholesterolemia is an independent risk factor for CHD in the elderly (>65 years old) as it is in younger patients. The attributable risk, which is the difference in absolute rates of CHD between segments of the population with higher or lower serum cholesterol levels, increases with age. Older patients potentially benefit to a greater extent from cholesterol lowering than do younger patients. Data from studies of elderly men in a variety of settings are consistent with a relative risk of at least 1.5 in the highest compared to the lowest quartile of cholesterol levels.^{98,99} Treatment of hypercholesterolemia in the elderly may result in reduction of absolute risk comparable to that obtained in younger persons.¹ Subgroup analyses of the West of Scotland (primary) and 4S (secondary) intervention studies show that elderly patients had lower CHD risk reduction (relative risk reduction 27% and 29%, respectively) compared to younger patients (relative risk reduction 40% and 39%, respectively).^{89,100} The Framingham study suggests that elderly women are at higher risk because of high blood cholesterol levels, but no other large studies included women, and the risks or benefits from cholesterol reduction are not well defined. Primary prevention in younger patients requires approximately 2 years before reduction in CHD risk is apparent, and this lag time should be taken into consideration during patient selection for therapy. Relative risk of nonlipid CHD risk factors does not decline with aging, and aggressive management of modifiable nonlipid risk factors is important in older patients. High-risk elderly patients are less likely to be prescribed statins, and their potent benefits are not realized.¹⁰¹ Because most women with CHD are elderly and at risk for osteoporosis, they are logical candidates for diet therapy with consideration of calcium intake consistent with osteoporosis prevention, exercise, and perhaps estrogen replacement therapy. Evidence suggests that statins reduce the risk of osteoporosis; however, data from various studies are conflicting.¹⁰²

Drug therapy in principle differs little between older and younger patients, and older patients respond as well as younger patients to lipid-lowering drugs.^{103,104} Based on the Heart Protection Study, which comprised more elderly patients than any other trial, simvastatin 40 mg/day reduced the CHD event rate in patients older than 70 years the same as in younger patients.¹⁰⁵ The gain in life expectancy may be small, depending on the patient's age at the start of treatment and the magnitude of cholesterol reduction.⁸² Changes in body composition, renal function, and other physiologic changes of aging may make older patients more susceptible to adverse effects of lipid-lowering drug therapy. In particular, older patients are more likely to have constipation (BARs), skin and eye changes (niacin), gout (niacin), gallstones (fibrates), and bone/joint disorders (fibrates, statins). Therapy should be started with lower doses and titrated up slowly to minimize adverse effects.

Women

Cholesterol is an important determinant of CHD in women, but the relationship is not as strong as that seen in men. HDL may be a more important predictor of disease in women.⁴ LDL and HDL genetic regulation in women and men does not appear to be different. Based on the Nurses' Health Study, obesity is an important determinant of CHD in women, with a relative risk of 3.3 in the highest Quetelet index (weight in kilograms divided by the square of the height in meters) compared to the lowest category (i.e., <21 vs ≥29); low HDL levels usually accompany obesity.¹⁰⁶ No major differences exist in the influence of exercise, alcohol ingestion, and smoking on lipid levels between men and women. Women in the highest tertile of cholesterol appear to be more responsive to dietary therapy than women in the lower tertiles and more responsive than predicted using formulas based on men.

Based on the Heart and Estrogen/Progestin Replacement Study (HERS)¹⁰⁷ and the Women's Health Initiative (WHI) trial,^{108–110} published national guidelines recommended similar types of lifestyle and risk factor goals and interventions as recommended by NCEP for the entire population.⁴ Hormone therapy may continue to have a role for treatment of postmenopausal symptoms; however, a notable exception is hormone replacement therapy and heart protection. Combined estrogen plus progestin hormone therapy for prevention of cardiovascular disease should not be initiated in postmenopausal women. Combined estrogen plus progestin hormone therapy for prevention of cardiovascular disease should not be continued in postmenopausal women. Other forms of menopausal hormone therapy (e.g., unopposed estrogen) for prevention of cardiovascular disease should not be initiated or continued in postmenopausal women pending the results of ongoing trials. Results of the Women's International Study of Long Duration Oestrogen after Menopause (WISDOM) confirm the lack of benefit seen in HERS and WHI.¹¹¹ In a post hoc analysis of the WHI, women who initiated hormone therapy closer to menopause tended to have a reduced CHD risk compared with the increased CHD risk in women more distant from menopause, but this trend did not meet statistical significance.¹⁰⁸

Cholesterol and triglyceride levels rise progressively throughout pregnancy, with an average increment in cholesterol of 30 to 40 mg/dL occurring around weeks 36 to 39. Triglyceride levels may increase by as much as 150 mg/dL. Drug therapy is not instituted, nor is it usually continued during pregnancy. If the patient is very high risk, a bile acid resin may be considered because no systemic drug exposure occurs.¹ Statins are category X and are contraindicated. Ezetimibe might be an alternative because it is a category C drug (animal studies have shown that the drug exerts teratogenic and embryocidal effects, no adequate and well-controlled studies in pregnant women are available, or no studies are available in either animals or pregnant women). Dietary therapy is the mainstay of treatment, with emphasis on maintaining a nutritionally balanced diet per the needs of pregnancy.

Children

Drug therapy in children is not recommended until they are 10 years and older, and the guidelines for institution of therapy and the goals of therapy are different from those in adults (see Table 23–9).³³ Younger children are generally managed with therapeutic lifestyle changes until after age 2 years.^{1,44} In the past bile acid sequestrants were recommended as first-line therapy, but evidence now shows that statins are safe and effective in children and provide greater lipid lowering than BAR.^{38,112,113} Severe forms of hypercholesterolemia (e.g., familial hypercholesterolemia) may require more aggressive treatment.

■ CONCURRENT DISEASE STATES

Nephrotic syndrome, end-stage renal disease and nephrotic syndrome, and hypertension compound the risk of dyslipidemia and may present difficult-to-treat lipid abnormalities. Abnormalities of lipoprotein metabolism in the nephrotic syndrome include elevated total and LDL-C, lipoprotein(a), VLDL, and triglycerides. The ratio of apolipoprotein C-III to apolipoprotein C-II is elevated, consistent with greater LPL inhibitor activity, and the extent of hypoalbuminemia is correlated with dyslipidemia. The basic abnormality appears to be overproduction of LDL apolipoprotein B from VLDL rather than reduced clearance of LDL-C and related proteins. Protein restriction and a “vegan” diet corrects lipid abnormalities to some extent. Statins have been shown to be effective in reducing elevated total cholesterol and LDL-C in the nephrotic syndrome, although the levels do not usually return to normal.¹¹⁴ Fibrin acid derivatives and statins reduce small, dense LDL-C by different

mechanisms, suggesting a potential role for combination therapy in optimizing the lowering of small, dense LDL-C and remnant lipoproteins. Statins appear to be safe and effective in renal insufficiency and may alter the natural course of declining renal function.^{115–119}

Renal insufficiency without proteinuria leads to hypertriglyceridemia, slightly elevated total cholesterol and LDL-C (particularly with chronic ambulatory peritoneal dialysis), and low HDL levels (especially during hemodialysis). These abnormalities are thought to be caused by a deficiency in apolipoprotein C-II, perhaps as a result of sustained use of heparin during hemodialysis and depletion of LPL, carbohydrate-induced obesity and hypertriglyceridemia, loss of carnitine during hemodialysis, use of acetate buffer (acetate is a precursor to fatty acid synthesis) during hemodialysis, and decreased LCAT activity during hemodialysis. Dialysis does not correct the lipid abnormalities. Renal transplantation may correct lipid abnormalities in some patients; however, use of transplantation-related medications, such as corticosteroids, cyclosporine, and certain antihypertensive agents (see Chaps. 15 and 92), may aggravate the lipid abnormalities in other patients. Cyclosporine interferes with the metabolism of statins metabolized by cytochrome P450 3A4 (Table 23–14), and patients must be observed closely for myositis and worsening renal function. Of interest, correction of lipid abnormalities may improve renal hemodynamics. Pravastatin and fluvastatin may be safer than other statins, but this must be validated in larger, long-term trials. Diet will modify lipoprotein levels, and polyunsaturated fatty acids may have a role in impeding the progression of renal disease as well as the cardiovascular complications. Bile acid sequestrants do not correct the lipid abnormalities seen in renal insufficiency. Lovastatin or its active metabolite may accumulate in renal insufficiency, and lower doses of reductase inhibitors should be used to avoid adverse effects. Gemfibrozil can be used with caution; its pharmacokinetics are unchanged and it lowers triglycerides and increases HDL.¹²⁰ Statins (simvastatin, lovastatin and atorvastatin) and fibrin acid derivatives may increase the risk of severe myopathy, and attention to symptoms of myositis is needed. Niacin may be useful in nondiabetic patients with renal insufficiency.

Hypertensive patients have a greater-than-expected prevalence of high blood cholesterol levels; conversely, patients with hypercholesterolemia have a higher than expected prevalence of hypertension caused by the metabolic syndrome. Recommendations for management of hypertension in patients with hypercholesterolemia include avoiding use of drugs that elevate cholesterol, such as diuretics and β -blockers, and using agents that either are lipid neutral or may reduce cholesterol slightly (see Chap. 15).¹ Bile acid sequestrants may bind to thiazide diuretics and some β -blockers and may interfere with their absorption. Reactions may be avoided by giving the antihypertensive 1 hour before or 4 hours after the resin. Niacin may magnify the hypotensive effects of vasodilators.

■ PHARMACOECONOMIC CONSIDERATIONS

The clinical benefits of lipid-lowering therapy for primary and secondary intervention are well established based on the results of studies showing a reduction in CHD morbidity and mortality.^{121,122} The balance of benefits and costs has been examined in a few studies.^{82,95} The cost per year of life saved has been estimated to range from less than \$10,000 to more than \$1 million dollars, depending on the presence or absence of CHD, patient's age, baseline total or LDL-C level, reduction in cholesterol, and number of risk factors present. **9** Intervention with statin therapy in general is cost effective in patients with known CHD, with CHD risk equivalents, or with a 10-year risk of 10% to 20%. Other types of therapy may be cost effective if certain assumptions concerning compliance and efficacy are met. Based on 4S, the range for secondary intervention is \$3,800 for a 70-year-old man with a high cholesterol level to \$27,400 per year of life gained for a middle-aged woman with an average

cholesterol level.¹²³ In contrast, primary prevention in men based on the West of Scotland trial averages about \$35,000 per year of life gained.¹²⁴ These studies demonstrate that primary and secondary intervention are well within the accepted boundary of less than \$50,000 for a medical intervention to be considered cost effective. Based on the specific lipoprotein phenotype, fibric acid derivatives, niacin, or combination therapy of statins plus BAR may be cost effective. Cost effectiveness is maximized by treating high-risk patients and those with established CHD.

Specialty lipid clinics have become increasingly popular, and many use pharmacists to provide direct patient care in this setting. An interesting analysis showed that a specialty clinic may be more expensive (\$659 ± \$43 vs \$477 ± \$42 per patient, $P < 0.001$) than usual care. However, the overall cost effectiveness is improved when expressed as program costs per unit (mmol/L) reduction in the LDL-C, a measure of cost effectiveness that was significantly lower for specialized care (\$758 ± \$58 vs \$1,058 ± \$70, $P = 0.002$) because more patients achieve their targeted goal.¹²⁵ Project IMPACT (Improve Persistence and Compliance with Therapy) demonstrated that pharmacists, working collaboratively with patients and physicians, can improve persistence and compliance, and that nearly two thirds of patients achieved their NCEP lipid goal.¹²⁶ Other programs showed similar trends.^{67,127,128}

■ OTHER THERAPIES

Partial ileal bypass has been used for treatment of severe heterozygous and homozygous familial hypercholesterolemia; however, it is ineffective in the latter case. Ileal bypass removes the site of bile acid reabsorption, depleting the bile acid pool and increasing the catabolism of cholesterol. The Program on the Surgical Control of the Hyperlipidemias (POSCH), a randomized trial of diet versus surgery, reported that total cholesterol and LDL-C were decreased (23.3% and 37.7%, respectively) and HDL increased (4.3%) in patients who had undergone ileal bypass for hypercholesterolemia.⁹⁷ Surgery delayed overall death by nearly 3 years ($P = 0.032$) and delayed CHD mortality by nearly 4 years ($P = 0.046$) compared to the control group. Revascularization procedures were delayed by an average of 7 years ($P < 0.001$). Postsurgery diarrhea was more common in the surgical group, as were the rates of kidney stones (4% vs 0.4%), gallstones (10% vs 2%), and bowel obstruction (13.5% vs 3.6%).

Portacaval shunts have been used to decrease the formation of LDL-C, with reported reductions of 10% to 20%. Plasma exchange

combined with niacin was found to reduce plasma cholesterol levels by approximately 50% over 5 years in patients with homozygous familial hypercholesterolemia, and coronary atherosclerosis did not progress as documented by angiography. LDL apheresis (i.e., selective removal of LDL-C via a filtering system) plus statin therapy is effective in lowering LDL-C and appears to affect the progression of vascular disease. Combined liver and heart transplantation in patients with homozygous familial hypercholesterolemia reduced total cholesterol and LDL-C concentrations from approximately 1,100 and 900 mg/dL before surgery to approximately 300 and 185 mg/dL after surgery, respectively. Liver transplantation replaced the missing LDL receptors, enhanced catabolism, and reduced lipoprotein synthesis in this patient population.

■ SUMMARY OF MAJOR STUDIES

10 Primary and secondary prevention diet and drug trials have been performed to determine whether lowering cholesterol levels will prevent CHD. These trials are summarized in Tables 23–15 and 23–16. A number of earlier angiographic studies demonstrated that cholesterol reduction led to regression of atherosclerosis and plaque stabilization. Most of the primary and secondary studies were double blinded, randomized, and placebo controlled, lasted for at least 5 years, and had sufficient patient numbers to be meaningful. Exceptions to these qualifications were seen in the early studies, such as the Newcastle and Edinburgh trials, which were small and generally did not show much benefit; and the Coronary Drug Project (CDP), using dextrothyroxine, which was terminated early because of observed adverse effects on CHD mortality. The Helsinki Heart Study, using gemfibrozil, resulted in a reduction in nonfatal MI, which was the primary contributor to reduced CHD incidence (Table 23–15).¹⁴

Total cholesterol and LDL-C were reduced an average of 13.4% and 20.3%, respectively, by cholestyramine in the Lipid Research Clinics Coronary Primary Prevention Trial (LRC-CPPT). The reduction of lipid levels was related to the amount of drug ingested (5.4% reduction in total cholesterol with 1–2 packets vs 19.0% reduction with ≥5 packets).¹²⁹ The prescribed dose of cholestyramine was 24 g (or 6 packets) per day. The cholestyramine group experienced a 19% reduction in risk ($P < 0.05$) of the primary end point of definite CHD death and/or definite nonfatal MI, reflecting a 24% reduction in definite CHD death and a 19% reduction in nonfatal MI. Other end points of new positive exercise tests, angina, and coronary bypass surgery were reduced by 25%, 20%, and 21%, respectively. Death from all causes was

not significantly reduced by cholestyramine secondary to more accidents and violence in this group. The mean falls in total cholesterol and LDL-C in the cholestyramine group were 8% and 12% relative to levels in placebo-treated men, providing evidence that for every 1% reduction in cholesterol, a 2% decline in CHD mortality can be realized.

AFCAPS/TexCAPS was a primary prevention trial conducted in 6,605 men and women aged 57 to 63 years with average total cholesterol (<221 mg/dL) and LDL (<150 mg/dL) who were treated with lovastatin 20 to 40 mg/day for 5.2 years. The study showed a 37% reduction ($P < 0.001$) in the risk for first acute major coronary event (fatal or nonfatal MI, unstable angina, or sudden cardiac death).⁹⁰ The need for revascularization procedures was reduced by 33% ($P < 0.001$). The implications of this trial are enormous; based on these results, millions of “normal” people potentially could benefit from lipid lowering with statins. The number of patients who need to be treated (Table 23-15) for primary prevention ranged from 43 in the West of Scotland trial to 71 in the Helsinki Heart Study. This range is within the typical boundary used for treatment decisions and described previously; cost effectiveness is achieved routinely in patients with moderate to high risk. The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial—Lipid Lowering Trial (ALLHAT-LLT) tested pravastatin 40 mg/day versus placebo in hypertensive patients with at least one CHD risk factor. Pravastatin did not reduce either all-cause mortality or CHD significantly compared with usual care in older participants with well-controlled hypertension and moderately elevated LDL-C. The results may be due to the modest differential in total cholesterol (9.6%) and LDL-C (16.7%) between pravastatin and usual care compared with prior statin trials supporting cardiovascular disease prevention.¹³⁰ The long-awaited WHI trial proved to be disappointing, showing no beneficial effects on CHD event reduction in the hormone replacement arm (conjugated equine estrogens + medroxyprogesterone) or the conjugated equine estrogens alone arm compared to placebo.^{107,109} Women did experience greater risk for thromboembolism, a slight increase in breast cancer, and a reduced risk of hip fracture. Consequently, hormone replacement therapy can no longer be recommended for cardiovascular protection.⁴ In the WISDOM trial, comparison of hormone therapy ($n = 2,196$) versus placebo ($n = 2,189$) revealed a significant increase in the number of major cardiovascular events (7 vs 0, $P = 0.016$) and venous thromboembolism (22 vs 3,

hazard ratio 7.36, 95% confidence interval 2.20–24.60), confirming the findings of HERS and WHI. There were no statistically significant differences in the numbers of breast or other cancers, cerebrovascular events, fractures, and overall death.¹¹¹

In the CDP, niacin significantly reduced definite nonfatal MI compared to placebo (10.1% vs 13.9%), whereas clofibrate did not reduce death from any cause or nonfatal or fatal MI during the 5-year followup.¹³¹

One of the most important studies published is 4S, a secondary intervention trial with a large number of patients.¹³² Simvastatin 20–40 mg/day reduced LDL-C by 35% and reduced the risk of death from any cause by 30%. Coronary deaths were reduced with simvastatin (relative risk 0.58, confidence interval 0.46–0.73). Therapy was shown to be effective in women (18%–19% of patients enrolled) and in the elderly (≥ 60 years). The relative risk of death or major coronary event was reduced to a greater extent in the elderly than in younger patients. Death from noncardiovascular causes was similar for simvastatin and placebo (2.1% and 2.2%, respectively). The survival curves for simvastatin and placebo began to separate at 1 year and became more divergent with additional followup. 4S clearly demonstrates the benefit of cholesterol lowering and placates long-held fears of death from non-CHD causes. The Long-Term Intervention with Pravastatin in Ischemic Disease (LIPID) study ($N = 7,498$ men and 1,516 women) investigated the effect of pravastatin therapy over 6 years on CHD mortality in patients with prior MI or unstable angina and mean cholesterol level of 219 mg/dL.¹³³ Pravastatin reduced the risk of CHD mortality by 24% (8.3% vs 6.4%, $P = 0.0004$) and total mortality by 23% (14.1% vs 11.0%, $P = 0.00002$), reduced stroke by 20% (4.3% vs 3.5%, $P = 0.22$), and reduced the need for coronary artery bypass graft surgery (11.3% vs 8.9%, $P = 0.0001$) and percutaneous transluminal coronary angioplasty (5.3% vs 4.4%, $P = 0.04$).

The Veterans Administration High-Density Lipoprotein Intervention trial (VA-HIT) was a double-blinded trial that compared gemfibrozil (1,200 mg/day) with placebo in 2,531 men with CHD, HDL-C level ≤ 40 mg/dL, and LDL-C level ≤ 140 mg/dL.¹³⁴ The primary study outcome was nonfatal MI or death from coronary causes. Median followup was 5.1 years. At 1 year, mean HDL-C level was 6% higher, mean triglyceride level was 31% lower, and mean total cholesterol level was 4% lower in the gemfibrozil group than in the placebo group. LDL-C levels did

not differ significantly between groups. A primary event occurred in 21.7% of the patients assigned to placebo and in 17.3% of the patients assigned to gemfibrozil. The overall reduction in the risk of an event was 4.4 percentage points, and the reduction in relative risk was 22% ($P = 0.006$). This trial presents the strongest evidence to date that raising HDL-C and lowering triglycerides levels reduce risk for CHD.

The Atorvastatin Versus Revascularization Treatment (AVERT) trial compared atorvastatin 80 mg/day with percutaneous transluminal coronary angioplasty.¹³⁵ The followup period was 18 months. Of the patients who received aggressive lipid-lowering treatment with atorvastatin, 13% had ischemic events compared to 21% of patients who underwent angioplasty. Thus, the incidence of ischemic events was 36% lower in the atorvastatin group over an 18-month period ($P = 0.048$, which was not statistically significant after adjustment for interim analyses). This reduction in events was the result of a smaller number of angioplasty procedures, coronary artery bypass operations, and hospitalizations for worsening angina (the most common end point). Compared to the patients who were treated with angioplasty and usual care, the patients who received atorvastatin had a significantly longer time to the first ischemic event ($P = 0.03$). In low-risk patients with stable CAD, aggressive lipid-lowering therapy is at least as effective as angioplasty and usual care in reducing the incidence of ischemic events.

The Prospective Study of Pravastatin in the Elderly at Risk (PROSPER) investigates men and women in the age range from 70 to 82 years at risk for cardiovascular disease and found that pravastatin 40 mg/day reduced CHD events by 24%, with no effect on cognitive function.¹³⁶ The more recent Thrombolysis in Myocardial Infarction 22 (TIMI-22) study (also known as PROVE-IT [Pravastatin or Atorvastatin Evaluation and Infection Therapy]), enrolled 4,162 patients who had been hospitalized for an acute coronary syndrome within the preceding 10 days and compared pravastatin 40 mg/day (standard therapy) with atorvastatin 80 mg/day (intensive therapy).¹³⁷ An intensive lipid-lowering statin regimen with atorvastatin 80 mg/day provided greater protection against death or major cardiovascular events than did a standard regimen. This study clearly points to “lower is better” for LDL concentration and likely will lead to revision in guideline goals to lower LDL levels. The Treating to New Targets (TNT) study assessed the efficacy and safety of lowering LDL-C levels to <100 mg/dL (2.6 mmol/L) in patients with stable CHD.^{138,139} Intensive lipid-lowering therapy with atorvastatin 80 mg/day in patients with stable CHD provided significant clinical benefit beyond than treatment with atorvastatin 10 mg/day, providing additional evidence that intensive lipid lowering brings greater benefits.

Statins reduce the incidence of strokes among patients at increased risk for cardiovascular disease. Whether statins reduce the risk of stroke after a recent stroke or transient ischemic attack (TIA) was addressed by Stroke Prevention by Aggressive Reduction in Cholesterol Levels (SPARCL). During a median followup of 4.9 years, 265 patients (11.2%) who received atorvastatin 80 mg/day and 311 patients (13.1%) who received placebo had a fatal or nonfatal stroke (5-year absolute reduction in risk 2.2%, adjusted hazard ratio 0.84, 95% confidence interval 0.71–0.99, $P = 0.03$; unadjusted $P = 0.05$).¹⁴⁰

The enzyme ACAT esterifies cholesterol in a variety of tissues. In some animal models, ACAT inhibitors have antiatherosclerotic effects. However, when tested in clinical trials, ACAT inhibition was not an effective strategy for limiting atherosclerosis and may promote atherogenesis.¹⁴¹

Statins differ in their pharmacokinetic properties and in pleiotropic effects (i.e., nonlipid lowering). The contribution of lipid lowering alone (a class effect) versus other effects (antiinflammatory, antithrombotic) is controversial.

Proteinuria has been associated with high-dose rosuvastatin therapy (40 mg/day), but a review of a clinical trial database revealed an increase in the estimated glomerular filtration rate for rosuvastatin-treated patients that was consistent across all major demographic and clinical subgroups of interest, including patients with baseline proteinuria, patients with baseline estimated glomerular filtration rate <60 mL/min/1.73 m², and patients with hypertension and/or diabetes.¹⁴²

The role of nontraditional risk factors (high-sensitivity C-reactive protein, homocysteine) is being studied and may lead to recommendations for the use of these tests in patient evaluation.

EVALUATION OF THERAPEUTIC OUTCOMES

Short-term evaluation of therapy for hyperlipidemia is based on response to diet and drug treatment as measured in the clinical laboratory by total cholesterol, LDL-C, HDL-C, and triglycerides for patients being treated for primary intervention, as well as on response to secondary intervention. The followup interval is dependent on the severity of illness, and patients with known CAD or multiple risk factors should be monitored more closely. Less commonly used laboratory measurements include C-reactive protein, homocysteine, apolipoprotein B, and lipoprotein(a) levels. Because many patients being treated for primary hyperlipidemia have no symptoms and may not have any clinical manifestations of a genetic lipid disorder such as xanthomas or eruptions, monitoring and outcome are solely laboratory based. In patients treated for secondary intervention, symptoms of atherosclerotic cardiovascular disease (e.g., angina or intermittent claudication) may improve over months to years. In patients have xanthomas or other external manifestations of hyperlipidemia, the lesions should regress with therapy. Lipid measurements should be obtained in the fasted state to minimize interference from chylomicrons. Once the patient is stable, monitoring is needed at intervals of 6 months to 1 year. The goals for LDL-C and HDL-C are listed in Tables 23–8 and 23–9.

Patients with multiple risk factors and established CHD should be monitored and evaluated for progress in managing their other risk factors, such as hypertension, smoking cessation, exercise and weight control, and glycemic control if diabetic. The goals are to maintain blood pressure $<130/80$ mm Hg, especially for patients with diabetes or renal insufficiency, stop smoking, maintain an ideal body weight, exercise for at least 20 minutes per day at least three times per week, and keep plasma glucose concentration <100 mg/dL (threshold for glucose intolerance). Invasive evaluation, such as cardiac catheterization, is useful in patients with established CHD and typically is used for planning revascularization rather than monitoring of lipid-lowering therapy.

Evaluation of dietary therapy is part of the outcome evaluation for treating hyperlipidemia, and the assistance of a dietitian is recommended. Use of diet diaries and recall survey instruments enables systematic collection of information about diet and may improve patient adherence to dietary recommendations. Patients undergoing resin therapy should have a fasting lipoprotein profile checked every 4 to 8 weeks until a stable dose is achieved; triglycerides should be checked at stable dose to ensure levels have not increased. Niacin requires baseline liver function tests, and uric acid

CLINICAL CONTROVERSIES

The CETP inhibitor torcetrapib was associated with a substantial increase in HDL-C and decrease in LDL-C. It also was associated with an increase in blood pressure and no significant decrease in the progression of coronary atherosclerosis. The lack of efficacy may be related to the mechanism of action of this drug class or to molecule-specific adverse effects. Other means of raising HDL-C (HDL mimetics, which include apolipoprotein A-I mutants and peptide mimetics of apolipoprotein A-I and HDL Milano A, a synthetic form of HDL) still hold hope of HDL modification leading to a reduction in clinical events.

and glucose concentrations; repeat tests are appropriate at doses of 1,000–1,500 mg/day. Myopathy or diabetes-like symptoms should be investigated and may require CK or glucose determinations; more frequent monitoring in diabetics may be necessary. A fasting lipoprotein profile 4 to 8 weeks after the initial dose or after dose changes with statins is appropriate. Liver function tests should be obtained at baseline and periodically thereafter based on package insert information; recognized experts believe that monitoring for hepatotoxicity and myopathy should be symptom triggered.^{56,61} Ezetimibe requires little specific monitoring.

BARBARA J. HOEBEN AND ROBERT L. TALBERT

KEY CONCEPTS

- 1 The prevalence of peripheral arterial disease is dependent upon patient age and the presence of traditional risk factors for cardiovascular disease. Many patients are undiagnosed and are at substantial risk for coronary and cerebrovascular events.
- 2 The clinical presentation of peripheral arterial disease is variable and includes a range of symptoms. The two most common characteristics of peripheral arterial disease are intermittent claudication and pain at rest in the lower extremities.
- 3 The ankle–brachial index (ABI) is a simple, noninvasive, quantitative test that has proved to be a highly sensitive and specific tool in the diagnosis of peripheral arterial disease.
- 4 As with any atherosclerotic condition, several risk factors play an important role in the morbidity and mortality of peripheral vascular disease. Many of these risk factors can be modified with the help of various nonpharmacologic and pharmacologic interventions.
- 5 Nonpharmacologic interventions, such as smoking cessation and walking exercise programs, can positively impact several of the pathophysiologic abnormalities present in patients with peripheral arterial disease.
- 6 Data proving that antiplatelet therapies can prevent or delay the progression of peripheral arterial disease are unavailable. However, aspirin therapy has repeatedly been proven to significantly reduce serious vascular events in these “high-risk” patients and, in the absence of contraindications, is highly recommended.
- 7 Patients who continue to experience severe intermittent claudication even after implementation of appropriate exercise therapy and therapeutic lifestyle changes may benefit from additional pharmacologic therapy with cilostazol.

Peripheral arterial disease (PAD), the most common form of peripheral vascular disease, is a manifestation of progressive narrowing of the arteries due to atherosclerosis.¹ PAD is associated with elevated risk of morbidity and mortality from cardiovascular disease (CVD), even in the absence of a history of acute myocardial infarction, stroke, or other manifestations of CVD.^{1–3} Patients with PAD have approximately the same relative risk of death from CVD as do patients with a history of coronary or cerebrovascular disease,

and PAD should be considered a surrogate marker of subclinical coronary artery disease (CAD) and other vascular territories.^{1,4,5} Treatment of PAD focuses on decreasing the functional impairment caused by symptoms of intermittent claudication through nonpharmacologic and pharmacologic therapy and minimizing the impact of other cardiovascular risk factors.⁶

EPIDEMIOLOGY

1 Using the definition of an ankle–brachial index (ABI) <0.9 in either leg, the National Health and Nutrition Examination Survey (NHANES) found a 4.3% prevalence of PAD among adults age 40 years and older in the United States.² The prevalence of PAD is highly dependent on patient age, being infrequent in younger individuals and common in older individuals (Fig. 24–1). In age- and gender-adjusted logistic regression analyses, black race/ethnicity (odds ratio [OR] 2.83), current smoking (OR 4.46), diabetes (OR 2.71), hypertension (OR 1.75), hypercholesterolemia (OR 1.68), and impaired renal function (estimated glomerular filtration rate <60 mL/min/1.73 m²; OR 2.00) were associated with more prevalent PAD.^{2,7} Individuals with PAD are more likely to have a self-reported history of any CAD or CVD but, interestingly, no association with elevated body mass index. The reported relative risk of death from CVD in patients with PAD ranges from 2 to 5.1 in those with or without CVD and 2.9 to 5.7 in those with known CVD.⁸ CVD accounts for 75% of all deaths in patients with PAD.⁹ The risk of death is approximately the same in men and women and is elevated even in asymptomatic patients. Annual mortality is 25% in patients with critical leg ischemia who have the lowest ABI values.¹⁰

More than five million (estimated range four to seven million) adults age 40 years and older have PAD. Ninety-five percent of individuals with PAD have at least one cardiovascular risk factor; the majority of patients have multiple risk factors for CVD.² Based on the PAD Awareness, Risk, and Treatment: New Resources for Survival

FIGURE 24-1. Prevalence of peripheral arterial disease by age and gender.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

(PARTNERS) program, the prevalence of PAD seen in primary care practices is high, yet physician awareness of the PAD diagnosis is relatively low.¹¹ In this cross-sectional study, PAD was detected in 29% of 6,979 patients. Eighty-three percent of the patients were aware of their diagnosis compared to only 49% of their physicians. The reason for this observation is that patient self-report of symptoms and use of questionnaires for detecting PAD are not sufficiently sensitive and specific to reproducibly diagnosis PAD, and the cardinal symptom of PAD—intermittent claudication—is present in the minority of patients (1%–27%).^{8,12,13} A simple ABI measurement will identify a large number of patients with previously unrecognized PAD. Atherosclerosis risk factors were highly prevalent in PAD patients, but these patients received less intensive treatment for lipid disorders and hypertension and were prescribed antiplatelet therapy less frequently than were patients with CVD. These results demonstrate that underdiagnosis of PAD in primary care practice may be a barrier to effective secondary prevention of the high ischemic cardiovascular risk associated with PAD.¹¹ Because of the systemic nature of atherosclerosis and the high risk of ischemic events, patients with PAD should be considered for secondary prevention strategies, including aggressive modification of risk factors and antiplatelet drug therapy.^{8,14–16}

ETIOLOGY AND PATHOPHYSIOLOGY

PAD is most commonly a manifestation of systemic atherosclerosis in which the arterial lumen of the lower extremities becomes progressively occluded by atherosclerotic plaque.⁹ The major risk factors for development of atherosclerosis are older age (>40 years), cigarette smoking, diabetes mellitus, hypercholesterolemia, hypertension, and hyperhomocysteinemia.^{8,9,12} The arteries most commonly involved, in order of occurrence, are the femoropopliteal–tibial, aortoiliac, carotid and vertebral, splenic and renal, and brachiocephalic.¹⁷ Familial hypercholesterolemia leading to hypercholesterolemia and elevated low-density lipoprotein (LDL) levels is associated with accelerated development of atherosclerosis earlier and with more severe symptoms (e.g., intermittent claudication) and abnormal blood flow studies compared to controls.¹⁸ Intima–media thickness can be used as a surrogate phenotype for cardiovascular risk in familial hypercholesterolemia. Carotid and/or femoral artery atherosclerosis results in increased intima–media thickness and is correlated to cardiovascular risk in patients with familial hypercholesterolemia compared with normolipidemic individuals.

CLINICAL PRESENTATION AND DIAGNOSIS

2 The clinical presentation of PAD is variable, ranging from no symptoms at all (typically early in the disease) to symptoms of pain and discomfort (Table 24–1). This finding was illustrated in a study by Wang et al.,¹⁹ who attempted to aid the diagnosis of PAD by using defined categories of exertional leg pain in patients with and without PAD. They determined that not one of the five categories of leg pain (no pain, pain on exertion and rest, noncalf pain, atypical calf pain, and classic claudication) was sufficiently sensitive or specific to enable a link to a PAD diagnosis. The two most common characteristics of PAD are intermittent claudication and pain at rest in the lower extremities.^{19–22} Intermittent claudication is generally regarded as the primary indicator of PAD. It is described as fatigue, discomfort, cramping, pain, or numbness that occurs in the affected extremities (typically the buttock, thigh, or calf) during exercise and resolves within a few minutes with rest.^{20,21,23–25} Resting pain typically occurs later in the disease when the blood supply is not adequate to perfuse the extremity (critical limb ischemia). This condition most often is felt at night in the feet (typically the toes or heel) while the patient is lying in bed.^{20–22}

TABLE 24-1 Clinical Presentation of Peripheral Arterial Disease

General
• Patients with PAD are likely to be 40 years of age and older with hypertension, hypercholesterolemia, diabetes, impaired renal function, a history of coronary artery disease or cardiovascular disease, and/or a history of smoking.
Signs and symptoms
• The clinical presentation of PAD is variable and includes symptoms ranging from no symptoms at all (typically early in the disease) to pain and discomfort.
• The two most common characteristics of PAD are intermittent claudication and pain at rest in the lower extremities.
• Intermittent claudication is generally regarded as the primary indicator of PAD. It has been described as fatigue, discomfort, cramping, pain, or numbness in the affected extremities (typically the buttock, thigh, or calf) during exercise and resolves within a few minutes with rest.
• Physical examination may reveal nonspecific signs of decreased blood flow to the extremities (e.g., cool skin temperature, shiny skin, thickened toenails, lack of hair on the calf, feet, and/or toes).
Laboratory tests
• None specific to PAD.
Other diagnostic tests
• The ankle–brachial is a simple, noninvasive, quantitative test that has been proven to be a highly sensitive and specific (≥90%) tool in the diagnosis of PAD.

PAD, peripheral arterial disease.
Data from references 2, 7, 12, 19–26, 28, 30, 31, and 78.

As with any good medical encounter, obtaining a detailed patient history of symptoms and atherosclerosis risk factors (e.g., smoking, hypertension, hyperlipidemia, and diabetes) can be helpful in making the diagnosis of PAD. Unfortunately, as illustrated by the PARTNERS program, providers who rely on a history alone will miss approximately 85% to 90% of patients with PAD.²³ Therefore, physical examination of the patient is vital to proper diagnosis. Requesting that the patient remove socks and shoes may reveal nonspecific signs of decreased blood flow to the extremities (e.g., cool skin temperature, shiny skin, thickened toenails, lack of hair on the calf, feet, and/or toes) or, in severe cases, visible sores or ulcers that are slow to heal or even black in appearance.^{12,20–22,26–28}

An important criterion for accurate diagnosis of PAD is exclusion of other conditions having similar signs and symptoms. Differential diagnosis should rule out other neurologic conditions (e.g., peripheral neuropathy), musculoskeletal conditions (e.g., restless leg syndrome or spinal stenosis), inflammatory conditions (e.g., arthritis), and vascular conditions (e.g., deep-vein thrombosis or venous congestion), which may mimic PAD.^{12,21,25,28,29}

3 The ABI is a simple, noninvasive, quantitative test that has proved to be a highly sensitive and specific (≥90%) tool in the diagnosis of PAD.^{23,30,31} For measurement of the ABI, the patient lies in the supine position as systolic blood pressure is measured at the brachial arteries on both arms and the dorsalis pedis and posterior tibial arteries of the legs using a standard sphygmomanometer and a continuous-wave Doppler device. The pressures obtained at the dorsalis pedis and posterior tibial arteries are averaged and divided by the mean measurement taken at the left and right brachial arteries.^{8,26,32,33} ABI = 1 is considered normal, whereas ABI <0.9 is consistent with PAD. ABI from 0.7 to 0.9 correlates with mild PAD, 0.4 to 0.7 indicates moderate disease, and <0.4 indicates severe PAD.^{9,24,32} In addition to providing diagnostic information, the ABI measurement has been shown to be a strong predictor of future cardiovascular events associated with PAD.³⁴ The ABI can be useful after an exercise tolerance test (e.g., 5 minutes on a treadmill or 30 to 50 repetitions of heel raises). Patients with PAD will demonstrate a significant drop in ABI after exercise, but their pain will be normal or unchanged. ABI can rule out PAD and suggest alternate diagnoses.^{9,12,24,26} Not only is ABI an effective diagnostic tool, but a systematic review determined that ABI has high specificity for pre-

dicting future cardiovascular outcomes (incident coronary heart diseases, incident stroke, and cardiovascular mortality).³⁵

Other noninvasive tools are available for diagnosis of PAD. One study has suggested a calculation that takes into consideration the patient's history of acute myocardial infarction and the number of auscultated and palpated posterior tibial arteries.^{36,37} Magnetic resonance angiography can be used to examine the presence and location of significant stenosis, or lack thereof, and is a reasonable option in patients who are being considered for surgical revascularization.³⁸ Similarly, computed tomographic angiography can be used to determine the presence of significant stenosis and soft-tissue diagnostic information that may be associated with PAD (e.g., aneurysms).³⁸ However, because ABI is a sufficient means of diagnosis, arteriography is not necessary or encouraged.^{20,25,31}

TREATMENT

Peripheral Arterial Disease

■ GOALS OF TREATMENT

PAD is caused by atherosclerotic plaque formation in the arteries that results in decreased blood flow to the legs. Several of the treatment goals for patients with PAD involve the reduction of confounding variables that contribute to the disease process, progress, and eventual outcome. Specific goals should include increasing maximal walking distance, duration of walking, and amount of pain-free walking; and improving control of comorbid conditions that contribute to morbidity (e.g., hypertension, hyperlipidemia, and diabetes), resulting in improvement in overall quality of life and reduction in cardiovascular complications and death.

■ GENERAL APPROACH TO TREATMENT

4 As with any atherosclerotic condition, several risk factors play an important role in the morbidity and mortality of PAD. Many of these risk factors can be modified with the help of various nonpharmacologic and pharmacologic interventions.

■ NONPHARMACOLOGIC THERAPY

Smoking Cessation

5 Cigarette smoking not only increases the risk of developing PAD and other cardiovascular disorders, but the duration and quantity smoked can negatively impact disease progression (i.e., increase the risk of amputation) and increase mortality.^{8,29,34,39–43} As a result, providers must advise patients to quit and should offer nonpharmacologic and pharmacologic means to aid patients in that goal. Numerous studies have proved the effectiveness of individual or group behavior modification therapy with or without the addition of certain antidepressants (e.g., bupropion) or nicotine replacement therapies (e.g., gum or patches). Reassessment of smoking status and progress encouragement at each visit can help reemphasize to the patient the vital importance of this lifestyle change.

Exercise

5 Walking exercise programs for patients with PAD have been proven to result in increased walking duration and distance, increased pain-free walking, and delayed onset of claudication by 179%.^{14,27,29,40,41,44–48} Walking, or any aerobic exercise program conducted under the supervision of a healthcare provider, can positively impact several of the pathophysiologic abnormalities present in patients with PAD. Benefits of exercise programs include improving diabetes and lipid management, reducing weight, improving blood viscosity and flow, and reducing blood pressure.⁶ The American College of Cardiology/

American Heart Association Guidelines for the Management of PAD recommend supervised exercise training for patients with intermittent claudication, for a minimum of 30–45 minutes, performed at least three times per week.³⁸ A prospective, observational study has concluded that PAD patients with higher physical activity (as measured with a vertical accelerometer) have reduced mortality and cardiovascular events compared to those with low physical activity, regardless of confounders.⁴⁹ Exercise treadmill walking testing should be repeated at regular intervals (i.e., quarterly to biannually) to assess improvement or decline in walking duration and distance as well as time to pain onset while performing this activity. The type of aerobic activity recommended, as well as the duration and frequency of the activity, should be individually designed on a patient-to-patient basis.

Revascularization Therapy

Various surgical procedures are available for patients with severe, debilitating claudication who have attempted, and failed, other means of nonpharmacologic and pharmacologic therapy. The TransAtlantic Inter-Society Consensus (TASC) document on PAD provides clear recommendations for invasive therapy.²⁷ First, the patient must have a lack of adequate response to exercise therapy and risk factor modification. Second, the patient must have severe disability from intermittent claudication resulting in impairment of daily activities. Third, a thorough evaluation of the risks versus benefits of an invasive intervention must be preformed, including probability of success, anticipated future course of the disease if intervention is not performed, and evaluation of concomitant disease states.²⁷ Although the TASC is clear that revascularization is mostly reserved for those who do not respond to conservative therapy consisting of risk factor modification, exercise, and pharmacologic therapy, revascularization does have a role in patients with favorable anatomy, whose lifestyle and/or job performance are compromised and who have a favorable risk-to-benefit ratio based on procedural risk.¹² The decision to attempt percutaneous revascularization often is made with the guidance of diagnostic angiography. Angiography can help to identify the location and size of lesions and provide valuable information regarding the likelihood of success with surgical revascularization.²⁷

Percutaneous transluminal angioplasty (PTA) is an example of an invasive treatment of PAD. A randomized controlled clinical trial by Whyman et al.⁵⁰ determined that in a 2-year postintervention, PTA outcomes on maximum walking distance and ABI were not significantly different than outcomes in patients who had received only daily low-dose ASA ($P > 0.05$). Nevertheless, patients who had received PTA had significantly fewer occluded arteries ($P = 0.003$), but the true clinical significance of this finding was not realized in the time allotted for the study. PTA typically is reserved for patients whose lifestyle and/or job performance are compromised secondary to claudication despite adequate pharmacologic interventions and exercise.^{12,38}

Stent placement in PAD patients has been an area of study and controversy. A meta-analysis examining the use of stent placement versus PTA for treatment of aortoiliac occlusive disease determined that although stent placement and PTA yielded similar complication and mortality rates, posttreatment ABI was more improved with stents (0.87 with PTA and 0.76 with stents, $P < 0.03$) and the risk of long-term failure was 39% less with stent placement.⁵¹ However, other studies have not demonstrated improvement in patency rates in peripheral arteries versus PTA alone.²⁰ The TASC document provides specific recommendations for PTA, with or without stenting, depending on the how diffuse the disease process is, the number and size of the lesions, and the location of the lesions.²⁷

For patients with severe intermittent claudication resulting in critical leg ischemia, physicians may need to discuss alternate surgical interventions, including aortofemoral bypass, femoropopliteal bypass, or even amputation.^{20,21,40}

■ PHARMACOLOGIC THERAPY

Hypertension

Hypertension is a major risk factor for PAD and can lead to acute myocardial infarction, stroke, heart failure, and death.¹⁴ Current guidelines recommend that the treatment goal for blood pressure in patients with PAD mirror those in patients with documented CVD: 130/85 mm Hg.^{14,39} Although, the Heart Outcomes Prevention Evaluation (HOPE) study demonstrated that angiotensin-converting enzyme inhibitors reduced not only blood pressure but other cardiovascular events (e.g., acute myocardial infarction, stroke, and death) in high-risk patients, including those with PAD, no specific class of antihypertensives is recommended over another for treatment of hypertension in patients with PAD. Therefore, selection of drug therapy for hypertension should be made on the basis of comorbid disease states, drug costs and availability, drug allergies, or other possible limiting factors. For example, patients with documented CAD may receive a dual benefit by the selection of a β -blocker, whereas patients with concomitant Raynaud phenomenon may benefit from calcium channel blockers.^{14,39,52} Dosing, monitoring guidelines, and contraindications for specific agents are discussed in Chapter 15.

Hyperlipidemia

Although a reduction in lipid levels can reduce the progression of PAD and the severity of claudication, the current recommendations for management of hyperlipidemia in patients with PAD are based on only a few small studies and sub hoc analyses from larger trials.^{8,39,53,54} The Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III) considers PAD to be in the category of highest risk, or a coronary heart disease risk equivalent. Therefore, the Expert Panel recommends that LDL levels be maintained at <100 mg/dL and non-high-density lipoprotein (HDL) levels (total cholesterol – HDL cholesterol) maintained at <130 mg/dL.⁵³ Results of clinical trials conducted since issuance of the Expert Panel recommendation, specifically the Heart Protection Study (HPS)⁵⁵ and the Pravastatin or Atorvastatin Evaluation and Infection—Thrombolysis in Myocardial Infarction (PROVE IT)⁵⁶ trial, have led many clinical experts to now recommend an LDL goal of <70 mg/dL for additional retardation of atherosclerotic plaque formation in persons considered to be at very high risk, including patients with PAD.²⁰ Regardless of the goal LDL level chosen, initiation of patient therapeutic lifestyle changes (e.g., reduction in consumption of saturated fat, weight reduction, and increased physical activity) is vital to achieving these recommendations.^{16,53} Unfortunately, in many cases, therapeutic lifestyle changes alone will not achieve the desired goals.

Several options are available for initiating drug therapy to lower LDL levels in patients with PAD. Statins, bile acid sequestrants, and nicotinic acid all are effective treatment options. However, statins are the preferred starting agent in this patient population.^{23,40,53,55} As proven in the HPS, simvastatin demonstrated potent action in reducing LDL and also provided a significant reduction in cardiovascular events overall (e.g., acute myocardial infarction, stroke, and death).⁵⁵ If an increase in HDL levels also is necessary, niacin should be considered alone or in combination with a statin without the fear of worsening glucose metabolism, as previously believed.^{8,21,29,52,57} Dosing, monitoring guidelines, and contraindications for specific agents are discussed in Chapter 23.

Diabetes Mellitus

A meta-analysis of more than 95,000 diabetic patients provided additional support for the accepted premise that glycemic control serves as a risk factor for CVD.⁵⁸ The analysis demonstrated an

increasing risk of death from cardiovascular events as blood glucose concentrations increased, with the same relationship observed even at levels below the threshold of clinically defined diabetes mellitus. This relationship is just one illustration of the criticality of good glycemic control. Due to the high prevalence of PAD among diabetic patients, the American Diabetes Association recommends ABI screening for PAD in all diabetics older than 50 years.⁵⁹ Because of the presence of peripheral neuropathy, patients with diabetes may be less likely to experience or report symptoms of PAD, and the first sign may be as drastic as the appearance of a gangrenous foot ulcer. Therefore, although a lack of randomized controlled studies illustrates that the degree of glycemic control is predictive of the extent of PAD present, it is widely recommended that all patients with concomitant diabetes and PAD maintain good glycemic control, as evidenced by a hemoglobin A_{1c} level <7%.^{8,27,29,39,41,59,60} This recommendation is supported by a prospective cohort study of 1,894 diabetic patients. The study demonstrated that patients with poor glucose control (hemoglobin A_{1c} >7.5%) were five times more likely to develop intermittent claudication and to be hospitalized for PAD compared to patients with hemoglobin A_{1c} <6%.⁶¹ Despite this finding, a study by Rehring et al.⁶² of 365 patients with known PAD and concomitant diabetes showed that only 45.8% of these patients had hemoglobin A_{1c} <7%. Oral antidiabetic agents, insulin regimens, and other pharmacologic and nonpharmacologic strategies for reducing the risk of complications associated with diabetes mellitus are discussed at length in Chapter 77.

■ ANTIPLATELET DRUG THERAPY (TABLE 24–2)

Aspirin

6 By far, the most compelling evidence for the use of any pharmacologic agent in patients with PAD can be found for aspirin (acetylsalicylic acid [ASA]). The Antithrombotic Trialists' Collaboration (ATC) conducted a meta-analysis of 195 randomized trials, composed of more than 135,000 patients at high risk for occlusive arterial disease. The ATC concluded that low-dose ASA (75–160 mg) and medium-dose ASA (160–325 mg/day) led to a significant reduction in serious vascular events (12%) in “high-risk” patients, such as those with PAD.⁶³ The ATC also noted in this analysis that the risk of major extracranial bleed was similar between low-dose and medium-dose regimens.

Tran and Anand⁶⁴ conducted a systematic review of the literature in an effort to summarize the best evidence for oral antiplatelet therapy in patients with cerebrovascular disease, CAD, and PAD. This review included 111 trials (42 of which included patients with PAD, $n = 9,214$) and concluded that patients with PAD should use ASA (160–325 mg/day) or clopidogrel (75 mg/day) when ASA is not tolerated or contraindicated.^{64,65} This is in concordance with the recommendations of the Seventh American College of Chest Physicians (ACCP) Conference on Antithrombotic and Thrombolytic Therapy, which recommends lifelong ASA (75–325 mg/day) over clopidogrel, ticlopidine, and no antithrombotic therapy in patients with PAD.⁶⁶ Unfortunately, no data from large clinical randomized trials have yet shown that ASA, or any other antiplatelet therapy, actually can prevent or delay the progression of PAD.⁶⁶

ASA + Dipyridamole Extended-Release (Aggrenox)

The ATC also examined the use of dipyridamole extended-release (Aggrenox) in combination with ASA in “high-risk” patients, such as those with PAD. The meta-analysis of 25 trials (which included more than 10,000 patients) concluded that the addition of dipyridamole to aspirin led to a further reduction in serious vascular events over ASA

TABLE 24-2 Pharmacotherapy Options for Patients with Peripheral Arterial Disease

Agent	Daily Dose (Oral)	Mechanism of Action	Side Effects	Contraindications	Level of Evidence ^b
Aspirin	81–325 mg	Irreversibly inhibits prostaglandin cyclooxygenase in platelets, prevents formation of thromboxane A ₂	Gastrointestinal upset and/or bleeding	Active bleeding; hemophilia; thrombocytopenia	With coronary or cerebrovascular (grade 1A), without (grade 1C+)
Dipyridamole extended-release (Aggrenox)	400 mg (+ aspirin 50 mg)	May act by inhibiting platelet aggregation (complete mechanism of action unknown)	Angina, dyspnea, hypotension, headache, dizziness	Active bleeding; coronary artery disease (“coronary steal syndrome”)	Recommendation for use not specified in report
Cilostazol (Pletal) ^a	100 mg bid	Phosphodiesterase inhibitor, suppresses platelet aggregation; direct artery vasodilator	Fever from infection, tachycardia	All congestive heart failure patients (decreased survival)	With intermittent claudication (grade 2A)
Clopidogrel (Plavix)	75 mg	Inhibits binding of ADP analogues to its platelet receptor, causing irreversible inhibition of platelets	Chest pain, purpura generalized pain, rash	Active pathologic bleeding (e.g., peptic ulcer, intracranial hemorrhage)	Recommend clopidogrel over no antiplatelet therapy (grade 1C+)
Pentoxifylline (Trental)	1.2 g	Alters red blood cell flexibility; decreases platelet adhesion; reduces blood viscosity; decreases fibrinogen concentration	Dyspnea, nausea, vomiting, headache, dizziness	Recent retinal or cerebral hemorrhage; active bleeding	Not recommended in patients with intermittent claudication (grade 1B)
Ticlopidine (Ticlid)	500 mg	Inhibits binding of ADP analogues to its platelet receptor, causing irreversible inhibition of platelets	Leukopenia; rash; thrombocytopenia; neutropenia, agranulocytosis; aplastic anemia	Active bleeding, hemophilia; thrombocytopenia	Clopidogrel recommended over ticlopidine (grade 1C+)

^aCilostazol should be used in combination with antiplatelet therapy.

^bGrades of recommendation for antithrombotic and thrombolytic therapy are part of the Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy.

Data from references 5, 22, 29, 30, 63, 65, 66, and 79–83.

alone (6%); however, this reduction did not reach statistical significance ($P = 0.32$).^{63,64} Also to be taken into consideration is that most of the reduction in nonfatal stroke in this analysis came from one trial, and these data have not been replicated in other studies.^{63,65,67} The addition of dipyridamole to ASA may cause an increased risk of bleeding and gastrointestinal side effects compared to placebo, so the combination should not be used in patients with CAD.⁶⁷

Clopidogrel (Plavix)

The ATC meta-analysis also reviewed the effectiveness of clopidogrel 75 mg/day in “high-risk” patients, including those with PAD. The ATC concluded that although clopidogrel was able to reduce serious vascular events by 10%, this was significantly less than the reduction seen with ASA (12%, $P = 0.03$) described previously.⁶³ Included in the meta-analysis was the report from the Clopidogrel versus ASA in Patients at Risk of Ischemic Events (CAPRIE) trial, which concluded that clopidogrel 75 mg/day was more effective than ASA 325 mg/day in preventing vascular events in “high-risk” patients. In comparison to ASA therapy, the clopidogrel regimen resulted in an overall reduction in ischemic stroke, myocardial infarction, or vascular death from 5.83% to 5.32% ($P = 0.043$). This difference was even more pronounced in the subgroup analysis of PAD patients, in which clopidogrel therapy led to a significant reduction of 4.86% versus 3.71% in the ASA group ($P = 0.0028$).^{5,30,34} It must be noted that clopidogrel is significantly more expensive than ASA therapy, not only in terms of drug costs but also in cost of physician visits because clopidogrel is a prescription-only medication. For all these reasons, the current recommendations list clopidogrel as a first-line agent, but only in cases where ASA therapy is either not tolerated or contraindicated.^{63,65}

Ticlopidine (Ticlid)

Although ticlopidine has the same mechanism of action as clopidogrel and possesses a similar molecular structure, the results of clinical trials investigating the two agents are strikingly different.²² The Swedish Ticlopidine Multicenter Study (STIMS) had determined that ticlopidine therapy (500 mg/day) reduced total mortality in patients with intermittent claudication in comparison to placebo ($P = 0.015$).^{22,68,69}

However, the once promising results seen with ticlopidine therapy now have been overshadowed by the severe hematologic side effects unique to this agent. Ticlopidine has a black box warning from the Food and Drug Administration (FDA) warning providers that use of this agent can cause neutropenia/agranulocytosis, thrombotic thrombocytopenic purpura, and aplastic anemia.⁷⁰ Other agents, namely clopidogrel, are now used instead of ticlopidine.^{8,29,41}

■ INTERMITTENT CLAUDICATION (TABLE 24–2)

Cilostazol (Pletal)

7 In a head-to-head, randomized, placebo-controlled study of 698 patients with moderate-to-severe claudication, Dawson et al.⁷¹ assigned patients to cilostazol (100 mg twice daily), pentoxifylline (400 mg three times daily), or placebo in an effort to improve maximal walking distance. After 24 weeks, the cilostazol group demonstrated a 54% mean increase in distance versus pentoxifylline, which demonstrated only a 30% mean increase ($P < 0.001$).⁷¹ Similarly, a meta-analysis of eight randomized, double-blind, placebo-controlled, parallel-design trials supported this conclusion, with a reported increase in maximal walking distance and pain-free walking distance with cilostazol at doses of 50 mg and 100 mg twice daily ($P < 0.05$ for all) over placebo.⁷² Regrettably, improvement in walking distance has appeared to come with a price (in addition to the high drug cost); cilostazol has a black box warning from the FDA warning providers not to use this medication in patients with PAD and coexisting heart failure.³⁹ However, the Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy does suggest the use of this agent in patients with PAD who are not candidates for surgical interventions to improve severe intermittent claudication that persists even after implementation of appropriate exercise therapy and therapeutic lifestyle changes.⁶⁶

Pentoxifylline (Trental)

Unlike cilostazol, pentoxifylline has produced less promising results in clinical trials, as illustrated by the randomized, placebo-controlled

trial by Dawson et al.⁷¹ Not only did cilostazol outperform pentoxifylline with regard to improvement in walking distance, but the improvement seen with pentoxifylline was no different from placebo ($P = 0.82$).⁷¹ This nonsignificant improvement in walking distance has been observed in other studies as well.^{8,73} Meanwhile, other meta-analyses of pentoxifylline in comparison to placebo for improvement of maximal walking distance have shown minimal improvement over placebo, but the average effects were relatively small.^{8,74–77} For these reasons, the Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy does not recommend the use of this agent.⁶⁶

EVALUATION OF THERAPEUTIC OUTCOMES

It is vital that the physician counsel the patient on the evaluation measures that will be used to monitor the outcomes of therapeutic interventions for PAD. Various laboratory measurements will assess patient progress in glycemic control (i.e., hemoglobin A_{1c}) and lipid management (i.e., total cholesterol, LDL, HDL, and non-HDL cholesterol). Blood pressure measurements obtained in the clinic and by patient home monitoring can assess the effectiveness of antihypertensive therapy. Exercise treadmill walking testing should be repeated at regular intervals (i.e., quarterly to biannually) to assess improvement or decline in walking duration and distance, as well as the time to pain onset while performing this activity. Repeat ABI measurements should be assessed at each patient visit to determine if the disease process has stabilized or progressed. Most importantly to many patients, simple concern and questioning about improvements to their daily quality of life will highlight the physician's concern for their well-being and aid in the patient's overall general state of health.

Use of Vasopressors and Inotropes in the Pharmacotherapy of Shock

ROBERT MACLAREN, MARIA I. RUDIS, AND JOSEPH F. DASTA

KEY CONCEPTS

- 1 Continuous hemodynamic monitoring with an arterial catheter or a central venous catheter capable of measuring mixed venous oxygen saturation (SvO_2) or central venous oxygen saturation ($ScvO_2$) should be used early and throughout the course of septic shock to assess intravascular fluid status and ventricular filling pressures, determine cardiac output (CO), and monitor arterial and venous oxygenation. They can be used for monitoring the response to drug therapy and guiding dosage titration.
- 2 Early goal-directed therapy with aggressive fluid resuscitation in the emergency department within the first 6 hours of presentation improves survival of patients with sepsis and septic shock.
- 3 Derangements in adrenergic receptor sensitivity or activity frequently result in resistance to catecholamine vasopressor and inotropic therapy in critically ill patients. These changes may be a function of endogenous catecholamine concentrations, dosage/duration of exposure to and type of exogenously administered vasopressors, stage of septic shock, preexisting illness, and other factors.
- 4 In refractory septic shock, rational use of vasopressor or inotropic agents should be guided by receptor activity, pharmacologic and pharmacokinetic characteristics, and regional and systemic hemodynamic effects of the drug and should be tailored to the patient's physiologic needs. Pharmacologically sound combinations of vasopressor and/or inotrope agents should be initiated early to optimize and facilitate rapid response.
- 5 Goals of therapy with vasopressors and inotropes should be predetermined and should optimize regional perfusion to tissues (e.g., cardiac, renal, mesenteric, and periphery). This can be accomplished by continuous or intermittent measurements. $SvO_2/ScvO_2 > 70\%$ should be maintained. Arbitrarily targeting vasopressor and inotrope therapy to supranormal values of global oxygen-transport variables cannot be recommended because of lack of clear benefit and possible increased morbidity.
- 6 Much higher dosages of all vasopressors and inotropes than traditionally recommended are required to improve hemodynamic and oxygen-transport variables in patients with septic shock.
- 7 Dose titration and monitoring of vasopressor and inotropic therapy should be guided by the "best clinical response" while observing for and minimizing evidence of myocardial ischemia (e.g., tachydysrhythmias, electrocardiographic changes), renal (decreased glomerular filtration rate and/or urine production), splanchnic/gastric [low intramucosal pH, bowel ischemia], or peripheral (cold extremities) hypoperfusion, and worsening of partial pressure of arterial oxygen (PaO_2), pulmonary artery occlusive pressure, and other hemodynamic variables.
- 8 First-line therapy of septic shock is aggressive volume resuscitation with crystalloid or colloid types of fluids. Dopamine or norepinephrine typically is used as the initial vasopressor agent for hemodynamic support. Dopamine is limited by its ability to increase CO and complications of tachycardia, tachydysrhythmias, increase in pulmonary artery occlusive pressure, and decrease in splanchnic oxygen use. Low-dose dopamine should not be used to prevent renal failure. Norepinephrine may achieve greater hemodynamic response than dopamine and is less likely to cause tachydysrhythmias and a decrease in splanchnic oxygen utilization.
- 9 Phenylephrine may be a particularly useful alternative in patients who cannot tolerate tachycardia or tachydysrhythmia with dopamine or norepinephrine or in patients with known underlying myocardial dysfunction.
- 10 Epinephrine appears to be effective as a single agent and as an add-on agent. It is particularly useful in the young, in patients with otherwise healthy myocardium, and potentially in patients when used early in the course of treatment. However, because epinephrine causes a significant, yet transient, increase in lactate and worsening of splanchnic oxygen utilization, it is not the agent of first choice in patients with septic shock. It should be used cautiously in patients with a history of coronary artery disease or underlying cardiac disturbances.
- 11 Therapy with vasopressors and inotropes is continued until the myocardial depression and vascular hyporesponsiveness of septic shock improve, usually measured in hours to days. Discontinuation of vasopressor or inotropic therapy should be executed slowly; therapy should be "weaned" to avoid a precipitous worsening in regional and systemic hemodynamics.
- 12 Vasopressin produces vasoconstriction independent of adrenergic receptors and reduces the doses of catecholamine vasopressors. Replacement doses of vasopressin (0.01–0.04 units/min) can be considered in patients with septic shock refractory to catecholamine vasopressors despite adequate fluid resuscitation. Vasopressin may enhance urine production. Given the current data, corticosteroids can be administered to patients with septic shock when adrenal insufficiency is present or when vasopressors have been administered for prolonged periods without evidence of dose reduction.

TABLE 25-1 Hemodynamic and Oxygen-Transport Monitoring Parameters

Parameter	Normal Value ^a
Blood pressure (systolic/diastolic)	100–130/70–85 mm Hg
Mean arterial pressure (MAP)	80–100 mm Hg
Pulmonary artery pressure (PAP)	25/10 mm Hg
Mean pulmonary artery pressure (MPAP)	12–15 mm Hg
Central venous pressure (CVP)	8–12 mm Hg
Pulmonary artery occlusive pressure (PAOP)	12–15 mm Hg
Heart rate (HR)	60–80 beats/min
Cardiac output (CO)	4–7 L/min
Cardiac index (CI)	2.8–3.6 L/min/m ²
Stroke volume index (SVI)	30–50 mL/m ²
Systemic vascular resistance index (SVRI)	1,300–2,100 dyne • s/m ² • cm ⁵
Pulmonary vascular resistance index (PVRI)	45–225 dyne • s/m ² • cm ⁵
Arterial oxygen saturation (SaO ₂)	97% (range 95%–100%)
Mixed venous oxygen saturation (SvO ₂)	70%–75%
Arterial oxygen content (CaO ₂)	20.1 vol% (range 19–21)
Venous oxygen content (CvO ₂)	15.5 vol% (range 11.5–16.5)
Oxygen content difference (C[a-v]O ₂)	5 vol% (range 4–6)
Oxygen consumption index (Vo ₂)	131 mL/min/m ² (range 100–180)
Oxygen delivery index (DO ₂)	578 mL/min/m ² (range 370–730)
Oxygen extraction ratio (O ₂ ER)	25% (range 22–30)
Intramuscular pH (pHi)	7.40 (range 7.35–7.45)
Index (I)	Parameter indexed to body surface area

^aNormal values may not be the same as values needed to optimize the management of a critically ill patient.

Shock is an acute, generalized state of inadequate perfusion of critical organs that can produce serious pathophysiologic consequences, including death, when therapy is not optimal. Shock is defined as systolic blood pressure <90 mm Hg or reduction of at least 40 mm Hg from baseline with perfusion abnormalities despite adequate fluid resuscitation.¹ At one time, mortality from septic or cardiogenic shock exceeded 70%.¹ Currently, 10% to 30% of patients with severe sepsis are admitted to hospitals, and 8.6% of patients experience cardiogenic shock following an acute ST-segment elevation myocardial infarction.^{1–3} Mortality rates for shock of either cause are at least 30% to 50% despite enhanced treatment modalities and sophisticated monitoring techniques.^{1–3} This chapter reviews the theory and current status of hemodynamic monitoring and presents an update on the optimal use of inotropes and vasopressor drugs in shock states, specifically septic shock.^{3–10}

Hemodynamic and perfusion monitoring can be categorized into two broad areas: global and regional monitoring. Global parameters, such as systemic blood pressure and pulse oximetry, assess perfusion and oxygen utilization of the entire body. Regional monitoring techniques, such as tonometry, focus on oxygen flow and subsequent changes in metabolism of individual organs and tissues. Normal values for commonly monitored parameters are listed in Table 25–1. Evidence-based goals of therapy are listed in Table 25–2.^{3–10} The adequacy of regional perfusion can be assessed by indices of specific organ perfusion, although none of these indices alone is a reliable indicator of adequate resuscitation. These measurements include coagulation abnormalities (disseminated intravascular coagulation), altered renal function with reduced urine production or increased serum concentrations of blood urea nitrogen and creatinine, altered

TABLE 25-2 Evidence-Based Treatment Recommendations for Management of Severe Sepsis or Septic Shock

Recommendations	Grade
An arterial catheter should be placed as soon as practical to monitor blood pressure in all patients with septic shock requiring vasopressors.	E
Resuscitation of tissue hypoperfusion from severe sepsis or septic shock should begin as soon as the syndrome is recognized. An elevated serum lactate concentration identifies tissue hypoperfusion in patients at risk who are not hypotensive. During the first 6 hours of resuscitation, goals should include all of the following: (1) CVP 8–12 mm Hg, (2) MAP ≥65 mm Hg, (3) urine production ≥0.5 mL/kg/h, and (4) SvO ₂ or ScvO ₂ ≥70%.	B
Fluid resuscitation should be the initial step in hemodynamic support of septic shock.	B
Fluid resuscitation may consist of natural or artificial colloids or crystalloids. No evidence supports one type of fluid over another.	C
Fluid challenge in patients with suspected hypovolemia or inadequate arterial circulation can be administered at a rate of 500–1,000 mL of crystalloid or 300–500 mL of colloid over 30 minutes and repeated based upon response (blood pressure and/or urine production) and tolerance (intravascular volume overload).	E
When an appropriate fluid challenge fails to restore adequate blood pressure and organ perfusion, vasopressor therapy should begin. Vasopressor therapy also may be required transiently to sustain life and maintain perfusion in the face of life-threatening hypotension, even when a fluid challenge is in progress and when hypovolemia has not yet been corrected.	E
Either dopamine or norepinephrine is effective for increasing arterial blood pressure, and either can be used as a first-line vasopressor agent to correct hypotension in septic shock. Dopamine raises CO more than norepinephrine, but its use may be limited by tachycardia. Norepinephrine may be the more effective vasopressor.	C
The combination of norepinephrine and dobutamine is superior to dopamine in the treatment of septic shock.	D
Phenylephrine is an alternative for increasing blood pressure, especially in the setting of tachyarrhythmias.	D
Epinephrine can be considered for refractory hypotension, but adverse effects, including decreased mesenteric perfusion, are common.	D
Low-dose dopamine should <i>not</i> be used for renal protection or to maintain renal function during sepsis.	B
Vasopressin can be considered in patients with refractory shock despite adequate fluid resuscitation and administration of high-dose catecholamine vasopressor. It should be administered as hormone replacement at doses of 0.01–0.04 units/min.	C
A strategy of increasing cardiac index to achieve supranormal DO ₂ is <i>not</i> recommended.	A
Dobutamine can be used to increase CO in the presence of low cardiac index or low SvO ₂ or ScvO ₂ despite adequate fluid administration. If used in the presence of low blood pressure, it should be combined with vasopressor therapy. Dobutamine may cause tachycardia.	C
Intravenous corticosteroid therapy at hormone replacement doses (200–300 mg/d of hydrocortisone or equivalent corticosteroid dose) for 7 days can be used in septic shock when hypotension is present despite adequate fluid resuscitation and vasopressor therapy.	C
Daily corticosteroid doses >300 mg/d of hydrocortisone (or equivalent corticosteroid dose) should <i>not</i> be used for treating septic shock.	A
ACTH–250 mcg stimulation test should be used to identify adrenal insufficiency (≤9 mcg/dL increase in cortisol concentration 30–60 minutes after ACTH). Corticosteroid therapy should be initiated before stimulation test results are known. Corticosteroid therapy should be discontinued when adrenal insufficiency is absent (>9 mcg/dL increase in cortisol concentration 30–60 minutes after ACTH).	E
Once tissue hypoperfusion has resolved and in the absence of extenuating circumstances, such as significant coronary artery disease or acute hemorrhage, red blood cell transfusions should occur when hemoglobin decreases below 7 g/dL.	B

ACTH, adrenocorticotropic hormone; CO, cardiac output; CVP, central venous pressure; DO₂, oxygen delivery; MAP, mean arterial pressure; ScvO₂, central-venous oxygen saturation; SvO₂, mixed venous oxygen saturation. Strength of recommendations: A, supported by at least two large, randomized trials with clear-cut results (low risk of false-positive error or false-negative error); B, supported by one large, randomized trial with clear-cut results (low risk of false-positive error or false-negative error); C, supported by small, randomized trials with uncertain results (moderate-to-high risk of false-positive error or false-negative error); D, supported by at least one nonrandomized investigation with contemporaneous controls; E, supported by nonrandomized investigations with historical controls, case series, or expert opinion.

hepatic parenchymal function with increased serum concentrations of transaminases and bilirubin, altered gastrointestinal perfusion manifested by ileus and diminished bowel sounds, cardiac ischemia with elevated troponin levels and electrocardiographic changes, and altered sensorium.

GLOBAL PERFUSION MONITORING

ARTERIAL BLOOD PRESSURE MEASUREMENT

Mean arterial blood pressure (MAP) is the product of cardiac output (CO) and systemic vascular resistance (SVR). Conditions that may lower blood pressure in critically ill patients include cardiac failure (etiology may be myocardial infarction, arrhythmia, acute heart failure, or valvular disease) and hypovolemia (etiology may be hemorrhage, intractable diarrhea, or heat stroke) by lowering CO and vasodilation (etiology may be sepsis, drugs, anaphylaxis, acute hepatic failure, or neurotrauma) by lowering SVR. Arterial blood pressure is the end point of therapy; however, restoration of adequate pressure is the primary criterion of effectiveness.⁴ Profound hypotension (MAP <50 mm Hg) is associated with a pressure-dependent decrease in coronary and cerebral blood flow and may rapidly produce myocardial and cerebral ischemia. Arterial blood pressure can be determined by noninvasive and invasive methods. All noninvasive blood pressure monitoring techniques depend on the use of an occluding cuff. Systolic and diastolic blood pressures are further determined by auscultation, palpation (systolic pressure only), oscillometry, or Doppler technique (systolic pressures are most reliable). Auscultation is the most commonly used method outside the intensive care unit (ICU). Its use, however, is limited in patients with hypovolemia, hypothermia, or cardiogenic shock when pulses or Korotkoff sounds may be difficult to hear. Similar constraints exist for the palpation and oscillometric methods. However, oscillometry is preferred in edematous patients. Oscillometry measures blood pressure by sensing arterial blood pressure changes, or oscillations, against an inflated cuff. Rapid changes in oscillation amplitude correspond to systolic and diastolic pressure. It is the only noninvasive method to measure MAP even in low-flow states and lends itself to automatic cycling and serial measurements (every 1–3 minutes) that do not require operator intervention, a key component in ICU monitoring. The use of narrow cuffs or cuffs applied too loosely can result in falsely high readings, whereas wide cuffs may produce falsely low readings.^{6,8} Fingertip devices offer another avenue for continuous indirect blood pressure measurement, but their accuracy in ICU patients may be significantly diminished by concurrent administration of vasoactive drugs.

1 The use of invasive arterial catheters makes possible the continuous measurement of MAP as well as procurement of blood samples for blood gas monitoring. The radial artery is the most commonly used vessel, but the dorsalis pedis, femoral, brachial, and axillary arteries and the umbilical artery in the newborn also can be accessed. This method of blood pressure monitoring is the standard technique used in the ICU against which all other methods are compared. Major complications of peripheral artery catheterization include infection and distal ischemia. Acute distal ischemia and catheter-related bacteremia occur in <1% of catheter insertions. This translates to 2.9% of bloodstream infections per 1,000 catheter-days.¹¹ Ischemia is most common in patients with multiple or prolonged arterial cannulations, hypertension, or vasopressor therapy.⁶ Invasive techniques are labor intensive, require aseptic techniques, and offer potential sources of equipment errors, such as length and quality of tubing, air bubbles, stopcocks, thrombus formation, tube kinking, and transducer placement. Hypertension, advanced age, and atherosclerosis also may affect the accuracy of invasive blood pressure readings.⁷

CENTRAL VENOUS CATHETER

1 The central venous catheter is used to measure the central venous pressure (CVP), to obtain venous blood gas samples, and to administer drugs or fluids directly to the central circulation. A triple-lumen catheter frequently is used, whereby drugs with known incompatibility can be administered. Blood volume, venous wall compliance, right-sided cardiac function, intraabdominal and intrathoracic pressures, and vasopressor therapy affect CVP. The CVP is not a reliable estimate of blood volume but can be used to qualitatively assess blood volume changes in patients during the early phases of fluid resuscitation. The goal of fluid administration is to maintain the CVP at 8 to 12 mm Hg, but values of 15 mm Hg may be targeted in mechanically ventilated patients to account for increased intrathoracic pressures.^{5,6} Sustained elevated pressures may be indicative of fluid overloading. Few data support the use of CVP monitoring in the ICU. However, initial reports in septic patients suggest that CVP monitoring of fluid therapy during shock was associated with a 50% reduction in mortality.⁸

PULMONARY ARTERY CATHETER

1 Pulmonary artery catheterization, introduced in 1970, is routinely performed in many ICUs. With this catheter, the practitioner can obtain multiple cardiovascular parameters, including CVP, pulmonary artery pressure, pulmonary artery occlusive pressures (PAOP), CO, and SVR. Mixed venous blood samples from the pulmonary artery also can be obtained. In an effort to reduce blood loss from samples, many clinicians use special pulmonary artery catheters, called *fiberoptic catheters*, which measure mixed venous oxygen saturation (SvO₂). Trends in venous oxygen saturation can be observed and necessary action taken, if needed. Most important, inflation of the balloon at the catheter tip occludes the pulmonary artery, isolates the distal catheter tip from the right side of the heart, and allows the user to measure the PAOP, an approximate measure of the left ventricular end-diastolic volume and a major determinant of left ventricular preload. Some centers use a new pulmonary artery catheter capable of continuously measuring the right ventricular end-diastolic volume index. The right ventricular end-diastolic volume index may be a better predictor of CO than PAOP, but its clinical utility during shock remains to be studied. Ideally, the pulmonary artery catheter should be positioned fluoroscopically; however, satisfactory placement also may be obtained by observing pulmonary artery pressure readings and electrocardiographic waveforms during catheter advancement. Proper positioning in the lower lung (zone 3) is essential to measure PAOP and to prevent distal pulmonary artery collapse. Poor wedging may be caused by catheter migration, patient movement, mechanical ventilation, or eccentric balloon inflation. Pulmonary artery catheters equipped with a distal thermistor also allow measurement of CO by thermodilution. Rapid injection of saline or dextrose solutions via the right atrial port allows complete mixing of blood with injectate, and the resulting change in blood temperature is measured in the pulmonary artery. From the temperature change, the patient's CO can be calculated. Newer pulmonary artery catheters contain a temperature coil that intermittently warms the blood in the right ventricle for near-continuous CO measurement. Significant tricuspid regurgitation, an intracardiac shunt, and significant positive end-expiratory pressure decrease the validity of CO measurements. The most common complications of pulmonary artery catheterization include mural thrombus formation (14%–91%), transient ventricular tachydysrhythmias (11%–63%), pulmonary infarction (1%–7%), pulmonary artery rupture (0.06%–2.0%), and sepsis (0.3%–0.5%).¹² Most pulmonary artery catheters are heparin bonded, and the relative risk (RR) of infection is 2.6 per 1,000 patient-days, similar to the risk with central venous catheters of 2.3

per 1,000 patient-days.¹¹ Despite its ubiquitous use, much controversy surrounds the utility and safety of the pulmonary artery catheter, including issues surrounding correct placement and impact of the device on patient outcome.¹³ As a result, recommendations have been made to standardize and monitor clinician education on proper use of the catheter (see www.pacep.org), to conduct clinical trials assessing the safety and efficacy of the catheter, and to evaluate new device technology on patient outcome.¹² The most recent guidelines suggest a careful evaluation of the indications and the risk of placing a pulmonary artery catheter for resuscitation of critically ill patients.¹⁴

① The optimal PAOP needs to be individualized for each patient. Administering a fluid bolus followed by simultaneous PAOP and CO measurements with the goal of increasing the PAOP until CO does not change can be accomplished and is based on Starling's law of the heart. However, clinical experience suggests that most patients have an optimal response to PAOP values in the range from 12 to 15 mm Hg.

CLINICAL CONTROVERSY: CVP VERSUS PAOP

Limited data are available comparing the use of CVP and PAOP for guiding therapy in patients in shock. The results of a study of patients with acute respiratory distress syndrome suggest CVP and PAOP are equivalent in terms of clinical outcomes, including mortality.¹⁵ Therefore, a pulmonary artery catheter should be inserted when hemodynamic data are needed that cannot be obtained from a central venous catheter or when the validity of measurements from the central venous catheter is questionable.

OXYGEN TENSION AND SATURATION MONITORING

Partial pressure of arterial oxygen (PaO_2) and arterial oxygen saturation (SaO_2) can be measured subjectively by assessing capillary refill or invasively by obtaining an arterial blood sample. Arterial blood gases measured by conventional arterial sampling are considered standard, but their accuracy and usefulness are affected by poor sampling techniques, transportation and analysis delays, analyzer accuracy, sample cellular metabolism, and inability to trend results. Indwelling fiberoptic and electrochemical systems allow continuous monitoring and trend analyses of blood pH, PaO_2 , and partial pressure of arterial carbon dioxide (PaCO_2) while decreasing patient blood loss from less frequent sampling. Unfortunately, studies evaluating the in vitro accuracy of these devices may not apply to the ICU environment. The indwelling sensors may exhibit lower PaO_2 , higher PaCO_2 , and lower pH than central arterial blood when peripheral flow is diminished. Furthermore, sensor contact with blood vessel wall and vigorous arterial line flushing diminish sensor accuracy.

① SvO_2 depends on CO, oxygen demand, hemoglobin, and SaO_2 . It can be measured in patients using a pulmonary artery catheter. Initially, critically ill septic patients may present with a low SvO_2 value (<70%) indicating high extraction of oxygen by tissues and lack of adequate oxygen delivery (DO_2 , or DO_2I , indexed to body surface area) to tissues. In patients with sepsis and other conditions who present with a low SvO_2 value, rapid intervention should be undertaken to increase DO_2 to tissues, with the goal of obtaining $\text{SvO}_2 > 70\%$.¹⁶ The length of time SvO_2 is <70% is associated with mortality.¹⁷ As sepsis worsens, however, SvO_2 often is >70%. This occurs because of a maldistribution of blood flow and a lack of extraction of oxygen in the arteriolar beds.

① Central venous oxygen saturation (ScvO_2) is a less invasive measure of venous oxygen saturation because the catheter is placed at the junction of the inferior and superior venae cavae rather than at the pulmonary artery. It is as accurate as SvO_2 but provides slightly higher

normal values.^{18,19} Although controversial, many clinicians use these measurements interchangeably. Concentrations of $\text{ScvO}_2 < 70\%$ reliably indicate inadequate oxygenation in shock states and detect subclinical ("cryptic") shock much earlier than hypotension.¹⁸ Targeting fluid and hemodynamic resuscitation to achieve $\text{ScvO}_2 > 70\%$ is a sensitive indicator and measure of the extent of global tissue hypoxia, as well as a determinant of the adequacy of hemodynamic resuscitation.¹⁸ Targeting resuscitation to achieve $\text{ScvO}_2 > 70\%$ is associated with improved survival in patients with sepsis and septic shock.¹⁹

OXYGEN DELIVERY AND CONSUMPTION

The concept of tissue oxygen debt as a determinant of organ damage in critical illness was proposed in the 1970s. In normal individuals, oxygen consumption (VO_2 or VO_2I , indexed to body surface area) depends on DO_2 (or DO_2I) up to a certain critical level (VO_2 flow dependency). At this point, tissue oxygen requirements apparently are satisfied, and further increases in DO_2 will not alter VO_2 (VO_2 flow independency). Although animal models of sepsis have substantiated this relationship, studies in critically ill humans show a continuous, pathologic dependence relationship of VO_2 with DO_2 . Furthermore, ICU survivors exhibited higher DO_2 and VO_2 values than did nonsurvivors. This finding became the basis for targeting supranormal DO_2 and VO_2 values in the treatment of ICU patients.⁸ However, a meta-analysis of randomized clinical trials involving 1,016 adult ICU patients failed to show that achievement of this goal improved patient mortality.²⁰ This may have been due in part to the heterogeneous nature of the ICU patients studied, lack of study blinding, crossover patients (control patients who achieve supranormal DO_2 and VO_2 values by themselves), or lack of adequate control of cointerventions.

The debate continues in more homogeneous patient populations. In high-risk surgical patients, supranormal DO_2 values decreased mortality.^{21,22} Two randomized studies published after the meta-analysis further evaluated the effect of increasing DO_2I values to >600 mL/m²/min in a homogeneous population of elderly surgical patients with systemic inflammatory response syndrome, sepsis, severe sepsis, or septic shock, with conflicting results. In one study, among patients between 50 and 75 years of age the intervention group had a significant increase in survival at 24 hours (21% vs 52%; $P = 0.01$) compared with the control group.²¹ This benefit was not seen in patients older than 75 years. The authors suggested that the combination of increasing DO_2 and maintaining the oxygen extraction ratio (O_2ER) at <25% without a changing VO_2 may be helpful in maintaining or improving the body's reserve in meeting the oxygen demands. This may be particularly true in older patients who have a lower baseline VO_2 . In the second study, the same intervention revealed a significant reduction in 60-day survival (15.7% vs 50%; $P < 0.05$) in high-risk elderly surgical patients randomized to supranormal DO_2 goals.²² Thus, whether supranormal DO_2 is beneficial and whether the mechanism of benefit of supranormal DO_2 in these patients is prevention and reversal of tissue hypoxia remain unclear. A review of alternative potential mechanisms of beneficial effect of supranormal DO_2 suggests that catecholamines exert antiinflammatory actions by modulating cytokine response.²³ In general, catecholamines inhibit the production of inflammatory cytokines (e.g., interleukin [IL]-6, tumor necrosis factor [TNF]- α) and may enhance synthesis of antiinflammatory cytokine (e.g., IL-4 and IL-10).²³ The actions of epinephrine on these cytokines are blocked by propranolol and thus are mediated by adrenergic β -receptors. These data must be interpreted with caution because most studies used animal or cell models of sepsis, pretreated patients with vasopressors prior to endotoxin infusion, and used doses that may not always be clinically relevant. Another problem with therapy directed to achieve supranormal oxygen transport values is that the apparent linear relationship between DO_2 and VO_2 has been questioned because both share variables, and this *mathematical cou-*

pling can produce artifactual relationships between variables. The DO_2 and VO_2 indexed parameters are calculated as follows:

$$\text{DO}_2 = \text{CI} \times \text{CaO}_2$$

$$\text{VO}_2 = \text{CI} \times (\text{CaO}_2 - \text{CvO}_2),$$

where CI = cardiac index, CaO_2 = arterial oxygen content determined by hemoglobin concentration and SaO_2 , and CvO_2 = mixed venous oxygen content determined by hemoglobin concentration and SvO_2 .

However, variable relationships between DO_2 and VO_2 have been observed when VO_2 was measured independently by indirect calorimetry. Therefore, a linear relationship between DO_2 and VO_2 may be the result of mathematical coupling or flow-dependent VO_2 . Currently available data do not support the concept that patient outcome or survival is altered by treatment measures directed toward achieving supranormal DO_2 and VO_2 values.²⁰ In fact, a consensus conference concluded that although pulmonary artery catheterization is useful for guiding therapy, routinely increasing cardiac index to predetermined supranormal values does not improve outcome.⁴ Furthermore, achievement of a supranormal DO_2 does not ensure parallel improvements in regional organ blood flow and oxygenation.¹⁹ The VO_2/DO_2 ratio, or O_2ER , can be used to assess adequacy of perfusion and metabolic response. Patients who are able to increase VO_2 when DO_2 is increased show improved survival. However, low VO_2 and O_2ER values are indicative of poor oxygen utilization and lead to greater mortality.²⁰ Another approach that may decrease the effect of mathematical coupling and provide individualized therapy may lie in titrated therapy, with sequential measurements of DO_2 and VO_2 to achieve VO_2 flow independency along with normalization of blood lactate and hemodynamic parameters.

② The most recent data regarding goal-directed therapy in the hemodynamic support of sepsis relates to the importance of achieving predetermined parameters early in the management of sepsis. In a meta-analysis of early (defined as 8–12 hours postoperatively or before the development of organ failure) versus late (defined as after onset of organ failure) resuscitative efforts in patients stratified according to severity of illness (determined by control group mortality >20% [12 studies] or <15% [9 studies]) and targeting supranormal oxygen-transport variables, the data suggest that timing of resuscitation matters.²⁴ Early goal-directed therapy reduced mortality and the development of organ failure in patients who were more severely ill and when therapeutic interventions produced differences in DO_2 . Moreover, outcome was not improved significantly in less severely ill patients (control group mortality <15% and normal DO_2 values as goals) or when therapy did not improve DO_2 .²³

② In a prospective, randomized controlled trial of sepsis, Rivers et al.¹⁹ demonstrated a significant reduction in mortality (30.5% versus 46.5%; $P < 0.001$) in patients with severe sepsis and septic shock randomized to receive therapy based on goal-directed hemodynamic end points that were achieved within 6 hours of hospital presentation. They used a strategy of serial administering (1) fluids rapidly to achieve CVP 8–12 mm Hg, (2) vasopressor agents to achieve MAP at least 65 mm Hg, (3) red blood cell transfusion to maintain hematocrit >30%, and (4) dobutamine to achieve $\text{ScvO}_2 > 70\%$. This approach demonstrates the benefits of initiating therapy early in the course of sepsis and directs therapy toward clearly defined goals in a consistent manner. The results of this study cannot delineate which end point or combination of end points was most beneficial, so until proven otherwise, clinicians should direct therapy to achieve all the hemodynamic goals of this study. In addition, whether these goals must be maintained after resuscitation is unknown. Therefore, after resuscitation and assuming patients do not have coronary artery disease, red blood cell transfusions should be administered in patients with hemoglobin <7 g/dL to maintain a hemoglobin concentration 7–9 g/dL (or

hematocrit approximately 21%–27%).^{4,5} Several observational studies have shown that improvement of organ function within the first 24 hours of therapy with maintenance of hemodynamic variables for at least 48 hours with goals similar to those in the study by Rivers et al. is associated with improved survival.^{17,25} The results of several before and after evaluations of protocols or order sets designed to achieve the hemodynamic end points of early goal-directed therapy show that implementation is easily accomplished, and patient outcomes, including survival, are improved.^{26–28} Therefore, healthcare facilities should implement strategies to achieve early goal-directed therapy using the predefined hemodynamic variables of the study by Rivers et al. Directing therapy to increase the goal MAP from 65 to 85 mm Hg with higher doses of vasopressor agents does not confer additional improvement in organ function.²⁹

BLOOD LACTATE

Lactate is a metabolic product of pyruvate. Its production is increased under anaerobic conditions, such as may occur during shock. Blood lactate concentrations are used as a diagnostic and prognostic tool in sepsis; they also are used to measure the repayment of oxygen debt to tissues.¹⁶ It is a useful tool in combination with DO_2 and VO_2 because these measures change independently of one another. Serial lactate concentrations may show better correlation with outcome than oxygen transport parameters and may be superior to hemodynamic markers in determining adequacy of restoration of systemic oxygenation.¹⁶ However, several caveats guide the use of lactate concentrations in septic patients.⁶ First, lactate may accumulate in patients with other conditions, such as significant hepatic dysfunction or acute respiratory distress syndrome, who are not in shock. Second, both well-perfused and poorly perfused tissues contribute to arterial and mixed venous lactate concentrations and therefore are not reflective of regional perfusion. Third, although increased lactate concentrations have been correlated with increased mortality, the utility of blood lactate measurements in guiding therapy has not been clearly demonstrated. Fourth, elevated lactate concentrations may result from cellular metabolic failure rather than global hypoperfusion in shock. Serial blood lactate measurements are more useful than single isolated measurements.

REGIONAL PERFUSION MONITORING

GASTROINTESTINAL TONOMETRY

Blood pressures, CO, blood lactate, and global oxygen homeostasis parameters do not offer information about the function of individual organs. Organ-specific hypoxia may be evident by coagulopathy as indicated by thrombocytopenia (platelet count <100,000/L and/or prolonged clotting times [international normalized ratio >1.5 or activated partial thromboplastin time at least 1.5-fold the upper limit of normal]), impaired renal function with urine production <0.5 mL/kg/h and/or increased serum concentrations of blood urea nitrogen and creatinine, altered hepatic function with substantially increased serum concentrations of transaminases and bilirubin, altered gastrointestinal perfusion manifested by ileus and diminished bowel sounds, cardiac ischemia with elevated troponin levels and electrocardiogram changes, and altered sensorium.^{4–10} Objective measurement of regional perfusion to detect inadequate tissue oxygenation has focused on the splanchnic circulation, which is sensitive to changes in blood flow and oxygenation for several reasons. First, the normally large majority of blood flow to the gut mucosa is redistributed toward the serosa and muscularis. Second, the gut may have a higher critical DO_2 threshold than other organs. Third, the tip of the villus has a countercurrent oxygen-exchange mechanism, rendering it highly sensitive to alterations in regional blood flow and oxygenation.¹⁶

Gastric tonometry measures gut luminal partial pressure of carbon dioxide (PCO_2) at equilibrium by placing a saline- or air-filled gas-permeable balloon in the gastric lumen. Assuming that CO_2 permeates freely among tissues and that the arterial bicarbonate (HCO_3^-) concentration is equal to that of the gut mucosa, the intramucosal pH (pHi) may be calculated using the Henderson-Hasselbalch equation:

$$\text{pHi} = 6.1 \log (\text{HCO}_3^-) / 0.03 \times \text{PCO}_2$$

Increases in mucosal PCO_2 and calculated decreases in pHi are associated with mucosal hypoperfusion and perhaps increased mortality.³⁰ Calculation of pHi can be confounded by increases in luminal PCO_2 , such as may occur when buffering antacids are used. Histamine₂-receptor antagonists or proton pump inhibitors can be used instead. The presence of respiratory acid-base disorders; systemic bicarbonate administration; arterial blood gas measurement errors; or enteral feeding products, blood, or stool in the gut may confound pHi determinations.⁶ As a result, many clinicians believe that the change in gastric mucosal PCO_2 may be more accurate than pHi.⁶ Furthermore, because mucosal PCO_2 is influenced by arterial PCO_2 , the consensus is that the mucosal-arterial PCO_2 difference (PCO_2 gap) likely is the optimal measurement.³⁰ Gastric tonometry can be performed using either a saline- or air-filled balloon. The time delay (30 minutes) associated with equilibration of saline inside the balloon makes this method inconvenient for routine bedside monitoring. An air-filled balloon requires a shorter equilibrium time, is simpler to use, and is equally accurate.³¹ However, the clinical utility of gastric tonometry remains uncertain. Clinical trials of pHi-directed therapy have not shown consistently that gastric tonometry reduces mortality in critically ill patients.³⁰ In a study of 28 patients with septic shock, gastric tonometry measurements were not beneficial during initial resuscitation; however, after stabilization, pHi, mucosal PCO_2 , and PCO_2 gap were independent predictors of hospital mortality.³²

Evidence suggests that the most proximal part of the gastrointestinal tract, the sublingual mucosa, may be an acceptable location for monitoring regional perfusion and PCO_2 . Sublingual capnometry is noninvasive, is not technically complex, and provides results within minutes.³³ The device consists of a disposable sublingual carbon dioxide pressure (PslCO_2) sensor, a fiberoptic cable that connects the disposable sensor to a blood gas analyzer, and a blood gas monitoring instrument. A small study of 22 critically ill patients with and without sepsis and septic shock attempted to validate the usefulness of sublingual capnography.³⁴ The study measured simultaneous gastric and sublingual PCO_2 along with traditional hemodynamic parameters. PslCO_2 correlated well with mucosal PCO_2 ; however, the initial sublingual-to-arterial PCO_2 gap was a better predictor of mortality than the mucosal-to-arterial PCO_2 gap. Another small study of 18 patients with septic shock also found significant correlation between gastric and sublingual PCO_2 , but enhancement of DO_2 with dobutamine better correlated with the decrease in PslCO_2 gap than gastric PCO_2 gap.³⁵ These pilot studies must be expanded before this technology becomes part of routine practice, but it offers the possibility of noninvasively measurement of regional perfusion.

MYOCARDIAL DYSFUNCTION

Although loss of vascular tone is the hallmark of septic shock, myocardial dysfunction characterized by transient impairment of contractility is a recognized complication. The range of left ventricular ejection fraction (LVEF) upon presentation is wide, but approximately 35% of patients with septic shock have left ventricular hypokineses (mean ejection fraction $38\% \pm 17\%$) and low CO .³⁶ Because LVEF also is affected by preload and afterload, the low SVR of septic shock may mask depressed myocardial contractility that may be revealed upon restoration of MAP by administration of fluid and vasopressors. Cardiac troponin release in septic patients occurs in the

absence of flow-limiting disease, likely due to a loss in membrane integrity with subsequent leakage or microvascular thrombosis. Elevation of cardiac troponin concentrations in patients with sepsis indicates left ventricular dysfunction and portends a poor prognosis.³⁷ Early recognition of myocardial dysfunction is crucial for administration of appropriate therapy. In the absence of other mechanisms for assessing cardiac function, echocardiographic findings and troponin concentrations may help guide and monitor therapy. Whereas cardiac troponins may be integrated into the monitoring of myocardial dysfunction to identify patients requiring aggressive therapy, natriuretic peptides have not been shown to correlate with LVEF and should not be routinely monitored.³⁷

VASOPRESSORS AND INOTROPES

5 Vasopressors and inotropes in patients with septic shock are required when volume resuscitation fails to maintain adequate blood pressure (MAP 65 mm Hg) and organs and tissues remain hypoperfused despite optimizing CVP to 8 to 12 mm Hg or PAOP to 12 to 15 mm Hg. However, vasopressors may be needed temporarily to treat life-threatening hypotension when filling pressures are inadequate despite aggressive fluid resuscitation.⁴ Inotropes are frequently used to optimize cardiac function in cases of cardiogenic shock.³ The clinician must decide on the choice of agent, therapeutic end points, and safe and effective doses of vasopressors and inotropes to be used. This section reviews adrenergic receptor pharmacology, exogenous catecholamine use, and alterations in receptor function in critically ill patients. It also provides guidelines for the clinical use of adrenergic agents, optimization of pharmacotherapeutic outcomes, and minimization of adverse effects in critically ill patients with septic shock. Therapies of hypovolemic shock and cardiogenic shock are discussed in other chapters.

Of note, agents other than catecholamines have been used as inotropes and vasopressors in shock states. They include phosphodiesterase III inhibitors, naloxone, nitric oxide synthase (NOS) inhibitors, and calcium sensitizers. This chapter focuses on catecholamines. Vasopressin and corticosteroids, as they relate to septic shock, also are emphasized because they have pharmacologic interactions with catecholamines, possess hemodynamic effects, and are frequently used.

CATECHOLAMINE RECEPTOR PHARMACOLOGY

4 Comparative receptor activity of endogenous and exogenously administered catecholamines is summarized in Table 25-3.³⁻¹⁰ Endogenous catecholamines are responsible for regulation of vascular and bronchiolar smooth muscle tone and myocardial contractility. These effects are mediated by sympathetic adrenergic receptors of the autonomic nervous system located in the vasculature, myocardium, and bronchioles. Postsynaptic adrenoceptors are located at or near the synaptic junction. These receptors can be activated by naturally circulating or exogenous catecholamines (e.g., norepinephrine, epinephrine, and phenylephrine), whereas presynaptic adrenoceptors are stimulated by locally released neurotransmitters (e.g., norepinephrine) and are controlled by a negative feedback mechanism.

The signal transduction pathways associated with catecholamine- and vasopressin-induced effects in the heart and blood vessels are illustrated in Fig. 25-1. Agonists of β -adrenoceptors and dopamine (D_1) receptors stimulate adenylate cyclase by a G-protein (G_s)-dependent mechanism (Fig. 25-1, top). Adenylate cyclase generates cyclic adenosine monophosphate (cAMP) from adenosine triphosphate (ATP). cAMP-Dependent protein kinase A, which is activated by elevations in intracellular cAMP, phosphorylates target proteins to modify cellular function. Through these mechanisms, β_1 -adrenocep-

TABLE 25-3 Adrenergic, Dopaminergic, and Vasopressin Receptor Pharmacology and Organ Distribution

Effector Organ	Receptor Subtype	Physiologic Response
Heart		
Sinoatrial node	β_1, β_2	Increased heart rate
Atria	β_1, β_2	Increased contractility

tor activation exerts positive inotropic and chronotropic effects in the heart, and β_2 -adrenoceptor and D_1 -receptor activation induces vascular smooth muscle relaxation. Agonists of α_1 -adrenoceptors or vasopressin (V_1) receptors stimulate phospholipase C- β (PLC- β) through a G-protein (G_q)-dependent process (Fig. 25–1, bottom). PLC- β produces inositol trisphosphate and diacylglycerol from cell membrane phosphatidylinositol biphosphate. Diacylglycerol activates protein kinase C, an enzyme that phosphorylates several key proteins (e.g., extracellular signal-regulated kinases, c-Jun NH2-terminal kinases, and mitogen-activated protein kinases) that modify cellular function (e.g., hypertrophy). Inositol trisphosphate elicits the release of calcium from intracellular stores, such as the sarcoplasmic reticulum. Calcium forms a complex with calmodulin, which then activates calcium-calmodulin-dependent protein kinases (CaMK). CaMKs phosphorylate target proteins to alter cellular function. Myosin light-

chain kinase is an example of a CaMK. Its action of phosphorylating myosin light chain leads to vascular smooth muscle contraction.

The normal heart contains primarily postsynaptic β_1 -receptors, which when stimulated cause increased rate and force of contraction. This effect is mediated by activation of adenylate cyclase and subsequent generation and accumulation of cAMP. Stimulation of postsynaptic cardiac α_1 -receptors causes a significant increase in contractility without an increase in rate, an effect mediated by PLC rather than adenylate cyclase. The increased contractility is more pronounced at lower heart rates and has a slower onset and longer duration in comparison with β_1 -mediated inotropic response. Presynaptic α_2 -adrenoceptors also are found in the heart and appear to be activated by norepinephrine released by the sympathetic nerve itself. Their activation inhibits further norepinephrine release from the nerve terminal.

Both presynaptic and postsynaptic adrenoceptors are present in the vasculature. Postsynaptic α_1 - and α_2 -receptors mediate vasoconstriction, whereas postsynaptic β_2 -receptors induce vasodilation. Presynaptic α_2 -receptors inhibit norepinephrine release in the vasculature, also promoting vasodilation. Presynaptic β_1 -adrenoceptors promote neurotransmitter release. Stimulation of peripheral D_1 -receptors produces renal, coronary, and mesenteric vasodilation and a natriuretic response. Stimulation of D_2 -receptors inhibits norepinephrine release from sympathetic nerve endings, sequesters prolactin and aldosterone, and may induce nausea and vomiting. D_1 - and D_2 -receptor stimulation also suppresses peristalsis and may precipitate ileus.^{3–9}

ALTERED ADRENOCEPTOR FUNCTION: IMPLICATIONS FOR CRITICALLY ILL PATIENTS

3 Most of the work describing receptor function and associated clinical pharmacology has been performed in either animal models or human volunteers. In critically ill septic patients, derangements in adrenergic receptor activity may result in resistance to exogenously administered catecholamine.^{38–43} This “desensitization” frequently is characterized by myocardial and vascular hyporesponsiveness to high dosages of inotropes and vasopressor agents. Prolonged exposure of vascular endothelial tissue to vasopressor drugs (α -adrenergic agonists) or endogenous catecholamines may promote additional receptor downregulation. Increased endogenous catecholamine concentrations have been reported in endotoxemic and other critically ill patients, suggesting an acquired adrenergic receptor defect and desensitization of adrenergic receptors and alteration in voltage-sensitive calcium channels.^{38–42} The problem in critically ill patients may be related to decreased receptor activity or density. However, in patients with septic shock, catecholamine concentrations are even higher, so abnormalities in adrenergic receptor function are greater, with associated reductions in the concentrations of intracellular signal transduction mediators. The worsened receptor abnormality may be explained by defects distal to the receptor site, such as uncoupling of adrenergic receptors from adenylate cyclase or PLC, or dysfunction in the regulatory G-protein unit of signal transduction pathways.^{38–42}

In addition to catecholamines, circulating inflammatory cytokines may be partly responsible for distal alterations. Macrophage-derived IL-1 and TNF- α produce impaired coupling of β -adrenoceptors to adenylate cyclase.^{38,39} Patients with septic shock have exhibited impaired β -adrenergic receptor stimulation of cAMP associated with myocardial hyporesponsiveness to various vasopressors and inotropes.^{38,39} However, increased chronotropic sensitivity to β -adrenergic stimulation with hypersensitivity of the adenylate cyclase system to isoproterenol stimulation also has been reported in animal models of bacteremia and endotoxemia. In the presence of intrinsic myocardial dysfunction and increased metabolic demands, this dysfunctional adrenergic system is incapable of mobilizing functional cardiac reserve to maintain adequate myocardial performance.^{38–40}

FIGURE 25-1. Signal transduction pathways in heart and blood vessels. *Top.* Catecholamine (CCA)-induced effects mediated in heart (β_1) or vascular smooth muscle (β_2 , D_1). (AC, adenylate cyclase; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; PKA, cAMP-dependent protein kinase; +, stimulation.) *Bottom.* CCA (α_1) and vasopressin (VP)-induced actions in vascular smooth muscle. (Ca^{++} , calcium ion; CaMK, calcium/calmodulin-dependent protein kinase; DAG, diacylglycerol; IP_3 , inositol trisphosphate; PIP_2 , phosphatidylinositol bisphosphate; PKC, protein kinase C; PLC- β , phospholipase C- β ; SR, sarcoplasmic reticulum.) These pathways have been extensively simplified, and denoted cellular effects represent one of many produced. (Figure based on data from references 4–6, 10, 42, 44, 45, and 89.)

IL-1 and TNF- α have been shown to suppress gene expression of α_1 -adrenoceptors, resulting in fewer receptor proteins.⁴⁰ Overproduction of nitric oxide (NO) by inducible nitric oxide synthase (iNOS) directly contributes to vasodilation by cyclic guanosine monophosphate-mediated smooth muscle relaxation. NO indirectly produces vasodilation by combining with superoxide to form peroxynitrite, a highly toxic reactive species that causes endothelial dysfunction, uncoupling of α_1 -adrenoceptors to PLC, and deactivation of catecholamines.^{41,42} The result of sepsis-induced inflammation is a system that promotes adrenergic receptor dysfunction to accentuate vasodilation and shock.

4 Functional α_1 -adrenergic receptor changes occur at various stages of sepsis; thus, adrenoceptor sensitivity may be time dependent during progression of sepsis to septic shock. The findings are not always consistent in various animal models of sepsis and in critically ill septic patients. Time-dependent alterations in the production of NO, a potent vasodilator, may explain the apparent differences in vascular reactivity to phenylephrine during the phases of endotoxemia.⁴³ This finding suggests that the clinical response to vasopressor and possibly inotropic agents is variable during the stages of hemodynamic, myocardial, and peripheral vascular derangements of septic shock. In contrast, in critically ill septic patients in the ICU (24–48 hours from hospital admission), β -adrenergic receptor changes already were present, although the progression of desensitization of receptors earlier in sepsis was not quantified.³⁹ In summary, α - and β -adrenergic receptor derangements may vary among patients and during each bacteremic insult; therefore, doses of catecholamines

vary among patients and during the insult. For these reasons, these drugs should be dosed to clinical end points and not to arbitrary maximal doses.

VASOPRESSIN AND CORTISOL: IMPLICATIONS ON CATECHOLAMINES

12 Endogenous arginine vasopressin, a peptide hormone also known as antidiuretic hormone, is important for osmoregulation under normal physiologic conditions. Vasopressin is produced in the hypothalamus, stored in the posterior pituitary, and released from magnocellular neurons of the hypothalamus.^{44,45} Increased serum osmolality and hypovolemia are the major stimuli for vasopressin release.^{44,45} Other stimuli commonly associated with shock are dopamine, histamine, angiotensin II, prostaglandins, pain, hypoxia, acidosis, hypotension, hypercarbia, and α_1 -adrenergic receptor stimulation. Vasopressin release is inhibited by NO, natriuretic peptides, γ -aminobutyric acid, β -adrenergic receptor stimulation, and α_2 -adrenergic receptor stimulation.^{44,45}

Vasopressin has minimal to no inotropic or chronotropic effects. Vasopressin-induced vasoconstriction occurs through a variety of direct and indirect mechanisms.^{44,45} Stimulation of vascular V_1 receptors causes vasoconstriction by receptor-coupled activation of PLC and calcium release from intracellular stores via secondary messengers similar to α_1 -adrenergic stimulation. Vasopressin also directly inhibits vascular potassium-sensitive ATP channels to activate vascular calcium channels independent of V_1 receptors (Fig. 25–1). V_1 -

receptor stimulation inhibits the actions of IL-1 β and thereby facilitates vasoconstriction. Vasopressin also increases the activity of adrenergic receptors. The greatest vasoconstriction occurs in the skin and soft tissue, skeletal muscle, fat tissue, pancreas, and thyroid gland.

V₂ receptors located in the kidneys are responsible for the antidiuretic properties of vasopressin.^{44,45} Stimulation of V₂ receptors facilitates integration of aquaporins into the luminal cell membrane of distal tubules and collecting duct capillaries to increase permeability and thus retain intravascular volume. However, vasopressin stimulation of V₁ receptors causes vasoconstriction of efferent arterioles and relative vasodilation of afferent arterioles to increase glomerular perfusion pressure and filtration rate to enhance urine production.

Vasopressin rapidly increases serum cortisol concentration by stimulating V₃ receptors in the pituitary gland to enhance the release of adrenocorticotrophic hormone (ACTH).^{44,45} Cortisol helps regulate the proinflammatory state associated with sepsis and increases blood pressure through several mechanisms, including inhibition of iNOS to reduce NO production, reversal of adrenergic receptor desensitization, and increased intravascular volume through retention of sodium and water.

Normal serum vasopressin concentrations are <4 pg/mL.^{44,45} Serum vasopressin concentrations are elevated with hypotension. Vasopressin response in septic shock is biphasic. During the first 8 hours of septic shock requiring catecholamine adrenergic therapy, serum concentrations of vasopressin are appropriately high to help maintain blood pressure and organ perfusion. Thereafter, serum vasopressin concentrations decline dramatically over the next 96 hours to physiologically normal but inappropriately low values, resulting in a state of “relative deficiency.” In contrast, serum vasopressin concentrations remain elevated in patients with cardiogenic shock, requiring at least 1 day of hemodynamic support with catecholamine agents. Administration of vasopressin at 0.01 to 0.06 units/min produces concentrations similar to those observed in early septic shock and other hypotensive states; however, vasopressin concentrations do not correlate with blood pressure.

The mechanism of vasopressin insufficiency in septic shock is not well understood. Neurohypophyseal stores in the posterior lobe of the pituitary gland are depleted during septic shock, likely as a result of excessive and continuous baroreceptor stimulation that eventually exhausts the limited vasopressin secretory stores. In addition, secretion of vasopressin is inhibited by enhanced endothelial production of NO, high circulating concentrations of adrenergic agonists (both endogenous and exogenous), and tonic inhibition by stretch receptors in response to volume replacement and mechanical ventilation.

As with vasopressin, during sepsis a state of “relative adrenal insufficiency” is produced by continuous activation of the hypothalamic–pituitary–adrenal axis by IL-1, IL-6, and TNF- α that causes depletion of cortisol in the adrenal glands.⁴⁶ Administration of corticosteroids has been shown to improve arterial pressure while minimizing the dose of catecholamine vasopressors.^{47,48} Current proposed mechanisms of the vasoconstrictor effect of corticosteroids include increasing the number and stimulating the function of α_1 - and β -adrenergic receptors and attenuating the production of inflammatory mediators responsible for vasodilation.

12 The use of corticosteroids for treatment of septic shock has been a topic of controversy for many years. Meta-analyses of early studies of steroids in patients with sepsis demonstrated a lack of benefit and potential harm in sepsis and septic shock.^{49,50} Interest in corticosteroid use is renewed because of the increased awareness of adrenocortical insufficiency in critically ill patients with septic shock.⁴⁶ Relative adrenal insufficiency has been defined as a poor adrenal response (<9 mcg/dL [250 nmol/L] irrespective of the initial serum cortisol level) to a dose of synthetic ACTH, indicating a low functional reserve of the adrenal cortex.⁵¹ Although absolute insufficiency is rare, relative adrenocortical insufficiency in the presence of normal or high cortisol

concentrations at baseline is present in 30% to 50% of patients with septic shock and is associated with a poor outcome.^{46,51}

CLINICAL CONTROVERSY: DIAGNOSING RELATIVE ADRENAL INSUFFICIENCY

The diagnosis of relative adrenal insufficiency in septic shock is based on serum cortisol concentration(s) rather than clinical parameters. Some leading experts suggest defining adrenal insufficiency as a random cortisol concentration <15 to 25 mcg/dL, irrespective of ACTH testing results because the test dose of ACTH may cause sufficient cortisol production in patients with mild-to-moderate adrenal insufficiency. In the only study to correlate mortality with adrenal response, an elevated random cortisol concentration (>34 mcg/dL) was an independent predictor of mortality.⁵¹ The predictive value of mortality further increased if ACTH response was <9 mcg/dL, suggesting that the risk of mortality is greatest in situations of adrenal gland “fatigue” (i.e., degree of stress is not matched by sufficient cortisol production by the adrenal glands despite operating at maximal functional capacity).

CLINICAL PHARMACOLOGY OF VASOPRESSORS AND INOTROPES

4 12 The receptor selectivity of clinically used, catecholamine-based vasopressors and inotropes and hemodynamic effects are listed in Table 25–4. In general, these drugs are rapid acting, with short durations of action. As such, these drugs are given as continuous infusions and titrated rapidly to predetermined effects. Vasopressin is administered as a replacement dose of 0.01 to 0.04 units/min and should not be titrated. Careful monitoring and calculation of infusion rates are advised for all vasopressors because dosing adjustments are made frequently, and varying admixtures and concentrations are used in volume-restricted patients.

8 Dopamine is often considered a first-line initial therapy in patients with septic shock because it increases blood pressure by increasing myocardial contractility and vasoconstriction.^{4–10} Dopamine has been described as having dose-related receptor activity at D₁-, D₂-, β_1 -, and α_1 -receptors (Table 25–4). Unfortunately, this dose-response relationship has not been confirmed in critically ill patients. In patients with septic shock, great overlap of hemodynamic effects occurs, even at doses as low as 3 mcg/kg/min.⁵² Tachydysrhythmias are common due to the release of endogenous norepinephrine by dopamine entering the sympathetic nerve terminal. Dopamine may increase PAOP through pulmonary vasoconstriction.^{6,7} This drug also may depress ventilation and worsen hypoxemia in patients dependent on the hypoxic ventilatory drive.

Dobutamine, a synthetic catecholamine, is primarily a selective β_1 -agonist with mild β_2 - and vascular α_1 -activity, resulting in strong positive inotropic activity without concomitant vasoconstriction. In comparison with dopamine, dobutamine produces a larger increase in CO and is less arrhythmogenic.^{7,40} α_1 -Adrenoceptors in the heart are directly stimulated by the (–) isomer of dobutamine, but β_1 - and β_2 -activity resides in the (+) isomer.^{7,40} This finding suggests that the strong inotropic action of dobutamine is a function of its structure, the additive effect of cardiac α_1 - and β_1 -agonist activity, and a relatively weak chronotropic effect limited to the (+) isomer action on the β -receptors. Clinically, β_2 -induced vasodilation and the increased myocardial contractility with subsequent reflex reduction in sympathetic tone lead to a decrease in SVR. Dobutamine is used optimally for patients in low CO states with high filling pressures or in those in cardiogenic shock; however, vasopressors may be needed to counteract arterial vasodilation.

TABLE 25-4 Receptor Pharmacology of Selected Inotropic and Vasopressor Agents Used in Septic Shock^a

Agent	α_1	α_2	β_1	β_2	D	V ₁	V ₂
Dobutamine (0.5–4 mg/mL D ₅ W or NS)							
2–10 mcg/kg/min	+	0	++++	++	0	0	0
>10–20 mcg/kg/min	++	0	++++	+++	0	0	0
Dopamine (0.8–3.2 mg/mL D ₅ W or NS)							
1–3 mcg/kg/min	0	0	+	0	++++	0	0
3–10 mcg/kg/min	0/+	0	++++	+	++++	0	0
>10–20 mcg/kg/min	+++	0	++++	+	0	0	0
Epinephrine (0.008–0.016 mg/mL D ₅ W or NS)							
0.01–0.05 mcg/kg/min	++	++	++++	+++	0	0	0
0.05–3 mcg/kg/min	++++	++++	+++	+	0	0	0
Norepinephrine (0.016–0.064 mg/mL D ₅ W)							
0.02–3 mcg/kg/min	+++	+++	+++	+ / ++	0	0	0
Phenylephrine (0.1–0.4 mg/mL D ₅ W or NS)							
0.5–9 mcg/kg/min	+++	+	+	0	0	0	0
Vasopressin (0.8 units/mL D ₅ W or NS)							
0.01–0.04 units/min	0	0	0	0	0	+++	+++

^aActivity ranges from no activity (0) to maximal (++++ activity).

D, dopamine; D₅W, dextrose 5% in water; NS, normal saline; V, vasopressin.

Based on data from references 4–7, 42, 45, and 46.

8 Norepinephrine is a combined α - and β -agonist that produces vasoconstriction primarily via its more prominent α -effects on all vascular beds, thus increasing SVR. Norepinephrine administration generally produces either no change or some increase in CO.^{53,54} In addition to dopamine, norepinephrine is considered an option for initial vasopressor therapy for septic shock.

9 Phenylephrine is a pure α_1 -agonist and is believed to increase blood pressure through vasoconstriction. Given the presence of cardiac α_1 -receptors, phenylephrine also may increase contractility and CO.⁵⁵ It is a therapeutic option in hypotensive patients experiencing a tachyarrhythmia when a vasopressor with minimal to no β_1 -agonist activity is indicated.

10 Epinephrine exerts combined α - and β -agonist effects. At the high epinephrine infusion rates used for patients with septic shock, predominantly α -adrenergic effects are seen, and SVR and MAP are increased. Epinephrine traditionally has been reserved as the vasopressor of last resort due to peripheral vasoconstriction, particularly in the splanchnic and renal beds.^{42,56,57}

12 Unlike adrenergic receptor agonists, the vasoconstrictive effects of vasopressin are preserved during hypoxia and severe acidosis. Several small studies have evaluated short-term infusions of vasopressin at doses <0.08 units/min as add-on therapy to patients requiring catecholamine adrenergic agents.^{44,45} The results show that initiating vasopressin in patients with septic shock increases SVR and arterial blood pressure to reduce the dose requirements of catecholamine adrenergic agents. These effects are rapid and sustained. Vasopressin causes vasodilation in the cerebral, pulmonary, coronary, and selected renal vascular beds by enhancing endothelial NO release through V₁-receptor stimulation in these tissues.⁴⁴ Organ-specific vasodilation reduces pulmonary artery pressure and may preserve cardiac and renal function. Several studies have shown substantial enhancement of urine production, likely due to increased glomerular filtration rate. At doses exceeding 0.04 units/min, vasopressin was associated with ischemia of the mesenteric mucosa, skin, and myocardium; elevated hepatic transaminases and bilirubin concentrations; hyponatremia; and thrombocytopenia. Limiting the dose to a maximum of 0.04 units/min may minimize the development of adverse effects.

CLINICAL APPLICATION

Vasopressors and Inotropes

5 8 Initial hemodynamic therapy for septic shock is administration of intravenous fluid (20–40 mL/kg), with the goal of attaining

CVP of 8 to 12 mm Hg.^{4–10} Crystalloid fluids (e.g., normal saline, Ringer lactate solution) and colloid fluids (e.g., albumin, hetastarch, dextrans, blood products) are considered equivalent for shock resuscitation. Crystalloid fluids are generally preferred unless patients are at risk for adverse events from redistribution of intravenous fluids to extravascular tissues and/or are fluid restricted (e.g., patients with renal dysfunction, decompensated heart failure, ascites compromising diaphragmatic function).

Traditional vasopressors and inotropes used for hemodynamic support of patients with hypotension refractory to fluid administration include dopamine, dobutamine, epinephrine, norepinephrine, and phenylephrine. Optimizing MAP to 65 mm Hg as the goal of vasopressor therapy does not uniformly correlate with decreased mortality in patients with septic shock.^{19,20} Historically, significant concerns about the adverse effects of vasopressors limited their use. The past focus of achieving supranormal oxygen-transport variables also has yielded poor results in patients with septic shock.²⁰ In fact, normalization of systemic DO₂ and VO₂, whether spontaneously or with intervention, is associated with improved outcome and is not dependent on administration of vasopressor agents. Part of the inability to detect an improvement with vasopressor or inotropic therapies may result from the limited ability to quantify regional tissue perfusion. However, use of early goal-directed therapy to ScvO₂ >70% has been shown to reduce mortality in patients with sepsis and septic shock.¹⁹

6 7 Dosage titration and monitoring of vasopressor and inotropic therapy should be guided by the “best clinical response” and the goals of early goal-directed therapy.^{4–10,19} Dopamine or norepinephrine is considered the agent of choice as initial vasopressor therapy. Norepinephrine may be added in cases where suboptimal response is obtained from dopamine but adding dopamine to norepinephrine does not provide a hemodynamic benefit. Phenylephrine may be tried as the initial vasopressor in cases of severe tachydysrhythmias. Regardless of which vasopressor is chosen, low doses are initiated and titrated rapidly (usually every 5–15 minutes) to clinical response. Clinically effective dosing of vasopressors and inotropes in septic shock often requires doses much larger than recommended by most references. These large infusion rates must be tempered with the development of adverse effects. The goal is to use the minimally effective infusion rate while minimizing evidence of myocardial ischemia (e.g., tachydysrhythmias, electrocardiographic changes), renal (decreased glomerular filtration rate and/or urine output), splanchnic/gastric (low pH_i, bowel ischemia), or peripheral (cold extremities) hypoperfusion, and worsening PaO₂, PAOP, and other hemodynamic variables.

11 Therapy with catecholamine vasopressors and inotropes is continued until the myocardial depression and vascular hyporesponsiveness (i.e., blood pressure) of septic shock improve, usually measured in hours to days. Discontinuation of vasopressor or inotropic therapy should be executed slowly; therapy should be “weaned” to avoid a precipitous worsening in regional and systemic hemodynamics. Careful monitoring of global and regional end points also should be geared toward discontinuation of vasopressors and inotropes as soon as the patient is hemodynamically stable. This requires moment-by-moment observation. Because vasopressors and inotropes often are started while the patient is not yet optimally volume resuscitated, clinicians should reevaluate intravascular volume status continuously so that the patient can be weaned from the vasopressor as soon as possible. Doses should be titrated carefully downward approximately every 10 minutes to determine if the patient can tolerate gradual withdrawal and eventual discontinuation of the vasopressor and/or inotrope. Discontinuation of agents may occur only minutes to hours after their initiation, or it may take days to weeks. Septic shock requiring vasopressor and/or inotropic support usually resolves within 1 week.

Vasopressin

12 At present, vasopressin therapy should not be initiated as first-line therapy. Lauzier et al. randomized 23 hyperdynamic septic shock patients to initial therapy with vasopressin 0.04 to 0.20 units/min or norepinephrine 0.1 to 2.8 mcg/kg/min for 48 hours to achieve MAP of 70 mm Hg.⁵⁸ Both agents increased MAP over 48 hours, but norepinephrine achieved the desired MAP significantly faster, and norepinephrine was required in 36% of the vasopressin patients. One patient who received vasopressin developed acute coronary syndrome with dose-dependent electrocardiographic changes. Additional studies are needed to determine the optimal dose, duration, and place in therapy of vasopressin relative to adrenergic agents. In addition, no randomized, blinded, placebo-controlled trials have shown improvement in long-term outcomes such as mortality and length of hospital stay. The preliminary results (not yet published at the time this chapter was prepared) of a randomized, double-blind study of 800 patients with septic shock requiring catecholamine vasopressors showed that 28-day mortality rates were similar when vasopressin 0.01 to 0.03 units/min or norepinephrine was added to traditional therapy (see www.utoronto.ca/criticalcare/Research/VASST.shtml). Until further safety data and larger efficacy trials are completed, vasopressin is not recommended as a replacement for norepinephrine or dopamine in patients with septic shock but may be considered in patients who are refractory to catecholamine vasopressors despite adequate fluid resuscitation. If used, vasopressin should be administered in doses not exceeding 0.01 to 0.04 units/min.^{44,45} Use of vasopressin for reducing the dose of adrenergic agents can be considered, but the risks must be considered prior to initiating therapy.

CLINICAL CONTROVERSY: VASOPRESSIN

Adding vasopressin reduces the dose of traditional catecholamine therapies and is associated with improved renal function. However, the occurrence of ischemic events to digits and splanchnic circulation may be increased with vasopressin. Therefore, the lowest possible dose should be implemented if vasopressin is used.

Corticosteroids

12 Since the two meta-analyses reported in 1995,^{49,50} several randomized controlled trials of low-dose corticosteroids in vasopressor-dependent septic shock patients have been published.^{46–48} These

studies used moderate physiologic doses (200–300 mg/day) of hydrocortisone. A meta-analysis of five studies ($n = 465$) showed that steroid therapy was associated with an overall improvement in survival rate (RR 1.23, 95% confidence interval [CI] 1.01–1.50; $P = 0.036$) and shock reversal (RR 1.71, 95% CI 1.29–2.26; $P < 0.001$).⁴⁷ These effects were beneficial in both responders and nonresponders to ACTH stimulation testing ($P = 0.63$ and $P = 0.75$, respectively). These studies also showed that low-dose corticosteroid administration improves hemodynamics and reduces the duration of vasopressor support. All these studies differ from earlier studies in that steroids were administered at lower total doses (hydrocortisone equivalents: 1,209 mg vs 23,975 mg; $P = 0.01$) starting later in septic shock (23 hours vs <2 hours; $P = 0.02$) for longer courses (6 days vs 1 day; $P = 0.01$) to patients with higher control group mortality rates (mean 57% vs 34%; $P = 0.06$) who were more likely to be vasopressor dependent (100% vs 65%; $P = 0.03$). The relationship between corticosteroid dose and survival was linear, with survival benefit at low doses ($P = 0.02$). Another meta-analysis of 16 trials ($n = 2,063$) found similar results with long-term administration of corticosteroids associated with lower mortality in hospital (RR 0.83, 95% CI 0.70–0.97; $P = 0.02$) and at 28 days (RR 0.80, 95% CI 0.67–0.95; $P = 0.02$) and greater shock reversal at 7 days (RR 1.22, 95% CI 1.06–1.40; $P = 0.006$).⁴⁸ Combining all corticosteroid studies did not reveal an increased risk for adverse events, including gastrointestinal hemorrhage (RR 1.16, 95% CI 0.82–0.1.65; $P = 0.4$), superinfections (RR 0.93, 95% CI 0.73–1.18; $P = 0.54$), and hyperglycemia (RR 1.22, 95% CI 0.84–1.78; $P = 0.30$). Of note, the results of both meta-analyses were heavily driven by data supplied by one study.⁵⁹ Annane et al.⁵⁹ randomized 300 patients with septic shock within 8 hours of hypotension to placebo or a daily combination of hydrocortisone 50 mg IV every 6 hours and fludrocortisone 0.05 mg orally for 7 days. Similar to the meta-analyses, use of hydrocortisone reduced 28-day mortality (odds ratio [OR] 0.65, 95% CI 0.39–1.07; $P = 0.09$), but all the benefit was seen in patients with adrenal insufficiency (OR 0.54, 95% CI 0.31–0.97; $P = 0.04$). The placebo group was more likely to continually require vasopressor therapy (hazard ratio [HR] 1.54, 95% CI 1.10–12.16; $P = 0.01$), but differences between groups were exhibited only in patients with adrenal insufficiency (HR 1.91, 95% CI 1.29–2.84; $P = 0.001$). Approximately 76% of patients were deemed adrenally insufficient. Only one study has been published since the most recent meta-analyses.⁶⁰ Oppert et al.⁶⁰ randomized 41 patients with septic shock within 4 hours of hypotension to placebo or continuous infusion hydrocortisone and found that patients treated with hydrocortisone required shorter therapy with vasopressors (53 hours vs 120 hours; $P < 0.02$). This effect was more pronounced in patients with adrenal insufficiency but still was evident in those with adrenal reserve. Of note, serum concentrations of the inflammatory cytokine IL-6 were significantly reduced with hydrocortisone, and this finding was equally apparent irrespective of adrenal function.

Given the current data, corticosteroids can be administered to patients with septic shock and adrenal insufficiency.⁴⁶ In the absence of adrenal function assessment, corticosteroids can be considered in cases of refractory shock, as approximately 75% of these patients have insufficient adrenal reserve.⁵⁹ Use of vasopressors for prolonged periods without evidence of dose reduction also warrants corticosteroid administration. Whenever corticosteroids are used for septic shock, a daily dose equivalent to 200 to 300 mg hydrocortisone should be continued for 7 days. At the time this chapter was prepared, the results of a randomized study of 499 patients with severe sepsis were released (not yet published) and showed that 28-day mortality rates were similar amongst patients with and without adrenal insufficiency (defined by an ACTH response of less than 9 mcg/dL) and that hydrocortisone did not alter mortality but did shorten the length of time patients required vasopressors by 2 to 3 days (see www.esicm.org/PAGE_corticus).

CLINICAL CONTROVERSY: CORTICOSTEROID THERAPY

Low-dose corticosteroid therapy for 7 days in patients with septic shock improves outcomes when adrenal insufficiency is present. Several questions surround the application of corticosteroid therapy in septic patients, including use in patients with sepsis but without shock, use when sufficient adrenal reserve is present, use when patients were taking corticosteroids prior to ICU admission, most effective dose and duration, use of corticosteroids other than hydrocortisone, and need for coadministration of fludrocortisone.

Adverse Effects

4 Catecholamine vasopressors may result in adverse peripheral vasoconstrictive, metabolic, and dysrhythmogenic effects that limit or outweigh their positive effects on the central circulation.^{8,40,42} Norepinephrine, phenylephrine, and epinephrine can produce lactic acidosis secondary to excessive constriction in peripheral arterioles or enhanced glycogenolysis, or as a result of mobilization of lactate from peripheral tissues as a result of improved oxygenation. Additionally, excessive peripheral vasoconstriction may cause ischemia or necrosis of already poorly perfused tissues such as the skin and the mesenteric and splanchnic circulations.^{42,56,57,61} Some of these profound vasoconstrictive effects have been compounded by the use of epinephrine and phenylephrine in patients with septic shock who are significantly hypovolemic. These agents are used in the context of late septic shock, where hypotension is refractory to less selective vasoconstrictors (e.g., norepinephrine or dopamine) such that very large doses of epinephrine or phenylephrine are required but provide little or no benefit. Myocardial ischemia and dysrhythmias may occur in patients with coronary artery disease, atherosclerosis, cardiomyopathies, left ventricular hypertrophy, congestive heart failure, or underlying dysrhythmias because of their inability to tolerate β_1 cardiac stimulation that mediates increases in CO. However, the effect usually is opposite in healthy myocardium and in young patients. β_1 Cardiac stimulation is well tolerated, ventricular filling pressures decrease, and CO and DO_2 increase, with a resulting increase in peripheral perfusion. The dysrhythmogenic potential of the catecholamine vasopressors includes a variety of resulting atrial and ventricular arrhythmias. Sympathomimetic vasopressors also have been found to possess immunomodulatory actions, primarily mediated by β_2 -adrenergic actions (e.g., epinephrine) because almost all immune cells express this receptor.⁴² The actions include downregulating expression of proinflammatory cytokines such as $\text{TNF-}\alpha$ by neutrophils, suppression of oxygen free radical production from neutrophils, and direct proapoptotic effects. Dopamine suppresses prolactin secretion from the anterior pituitary gland, which may lead to reduced T-cell responsiveness.⁴² These effects may be either beneficial or deleterious by dampening harmful effects of oxygen free radical-mediated tissue injury or by reducing neutrophilic defense against bacteria.

Vasopressor catecholamines have the potential to cause extravasation-associated tissue damage if infusions infiltrate during peripheral administration. In the event of infiltration, an α -receptor antagonist such as phentolamine (10 mg in 10 mL saline) should be injected intradermally to reverse local vasoconstriction, with administration of vasopressor drugs into a large central vein.

Dopamine

Dopamine frequently is the initial vasopressor used for patients with septic shock.⁴⁻¹⁰ Doses of 5 to 10 mcg/kg/min are initiated to improve MAP. Most studies of patients with septic shock have shown that dopamine at these doses increases the cardiac index by improving

contractility and heart rate, primarily from its β_1 effects. It increases MAP and SVR as a result of both increased CO and, at higher doses (>10 mcg/kg/min), its α_1 effects.

6 8 The clinical utility of dopamine as a vasopressor in the setting of septic shock is limited because large doses frequently are necessary to maintain CO and MAP. At doses exceeding 20 mcg/kg/min, further improvement in cardiac performance and regional hemodynamics is limited. Its clinical use frequently is hampered by tachycardia and tachydysrhythmias, which may lead to myocardial ischemia. Although tachydysrhythmias theoretically should not be expected to occur until administration of dopamine 5 to 10 mcg/kg/min, these β_1 effects are observed with doses as low as 3 mcg/kg/min. They seem to be more prevalent in patients who are inadequately resuscitated (hypovolemic), in the elderly, in those with preexisting or concurrent cardiac ischemia or dysrhythmias, and in patients currently receiving other dysrhythmogenic agents, including vasopressors and inotropes.

8 Dopamine increases PAOP and pulmonary shunting to decrease PaO_2 .⁴² The increase in PAOP may be due to changes in diastolic volumes from decreased cardiac compliance or increased venous return to the heart by α -adrenergic receptor-mediated venoconstriction. This may affect gas exchange and decrease PaO_2 . The increase in pulmonary shunting also may result from acute enhancement of pulmonary blood flow to nonhomogeneous lung regions. Thus, dopamine should be used with caution in patients with elevated preload because the drug may worsen pulmonary edema. In the instance of high filling pressures, tachycardia, or tachydysrhythmias, dopamine should be replaced by another vasopressor and/or inotrope such as norepinephrine, dobutamine, phenylephrine, or epinephrine, depending on the desired effect.

The effect of dopamine on global oxygen-transport variables parallels the hemodynamic effects. Although dopamine improves global DO_2 in septic patients, it may compromise O_2ER in the splanchnic and mesenteric circulations by α_1 -mediated vasoconstriction. Splanchnic blood flow and DO_2 increase with dopamine, but with no preferential increase in splanchnic perfusion as a fraction of CO and systemic increases in DO_2 .^{62,63} Indeed, large doses of dopamine worsen pHi and the PCO_2 gap.^{64,65} This is reflected by a decrease or lack of change in regional VO_2 and a decrease in tissue O_2ER .⁶¹ Dopamine at low or pressor doses directly impedes gastric motility in critical illness⁶⁶ and may aggravate gut ischemia in septic shock.^{67,68} Similar to high-dose administration, low-dose dopamine increases splanchnic blood flow but lowers splanchnic VO_2 in sepsis.⁶⁸ Therefore, dopamine at all doses impairs hepatosplanchnic metabolism despite an increase in regional perfusion. Lastly, immune suppression of T-cell proliferation and inhibited secretion of growth and thyroid hormones and prolactin are other potentially clinically significant unwanted neuroendocrine effects of dopamine.

8 Currently, insufficient evidence promotes the use of dopamine as a first-line agent because regional hemodynamics, oxygen-transport variables, and functional parameters of improved organ perfusion are not consistently enhanced in a sustained manner and may be negatively impaired. The negative findings of low-dose dopamine use (see Low-Dose Dopamine below) and the deleterious effects of inotropic and vasopressor doses of dopamine on regional hemodynamics and oxygen transport raise controversy over whether dopamine should be considered the first-line vasopressor agent in patients with severe sepsis or septic shock.^{4,6-8} The results of an observational study found dopamine use was an independent factor associated with ICU mortality in all 1,058 patients with shock (OR 1.67, 95% CI 1.19–2.35; $P = 0.003$) and the subgroup of 462 patients with septic shock (OR 2.05, 95% CI 1.25–3.37; $P = 0.005$).⁶⁹ Until dopamine is found to have definitive deleterious clinical outcomes compared to other vasopressors, empirical use of dopamine in a hypotensive patient in whom a pulmonary arterial catheter has not been inserted and in

whom the cause of hypotension—low CO or vasodilation—is yet undetermined still may be reasonable.^{3,5,9,10} In addition, unlike other vasopressor agents, dopamine is available as premixed ready-to-use solutions of various concentrations that can be stored in automated distribution systems for rapid initiation.

Low-Dose Dopamine

In the critical care setting, low doses (1–3 mcg/kg/min) of dopamine once were advocated for use in patients with septic shock receiving vasopressors with or without oliguria. The goal of this therapy is to minimize or reverse renal vasoconstriction caused by other pressors, to prevent oliguric renal failure, or to convert oliguric to nonoliguric renal failure. At low dosages, dopamine has been shown to increase urine production as a result of enhanced renal blood flow from its D_1 -receptor-mediated vasodilation, its D_2 -receptor-mediated natriuretic effects (inhibition of Na^+/K^+ ATP of renal tubular cells), or its β_1 -receptor-mediated increase in cardiac index.^{70,71} In healthy subjects, the addition of dopamine to incremental doses of norepinephrine may blunt norepinephrine-induced renal vasoconstriction, thereby maintaining renal blood flow, natriuresis, urine production, and glomerular filtration.⁵² These effects also have been observed during the course of dopamine administration in oliguric⁶² and nonoliguric^{57,63,70} patients with septic shock. For this reason, low doses of dopamine sometimes are added to other vasopressors (e.g., norepinephrine).

Tolerance to the vasodilatory effects of dopamine after 24 to 48 hours is evident in nonoliguric patients with sepsis syndrome and has been reported in other conditions.^{72,73} The lack of response to dopamine in patients with septic shock receiving vasopressors and the tolerance to low-dose dopamine that develops in responders may be explained in part by time- and disease-dependent desensitization of the dopamine receptors^{72,73}; this may not occur in patients with sepsis syndrome⁷² or in normal volunteers.⁵² Furthermore, differences in the extent of preexisting vasodilation and the pathophysiology of renal dysfunction in oliguric and septic shock patients may contribute to the inconsistent responses to administration of low doses of dopamine. A paucity of evidence suggests that the etiology of acute renal failure from sepsis is due to efferent arteriole vasodilation and that potential beneficial outcomes with dopamine, and other vasopressors, are due to enhanced CO.^{74,75} Enhanced urine production has been shown to occur in hyperdynamic shock with use of agents that constrict the efferent arteriole such as vasopressin and norepinephrine; however, delineating the effects of improved arterial blood pressure and CO associated with these agents from regional renal effects is difficult.^{44,45,64,65,76}

Two studies have settled the debate surrounding low-dose dopamine. Friedrich et al.⁷⁷ performed a meta-analysis to determine if low-dose dopamine reduces mortality or the need for dialysis in patients with critical illness. Among 61 clinical trials ($n = 3,359$), low-dose dopamine had no effect on mortality (RR 0.96, 95% CI 0.78–1.19), need for dialysis (RR 0.93, 95% CI 0.76–1.15), or occurrence of adverse events (RR 1.13, 95% CI 0.90–1.41). Low-dose dopamine improved urine production by 24% (CI 14%–35%) on the first day of therapy but failed to maintain this effect on days 2 and 3. No improvements in serum creatinine concentration (4% relative increase, 95% CI 1%–7%) and measured creatinine clearance (6% relative increase, 95% CI 1%–11%) occurred. One adequately designed prospective, controlled trial has been conducted with low-dose dopamine in critically ill patients.⁷⁸ This study was cited in the meta-analysis by Friedrich et al. Bellomo et al.⁷⁸ randomized 328 critically ill patients with early renal dysfunction to either low-dose dopamine (2 mcg/kg/min) or placebo and found no differences in peak serum creatinine concentration ($245 \pm 144 \mu\text{mol/L}$ vs $249 \pm 147 \mu\text{mol/L}$), increase in serum creatinine concentration ($62 \pm 107 \mu\text{mol/L}$ vs $66 \pm 108 \mu\text{mol/L}$), need for renal replacement therapies (27.7% vs 24.5%), and urine production at any time point. On the basis of

available evidence, low-dose dopamine for treatment or prevention of acute renal failure cannot be justified and should be eliminated from routine clinical use.^{74,75}

Norepinephrine

Norepinephrine was first used 3 decades ago for treatment of hypotensive states prior to the development of the synthetic catecholamines dopamine and dobutamine. Traditionally, norepinephrine was viewed as causing significant peripheral tissue vasoconstriction, which could selectively impair regional blood flow and thus DO_2 to the renal and splanchnic beds. However, clinical studies of norepinephrine now support the primary use of norepinephrine to restore blood pressure in septic shock.^{53,79} Several retrospective analyses have demonstrated improved MAP and mortality in ICU patients with severe hypotension treated with norepinephrine either as first-line therapy or after therapeutic failure with fluid resuscitation and dopamine treatment.⁶ However, in patients with increased sequential organ failure assessment scores and associated multiorgan failure, treatment with norepinephrine no longer offered an advantage. Early aggressive vasopressor support may be key to a positive outcome in septic shock. Use of norepinephrine as first-line therapy may be more rational because norepinephrine is more potent than dopamine and is more effective in increasing MAP. It has combined strong α_1 -activity and less potent β_1 -agonist effects while maintaining weak vasodilatory effects of β_2 -receptor stimulation. In clinical practice, however, norepinephrine often is initiated after vasopressor doses of dopamine (4–20 mcg/kg/min) alone or in combination with dobutamine (5 mcg/kg/min) fail to achieve desired goals.^{4–10} Doses of dopamine and dobutamine are kept constant or stopped; in some instances, dopamine is kept at low doses for purported renal protection.

7 Norepinephrine infusions can be titrated to preset goals of MAP (usually at least 65 mm Hg), improvement in peripheral perfusion (to restore urine production or decrease blood lactate), and/or achievement of desired oxygen-transport variables while not compromising the cardiac index. Norepinephrine 0.01 to 2 mcg/kg/min reliably and predictably improves hemodynamic parameters to “normal” or “supranormal” values in most patients with septic shock. As with 6 other vasopressors, norepinephrine doses exceeding those recommended by most references frequently are needed in critically ill patients with septic shock to achieve predetermined goals. A significant increase in MAP generally is caused by an increase in SVR. In contrast to dopamine, heart rate generally does not increase significantly with norepinephrine because of diminished stimulation of cardiac β_1 -receptors in septic shock and reflex bradycardia from increased SVR.^{54,80} In a study of 10 patients with septic shock in whom norepinephrine doses were increased to 23, 31, and 47 mcg/min to maintain MAPs of 65, 75, and 85 mm Hg, mean heart rates were 95, 101, and 105 beats/min, respectively.⁵⁴ The increasing doses of norepinephrine required for the three levels of MAP resulted in a progressive increase in the cardiac index (mean values 4.7, 5.3, and 5.5 L/m²/min, respectively).⁵⁴ Others have demonstrated no change or a minor increase in the cardiac index with norepinephrine in patients with septic shock.⁵³ In contrast to dopamine, norepinephrine does not influence PAOP.⁸¹

The effect of norepinephrine on oxygen transport parameters is variable and depends on baseline values and concurrently administered vasoactive agents. In most studies of norepinephrine alone, either an increase or no change in DO_2 is seen with no change in O_2ER , particularly when mean DO_2 values were “supranormal” prior to therapy.^{61,64,65} Norepinephrine has demonstrated either no effect or improvement in PCO_2 gap and pHi .^{61,65} Splanchnic blood flow and fractional blood flow are higher with norepinephrine than either dopamine or epinephrine despite higher CO with the two latter agents.^{61,81,82}

In a randomized study of 32 septic shock patients unresponsive to volume resuscitation, Martin et al.⁷⁶ found norepinephrine alone

was superior to dopamine in achieving and maintaining preset hemodynamic (MAP of at least 80 mm Hg) and oxygen-transport variables for at least 6 hours (93% vs 31% of patients, $P < 0.001$). Of the 11 patients who did not respond to dopamine, 10 achieved the desired hemodynamic goal when norepinephrine was added. The authors suggested that differences between the two agents resulted from norepinephrine's combined increase in VO_2 and decrease in lactate concentrations due to reversal of splanchnic ischemia and efficient hepatic clearance of lactate or a preferential increase in DO_2 to areas of greatest oxygen demand, thus optimizing O_2ER .

The same investigators showed in a prospective, observational cohort study of 97 adult patients with septic shock that use of norepinephrine to provide hemodynamic support was associated with a significant decrease in mortality (day 7: 28% vs 40%, $P < 0.005$; day 28: 55% vs 82%, $P < 0.001$; at hospital discharge: 62% vs 84%, $P < 0.001$).⁷⁹ Using stepwise logistic regression analysis, norepinephrine was found to be the only factor associated with significantly improved survival ($P = 0.03$). Despite the drawback of lack of randomization, this study is the first to demonstrate a survival benefit with any vasopressor. In an interventional study, Martin et al.⁵³ showed that addition of norepinephrine in patients with dobutamine-resistant septic shock resulted in significant improvements (40%) in the cardiac index and stroke volume index during a 4 hour study period. This occurred despite an increase in left ventricular afterload, suggesting that either a positive inotropic effect or the correction of systemic hypotension was responsible. The authors further speculated that older patients may benefit from a combined α - and β -vasopressor versus a pure β -agonist given the higher incidence of coronary disease and compromised ventricles in this patient population. By virtue of restored MAP and hence coronary perfusion, cardiac index is increased in older patients, whereas in younger patients with less coronary artery disease and a higher cardiac index at baseline, norepinephrine acts primarily as a vasopressor. In younger patients in this study, norepinephrine did not significantly increase the cardiac index or stroke volume index.

Whereas the effects of norepinephrine on MAP, SVR, cardiac index, and heart rate appear to be desirable and more predictable, the effect of norepinephrine on urine production may depend on concurrently administered vasoactive agents.^{6,81} The results of many studies are difficult to interpret because of concurrent inotropic support with dobutamine and dopamine or low doses of dopamine precluding the attribution of any beneficial effects to norepinephrine alone. In the randomized study of norepinephrine and dopamine by Martin et al.,⁷⁶ urine production increased with norepinephrine but not with dopamine (22 ± 7 mL/h to 189 ± 52 mL/h vs 24 ± 6 mL/h to 8.2 ± 10 mL/h; $P < 0.001$). Adding norepinephrine to the dopamine group increased urine production to 107 ± 125 mL/h. An increase in urine production may be due to increased renal perfusion pressure secondary to elevated MAP from improved CO and SVR or the localized vasoconstrictive effect of norepinephrine in the kidney (greater vasoconstriction of the efferent arteriole than the afferent arteriole) to increase the glomerular filtration rate.

Taken together, these data suggest that norepinephrine should be repositioned as the vasopressor of choice in patients in septic shock because of its multiple benefits: (1) norepinephrine may decrease mortality in septic shock, (2) it reverses inappropriate vasodilation and low global oxygen extraction, (3) it attenuates myocardial depression at unchanged or increased CO and increased coronary blood flow, (4) it improves renal perfusion pressure and renal filtration, (5) it enhances splanchnic perfusion, and (6) it is less likely than other vasopressors to cause tachycardias and tachydysrhythmias.^{79,80,83}

Dobutamine

Dobutamine is an inotrope with vasodilatory properties (a "inodilator"). It is used for treatment of septic and cardiogenic shock to

increase the cardiac index, typically by 25% to 50%. In septic shock, LVEF and right ventricular function are depressed despite a high cardiac index, whereas ventricular volumes and compliance are increased. Stroke index is maintained by an increased heart rate and ventricular dilation. In survivors, myocardial depression is reversible and normalizes 5 to 10 days after onset of sepsis.⁷ Dobutamine has been shown to increase stroke index, left ventricular stroke work index, and thus cardiac index and DO_2 without increasing PAOP in septic shock in animals, in human volunteers, and in controlled studies of human septic shock.⁷ The ability of dobutamine to enhance cardiac index and DO_2 during septic shock appears to be related to its chronotropic effect.⁸⁴

Most prospective, randomized controlled studies of therapy directed toward achieving supranormal hemodynamic variables with dobutamine were performed in surgical and medical ICU patients with septic shock refractory to concurrently administered vasopressors (dopamine and/or norepinephrine).⁷ The achievement of supranormal oxygen transport values with dobutamine is of little value compared with treatment to normal values. In addition, administration of dobutamine to achieve these high values has resulted in an unchanged or increased mortality rate and/or a greater incidence of adverse effects,⁸⁵ with the exception of a study of older, nonseptic, high-risk surgical patients.²² Results in medical and surgical patients may differ because of differences in time of starting dobutamine infusion, duration of the infusion, and dosages administered. Among critically ill, high-risk trauma and surgical patients receiving dobutamine, subgroups of patients with septic shock (6%–34%) have small and insignificant changes in DO_2 , VO_2 , O_2ER , and cardiac index.⁸⁶ The lack of response may be related to late treatment (>72 hours after surgery) resulting in irreversible changes due to hypoperfusion and hypoxia. In a group of medical patients, the lack of sustained effect may have been attributed to the fact that very large doses were needed to achieve the desired effects over a longer treatment period (72 hours). The requirement for vasopressor support with dopamine may have decreased O_2ER and negated the beneficial effects of increased delivery with dobutamine. O_2ER , mixed venous oxygen tension, and relative changes in SVR were not reported. In populations of medical and surgical patients, dobutamine did not increase the likelihood of patients achieving supranormal oxygen-transport variables. Continuation of dobutamine until death or resolution of acute illness resulted in increased mortality despite an increase in the mean area under the DO_2 curve.⁸⁵ This is explained in part by the fact that no change in VO_2 was seen, and thus O_2ER decreased. Also, much higher doses of dobutamine were used in this study compared with the previous study (5–200 mcg/kg/min vs 5–20 mcg/kg/min). Seventeen of the 50 patients in the experimental group received dobutamine 50 mcg/kg/min or more at some time during the study. Despite these high doses, 35 (70%) of 50 patients were unable to achieve the predetermined goals. In fact, dose increments of dobutamine were limited by complications in half of the dobutamine patients in the treatment group, with occurrence of tachycardia, ischemic changes on electrocardiogram, hypertension, and tachydysrhythmias despite the absence of preexisting cardiac abnormalities.⁸⁵

Studies have focused on the effects of dobutamine on gastric mucosal flow and the splanchnic circulation. The addition of dobutamine to norepinephrine or epinephrine improves gastric mucosal perfusion without increasing the cardiac index.^{87,88} This is consistent with findings that dobutamine may improve pHi and mucosal perfusion in septic patients.⁸⁹ The addition of dobutamine to norepinephrine or epinephrine treatment has been shown to improve gastric mucosal perfusion as measured by improvements in pHi, arterial lactate concentrations, and PCO_2 gap.^{88,90–92} These findings likely relate to blood flow redistribution toward gastric mucosa.⁸⁹ This effect may be due to either an increase in the fraction of CO distributed to the global hepatosplanchnic blood flow⁸⁷ and/

or a redistribution of blood flow within gastric wall layers toward mucosal by “stealing” blood away from the muscularis potentially as a result of the greater β_2 -mediated vasodilation attributable to norepinephrine. This hypothesis is supported by four other investigations,^{90–93} including one showing that sublingual microcirculation improved after dobutamine was given to vasopressor-dependent septic shock patients.⁹³ The changes in capillary perfusion were unrelated to arterial pressure or cardiac index.⁹³

In many of these studies, a constant dose of dobutamine (usually 5 mcg/kg/min) was added to norepinephrine or epinephrine and compared with either vasopressor alone to determine comparative effects on systemic and regional hemodynamics and oxygen-transport variables.^{88,90–92} At the same increase in MAP, no significant difference in the systemic hemodynamic variables was observed between treatment groups. The combination of dobutamine and norepinephrine results in a lower increase in heart rate compared with use of other vasopressors alone. There is no difference in DO_2I between groups. Arterial lactate concentrations decrease significantly with norepinephrine and dobutamine compared with dopamine and epinephrine infusions. Norepinephrine and dobutamine infusion is associated with a higher pH compared with epinephrine infusion, but the differences are not statistically different. The difference between gastric and arterial PCO_2 with norepinephrine and dobutamine tends to be lower compared with values obtained with dopamine, epinephrine, and norepinephrine alone. Therefore, for the same level of MAP as the therapeutic goal in patients with septic shock, gastric mucosal perfusion and tissue oxygen utilization are most improved with norepinephrine and dobutamine.

6 Dobutamine should be started at dosages ranging from 2.5 to 5 mcg/kg/min. In a study of early goal-directed therapy, dobutamine was administered to 13.7% of patients within 6 hours of resuscitation to achieve $\text{ScvO}_2 > 70\%$.¹⁹ Although a dose response may be seen, evidence now suggests that doses > 5 mcg/kg/min may provide limited beneficial effects on oxygen transport values and hemodynamics and may increase adverse cardiac effects.⁹³ If given to patients who are intravascularly depleted, dobutamine will result in hypotension and a reflexive tachycardia. Pathophysiologic factors influence dosing requirements and pharmacokinetic parameters over the time course of the illness and the duration of the infusion. Decreases in PaO_2 , as well as myocardial adverse effects such as tachycardia, ischemic changes on electrocardiogram, tachydysrhythmias, and hypotension, are seen.^{85,89} Thus, infusion rates should be guided by clinical end points and $\text{SvO}_2/\text{ScvO}_2$. Dobutamine, like other inotropes, usually is given until improvement in myocardial function with resolution of the septic episode or dose-limiting side effects are observed.

Phenylephrine

6 Despite its purported use in refractory septic shock, little information is available regarding the clinical efficacy of phenylephrine. Nevertheless, it is an attractive agent for use in sepsis because of its selective α -agonism with primarily vascular effects. It is generally initiated at dosages of 0.5 mcg/kg/min and can be titrated every 5 to 15 minutes to desired effects.

Three clinical trials have evaluated phenylephrine use in 38 patients with septic shock. Phenylephrine (0.5–9 mcg/kg/min), used alone or in combination with dobutamine or low doses of dopamine, improves blood pressure and myocardial performance in fluid-resuscitated septic patients.⁹⁴ Incremental doses of phenylephrine administered over 3 hours result in linear dose-related increases in MAP, SVR, heart rate, and stroke index when administered alone as a single agent in stable, nonhypotensive but hyperdynamic, volume-resuscitated surgical ICU patients. In septic shock, phenylephrine did not impair the cardiac index, PAOP, or peripheral perfusion.^{55,95} Phenylephrine administration improves myocardial performance in hyper-

dynamic, normotensive septic patients but worsens myocardial performance in cardiac controls.⁹⁴ In sepsis, phenylephrine improves MAP by increasing the cardiac index through enhanced venous return to the heart (increase in CVP and stroke index) and by acting as a positive inotrope. In cardiac patients, myocardial performance worsens as a result of a decrease in the cardiac index and an increase in SVR.

In septic shock, phenylephrine appears to increase global tissue oxygen use, although information regarding the relationship of the oxygen-transport variables with increases in MAP and cardiac index is conflicting.^{55,95} Increases in VO_2 appear to be dissociated from DO_2 , representing an increase in O_2ER as the cardiac index remains unchanged. Increases in VO_2 may result from redistribution of blood flow to previously underperfused areas, improving oxygen use as a result of changes in MAP and SVR. With phenylephrine administration, no organ dysfunction was documented, and evidence of globally improved peripheral tissue perfusion was observed as lactic acid concentration fell or remained unchanged and urine production increased significantly at increased or maximal VO_2 . An increased O_2ER may contribute to improved tissue use.^{55,95} In one small study, measured DO_2 and VO_2 values paralleled MAP in most patients.⁹⁵ As with epinephrine, phenylephrine dosages (1.3–3.7 mcg/kg/min) required to achieve goals of therapy were significantly higher than dosages traditionally recommended for use. When phenylephrine (0.5 mcg/kg/min) was titrated to a plateau in VO_2 or the appearance of adverse cardiac effects, both DO_2 and VO_2 increased at least 15%. When combined with dobutamine, phenylephrine resulted in a more consistent and statistically significant increase in both DO_2 and VO_2 . However, these observations may be biased because baseline DO_2 and VO_2 values were somewhat higher in patients who did not require dobutamine (5/11 patients). In a second study, use of phenylephrine as a single agent without another cardiostimulant agent was evaluated in 10 septic, hyperdynamic surgical ICU patients.⁵⁵ Eight patients had a clinically significant increase (at least 15%) in VO_2 with variable doses of phenylephrine, whereas DO_2 increased in only three patients. Phenylephrine predictably increased MAP but not VO_2 in a dose-dependent fashion in the surgical patient population.

Few data regarding the effect of phenylephrine on regional hemodynamics and oxygen-transport variables are available. When phenylephrine replaced norepinephrine in patients with septic shock, phenylephrine selectively reduced splanchnic blood flow and thus splanchnic DO_2 and splanchnic lactate uptake rate without changing the overall splanchnic VO_2 .⁹⁶ Because all these parameters normalized when norepinephrine was reinstated, these data suggest that exogenous β -adrenergic stimulation (norepinephrine) may determine hepatosplanchnic perfusion and oxygen availability but not utilization in septic shock. This study also demonstrated that although the phenylephrine-induced reduction in splanchnic DO_2 reduced the de novo synthesis of glucose (a highly oxygen-dependent pathway in the periportal region), it did not affect the formation of monoethylglycinexylidide, a metabolite of lidocaine (a cytochrome P450-dependent pathway in the perivenous region). This finding demonstrates the heterogeneity of metabolic function in different areas of the liver.

The available data on hemodynamics, oxygen-transport variables, and mortality with phenylephrine in septic shock patients may not be generalizable because of the small numbers of patients evaluated. Adverse effects, such as tachydysrhythmias, are notably infrequent with phenylephrine, particularly when it is used as a single agent or at higher doses, because phenylephrine does not exert any activity on β_1 -adrenergic receptors. Whether the beneficial effects can be sustained with longer administrations of phenylephrine is unclear.⁵⁵ In an experimental animal model, however, sustained endotoxemia (48 hours) did not result in desensitization of α_1 -adrenergic responsiveness when phenylephrine was used.⁴³ Other mechanisms may be

responsible for the ineffectiveness ⁹ of vasopressors during advanced sepsis. Phenylephrine may be a particularly useful alternative in patients who cannot tolerate tachycardia or tachydysrhythmias with use of dopamine or norepinephrine, in patients with known underlying myocardial dysfunction, and in patients who are refractory to dopamine or norepinephrine (because of β -adrenergic receptor desensitization). As with other vasopressors, phenylephrine is continued until resolution of the hemodynamic instability associated with the septic episode and is weaned when patients are clinically stable.

Epinephrine

¹⁰ By convention, epinephrine has been reserved as a last-line agent for hemodynamic support of sepsis. Few objective data evaluating its comparative efficacy in early sepsis are available; most studies have examined the effects of epinephrine in refractory septic shock.⁸⁹ Despite this lack of data, epinephrine is an acceptable choice as a single agent because of its combined vasoconstrictor and inotropic effects. ⁹ Epinephrine infusion rates of 0.04 to 1 mcg/kg/min alone increase hemodynamic and oxygen-transport variables to “supranormal” values without adverse effects in septic patients without coronary artery disease. Among 69 patients evaluated in five studies, epinephrine alone or combined with either dobutamine or low doses of dopamine achieved the desired outcomes.⁸⁹ Large doses (0.5–1 mcg/kg/min) often were required when epinephrine was added to other agents. Smaller doses (0.10–0.50 mcg/kg/min) are effective if dobutamine and dopamine infusions are kept constant, potentially as a result of less exposure to β -receptor stimulation and thus less receptor desensitization. The same holds true when epinephrine is used as a first-line agent and when it is used in younger patients. A linear dose–response curve is seen, with rapid improvement of hemodynamic variables and DO_2 . Although DO_2 increases mainly as a function of consistent increases in the cardiac index and a more variable increase in ¹⁰ SVR, VO_2 may not increase, and O_2ER may fall. A transient fall in pHi may be seen during epinephrine administration, and the impairment in gastric mucosal perfusion can be counteracted in part by dobutamine. Furthermore, lactate concentrations may rise during the first few hours of epinephrine therapy but normalize over the ensuing 24 hours in survivors.⁸⁹ The increase in lactate may be a result of worsened DO_2 to the liver (and subsequent anaerobic metabolism) or to the hepatosplanchnic circulation or, alternately, may be due to a direct increase in calorogenesis and breakdown of glycogen and lactate production as a result of epinephrine. However, evidence suggests that epinephrine, in contrast to dopamine, increases the proportion of total CO delivered to the splanchnic circulation, although VO_2 is not increased sufficiently to increase O_2ER . In contrast, when epinephrine is compared with a short infusion (2 hours) of a combination of norepinephrine and dobutamine, epinephrine preferentially decreases splanchnic DO_2 , worsens pHi, and increases systemic lactate concentration without increasing VO_2 . Methodologic limitations of many of these studies included nonrandomized crossover periods, potentially leading to pharmacologic carryover; failure of patients to achieve a steady state before crossover; and use of time-dependent response measures. Also unclear is whether patients were comparable at baseline—that is, whether they had received the same or other vasoactive agents before the study period and for how long.⁸⁹

¹⁰ Because data on the effects of vasopressors on splanchnic circulation in humans are limited and are confounded by the concurrent use of multiple agents, De Backer et al.⁶¹ conducted a study in which regional hemodynamic effects of three catecholamine vasopressors were evaluated individually in septic shock patients. A sample of 20 patients with septic shock was divided into two groups: a moderate shock group, in which the MAP was at least 65 mm Hg with dopamine doses between 10 and 20 mcg/kg/min, and a severe

group, in which MAP was <65 mm Hg. After a stable dose of dopamine, patients were randomized to either norepinephrine or epinephrine initially and then the other agent after a period of at least 45 minutes with each agent. Systemic and regional measurements were taken for each drug. Minimal differences between agents were noted for moderate shock. However, in the severe shock group, epinephrine resulted in higher DO_2 and VO_2 but lower absolute and fractional splanchnic blood flow. Although the PCO_2 gap was not different, indocyanine green clearance was lower with epinephrine compared with norepinephrine. No detrimental effects on splanchnic circulation were found with dopamine. This study concluded that epinephrine titrated to blood pressure in patients with severe septic shock causes deterioration in splanchnic circulation and induces changes in splanchnic metabolism. Given that these changes are likely deleterious, high-dose epinephrine should be avoided in severe septic shock patients.⁶¹

Four studies have compared epinephrine with either norepinephrine alone or norepinephrine in combination with dobutamine to determine their comparative effects on systemic and regional hemodynamics and oxygen-transport variables.^{87,90–92} Two randomized studies compared the effects of epinephrine with the combination of norepinephrine and dobutamine on gastric perfusion, systemic and pulmonary hemodynamics, hepatic function, and blood gases in a total of 52 patients with septic shock.^{90,91} Epinephrine or norepinephrine was started at a dose of 0.1 mcg/kg/min and titrated rapidly to achieve MAP of 70 to 80 mm Hg. Dobutamine was infused continuously at 5 mcg/kg/min. At the same increase in MAP, no significant differences in the systemic or pulmonary hemodynamic and blood gas variables were observed between treatment groups. Epinephrine tended to induce greater increases in the cardiac index and oxygen transport compared with norepinephrine and dobutamine. Epinephrine also significantly increased gastric mucosal blood flow compared with norepinephrine and dobutamine without modifying clearance of indocyanine green. The effects seen with epinephrine most likely were the result of an increase in the cardiac index. In the short term, however, epinephrine was associated with increased lactate concentrations, decreased pHi, and widened PCO_2 gap. All these variables improved in the group that received norepinephrine and dobutamine.

The two other studies are prospective, randomized crossover studies performed in dopamine-resistant, volume-replete patients with septic shock.^{87,92} The design and results of the two studies are similar. Dopamine, epinephrine, norepinephrine, and norepinephrine plus dobutamine were adjusted to a MAP of 70 mm Hg. Epinephrine and the combination of norepinephrine and dobutamine both produced a significant increase in heart rate compared with norepinephrine alone. Epinephrine also significantly increased the cardiac index and DO_2 compared with norepinephrine alone as well as with norepinephrine and dobutamine. For the same level of MAP, epinephrine and the combination of norepinephrine and dobutamine induced a greater increase in mucosal perfusion than did norepinephrine alone, but the same ratio between gastric mucosal perfusion and DO_2 was observed with norepinephrine and dobutamine and with epinephrine or norepinephrine alone. However, O_2ER values were lower with epinephrine infusion compared with the other three groups. Arterial lactate concentrations decreased significantly with norepinephrine and dobutamine as compared with dopamine and epinephrine infusions. In addition, pHi and PCO_2 improved more with norepinephrine and dobutamine than with epinephrine or norepinephrine alone, but the differences were not statistically different. These results can be explained by the vasodilatory effect of dobutamine on gastric mucosal microcirculation resulting in a redistribution of blood flow toward the mucosa.⁸⁷ The results of these studies suggest that epinephrine has deleterious effects on regional hemodynamics and oxygen utilization. Of all the vasopressors, epinephrine exhibits the most pronounced capacity to induce hyperglycemia by increased gluconeogenesis and

glycogenolysis with α -mediated suppression of insulin secretion.⁴² The increase in lactate concentrations with epinephrine may be secondary to exaggerated aerobic glycolysis rather than anaerobic metabolism from decreased oxygen utilization.

6 It is important to note that despite the large doses used in all the studies discussed, clinically important dysrhythmias or cardiac ischemia were reported rarely in patients of any age or underlying cardiac status. Nevertheless, caution must be exercised before considering epinephrine for managing hypoperfusion in hypodynamic patients with coronary artery disease, in whom ischemia, chest pain, and myocardial infarction may result. Based on the current evidence, epinephrine should be avoided in septic shock. Although it effectively increases CO and DO_2 , it has deleterious effects on the splanchnic circulation. If it is used as a second-line agent in septic shock, factors that may influence successful therapy with epinephrine include the time from onset of septic shock to effective therapy and the age of the population.

Vasopressin

12 Studies involving vasopressin infusion for management of septic shock show rapid and sustained improvement in hemodynamic parameters. These effects are evident with administration of doses not exceeding 0.08 units/min. Administration of doses >0.04 units/min and 0.05 units/min are associated with negative changes in CO and mesenteric mucosal perfusion, respectively. The reduction in CO likely is the result of lowered stroke volume.⁴⁴ The studies that reported cardiac function indicate patients had adequate CO prior to initiating vasopressin therapy. Therefore, vasopressin use in septic shock patients with cardiac dysfunction warrants extreme caution. Cardiac ischemia appears to be a rare occurrence and may be related to administration of doses >0.05 units/min.⁴⁴

Mesenteric ischemia associated with vasopressin may be clinically relevant. Two studies demonstrated increased hepatic transaminases and total bilirubin concentrations during vasopressin therapy, suggesting impaired hepatic blood flow or a direct effect on excretory hepatic function.^{42,44} Three prospective studies of a total of 30 patients with septic shock requiring moderate-to-high doses of norepinephrine found that pHi and PCO_2 gap rapidly worsened after vasopressin at doses of 0.04 to 1.8 units/min was added, despite increased splanchnic blood flow and fractional blood flow.^{97–99} Two randomized studies demonstrated contrasting results, likely because of their study designs.^{100,101} Dunser et al.¹⁰⁰ randomized 48 patients with vasodilatory shock to norepinephrine alone or norepinephrine with vasopressin 0.07 units/min for 48 hours. The PCO_2 gap rose after 1 hour in the norepinephrine group and then stabilized, whereas the combination induced a progressive rise in the PCO_2 gap and reached the same values as norepinephrine alone at 48 hours.¹⁰⁰ Patel et al.¹⁰¹ randomized 24 septic shock patients requiring high-dose norepinephrine to 4 hours of additional norepinephrine or vasopressin at a median dose of 0.06 units/min. The PCO_2 gap remained unaltered in both groups. Differences between studies may reflect the time of initiation relative to onset of shock, the stage of shock, and study duration. It is not surprising that even replacement doses of vasopressin in septic shock are associated with mesenteric mucosal hypoperfusion because mesenteric vasoconstriction occurs at vasopressin serum concentrations as low as 10 pg/dL, and the effect is dose dependent.⁴⁴ Of concern is the additive effective with norepinephrine despite substantially reduced doses of norepinephrine when vasopressin is initiated.^{97–99} Although controversial, the degree of hypoperfusion with vasopressin may be greater than with norepinephrine alone⁴⁴ unless the dose of norepinephrine is markedly increased to maintain adequate arterial blood pressure. Vasopressin's strongest vasoconstrictive action occurs in the skin and soft tissues, skeletal muscles, and fat tissues. As a result, ischemic skin lesions have been observed in several studies, with an

occurrence rate as high as 30% after vasopressin was added to norepinephrine-resistant shock.^{44,101}

Although vasopressin may have deleterious effects on mesenteric and skin perfusion, studies report vasodilation of cerebral, pulmonary, coronary, and some renal vasculature beds. The clinical outcomes associated with selective vasodilation are not yet determined except for enhanced urine production in patients not anuric at baseline.^{44,100} Whereas V_2 stimulation promotes water retention from the distal tubules and collecting ducts, V_1 receptors cause vasoconstriction of efferent arterioles and relative vasodilation of afferent arterioles to increase glomerular perfusion pressure and filtration rate, enhancing urine production. Animal data suggest that urine production is not increased with even higher vasopressin doses, likely because of relative vasoconstriction of the afferent arteriole to reduce glomerular filtration rate.⁴⁴ In the studies reporting benefit, the maximum dose used was 0.08 units/min.⁴⁴

In order to minimize the potential for adverse events and maximize the beneficial effects, vasopressin doses should be limited to 0.04 units/min. Most studies initiated vasopressin as add-on therapy to one or two catecholamine adrenergic agents rather than as first-line therapy or salvage therapy. The results of these studies showed that vasopressin markedly reduced the requirements for adrenergic agents, but few studies demonstrated complete discontinuation of these therapies. Therefore, vasopressin should be used only if response to one or two adrenergic agents is inadequate or as a method for reducing the dose of these therapies. Increased arterial pressure should be evident within the first hour of vasopressin therapy, at which time the dose(s) of adrenergic agent(s) should be reduced while maintaining blood pressure. This method should help limit the degree of ischemia.

Most studies evaluated vasopressin use for <48 hours, and several studies reported difficulty discontinuing vasopressin therapy. Whether additional benefits, deleterious effects, or tolerance is observed with longer infusions remains unclear. Because vasopressin is being used to replace a physiologic deficiency, it stands to reason that the requirement for vasopressin will subside with reversal of the septic process. Attempts to discontinue vasopressin should occur when the dose(s) of adrenergic agent(s) has been minimized (e.g., dopamine ≤ 5 mcg/kg/min, norepinephrine ≤ 0.1 mcg/kg/min, phenylephrine ≤ 1 mcg/kg/min, epinephrine ≤ 0.15 mcg/kg/min). At present, vasopressin should not be initiated as first-line therapy or added to existing therapy solely because a patient is septic.

Corticosteroids

12 Corticosteroids can be initiated in cases of septic shock when adrenal insufficiency is present or when weaning of vasopressor therapy proves futile.⁴⁶ Adverse events are few because corticosteroids are administered for a finite period of time, usually 7 days. Acutely, elevated serum concentrations of blood urea nitrogen, white blood cell count, and glucose occur. Although long-term administration of corticosteroids is associated with several chronic disease states, a meta-analysis did not show an increase in adverse events, including gastrointestinal hemorrhage and infections (RR 0.93, 95% CI 0.73–1.18; $P = 0.54$), impacting critically ill patients.⁴⁸ Therefore, therapy of septic shock with corticosteroids improves hemodynamic variables and lowers catecholamine vasopressor dosages with minimal to no effect on patient safety.

EXPERIMENTAL THERAPIES

NITRIC OXIDE SYNTHASE INHIBITORS

NO is a short-acting, potent vasodilator derived from enzymatic oxidation of arginine. Its production is under control of NOS. This

enzyme is present (expressed) in two forms: a constitutive form (eNOS) and an inducible form (iNOS). Small amounts of NO normally are produced by the vascular endothelium under the control of eNOS for physiologic control of vascular tone and blood flow distribution. Under pathophysiologic conditions such as stimulation by lipopolysaccharide or cytokines, iNOS becomes diffusely expressed, producing large amounts of NO. The latter has been implicated in the cardiovascular failure of septic shock.^{102–104}

Pharmacologic inhibition of NO production has been investigated as an adjunct to standard therapies of septic shock. L-Arginine analogs such as monomethyl-L-arginine (L-NMMA) and L-arginine-methylester (L-NAME) are competitive inhibitors of NOS and have been shown to increase blood pressure, partially restore vascular reactivity, and reduce vasopressor use.^{102–104} However, because these arginine analogs nonselectively block eNOS and iNOS, their use has been associated with extensive vasoconstriction, decreased CO, and regional hypoperfusion, thus promoting organ failure and mortality.^{102–104} Some S-substituted thiourea derivatives have demonstrated, both in vitro and in vivo (rodent), dose-dependent selectivity for iNOS inhibition, but the clinical application must be evaluated. A phase I/IIa clinical trial of septic shock patients is underway (see www.medinox.com).

METHYLENE BLUE

Methylene blue counteracts eNOS, iNOS, and soluble guanylate cyclase to reduce serum concentrations of NO and cyclic guanosine monophosphate. Despite these effects, methylene blue does not alter the expression of inflammatory cytokines.¹⁰⁵ Clinically, methylene blue at doses of 0.25 to 3 mg/kg/h increases SVR, MAP, myocardial contractility, and DO₂ in septic shock patients refractory to vasopressors.^{105–108} Additional studies are needed before methylene blue can be recommended; at present it has been used only for salvage therapy.

TERLIPRESSIN

Terlipressin, an investigational prodrug that is converted into lysine vasopressin, has been used in septic shock patients.¹⁰⁹ This drug has a half-life of 6 hours and acts via vascular V₁ receptors and renal tubular V₂ receptors.¹¹⁰ In one report, terlipressin 1 mg was given intravenously to 15 patients with norepinephrine-resistant septic shock.¹¹⁰ Terlipressin increased MAP at 30 minutes, and the effect lasted for 24 hours. Despite a decrease in CO, terlipressin increased gastric mucosal perfusion, urine production, and creatinine clearance. An open-label study randomized 20 septic shock patients after fluid resuscitation to terlipressin 1 mg or norepinephrine after fluid resuscitation.¹¹¹ Despite significant decreases in heart rate, cardiac index, and DO₂I with terlipressin, blood pressure was increased to a greater extent than with norepinephrine.¹¹¹ Both agents improved urine production and decreased serum lactate concentration. These preliminary findings suggest that a clinical trial evaluating mortality as well as hemodynamic effects should be conducted.

LEVOSIMENDAN

Levosimendan is a novel inotropic and vasodilator calcium-sensitizing drug. In acute decompensated heart failure, it improves cardiac contractility by sensitizing troponin C to calcium. A blinded study randomized 28 septic shock patients with left ventricular dysfunction despite at least 48 hours of conventional therapy that included dobutamine to levosimendan 0.2 mcg/kg/min or dobutamine 5 mcg/kg/min for 24 hours.¹¹² At the same MAP, levosimendan decreased PAOP, increased LVEF and cardiac index, improved PCO₂ gap, and enhanced urine production. Additional clinical trials of levosimendan in septic shock are needed.

DOPEXAMINE AND ISOPROTERENOL

Dopexamine is a structural and synthetic analog of dopamine that exerts systemic vasodilation through stimulation of β_2 -adrenoceptors and peripheral D₁ and D₂ receptors and weak inotropic properties through stimulation of β_1 -adrenoceptors. It has been used in patients with acute heart failure and septic shock. Similar to dobutamine, dopexamine is administered in combination with a vasopressor agent in septic shock. In small studies of septic shock, dopexamine produced a dose-related (range 2–6 mcg/kg/min) increase in cardiac index, stroke volume, and heart rate, as well as a decrease in SVR over the course of 0.5 to 1 hour while the dosages of other vasopressors were kept constant.^{113–118} The increase in myocardial oxygen demand is less than with dopamine, but tachycardia and tachydysrhythmia may lead to myocardial ischemia, especially when ischemic heart disease is present. Global oxygen-transport variables are similar to those of dopamine: DO₂ increases but VO₂ increases insufficiently, resulting in impaired O₂ER. The combined β_2 -adrenoceptors and peripheral D₁ agonistic effects of dopexamine should improve distribution of blood flow. However, the results of studies of dopexamine use in septic shock failed to show preferential increase in splanchnic blood flow.^{115–118} In fact, gastric pHi was lowered. When administered over 7 days, dopexamine had no impact on gastrointestinal barrier and renal function.¹¹⁸ Therefore, initial data do not support a role for dopexamine in improving regional hemodynamics and blood flow, but studies continue to investigate dopexamine as an alternative therapy for septic shock.

Isoproterenol is a synthetic catecholamine that stimulates only β_1 - and β_2 -adrenoceptors to produce vasodilatory and inotropic effects. Although not thought of as a traditional agent for managing septic shock, isoproterenol has received attention because of the concepts of early goal-directed therapy.¹⁹ The strong β -adrenergic effects of isoproterenol make it a potential alternative to dobutamine for optimizing DO₂ in patients with low SvO₂ despite use of other therapies (e.g., fluid resuscitation, vasopressors, red blood cell transfusion). A study of 14 patients with septic shock and SvO₂ <70% despite volume administration, norepinephrine, and red blood cell transfusion showed that adding isoproterenol over a 12-hour period increased SvO₂, cardiac index, and stroke index without increasing heart rate or causing myocardial ischemia.¹¹⁹ Although these results are intriguing, additional studies are needed to define the role of isoproterenol, especially considering that dobutamine has become standard therapy for early goal-directed therapy. At present, isoproterenol is an agent of last resort.

OTHER THERAPIES

As with vasopressin and cortisol, critical illness impairs hypothalamic–pituitary function, producing relative deficiencies of triiodothyronine (T₃) and thyroxine (T₄). This condition, referred to as *euthyroid sick syndrome*, may contribute to hypotension.¹²⁰ Concentrations of thyrotropin-releasing hormone and thyroid-stimulating hormone are inappropriately low. Measured concentrations of free T₃ and T₄ may be low or normal, but synthesis is consistently impaired. Only scant data regarding the replacement of these hormones in critically ill patients are available, and the results are variable depending on the extent of additional hormone replacement (growth hormone, gonadotropin-releasing hormone, leptin, insulin, thyrotropin-releasing hormone, and thyroid-stimulating hormone). Given the data for replacing vasopressin and cortisol in septic shock, it is reasonable to assume that one day a “thyroid replacement” regimen will be offered as an adjunctive treatment to vasopressors.

Drotrecogin alfa (activated) or activated protein C has been established as a treatment of severe sepsis because it reduces mortality when used early in patients with at least two organ dysfunctions or an

Acute Physiology and Chronic Health Evaluation (APACHE) II score of 25.¹²¹ Drotrecogin alfa (activated) promotes fibrinolysis, inhibits coagulation, and modulates inflammation. Animal studies suggest that inhibition of TNF- α and inactivation of iNOS by drotrecogin alfa (activated) prevents endotoxin-induced hypotension. A study of 22 septic shock patients treated with drotrecogin alfa (activated) showed that the norepinephrine dose decreased 33% over 24 hours.¹²² In contrast, the norepinephrine dose increased 38% in the matched control group despite MAP values similar to the drotrecogin alfa (activated) group. Although these results deserve further investigation, drotrecogin alfa (activated) likely will never be administered solely for hemodynamic support of septic shock patients because it is an expensive agent with concerns of hemorrhage as a side effect. Ultimately, patients who “qualify” for drotrecogin alfa (activated) will receive it irrespective of hemodynamic effect.

GENERAL CONCLUSIONS AND RECOMMENDATIONS

The choice of vasopressor or inotropic agent in septic shock should be made according to the needs of the patient (Fig. 25–2). The traditional algorithm suggests a stepwise approach, first using dopamine and then norepinephrine. Dobutamine is added for low CO states or to optimize SvO₂/ScvO₂. Occasionally, epinephrine and phenylephrine are used when necessary. Although this approach is empirical, it is used broadly in clinical practice and has been justified by the desire to avoid strong vasoconstriction and by the

sense of safety resulting from graded doses of dopamine. This dose-response relationship, however, has never been established in critically ill patients. In addition, observations of improved outcomes with norepinephrine and decreased regional perfusion with dopamine are calling into question the use of dopamine as a first-line agent. Although goal-directed therapies to supranormal values cannot be recommended, developing a strategy to titrate therapy early in the course of illness to predetermined values is an acceptable approach. For all catecholamine vasopressors, doses higher than recommended traditionally are required for goal-directed therapy to MAP and for normalization of oxygen-transport variables, DO₂, and VO₂. Attainment of supranormal DO₂ and VO₂ values is difficult in most patients, even when large doses are used. Patients who develop supranormal DO₂ and VO₂ values have lower mortality, but whether this effect is achieved intrinsically or with exogenous administration of vasopressors/inotropes appears inconsequential. Therefore, goal-directed therapy to supranormal oxygen-transport variables cannot be recommended because little or no benefit has been demonstrated. Further work is required to better elucidate the differential effects of vasopressors on regional hemodynamic and oxygen-transport values as measures of local tissue perfusion.

The algorithmic approach (Fig. 25–2) we recommend for use of vasopressors and inotropes in the hemodynamic support of critically ill septic patients is consistent with the recommendations made in the Surviving Sepsis Campaign⁵ and the American College of Critical Care Medicine’s guidelines to the hemodynamic support of adult patients with sepsis (Table 25–2).^{4,6} Although difficult to demonstrate, true differences in clinical outcomes as a result of differences in

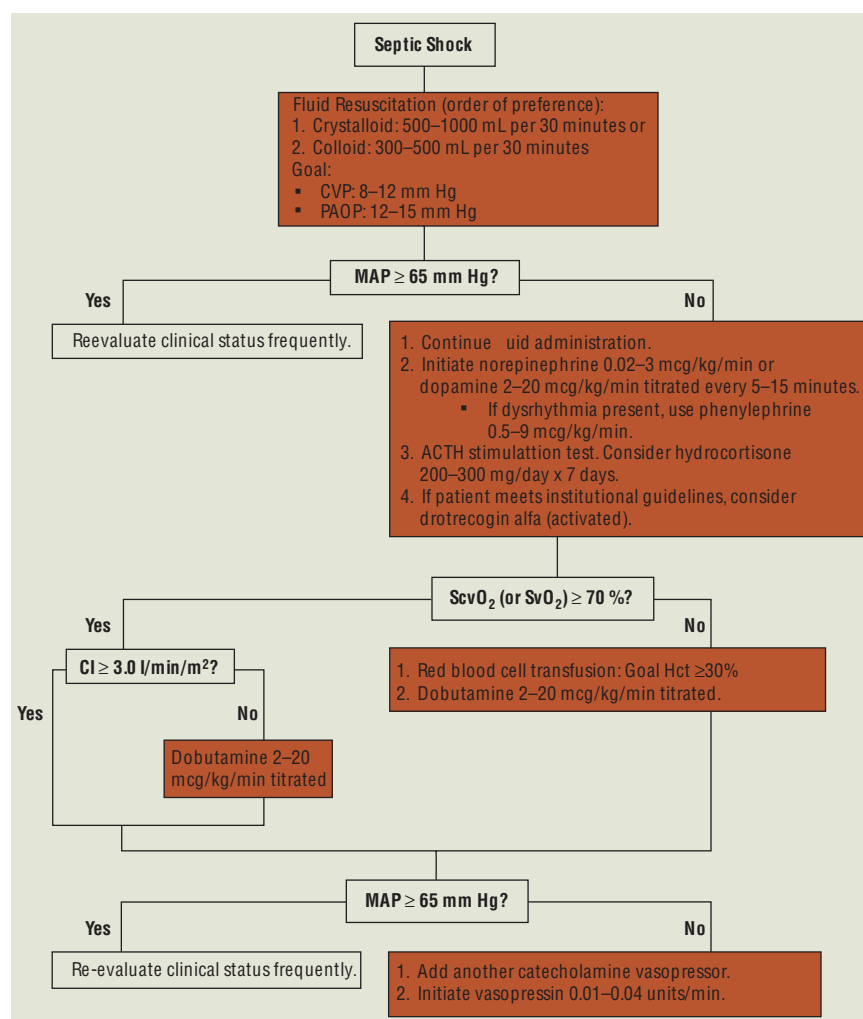

FIGURE 25-2. Algorithmic approach to resuscitative management of septic shock. Algorithmic approach is intended to be used in conjunction with clinical judgment, hemodynamic monitoring parameters, and therapy end points, as discussed in the text. (ACTH, adrenocorticotrophic hormone; CI, cardiac index; CVP, central venous pressure; Hct, hematocrit; MAP, mean arterial pressure; PAOP, pulmonary artery occlusive pressure; ScvO₂, central venous oxygen saturation; SvO₂, mixed venous oxygen saturation.) (Figure based on data from references 4–6 and 19.)

the pharmacologic activity of vasopressors and inotropes may exist. For example, evidence suggests that norepinephrine, when used appropriately with fluid replenishment, is safe and effective in treating septic shock; it decreases mortality, particularly when started early in the course of septic shock. It is effective in optimizing hemodynamic variables and improving systemic and regional (e.g., renal, gastric mucosal, and splanchnic) perfusion. Epinephrine causes a greater increase in the cardiac index and DO_2 and increases gastric mucosal flow but may not preserve splanchnic circulation adequately. Epinephrine may cause a short-lived increase in lactic acid that resolves in 24 hours, and no difference in clinical outcome has been documented. Epinephrine may be particularly useful when used earlier in the course of septic shock in young patients and in those with no known cardiac abnormalities. Unlike epinephrine, dopamine does not increase the proportion of CO that preferentially goes to the splanchnic circulation. The ability of dopamine to increase CO by no more than 35% accompanied by a tachycardia or tachydysrhythmias limits its utility. Dopamine, as opposed to norepinephrine, has been shown to worsen splanchnic VO_2 and O_2ER and is of limited value in improving urine production. Low-dose dopamine has not been shown consistently to increase the glomerular filtration rate, does not prevent renal failure, and actually worsens splanchnic tissue oxygen utilization. Low-dose dopamine should not be used. Phenylephrine should be used when a pure vasoconstrictor is desired in patients who may not require or cannot tolerate the β -effects of dopamine or norepinephrine with or without dobutamine. In patients with a high filling pressure and hypotension, the combination of phenylephrine and dobutamine may be useful.

Shortcomings of study methodology prevent the establishment of definitive conclusions. As a consequence, published guidelines for the management of severe sepsis and septic shock have many inconclusive recommendations (Table 25–2). Short infusions (not exceeding 2 hours) during studies may show differences that are not clinically significant after 24 hours, as demonstrated for epinephrine and dobutamine. Clinically, vasopressors and inotropes are used for hours to days. Possible confounding factors are the variable times at which studies are initiated with respect to the stage of sepsis or septic shock, the inherent differences in circulating catecholamine concentrations, changes in receptor activity, as well as differences in prestudy duration and type of exogenous catecholamine administration.

Initial uncontrolled studies with vasopressin suggest a potential role in the management of vasopressor-refractory septic shock patients, although further data are needed. Vasopressin appears to reduce the requirements of adrenergic agents, but few studies demonstrate complete discontinuation of these therapies. Therefore, vasopressin should be used only if response to one or two adrenergic agents is inadequate or as a method for reducing the dose of these therapies. Close monitoring of ischemic events is needed. Data indicate that moderate doses of hydrocortisone (200–300 mg/day) administered over 5 to 7 days may reverse septic shock and dependency on vasopressor agents, particularly in patients with relative adrenal insufficiency. As a result of a recent multicenter study, the presence of adrenal insufficiency to indicate therapy with corticosteroids is controversial and the authors believe testing of adrenal function will not be recommended in future consensus statements. Data on optimal dosing and definitive outcomes still are needed.

Further pharmacotherapeutic and outcomes studies are required to elucidate the place in therapy of individual vasopressors and inotropes or their combinations in the supportive care of patients with bacteremia or septic shock. As supportive therapy, it is imperative that primary therapy aimed at the source of (antimicrobials) and consequences of (anticytokines) infection be initiated quickly to afford the patient the best chance of survival. Once this goal is accomplished, we will need to direct our efforts to pharmacoeconomics and the cost effectiveness of these therapies.

ABBREVIATIONS

ACTH:	adrenocorticotrophic hormone
APACHE:	Acute Physiology and Chronic Health Evaluation
ATP:	adenosine triphosphate
CaMK:	calcium/calmodulin-dependent protein kinase
cAMP:	cyclic adenosine monophosphate

BRIAN L. ERSTAD

KEY CONCEPTS

- 1 Plasma does not have to be lost from the body for hypovolemic shock to occur.
- 2 Patients may die of hypovolemic shock despite having normal serum electrolyte concentrations.
- 3 Although the Starling equation of fluid transport is useful for understanding the factors involved in fluid shifting between compartments, it is not a practical tool for use in the clinical setting.
- 4 Patients may have complications and death as a result of reperfusion injury as well as the initial insult.
- 5 The clinical presentation of patients with hypovolemic shock can vary substantially depending on concomitant disease states, medications, and cause of hypovolemia.
- 6 The initial monitoring of a patient with suspected volume depletion always should include vital signs, urine output, mental status, and physical examination.
- 7 The need for intravenous (versus oral) rehydration in children often is overestimated.
- 8 Crystalloid (sodium-containing) solutions should be used for most forms of circulatory insufficiency that are associated with hemodynamic instability.
- 9 Crystalloid solutions are preferred over colloid solutions for circulatory insufficiency as a result of decreased plasma volume.
- 10 With adequate fluid administration, vasoactive medications usually are not needed for the patient with circulatory insufficiency as a result of decreased plasma volume.

This chapter discusses the assessment and management of hypovolemic shock. Spinal shock resulting from loss of sympathetic activity and anaphylactic shock resulting from increased vascular permeability often are considered separately from hypovolemic shock because fluid loss from the body is not necessary for their occurrence. Although these forms of shock are not discussed in detail, it is important to note that the initial therapy for both is the same as for hypovolemic shock (i.e., adequate volume replacement) because circulating volume is decreased. In this regard, adequate fluid

resuscitation to maintain circulating blood volume is a common principle in managing all forms of shock.

EPIDEMIOLOGY

Because shock is not a reportable category by state and federal agencies that track causes of death, the incidence is unknown. Estimates of deaths due to shock are complicated by differences in definitions and classification systems. Part of the problem is defining when progressive circulatory insufficiency results in the loss of normal compensatory responses by the body, which could reverse the processes leading to irreversible organ dysfunction. This loss of appropriate compensation varies from patient to patient and is not always readily apparent during the initial patient presentation. Therefore, forms of hypovolemic shock, such as hemorrhagic shock, are subsumed by more readily identifiable categories of death, such as accidental injuries and homicides. Crude and conservative estimates of death due to hypovolemic shock are available for some of its forms. At least 100,000 deaths each year in the United States are due to perioperative bleeding,¹ and approximately 5,000 deaths are due to hyperthermia and dehydration associated with heat exposure.² The figures are much higher when considered on a global basis. For example, electrolyte depletion and dehydration due to diarrheal disease result in approximately two million deaths each year in children younger than 5 years.³ The most liberal estimates of death include all causes of circulatory failure (i.e., the last stage of shock).

ETIOLOGY

- 1 Hypovolemic shock may result from blood loss (plasma and red blood cells) due to trauma, surgery, or internal hemorrhage or from plasma loss due to fluid sequestered within the body or lost from the body (Table 26-1). In some cases, such as in postoperative patients, a number of these problems occur at the same time. For example, a patient may have blood loss secondary to trauma or surgery, with additional fluid being third spaced (e.g., as tissue edema in the gastrointestinal tract with a concomitant ileus) and lost through a

TABLE 26-1 Causes of Hypovolemic Shock^a

Decreased blood (plasma + red blood cells) volume
External: Surgery or trauma
Internal (e.g., gastrointestinal bleeding)
Decreased plasma volume
External: Losses from urine, gastrointestinal tract (e.g., vomiting, nasogastric suctioning, fistula, diarrhea), lungs, or skin (including thermal injury)
Internal (decreased oncotic pressure or increased capillary permeability): fluid accumulation in bowel, peritoneal or pleural cavities

^aShock may result from various combinations of blood and plasma volume losses listed (i.e., causes are not mutually exclusive).

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

high-output gastrointestinal fistula postoperatively. As this example of third-spaced fluid indicates, fluid (i.e., plasma) does not have to be lost from the body for a person to develop hypovolemic shock, although the fistula output would clearly aggravate the situation. Approximately 20 L of fluid is secreted and reabsorbed daily in the gastrointestinal tract, so it is not surprising that volume loss could be substantial depending on the location of the fistula and function of the tract preceding the fistula.

Dehydration may result from primary water deficiency, usually because of decreased intake, but in some instances (e.g., diabetes insipidus) may result from increased losses of water. With most forms of dehydration, such as those caused by diarrheal disease and heat-related illness, a combination of inadequate intake and higher than normal losses occurs. In general, the term *dehydration* implies intracellular and interstitial fluid depletion, in contrast to *volume depletion*, which implies extracellular, and particularly intravascular, sodium and water loss. In the case of primary water deficit, cell dehydration occurs. Initially, the patient may be thirsty and possibly have some mental status changes, such as confusion. If cellular dehydration occurs slowly, intracellular substances, referred to as *idiogenic osmols*, develop that limit progressive complications (e.g., cerebral edema or coma). Death due to primary water deficit, if it occurs, is usually a result of delayed circulatory failure. With combined water and salt deficiencies, such as might occur with gastrointestinal (e.g., diarrhea) and skin losses (e.g., heat stroke), interstitial and intravascular depletion is an early occurrence. Fortunately, dehydration is relatively easy to prevent with routine vigilance and water replacement compared with some of the other causes of shock.

PATHOPHYSIOLOGY

2 Hypovolemic shock often is described in terms of monitoring parameters such as lowered blood pressure, but patients with shock may die despite normal surrogate markers of circulatory insufficiency. Therefore, an appropriate definition should mention the underlying problem, which is inadequate tissue perfusion resulting from circulatory failure. In the case of hypovolemic shock, the cause of the altered perfusion is fluid (or volume) depletion resulting from trauma, surgery, thermal injury, or some form of dehydration. Figure 26–1 provides a simplified view of the pathophysiology of circulatory insufficiency. Cell damage and death may occur from the primary insult or from reperfusion injury. The latter problem is associated most frequently with trauma and blood loss that cause the release of a multitude of mediators of inflammation and injury that have complex interactions. Cells have varying responses to hypoxia, ranging from astrocytes that quit functioning almost

immediately to hepatic cells that may function for several hours after injury.⁴ Left unmitigated, cell death occurs.

The body attempts to compensate for volume depletion beginning with autoregulatory changes involving smaller blood vessels. When the cause of circulatory insufficiency continues unabated, local mechanisms eventually fail to provide adequate compensation, and macrocirculatory changes ensue. Approximately 75% of blood volume is contained in venous capacitance vessels, with gravity being the major impediment to flow back to the heart.⁴ With increasing volume depletion, blood flow to the heart (preload) is decreased, with subsequent activation of baroreceptors and chemoreceptors leading to sympathetic discharge. Also, fluid shifting from the interstitial space to the intravascular space occurs through a phenomenon known as *transcapillary refill*, and hormones (e.g., adrenocorticotrophic hormone, angiotensin, catecholamines, and vasopressin) that cause sodium and water retention by the kidneys are released. The phenomenon of transcapillary refill means that the body can have fluid losses exceeding normal plasma volume. These responses cause alterations in stroke volume, heart rate, and peripheral vascular resistance so that blood pressure and hence tissue perfusion can be maintained.

The microcirculatory changes associated with shock are complex and difficult to study. Although some mediators such as endothelin-1 cause vasoconstriction, other mediators, such as adenosine and nitric oxide, yield vasodilation.⁵ These changes result in hypoperfusion or hyperperfusion depending on the area. As these microcirculatory changes fail to maintain adequate organ perfusion, more widespread sympathetic nervous system activation and vasoconstriction ensue. Failure to respond to sympathetic stimulation and fluid administration is indicative of the vasodilation that occurs in the final phase of circulatory failure leading to death.

The factors involved in fluid shifting between the intravascular and interstitial spaces are described by the modified Starling equation:

$$J_v = K_{fc} [(P_c - P_t) - [\sigma(\pi_c - \pi_t)]]$$

where J_v = net transvascular flow rate (cannot be measured in the clinical setting)

K_{fc} = capillary filtration coefficient for fluids (cannot be measured in the clinical setting)

P_c = capillary hydrostatic pressure (indirectly estimated in the clinical setting, e.g., pulmonary artery occlusive pressure)

P_t = tissue hydrostatic pressure (cannot be measured in the clinical setting)

σ = reflection coefficient for proteins (cannot be measured in the clinical setting)

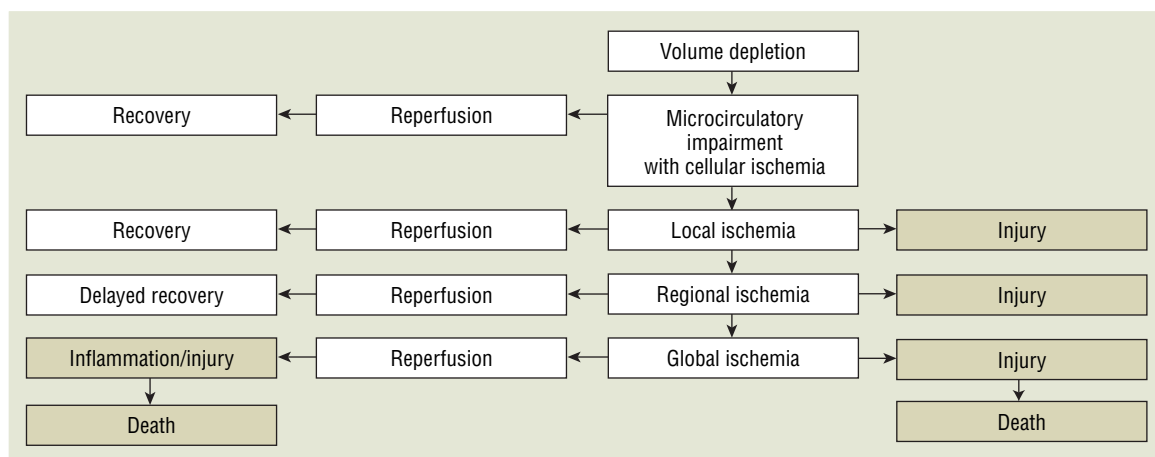

FIGURE 26-1. Pathophysiology of circulatory insufficiency.

π_c = plasma colloid osmotic pressure (not usually measured in the clinical setting, but technology is available)

π_t = tissue colloid osmotic pressure (cannot be measured in the clinical setting)

Proteins act as oncotic agents in each of these spaces to attract fluid, whereas hydrostatic forces push fluid into or out of the vessels. The equation has distinct permeability values for water and protein because each crosses the vascular membrane at a different rate. The values for the variables listed in the equation are not the same for capillaries in all parts of the body. For example, on a scale from 0 to 1 with 0 being free passage of protein and 1 being impermeable to protein, the typical value for the reflection coefficient in most capillaries is >0.9 . However, in the pulmonary capillaries the value is closer to 0.7 and approaches 0 in inflammatory states associated with increased capillary permeability.⁶ As the value approaches 0, the capillaries are freely permeable not only to the usual fluid and electrolytes but to plasma proteins such as albumin. Because albumin accounts for approximately 80% of the plasma oncotic pressure, its free passage into the interstitial space effectively negates its intravascular oncotic benefit. **3** Although the Starling equation is useful to practitioners in terms of understanding the factors involved in fluid shifting between compartments, the rate and direction of transvascular flow cannot be calculated accurately in the clinical setting because most factors cannot be measured directly and the values for the factors vary in different capillaries in the body.

The body's compensatory mechanisms may have beneficial and harmful consequences. For example, cardiac output can be increased substantially by increases in stroke volume or heart rate. Although this may be useful for providing blood flow to inadequately perfused tissues, it may cause large increases in oxygen consumption by the heart that could aggravate preexisting ischemia in patients with underlying coronary artery disease (CAD). Another example is the sympathetic nervous system-mediated vasoconstriction that causes blood to shift from the skin, skeletal muscle, and some internal organs such as the kidneys and gastrointestinal tract to organs (e.g., heart and brain) that are less tolerant of inadequate flow. If the vasoconstriction continues unabated, the hypoperfused organs eventually become damaged. Figure 26-2 provides an overview of the compensatory changes that occur with a loss of circulating blood volume.

4 In addition to the more acute implications of hypovolemia and attendant complications, reperfusion damage is likely to occur particularly after prolonged resuscitation attempts. In addition to oxygen free radical damage of cell membranes, a number of cellular (e.g., white blood cells and platelets) and humoral (e.g., procoagulants, anticoagulants, complement, and kinins) components are activated, causing the release of other inflammatory mediators.⁵ The resulting reperfusion injury may range from readily reversible organ dysfunction to multiple-organ failure and death.

Although the basic pathophysiology is similar for the various causes of hypovolemic shock, there are unique considerations relative to each. For example, whereas isolated head injuries associated with trauma typically do not result in substantial blood loss or shock, pelvic fractures may sequester several liters of blood as hematoma formation.⁵ Patients with traumatic or thermal injuries, as well as postoperative patients, may have substantial fluid accumulation in sites where the fluid cannot be readily transferred back into blood vessels (i.e., third-spaced fluid) for maintaining pressure. With these types of injuries, prompt control of compressible bleeding sources with rapid patient transfer to the hospital for definitive treatment may preclude the cascade of events leading to shock. Indeed, with trauma patients, a "scoop and run" approach that places a priority on rapid transport to a hospital is used by most urban hospitals.

In the case of hemorrhagic shock, prompt attention must be given to cell as well as plasma losses. Red blood cells lost during the bleeding episode may lead to ischemic damage in vital organs.

FIGURE 26-2. Activation of compensatory mechanisms with loss of circulatory volume. Certain stages may be absent depending on a number of factors, such as age, preexisting disease states, and cause of circulatory insufficiency. (ACTH, corticotropin; BP, blood pressure; CO, cardiac output; HR, heart rate; PVR, peripheral vascular resistance; RR, respiratory rate.)

Packed red blood cell transfusions may be needed to increase the oxygen-carrying capacity of the blood because oxygen transport is a function not only of cardiac output but also of hemoglobin concentration and saturation and of hemoglobin affinity for oxygen.

Clotting factors and platelets are also lost in hemorrhage. The resulting bleeding problems may be aggravated by the dilutional effect of fluid resuscitation on clotting factor activity. Fresh-frozen plasma that contains necessary clotting factors and platelets is often needed in massive blood loss to restore adequate coagulation. On the other hand, trauma patients are at increased risk for deep vein thrombosis and pulmonary embolism caused by multiple factors,

including vessel damage, abnormal blood flow patterns, and the hypercoagulable state associated with injury. Therefore, some form of venous thromboembolism prophylaxis usually is indicated in multiple-trauma patients or patients with severe single-system injuries (e.g., spinal cord damage).

The pathophysiology becomes more complicated if the severity of shock is sufficient to require admission to the intensive care unit (ICU) after initial resuscitation or surgery. Most patients admitted to the ICU have a systemic inflammatory response syndrome (SIRS), which is the body's response to injury. This syndrome is defined by a number of hypermetabolic changes reflected in the patient's temperature, white blood cell count and differential, and respiratory and heart rates. The stress response involves complex interactions between the nervous system and immunomodulating substances and has similar (if not the same) harmful and helpful consequences described with reperfusion following shock. If the underlying problems are left untreated, the patient with SIRS may develop multiple-organ dysfunction syndrome (MODS) during the final stages of illness.

CLINICAL PRESENTATION

5 The initial presentation of patients with suspected volume depletion can vary markedly depending on factors such as age, concomitant disease states and medications, and the etiology and rapidity of depletion (see Clinical Presentation box). Intravascular depletion as a consequence of blood loss is signified by postural vital sign changes, and such measurements should be performed unless the diagnosis is obvious, as in the case of bleeding associated with trauma. Early signs and symptoms of dehydration and intravascular depletion caused by gastrointestinal or urinary losses often are relatively nonspecific. Plasma volume losses of <10 mL/kg of body weight usually are associated with minor signs and symptoms of distress. Larger losses are not likely to be well tolerated (Table 26–2), particularly in patients older than 65 years. An 18-year-old athlete and a 65-year-old sedentary individual are likely to have much different responses to a similar amount of fluid loss. The young patient may lose one fourth of his or her circulating blood volume with minimal changes in arterial blood pressure and a relatively low heart rate. However, the elderly patient may have orthostatic changes in blood pressure that are not well tolerated by organs such as the kidneys.⁴ Unfortunately, this same elderly patient may not have common signs and symptoms of volume depletion, such as skin turgor changes or thirst, but instead may have more subtle changes (e.g., mental status alterations).

CLINICAL PRESENTATION OF HYPOVOLEMIC SHOCK

General

- The initial presentation of adult patients with suspected volume depletion could vary markedly depending on factors such as age, concomitant disease states and medications, and the etiology and rapidity of depletion.
- Plasma volume losses of <10 mL/kg of body weight usually are associated with minor signs and symptoms of distress.

Symptoms

- Patients may present with thirst, nausea, anxiousness, weakness, light-headedness, and dizziness.
- Patients may report scanty urine output and dark-yellow urine.

Signs

With more severe volume loss:

- Patients would have marked increases in heart rate (e.g., >120 beats/min) and respiratory rate (e.g., >30 breaths/min).

- Blood pressure would be decreased (e.g., systolic blood pressure <90 mm Hg).
- Mental status changes or unconsciousness may occur.
- Agitation may be present if the patient is conscious.
- Body temperature would be low or normal [e.g., 36° to 37°C (96.8° to 98.6°F)] in the absence of concomitant infection.

Laboratory Tests

- Sodium and chloride concentrations usually are high with acute depletion but may be low or normal depending on type of fluid intake.
- The ratio of blood urea nitrogen (BUN) to creatinine is likely to be elevated initially, but the creatinine level would increase as renal dysfunction occurs.
- The complete blood count should be normal in the absence of concomitant disease states such as infection; in hemorrhagic shock, the red cell count, hemoglobin, and hematocrit would decrease over time.
- With more severe volume depletion, other organs may become dysfunctional, which may be reflected in laboratory testing (e.g., elevated transaminase levels with hepatic dysfunction).

Other Diagnostic Tests

- Urine output would be decreased to <0.5 to 1 mL/h.

The diagnosis of dehydration and intravascular depletion in children is complicated by difficulties in obtaining an accurate history. However, some excellent resources are available for healthcare providers, such as the Centers for Disease Control and Prevention (CDC) guidelines (www.CDC.gov), which discuss the evaluation and management of diarrhea in patients of all ages. In younger children, parental observations are important for estimating fluid deficits and deciding whether hospitalization is necessary. Fortunately, prospective data suggest that parental histories are predictive of acidosis and the need for hospitalization.⁷ **6** Regardless of patient age or preexisting conditions, the initial monitoring of a patient with suspected volume depletion should include the following noninvasive param-

TABLE 26-2 Acute Circulatory Insufficiency: Initial Presentation and Therapy^a

	Mild	Severe
Plasma/blood loss	10 mL/kg adult 20 mL/kg child	30 mL/kg adult 35 mL/kg child
Mental status/level of consciousness	None—small changes (e.g., anxious, irritable)	Marked changes (e.g., confusion to unconsciousness)
Vital signs/orthostatic changes	Minor changes	Marked changes
Therapy	20 mL/kg lactated Ringer IV ^a over 10–15 min Unlikely to need blood cell replacement even if hemorrhagic loss	Lactated Ringer IV as rapidly as possible until response in adult, then decrease rate of infusion 20 mL/kg lactated Ringer IV in child (repeat quickly if minimal response); likely to need blood cell replacement and surgery if hemorrhagic

^aPatients may have intermediate degrees of volume loss in addition to those listed, but the amount of loss often is difficult to quantify. The presentations may also vary greatly in patients with similar amounts of loss (young athlete vs sedentary, elderly person). In patients particularly prone to complications associated with fluid overload, the fluid can be administered in multiple smaller boluses titrated to clinical response. See text for a more in-depth discussion of some of the guidelines in this table.

FIGURE 26-3. Noninvasive assessment of circulatory insufficiency.

ters: vital signs, urine output, mental status, and physical examination (Fig. 26–3).

Although the presenting signs and symptoms of circulatory insufficiency are variable, patients usually have decreased blood pressure, increased heart and respiratory rates, and a normal or low-normal temperature (e.g., 36° to 37°C [96.8° to 98.6°F]) in the absence of infection, exposure to extremes of temperature, and medications that impair thermoregulation. As mentioned earlier, recordings of vital signs must be interpreted in light of known or suspected baseline conditions. For example, alcohol, β -blockers, butyrophenones such as haloperidol, diuretics, and medications with anticholinergic effects may impair thermoregulation.⁸ Medications such as β -blockers and calcium channel blockers may alter resting blood pressure and heart rate, as well as the subsequent response to therapeutic interventions.

Although a blood pressure reading of 110/70 mm Hg (systolic/diastolic) may be acceptable in many patients, it may be inadequate in a patient with preexisting hypertension who normally has a blood pressure of 170/105 mm Hg. At the other extreme, patients with very low blood pressure may have inaudible or inaccurate determinations with cuff (sphygmomanometric) measurements. Chapter 15 details blood pressure measurement (e.g., cuff size, position). In this case, intraarterial monitoring is indicated. As a noninvasive tool, the respiratory rate may correlate better than the heart rate with volume loss, but respiratory rate often is not used.⁴ The respiratory rate may be elevated because of anxiety or as a compensatory mechanism for the metabolic acidosis caused by lactic acidosis associated with poor tissue perfusion.

Although the kidneys continually produce urine, the bladder stores the urine for intermittent elimination. For the initial diagnosis and management of acute circulatory insufficiency, a catheter can be inserted into the bladder for measuring urine output. In contrast to thirst, which is a relatively insensitive indicator of volume depletion, urine output is generally diminished with inadequate fluid administration and increases with appropriate resuscitation. This presumes, of course, that acute renal failure or medications such as diuretics are not altering the expected response. Adults should produce at least 0.5 to 1 mL/kg/h of urine, whereas children up to 12 years of age should produce at least 1 mL/kg/h (2 mL/kg/h if younger than 1 year).

Mental status changes associated with volume depletion, if present, may range from subtle fluctuations in mood to unconsciousness. Although the latter finding typically is indicative of more severe depletion, less dramatic findings should not be interpreted as indicating mild fluid deficits. Losses of 4 L of plasma volume may be associated only with lassitude in an otherwise healthy adult patient.⁴ Similar interpretation difficulties must be considered when performing the initial physical examination. An orderly progression from warm, reddish skin with appropriate capillary refill (rapid

return of blood flow to the extremity after removal of compression) to cold, cyanotic discoloration with impaired refill may not occur. Also, dry mucous membranes in elderly patients may be caused by mouth breathing or medications and not by fluid depletion.

TREATMENT

Hypovolemic Shock

■ DESIRED OUTCOME

The desired outcomes of therapy for circulatory insufficiency that has led to hypovolemic shock are to prevent further progression of the disease with subsequent organ damage and, to the extent possible, to reverse organ dysfunction that has already taken place.

■ GENERAL APPROACH TO TREATMENT

Milder forms of volume depletion may be managed in outpatient settings. For example, supplemental fluids can be added to the usual estimated daily requirements of 30 to 35 mL/kg in patients older than 12 years with dehydration. Commercially available carbohydrate/electrolyte drinks generally are more palatable than water and may promote earlier recovery. The rationale for combining carbohydrates with sodium is based on the cotransport absorption mechanism in the intestinal tract. With diarrheal states in particular, sodium absorption is impaired. Because water follows sodium, the diarrhea is likely to continue despite oral crystalloid fluid administration until the intestinal pathology resolves. However, when dextrose and sodium are combined in 1:1 equimolar amounts, both are absorbed via the cotransport mechanism, which also allows for absorption of water. This concept forms the basis for the World Health Organization's (WHO) oral rehydration solution, which contains 75 mmol/L of dextrose, 75 mmol/L of sodium, 20 mmol/L of potassium, 65 mmol/L of chloride, and 10 mmol/L of citrate for a total osmolarity of 245 mOsm/L.³ Commercially available over-the-counter rehydration drinks for children in the United States also have an osmolarity of approximately 250 mOsm/L but typically contain 50 mEq/L or less of sodium, and the dextrose-to-sodium ratio often is 3:1. How these differences between commercially available formulations and the WHO rehydration formula might affect hospitalization rates is unclear, but attempts to alter the commercially available products to make them more consistent with the WHO formula are not recommended.³ Improper home mixing of a previous WHO formulation led to cases of hyponatremia.⁹ Outpatient rehydration of children usually is recommended for those with uncomplicated (e.g., vomiting less than 48 hours) acute gastroenteritis and relatively mild dehydration after the exclusion of more severe illnesses such as bowel obstruction. **7** The need for intravenous (IV) rehydration often is overestimated. Randomized studies conducted in pediatric emergency departments have found oral rehydration to be at least as effective as IV rehydration,^{10,11} and in one study children receiving oral rehydration for acute gastroenteritis had shorter lengths of stay than those receiving IV rehydration (225 versus 358 minutes; $P < 0.01$). Furthermore, there was a trend toward decreased hospital admissions in the oral compared with the IV rehydration group (11% versus 25%; $P = 0.2$).¹¹

Hospitalization is indicated for more severe forms of circulatory insufficiency. If access to the circulatory system for administration of fluids and medication was not obtained prior to hospitalization, this should be a priority. Venous access generally is obtained during the preliminary examination process that includes the ABCs of life support (i.e., airway, breathing, and circulation), assessment of vital signs and mental status, and determination of urine output after

TABLE 26-3 Fluid Distribution and Major Indications^a

Fluid	Intracellular	Interstitial	Intravascular	Major Indication
Normal saline or lactated Ringer 3% sodium chloride	None →	750 mL 750 mL+	250 mL 250 mL+	Intravascular repletion in symptomatic patients Small amounts (e.g., 250 mL) by intermittent infusion have been used in conjunction with normal saline or lactated Ringer for intravascular depletion in patients with head trauma
5% dextrose/0.45% sodium chloride	333 mL	500 mL	167 mL	Maintenance fluid in euvoletic or dehydrated (sodium and water loss) patients with mild signs/symptoms of volume depletion
5% dextrose	667 mL	250 mL	83 mL	Dehydration (primarily water loss) in patients with mild signs/symptoms of volume depletion
5% albumin 25% albumin	None →	None →	1,000 mL ^b 1,000 mL+++ ^b	Intravascular repletion in symptomatic patients Usually given by intermittent infusion of small volumes (e.g., 50–100 mL) or by continuous infusion titrated to response in hypovolemic patients with excess interstitial fluid accumulation

^aBased on administration of 1 L of each solution for comparative purposes only. This amount of fluid, particularly for 3% saline and 25% albumin, would be inappropriate and likely harmful if given over a short period of time. Numbers are approximations; arrows indicate direction of fluid shift and plus signs indicate fluid pulled from other compartments.

^bAfter distribution and attainment of steady-state conditions, 60% of albumin (and associated fluid) is in interstitial compartment and 40% is in intravascular compartment.

catheterization. Whenever large-volume fluid resuscitation is expected, as in hemorrhagic shock, at least two IV catheters are desirable. Because flow is a function of tubing length and catheter diameter, large-bore peripheral IV lines are preferred over longer central lines. Unfortunately, vascular access in some patients may be problematic, and other routes (e.g., intraosseous infusion in children) may be necessary. One interesting method of fluid administration that has been investigated in elderly patients is subcutaneous infusion, or hypodermoclysis. This route of administration is not used commonly, probably because of concerns of adverse effects that were found in early studies that used excessively hypotonic or hypertonic solutions. Although alternative methods of fluid administration, such as hypodermoclysis, are desirable, well-conducted trials are needed before such methods can be recommended for routine use.

■ PHARMACOLOGIC THERAPY

8 Dextrose-in-water solutions may be appropriate for uncomplicated dehydration caused by water deprivation, but crystalloid (sodium-containing) solutions should be used for forms of circulatory insufficiency that are associated with hemodynamic instability. In the latter situation, IV solutions with sodium concentrations approximating normal serum sodium values usually are indicated because they cause more expansion of the intravascular and interstitial spaces compared with dextrose solutions (Table 26-3). Lactated Ringer and normal saline solutions are examples of such crystalloid solutions, although lactated Ringer solution is typically the preferred solution for major bleeding because it is unlikely to cause the hyperchloremic metabolic acidosis that is seen with infusion of large amounts of normal saline (Table 26-4). A “large” amount of fluid does not mean a single bolus volume typically used as fluid challenge in a critically ill patient. An isolated bolus (e.g., 250 to 500 mL) in a young adult trauma patient is unlikely to cause a substantial change in blood pressure or acid–base balance.¹² Therefore, multiple fluid boluses usually are needed in such patients to achieve hemodynamic stability in the perioperative period.

Although lactated Ringer solution does contain lactate, it does not cause substantial elevations in circulating lactate concentrations when used as a resuscitation solution.¹³ Once adequate plasma volume has been restored by fluid administration, the body can readily clear the blood of the excess lactate that has accumulated from both anaerobic metabolism and from lactated Ringer solution. However, blood samples for lactate determinations drawn through catheters (arterial and venous) that have not been cleared appropriately may have spurious increases or decreases in lactate concentrations because of retained lactated Ringer and nonlactated solutions

(e.g., varying concentrations of dextrose-in-water or sodium chloride), respectively.¹⁴ Therefore, blood samples for lactate concentration determinations should be drawn from a catheter that has been cleared adequately (e.g., 5 mL) of infusate after temporarily stopping the fluid infusion.

A number of pharmacologic therapies show promise in animal models of shock, but few demonstrate success in subsequent trials involving patients with shock. In large part this is a result of the lack of acceptable animal models of shock that mimic the pathophysiology of patients.¹⁵ In cases in which a relevant animal model is available, care must be taken when extrapolating the information to forms of shock other than the one under study. This may be the problem with naloxone, which has been shown to raise blood pressure in some studies of shock but not in others. In light of the lack of other demonstrated pharmaceutical interventions, fluids remain the mainstay of therapy, although their use is not devoid of controversy.

Larger-molecular-weight solutions (i.e., >30,000) known as *colloids* have been recommended in conjunction with or as replacements for crystalloid solutions. Examples of colloids used as plasma expanders include albumin, hetastarch, and dextran. Albumin is known as a *monodisperse colloid* because all its molecules are of the same molecular size and weight (~67,000), whereas hetastarch and dextran solutions are *polydisperse compounds* with molecules of varying molecular size that are roughly proportional to molecular weight [average molecular weights of 450,000 (range 10,000 to 1 million) for hetastarch, 40,000 (range 10,000 to 90,000) for dextran 40, or 70,000 to 75,000 (range 20,000 to 200,000) for dextran 70 or dextran 75, respectively]. In light of these differences, colloid

TABLE 26-4 Adverse Effects of Plasma Expanders: Crystalloids

Normal saline
Primarily extensions of pharmacologic actions (e.g., fluid overload, dilutional coagulopathy)
Hyperchloremic metabolic acidosis (has 154 mEq/L of chloride)
Hypernatremia (has 154 mEq/L of sodium)
Lactated ringer
Primarily extensions of pharmacologic actions (e.g., fluid overload, dilutional coagulopathy)
Hyponatremia (has 130 mEq/L of sodium)
Aggravation of preexisting hyperkalemia (has 4 mEq/L of potassium)
Hypertonic saline
Primarily extensions of pharmacologic actions (e.g., fluid overload, dilutional coagulopathy; intracellular volume depletion)
Hypernatremia (has 513 mEq/L of sodium)
Hyperchloremia (has 513 mEq/L of chloride)

comparisons are based on weight-averaged [(number of molecules at each weight \times particle weight)/total weight of all molecules] or number-averaged (arithmetic mean of all particles weights) molecular weight.¹⁶ The size and weight differences of the colloids have important implications for the distribution of the products because lower-molecular-weight substances are retained in the intravascular space for a shorter period of time as a result of more rapid leakage across the vessel membrane. The theoretical usefulness of colloids is based on their increased molecular weight (average molecular weight in the case of hetastarch and dextran) that corresponds to increased intravascular retention time in the absence of increased capillary permeability compared with crystalloids. Even in patients with intact capillary permeability, the colloid molecules eventually will leak through the membrane. In the case of albumin with a distribution half-life of 15 hours in normal subjects, approximately 60% of administered albumin molecules (and associated fluid) would be shifted to the interstitial space within 3 to 5 days of exogenous administration. In patients with altered permeability (e.g., acute respiratory distress syndrome), the leakage of albumin from the intravascular to the interstitial space may occur within hours, not days.

Albumin is available in 5% and 25% concentrations. Plasma protein fraction has oncotic actions similar to a 5% albumin solution, which is not surprising because albumin is the predominant protein in this product. When given in equipotent amounts, albumin is much more costly than crystalloid solutions. Additionally, the 5% and 25% albumin solutions typically are priced such that no cost savings is associated with dilution of the 25% product to make a 5% concentration. In general, dilution should be avoided because of the possibility of preparation errors; cases of hemolysis and death have occurred when 25% albumin was inappropriately diluted with sterile water for injection, causing a dramatic lowering of effective osmolality. The 5% albumin solution is relatively *iso-oncotic*, which means that it does not pull fluid into the compartment in which it is contained. In contrast, 25% albumin is referred to as *hyperoncotic* albumin because it tends to pull fluid into the compartment containing the albumin molecules. In general, the 5% albumin solution is used for hypovolemic states. The 25% solution should not be used for acute circulatory insufficiency unless it is used in combination with other fluids or it is being used in patients with excess total body water but intravascular depletion as a means of pulling fluid into the intravascular space. An example of the latter condition is cirrhosis with ascites in which total body water is substantially increased, but the patient is hypotensive as a consequence of lack of intravascular volume. This use of hyperoncotic albumin presumes that there is evidence of adverse effects associated with the excess water (e.g., interstitial fluid accumulation in the lungs) and that the albumin remains in the intravascular space long enough to be of benefit. Albumin has a variety of other functions, such as binding properties, inflammatory gene modification, and antioxidant and free radical scavenging effects, which have been used to justify its administration. Although appealing theoretically, improved patient outcomes related to these properties have not been documented in adequately powered, randomized, controlled trials.

Hetastarch 6% has comparable plasma expansion to a 5% albumin solution but usually is less expensive, which accounts for much of its use. Most of the trials comparing albumin with hetastarch for volume expansion have found no significant differences in clinically important outcomes (e.g., mortality). Few trials have directly compared hetastarch with crystalloid solutions for intravascular expansion. Although hetastarch often is stated as being contraindicated in bleeding disorders, it has been most studied in patients with blood loss (e.g., trauma and perioperative patients). Hetastarch should be avoided in situations where short-term impairments in hemostasis could have dire consequences, such as in patients undergoing

cardiopulmonary bypass surgery and patients with intracranial bleeding. Hetastarch may aggravate bleeding through mechanisms specific to this colloid (e.g., decreased factor VIII activity). These mechanisms have not been well elucidated and often are difficult to distinguish from the dilutional effects on clotting factors caused by all plasma expanders. Hetastarch may cause elevations in serum amylase concentrations but does not cause pancreatitis.

Dextran 40, dextran 70, and dextran 75 are available for use as plasma expanders in the United States. The numbers refer to the average molecular weight of the solutions. In general, dextran solutions are not used as often as albumin or hetastarch solutions for plasma expansion, possibly because of concerns related to aggravation of bleeding (i.e., anticoagulant actions related to inhibiting stasis of microcirculation) and anaphylaxis that is more likely to occur with the higher-molecular-weight solutions. However, both these concerns can be reduced if proper attention is paid to patient selection and, in the case of bleeding, published dosing guidelines with regard to the amounts of these products that should be infused. There are few comparative trials involving the dextran solutions, but the intravascular expansion within hours after infusion is approximately equal to the amount of dextran infused.

The crystalloid versus colloid debate was intensified when a metaanalysis by the well-respected Cochrane group found an overall increase in mortality associated with albumin using pooled results of randomized investigations.¹⁷ The metaanalysis involved 30 randomized trials with 1,419 patients (relative risk of death with albumin versus no administration or crystalloid administration 1.68, 95% confidence interval 1.26 to 2.23). For hypovolemia (caused by blood loss in the majority of studies), the risk of death associated with albumin administration was not quite statistically significant (relative risk 1.46, 95% confidence interval 0.97 to 2.22). However, with the notable exception of trauma patients, a subsequent and more comprehensive systematic review did not find increased mortality attributable to albumin.¹⁸ Furthermore, a landmark investigation involving almost 7,000 critically ill patients (conducted after the previously mentioned metaanalyses) did not find statistically significant differences in 28-day mortality between patients resuscitated with either normal saline or 4% albumin.¹⁹ As in the previous meta-analysis, there was a trend toward increased mortality in patients with trauma, particularly in a subset of patients with traumatic brain injury. This multicenter, randomized, double-blind investigation, referred to as the Saline versus Albumin Fluid Evaluation (SAFE) study, involved a heterogeneous group of ICU patients and was not sufficiently powered to look at various subsets, so clinicians must be cautious when extrapolating the results to more specific patient populations. With this caution in mind, this trial provides strong evidence that crystalloid solutions should be considered first-line therapy in patients with hypovolemic shock.

■ SPECIAL POPULATIONS

Trauma/Perioperative Patients

The need for immediate treatment of hemorrhagic circulatory insufficiency with plasma expanders (i.e., crystalloids or colloids) seems obvious, but no large, well-controlled trials conducted in humans have supported this practice. To the contrary, evidence suggests that fluid resuscitation beyond minimal levels (i.e., mean arterial pressure >40 to 60 mm Hg) is harmful. One prospective study involving 598 adult patients with gunshot or stab wound injuries to the torso and systolic blood pressure measurements of 90 mm Hg or less found that delayed fluid resuscitation until operation was associated with increased survival and discharge from the hospital ($P = 0.04$).²⁰ Since concerns were expressed about the comparability of the immediate and delayed resuscitation groups, particularly because true random-

ization did not take place, a followup randomized trial was conducted to verify the findings. There were no differences in survival (four deaths in each group) in the second trial regardless of whether systolic blood pressure was titrated to >100 mm Hg or to 70 mm Hg.²¹ Both studies were conducted in populated urban areas with approximately 2 hours from the time of injury to operation. Therefore, the results may not be applicable to rural areas with extended transport times. There also is a concern in applying the results of these investigations to patients with certain kinds of single-system injuries, particularly head trauma, where cerebral perfusion pressure is of primary importance. Although the applicability of these studies to other populations and settings is debatable, the *presumption* of benefits from immediate plasma expansion in all preoperative patients with circulatory insufficiency caused by hemorrhage is no longer valid. Instead, the initial priority should be surgical control of the bleeding source.

Despite the studies suggesting that vigorous prehospital resuscitation is not helpful and possibly is harmful, hypertonic solutions have several characteristics that make them attractive for acute resuscitation. The intravascular and interstitial expansion resulting from administration of these solutions is much greater than the volume infused by emergency personnel.

CLINICAL CONTROVERSY

Some clinicians believe that hypertonic solutions should be used for resuscitation of patients with head injuries who have concomitant circulatory insufficiency.

By causing redistribution (i.e., pulling fluid) from the intracellular space, hypertonic solutions cause rapid expansion of the intravascular compartment, which is essential for vital organ perfusion. In head-injured patients, it has been postulated that this redistribution should decrease intracranial pressure because the vessels of the brain are more impermeable to sodium ions than are vessels in other areas of the body. Additionally, hypertonic saline solutions have beneficial immunomodulating actions when compared with more isotonic solutions in experiments with animals, although these actions have not always translated into similar beneficial effects in patients.²²

Potential dosing and administration errors and related adverse events can occur when hypertonic saline is ordered and administered by clinicians relatively unfamiliar with its use. Potential adverse events include cellular crenation and damage caused by the dramatic fluid shifts associated with hypernatremia, hyperchloremic metabolic acidosis from hyperchloremia, and peripheral vein destruction from high osmolality. In the limited number of studies conducted in humans to date, such adverse effects have been uncommon and apparently of little clinical importance.^{23,24}

Unfortunately, beneficial outcome data attributable to administration of these hypertonic solutions are lacking. Most of these studies were conducted in prehospital and emergency department settings using 250 mL of 7.5% sodium chloride with or without 6% dextran 70. A metaanalysis of randomized, controlled trials found no statistical difference between the survival rates of patients receiving the hypertonic saline solutions and those receiving standard isotonic crystalloid solutions.²⁵ Additionally, a subsequent double-blind, randomized controlled trial involving 229 patients with hypotension and severe brain injury demonstrated no significant differences in neurologic function at 6 months when 250 mL of 7.5% saline or lactated Ringer solution was administered as part of a prehospital resuscitation regimen.²⁶ Part of the explanation for this finding may be related to supplemental crystalloid fluids that were given routinely to patients in both the treatment and control groups, which probably would increase the number of patients

needed to demonstrate a statistically significant difference in mortality. Until the concerns regarding efficacy and toxicity of these solutions have been resolved, normal saline could be considered an alternative for head-injured patients when a hypertonic solution is desirable because it contains 154 mmol/L of both sodium and chloride. Given their relatively poor intravascular expansion and association with poor outcome in animal models of closed head injury, hypotonic solutions should be avoided in this population.²⁷

In addition to crystalloid solutions, colloids have been used for plasma expansion in patients with hemorrhagic circulatory insufficiency. In the United States, albumin and starch (i.e., hetastarch) derivatives are used most commonly, although dextran solutions also are available commercially.

CLINICAL CONTROVERSY

Some clinicians believe that colloid solutions have advantages beyond crystalloid solutions that justify their use for patients with hypovolemic shock.

The major theoretical advantage of these compounds is their prolonged intravascular retention time compared with crystalloid solutions. In contrast to isotonic crystalloid solutions that have substantial interstitial distribution within minutes of IV administration, colloids remain in the intravascular space for hours or days, depending on factors such as capillary permeability.

The colloids, particularly albumin, are expensive solutions. Therefore, it is difficult to justify the additional cost of colloidal products unless the benefit-to-risk ratio is substantially greater than that associated with inexpensive crystalloid solutions. This does not appear to be the case based on randomized, controlled studies and metaanalyses comparing colloid and crystalloid solutions for acute circulatory insufficiency. Because other colloids, such as hetastarch, almost always have been compared with albumin and not with crystalloid solutions in published clinical studies (with no clinically important differences found), there is no reason to suspect that these other colloids have any unique advantages as volume expanders. Adverse effects associated with colloids appear to be uncommon and generally are extensions of their pharmacologic activity (Table 26–5), **9** but this is also true of crystalloids. The benefit-to-risk ratio appears to be similar for colloids and crystalloids; thus, based on cost, crystalloids are preferred for initial treatment of circulatory insufficiency.

The preceding discussion dealt primarily with acute circulatory insufficiency, but there are other considerations with regard to fluid replacement in elective surgical procedures. Preoperative fluid deficits in patients undergoing minor procedures may be associated with increased perioperative morbidity, some of which (e.g., drowsiness, dizziness) may be reduced by appropriate fluid administration prior to surgery.²⁸ However, care must be taken to avoid overhydration in the perioperative period because excess fluid will lead to weight gain and decreased pulmonary function. Some evidence suggests that fluid restriction on the day of surgery may reduce postoperative morbidity in patients undergoing major surgical procedures. In one randomized, multicenter trial, use of a restricted intraoperative and postoperative IV fluid protocol led to significantly fewer cardiopulmonary (7% versus 24%; $P = 0.007$) and wound (16% versus 31%; $P = 0.04$) complications.²⁹ As the preceding discussion indicates, the benefits and risks of fluid administration in the perioperative period are not just a function of too little or too much fluid but involve other patient- and procedure-related issues.

Another consideration in the patient with injuries or surgery is the potential need for blood product administration (Table 26–6) to replace oxygen-carrying and clotting functions. Although a small group of trauma patients respond to the initial fluid bolus and remain stable, most patients respond initially and then deteriorate.

TABLE 26-5 Adverse Effects of Plasma Expanders: Colloids

Albumin
Primarily extensions of pharmacologic actions (e.g., fluid overload; dilutional coagulopathy)
Amino acid profile and catabolism alterations (clinical significance?); potential protein overload if given with exogenous protein (e.g., parenteral nutrition)
Anaphylactoid/anaphylaxis reactions (life-threatening reactions rare; higher in patients with immunoglobulin A deficiency)
Infectious complications (all reported cases have been associated with improper handling by manufacturer or institution; no reported cases of human immunodeficiency virus or hepatitis transmission)
Interactions with medications and nutrients (clinical significance varies)
Metal loading, particularly aluminum (long-term administration in patients with renal failure)
Negative inotropic effect; reductions in ionized calcium concentrations (not well documented)
Pyrogenic reactions (not well documented)
Hetastarch
Primarily extensions of pharmacologic actions (e.g., fluid overload, dilutional coagulopathy)
Bleeding (decreases factor VIII/C activity; not recommended in patients at high risk for bleeding or in patients with severe bleeding conditions such as subarachnoid hemorrhage)
Macroamylase formation may cause elevation in blood amylase that leads to inaccurate diagnosis of pancreatitis
Anaphylactoid/anaphylaxis reactions
Pruritus (particularly when large amounts are given; may take months to resolve)
Dextrans
Primarily extensions of pharmacologic actions (e.g., fluid overload, dilutional coagulopathy)
Anaphylactoid/anaphylaxis reactions (increased incidence of anaphylaxis with increased molecular weight)
Bleeding (sometimes used for anticoagulant activity, so not recommended for patients with severe bleeding)

The latter patients, as well as patients undergoing blood loss associated with surgery, frequently need blood components such as packed red blood cells. In the case of the latter component, red blood cells contain hemoglobin that delivers oxygen to tissues. Neither crystalloids nor colloids perform this function.

Administration of excessive blood products may be counterproductive. In the case of red blood cells, attempts to raise the hematocrit to high-normal or supranormal concentrations may decrease oxygen delivery by increasing blood viscosity. Although there is no optimal hematocrit value for all patients, a minimum hematocrit concentra-

tion of 30% (equivalent to a hemoglobin concentration of 10 Gm/dl) traditionally has been used as the threshold for transfusion, particularly in patients at risk for ischemia, such as those with CAD. Use of a more liberal transfusion strategy has been called into question with the publication of a randomized, multicenter trial involving critically ill patients that found 30-day mortality to be similar whether patients were transfused at a hemoglobin concentration of 7 or 10 g/dL (18.7% versus 23.3%, respectively; $P = 0.11$).³⁰ The mortality during hospitalization was significantly lower in the restrictive group (22.2% versus 28.1%; $P = 0.05$). Although the investigators were cautious about extrapolating the results of this investigation to patients with myocardial ischemia, the study does question the use of a liberal transfusion strategy for critically ill patients.

Blood products are not risk-free. There is the rare but important risk of virus transmission [e.g., human immunodeficiency virus (HIV), hepatitis]. Citrate that is added to stored blood to prevent coagulation may bind to calcium, resulting in hypocalcemia, although potassium and phosphate concentrations often are elevated in stored blood, particularly when hemolysis has occurred during storage. Other issues that must be considered with blood product administration include monitoring for transfusion-related reactions and attention to appropriate warming, particularly when large volumes are given to pediatric patients, because hypothermia is associated with increased fluid requirements and mortality.

The periodic shortages, high costs, and adverse effect concerns related to blood products have prompted investigations of alternative “bloodless” strategies. In addition to the use of more restrictive transfusion thresholds, as mentioned previously, these strategies have included hemoglobin-based oxygen carriers and perfluorocarbon compounds to deliver oxygen to tissues. Other strategies have aimed at reducing blood loss through the use of improved procedural and surgical techniques, as well as the administration of hemostatic medications.

Patients with Thermal Injuries

There are a number of formulas for estimating fluid requirements in thermally injured patients, but there is little reason to choose one over another based on well-controlled studies. In general, the amount of loss corresponds to the size of the thermal injury. Approximately 3 to 4 mL/kg of isotonic fluid (lactated Ringer solution) for each percent burn can be used for calculating the expected fluid requirements for the first 24 hours after the burn. For example, a 60-kg person with 30% body surface area (BSA) burns is expected to require 5,400 to 7,200 mL of fluid over the initial 24 hours. Regardless of the calculated deficit, fluids should be administered until adequate tissue perfusion has been documented or adverse effects (e.g., pulmonary edema) occur. Crystalloids are preferred as initial therapy for burn victims because there is no substantial evidence that colloids mobilize edematous fluid, and there is a theoretical concern that extravascular fluid accumulation might be prolonged by the oncotic actions of albumin and other colloid products that have leaked through vessel walls.³¹ Additionally, there is no evidence that colloids reduce mortality in patients with thermal injuries.¹⁷ Some novel therapies for thermal resuscitation are currently under study. For example, in a prospective study involving patients with >30% BSA burns, antioxidant therapy with extremely high doses on IV vitamin C (66 mg/kg/h for 24 hours) reduced resuscitation fluid requirements and wound edema.³² The proposed mechanism is reduction in free radical-induced increases in capillary permeability.

TABLE 26-6 General Indications for Blood Products in Acute Circulatory Insufficiency Due to Hemorrhage^a

Packed red blood cells
Increase oxygen-carrying capacity of blood: Usually indicated in patients with continued deterioration after volume replacement or obvious exsanguination; must be warmed, particularly when used in children
Fresh-frozen plasma
Replacement of clotting factors: Generally overused; indicated if ongoing hemorrhage in patients with PT/PTT >1.5 times normal, severe hepatic disease, or other bleeding diathesis
Platelets
Used for bleeding due to severe thrombocytopenia (i.e., platelet count <10,000 mL) or rapidly dropping platelet counts as would occur with massive bleeding
Other products
With the exception of recombinant activated factor VII, which is currently undergoing trials for use in life-threatening hemorrhage unresponsive to traditional blood product administration, components such as cryoprecipitate and factor VIII are generally not indicated in acute hemorrhage but rather are used after specific deficiencies are identified

^aAlthough whole blood can be used for large-volume blood loss, most hospitals use component therapy, and use crystalloids or colloids for plasma expansion.
PT, prothrombin time; PTT, partial thromboplastin time.

CLINICAL CONTROVERSY

The appropriate use of invasive hemodynamic monitoring tools, such as right-sided heart catheterization in patients with hypovolemic shock, is controversial.

ONGOING MONITORING

One form of monitoring that may take place in the emergency and operating rooms, as well as in the ICU, requires placement of a central venous pressure (CVP) line. Monitoring of CVP provides the clinician with a somewhat insensitive yet useful estimate of the relationship between increased right atrial pressure and cardiac output. A protocol that used a particular type of central catheter to perform continuous monitoring of central venous oxygen saturation in conjunction with so-called goal-directed therapy in the first 6 hours of patient arrival in an urban emergency department resulted in decreased mortality compared to standard monitoring (30.5% vs. 46.5%, $P = 0.009$).³³ However, the patients in this study had severe sepsis and septic shock, so the results might not be applicable to other forms of shock with different pathophysiologic considerations. For example, in hemorrhagic shock due to trauma, the most important intervention is surgical control of bleeding, and anything that delays this control is likely to increase, not decrease, mortality. Until additional studies have been performed, it would be premature to recommend goal-directed therapy with the associated central venous monitoring in patients with nonseptic forms of shock, particularly shock due to blood loss. The monitoring of patients with various forms of hypovolemic shock becomes more controversial once initial stabilization has been achieved and the patient has been transferred to an ICU. This is particularly true with regard to the value of right-sided heart catheterization (also known as pulmonary artery or Swan-Ganz catheterization). Clearly, some form of intensive monitoring is important because patients in the postresuscitation phase of hypovolemic shock are at risk for various complications secondary to ischemia. A more complete discussion of invasive and noninvasive hemodynamic monitoring is given in Chapter 25.

A number of laboratory tests are indicated for subacute monitoring of shock in the ICU setting. These include a renal battery for assessing possible electrolyte alterations and kidney perfusion (e.g., BUN and creatinine). Among other things, a complete blood count will enable assessment of possible infection (white blood cell count), oxygen-carrying capacity of the blood (hemoglobin, hematocrit), and ongoing bleeding (hemoglobin, hematocrit, and platelet count). The prothrombin time (PT) and partial thromboplastin time (PTT) will give an indication of the ability of the blood to clot because, in the case of hemorrhagic shock, clotting factors are lost and diluted. An increasing lactate concentration (arterial, mixed venous, or central venous), an increasing arterial base deficit, or a decreasing bicarbonate concentration are consistent with inadequate perfusion leading to anaerobic metabolism with accumulation of lactic acid. Although the value of these surrogate markers for improving patient outcomes is more controversial, they are considered traditional end points of resuscitation in certain populations such as trauma patients.³⁴ Other tests may be indicated if organ dysfunction is likely. For example, when blood flow to the liver is interrupted because of sustained hypotension, a condition known as *shock liver* may occur. In this condition, the levels of transaminases on a liver panel may be markedly elevated in the first couple of days after marked hypotension, although the concentrations should decrease over time.⁴ Along with laboratory testing, a more extensive history can be obtained during the subacute monitoring period.

The value of pulmonary artery catheters has been debated hotly since their introduction. Such catheters are placed to obtain various oxygen-transport variables, some of which cannot be determined reliably from peripheral or other central vessels. The debate was intensified when early studies suggested improved outcomes when cardiac output and other oxygen-transport variables were raised to supranormal levels, the monitoring of which required placement of a pulmonary artery catheter. Subsequent studies using similar monitoring parameters associated with pulmonary artery catheterization gave conflicting results.³⁵

The controversy led to consensus conferences and workshops, the development of organizational guidelines, and the publication of a

metaanalysis (which found a statistically significant reduction in morbidity using pulmonary artery catheters to guide therapy).³⁶ Ultimately, a large randomized, controlled trial involving pulmonary artery catheters was conducted in high-risk surgical patients.³⁷ The trial involved 1,994 patients. The mortality was almost identical for the catheter and control groups (7.8% versus 7.7%, 95% confidence interval 2.3 to 2.5). There were no episodes of pulmonary embolism in the catheter group and eight episodes in the control group ($P = 0.004$). This trial is important not only because of the implications for high-risk surgical patients but also because it allows conduction of future trials in other patient populations without some of the ethical issues raised about such trials in the past.

Part of the concern regarding pulmonary artery catheterization relates to interpretation of its results by inexperienced practitioners. Studies in both Europe and the United States found that one of two physicians incorrectly interpreted a tracing from a pulmonary artery catheter.³⁸ This could explain some of the results of studies finding no benefits to pulmonary artery catheterization or, in some cases, worse outcomes in the pulmonary artery catheterization group by actions taken as a result of inaccurate measurements or misinterpretation of information obtained from the monitoring process.

Complications related to pulmonary artery catheter insertion, maintenance, and removal include damage to vessels and organs during insertion, arrhythmias, infections, and thromboembolic damage. To avoid the complications associated with pulmonary artery catheterization, other less invasive tools were developed to obtain similar information. For example, cardiac output determinations have been made by Doppler, bioimpedance, dye, and ionic dilution techniques, although such measurements would not provide other data that are obtained routinely with pulmonary artery catheters (e.g., left-sided heart filling pressure). Additionally, advances in pulmonary artery catheter technology that expand the information obtained from such monitoring (e.g., mixed venous oxyhemoglobin) are under investigation. However, given the lack of well-defined outcome data associated with pulmonary artery catheterization, its use is best reserved for complicated cases of shock not responding to conventional fluid and medication therapies.

Commonly measured and calculated hemodynamic and oxygen-transport indices associated with invasive monitoring are primarily global indicators of tissue perfusion. Attempts have been made to find regional and local indicators of hypoperfusion so that circulatory insufficiency could be treated before overt shock occurs. One focus of recent research has been monitoring modalities involving the gastrointestinal tract.

Although the literature is fairly consistent concerning low gastric intramucosal pH (pHi) values being predictive of death, pHi-guided therapy to decrease mortality has not been demonstrated.³⁹ Additionally, a number of technical considerations remain to be resolved when using pHi or, more recently, capnometry (luminal PCO_2 tonometry) for monitoring and therapy. Despite these concerns, measures of regional tissue oxygenation continue to be investigated through a variety of novel monitoring techniques.

In addition to regional monitoring of tissue perfusion, local methods of monitoring are being studied. For example, subcutaneous measurement of tissue oxygen pressure shows promise in preliminary investigations. Regional and local measurements likely will not replace more global indicators of perfusion; rather, the methods will complement each other.

ONGOING MANAGEMENT

Proper attention to plasma expansion must be continued into the intraoperative and postoperative periods. A number of neurohormonal changes take place that affect urine output, and patients may have substantial third spacing of fluid depending on the operation and preexisting conditions. Furthermore, postoperative patients are

prone to hyponatremia from renal generation of electrolyte-free water and from antidiuretic hormone release.⁴⁰ As in acute resuscitation, the administration of hypotonic solutions in the perioperative period does not prevent the decrease in extracellular volume that often occurs. Therefore, although excess fluid administration is to be avoided in the perioperative setting, isotonic crystalloid solutions should be used when fluids are indicated to prevent intravascular depletion and circulatory insufficiency.

Of the randomized studies comparing albumin with crystalloid solutions in the perioperative period, the majority found no statistically significant differences between groups.⁴¹ Any significant differences found involved isolated hemodynamic or respiratory variables with no obvious clinical correlates (e.g., duration of mechanical ventilation). Therefore, albumin and other colloids cannot be recommended for the prevention or initial treatment of circulatory insufficiency, although their use may be appropriate in patients who are not responding to crystalloids and are developing problems such as interstitial fluid accumulation. Practice guidelines published by a consortium of academic medical centers reflect this recommendation, but colloids continue to be used widely.⁴²

In general, medications are not indicated in the initial therapy of hypovolemic shock. With hypovolemia, the body's natural response is to increase cardiac output and to constrict blood vessels to maintain **10** blood pressure. There is no reason why most patients should need

inotropic or vasoactive agents, assuming that fluid therapy is adequate. For that matter, there is no evidence that these medications improve outcome in patients with hypovolemic shock. However, once the cause of acute circulatory insufficiency has been stopped or treated and fluids have been optimized, some patients continue to have signs and symptoms of inadequate tissue perfusion. This may be caused by reperfusion injury. Although the search for a cryptogenic source (e.g., intraabdominal bleeding in a trauma patient) should continue, the clinician may need to administer medications to improve perfusion.

Pressor agents such as norepinephrine and high-dose dopamine are to be avoided, if possible, because they may increase blood pressure at the expense of peripheral tissue ischemia. Some sources use stronger language and state that vasopressors are contraindicated in certain forms of shock (e.g., hemorrhagic). This does not help the clinician who is treating a patient with unstable blood pressure despite massive fluid replacement and increasing interstitial fluid accumulation. In such situations, inotropic agents such as dobutamine are preferred if blood pressure is adequate (e.g., systolic blood pressure ≥ 90 mm Hg) because they should not aggravate the existing vasoconstriction. The inotropic agents are justified by presumed inadequate cardiac output for the specific situation, although the measured values may be in the normal range.⁴

When pressure cannot be maintained with inotropic agents or when inotropic agents with vasodilatory properties cannot be used because of

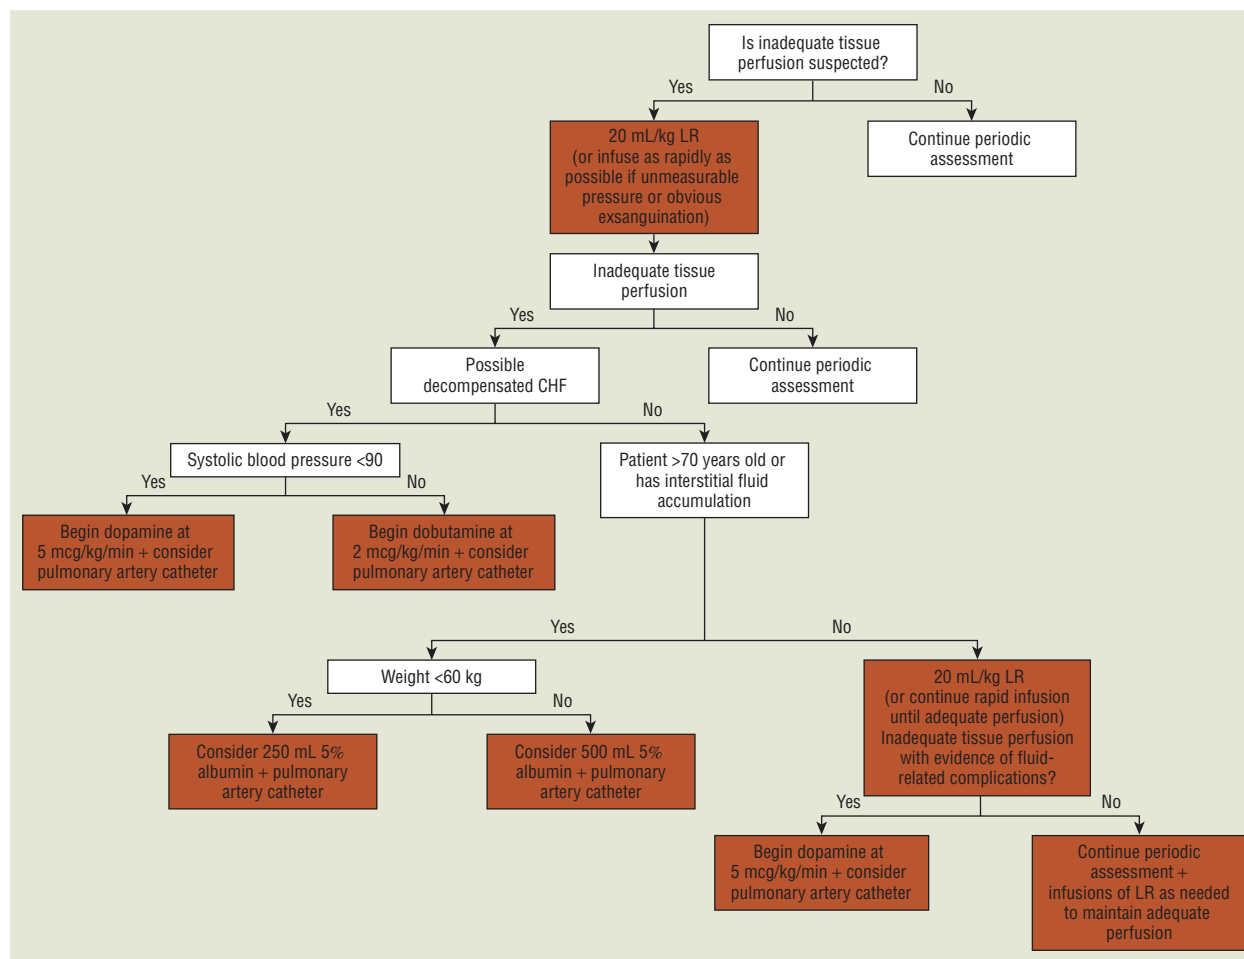

FIGURE 26-4. Hypovolemia protocol for adults. This protocol is not intended to replace or delay therapies such as surgical intervention or blood products for restoring oxygen-carrying capacity or hemostasis. If available, some measurements can be used in addition to those listed in the algorithm, such as mean arterial pressure or pulmonary artery catheter recordings. The latter can be used to assist in medication choices (e.g., agents with primary pressor effects may be desirable in patients with normal cardiac outputs, whereas dopamine or dobutamine may be indicated in patients with suboptimal cardiac outputs). Lower maximal doses of the medications in this algorithm should be considered when pulmonary artery catheterization is not available. Colloids that can be substituted for albumin are hetastarch 6% and dextran 40. See text for an in-depth discussion of these and other issues involved in this protocol. (CHF, congestive heart failure; LR, lactated Ringer solution.)

inadequate blood pressure concerns, pressors may be required as a last resort. In general, the need for pressors is predictive of the development of MODS and increased length of hospital stay.⁴³ Although the response to pressor agents may be variable in hypovolemic shock, there does not appear to be resistance as a consequence of altered receptor response, as is sometimes seen in patients with septic shock.⁴ Potent vasoconstrictors such as norepinephrine and phenylephrine should be given through central veins because of the possibility of extravasation and necrosis with peripheral administration.

In managing patients with hypovolemic shock, the clinician must be aware of potential adverse effects of medications being used for supportive care purposes. For example, some patients are particularly susceptible to the histamine release associated with morphine and may have substantial decreases in blood pressure. Propofol is commonly used for sedation in the ICU, but it may cause substantial decreases in blood pressure. The initial dose of propofol probably should be decreased by at least 50% in patients with hemorrhagic shock who have recently been resuscitated and by at least 80% (if it is given at all) in patients who may not be fully resuscitated.⁴⁴

A number of interesting treatments for shock are under investigation, including autotransfusion for removing harmful cytokines from the body. Various alternatives to conventional blood components also are being studied, such as stroma-free hemoglobin and perfluorocarbon compounds, as virus-free alternatives to red blood cell transfusion. Hopefully, these methods will be useful adjuncts to adequate volume replacement, which is the primary therapeutic intervention in managing acute circulatory insufficiency as a result of volume depletion.

PHARMACOECONOMIC CONSIDERATIONS

The primary therapy for hypovolemic shock is fluid replacement. The institutional cost of 1 L of most crystalloid solutions is less than \$1. Assuming that such fluids are used, the associated costs of personnel and equipment then become the primary economic considerations in the resuscitation of patients with hypovolemic shock. However, as mentioned, many clinicians recommend that colloid plasma expanders (e.g., albumin, hetastarch, or dextrans) be used to replace some or all of

the standard crystalloid solutions. Although the costs of these solutions vary depending on contractual arrangements, as might occur with purchasing groups, in general, albumin solutions are more expensive than hetastarch and dextran products. All these solutions are markedly more costly than crystalloid solutions; in some cases, the differences are 50- to 100-fold, even when used in equipotent amounts.

The only trial that investigated albumin use on a large-scale basis was an observational study involving 15 academic medical centers in the United States. Based on previously published guidelines, 62% of albumin use was defined as inappropriate, at a cost of \$124,939.⁴⁵ Presuming equal efficacy and toxicity (as available studies indicate) between crystalloid and colloid solutions, cost-minimization analysis clearly indicates the economic advantages of the crystalloids.

Because medications are not simply alternatives to crystalloids but rather are used when crystalloid therapy has been optimized, there is little reason to compare medication and fluid therapies from an economic perspective. Furthermore, there are no economic comparisons of the various inotropic and vasopressor medications used in the treatment of hypovolemic shock.

EVALUATION OF THERAPEUTIC OUTCOMES

Figure 26-4 is an algorithm that summarizes many of the treatment principles discussed in this chapter. The algorithm is an example of one approach to the adult patient presenting with hypovolemic shock. It presumes that initial rehydration attempts (i.e., outpatient or prehospital) were unsuccessful in restoring circulation. Obviously, modifications may be needed for patient-specific forms of hypovolemic shock. Other limitations of the algorithm should be recognized, particularly the decisions to add or to substitute colloid or medication therapies when crystalloid solutions are not yielding desired results and when to perform pulmonary artery catheterization for more invasive monitoring. Medications become more important for the ongoing management of hypovolemic shock, particularly when the patient is unresponsive to fluids (Fig. 26-5). Medications for more complicated cases of hemorrhagic shock should not detract from the primary effective resuscitative measure—surgical stabilization of bleeding.

SECTION 3 RESPIRATORY DISORDERS

CHAPTER

27

Introduction to Pulmonary Function Testing

JAY I. PETERS AND STEPHANIE M. LEVINE

KEY CONCEPTS

- 1 Normal ventilation–perfusion ratio. The function of the lungs is to maintain PaO_2 and PaCO_2 within normal ranges. This goal is accomplished by matching 1 mL mixed venous blood with 1 mL fresh air ($\dot{V}/\dot{Q} = 1$). Normally, ventilation (\dot{V}) is less than perfusion (\dot{Q}), and \dot{V}/\dot{Q} ratio is 0.8.
- 2 The air in the lung is divided into four compartments: tidal volume—air exhaled during quiet breathing; inspiratory reserve volume—maximal air inhaled above tidal volume; expiratory reserve volume—maximum air exhaled below tidal volume; and residual volume—air remaining in the lung after maximal exhalation. The sum of all four components is the total lung capacity.
- 3 Obstructive lung disease is defined as an inability to get air out of the lung. It is identified on spirometry when FEV_1/FVC (force expiratory volume in the first second of expiration/forced vital capacity [total amount of air that can be exhaled during a forced exhalation]) is <70% to 75%.
- 4 Reversible airway obstruction is common in asthma and chronic obstructive pulmonary disease. An increase in FEV_1 of 12% (and >0.2 L in adults) after an inhaled β -agonist suggests an acute bronchodilator response.
- 5 Restrictive lung disease is defined as an inability to get air into the lung and is best defined as a reduction in total lung capacity. It is suspected when FVC is low and FEV_1/FVC is normal.
- 6 Restrictive lung disease can be produced by a number of defects, such as increased elastic recoil (interstitial lung disease), respiratory muscle weakness (myasthenia gravis), mechanical restrictions (pleural effusion or kyphoscoliosis), and poor effort.

The primary function of the respiratory system is to maintain normality of arterial blood gases, that is, arterial pressure of oxygen

(PaO_2) and arterial pressure of carbon dioxide (PaCO_2). To achieve this goal, several processes must be accomplished, including alveolar ventilation, pulmonary perfusion, ventilation–perfusion matching, and gas transfer across the alveolar–capillary membrane. Alveolar ventilation is achieved by the cyclic process of air movement in and out of the lung. During inspiration, the inspiratory muscle contracts and generates negative pressure in the pleural space. This pressure gradient between the mouth and the alveoli draws fresh air (tidal volume) into the lung. Approximately one third of the inspired gas stays in the conducting airways (dead space), and two thirds reaches the alveoli.

1 The human lung contains a series of branching, progressively tapering airways that originate at the glottis and terminate in a matrix of thin-walled alveoli. Coursing through this matrix of alveoli is a rich network of capillaries that originates from the pulmonary arterioles and terminates in the pulmonary venules. The adequacy of respiration in each gas exchange unit depends on the opposition of a thin film of mixed venous blood with just the right amount of fresh alveolar gas. During “ideal” gas exchange, blood flow and ventilation are uniform; accordingly, there is no alveolar–arterial difference (or gradient) in the partial pressure of oxygen [$P(A-a)\text{O}_2$, sometimes called the $A-a$ gradient]. However, gas exchange is not perfect, even in the normal lung. Normally, alveolar ventilation is less than pulmonary blood flow, and the overall ventilation–perfusion ratio is 0.8 (not 1.0).

Normal expiration is a passive process, and when the inspiratory muscles end their contraction, the elastic recoil of the lung pulls the lung back to its original size and shape. This process makes the alveolar pressure positive relative to the pressure at the mouth, and air flows out of the lung. During inspiration, the respiratory muscles must overcome the elastic properties of the lung (elastic recoil) and the resistance to airflow by the airways. During expiration, the flow of air is determined primarily by the elastic recoil and airway resistance.

Different pulmonary function tests (PFTs) are used to evaluate the physiologic processes of the respiratory system. Physiologic abnormalities that can be measured by pulmonary function testing include obstruction to airflow, restriction of lung size, and decrease in transfer of gas across the alveolar–capillary membrane. Abnormal values on PFTs are outside the range of values obtained from a group of normal individuals matched according to age, height, sex, and race. A PFT is labeled abnormal when the results fall outside the range in which 95% of people the same age, height, and sex would be found (95% confidence interval). This definition is arbitrary and

Learning objectives, review questions,
and other resources can be found at
www.pharmacotherapyonline.com.

may misclassify a small percentage of normal individuals as having lung dysfunction; it also may miss patients with mild pulmonary disease. Therefore, clinical correlation and serial pulmonary function testing may be necessary for optimal interpretation of PFTs.

Potential uses of pulmonary function testing include evaluation of patients with known or suspected lung disease; evaluation of symptoms such as chronic cough, dyspnea, or chest tightness; monitoring of the effects of exposure to dust, chemicals, or pulmonary toxic drugs; risk stratification prior to surgery; monitoring of the effectiveness of therapeutic interventions; and objective assessment of impairment or disability.¹

DEFINITIONS OF LUNG VOLUMES AND EXPIRATORY FLOWS

2 The air within the lung at the end of a forced inspiration can be divided into four compartments or lung volumes (Fig. 27–1). The volume of air exhaled during normal quiet breathing is the *tidal volume* (V_T). The maximal volume of air inhaled above tidal volume is the *inspiratory reserve volume* (IRV), and the maximal air exhaled below tidal volume is the *expiratory reserve volume* (ERV). The *residual volume* (RV) is the amount of air remaining in the lungs after a maximal exhalation.

The combinations or sums of two or more lung volumes are termed *capacities* (Fig. 27–1). *Vital capacity* (VC) is the maximal amount of air that can be exhaled after a maximal inspiration. It is equal to the sum of IRV, V_T , and ERV. When measured on a forced expiration, it is called the *forced vital capacity* (FVC). When measured over an exhalation of at least 30 seconds, it is called the *slow vital capacity* (SVC). The VC is approximately 75% of the *total lung capacity* (TLC), and when the SVC is within the normal range, a significant restrictive disorder is unlikely. Normally, the values for SVC and FVC are very similar unless airway obstruction is present.

TLC is the volume of air in the lung after the maximal inspiration and is the sum of the four primary lung volumes (IRV, V_T , ERV, and RV). Its measurement is difficult because the amount of air remaining in the chest after maximal exhalation (RV) must be measured by indirect methods. The definition of restrictive lung disease is based on a reduction in TLC (i.e., an inability to get air into the lung or restriction to air movement on inhalation).

The *functional residual capacity* (FRC) is the volume of air remaining in the lungs at the end of a quiet expiration. FRC is the normal resting position of the lung; it occurs when there is no contraction of either

inspiratory or expiratory muscles and normally is 40% of TLC. *Inspiratory capacity* (IC) is the maximal volume of air that can be inhaled from the end of a quiet expiration and is the sum of V_T and IRV.

FVC, which represents the total amount of air that can be exhaled, can be expressed as a series of timed volumes. The *forced expiratory volume in the first second of expiration* (FEV_1) is the volume of air exhaled during the first second of the FVC maneuver. Although FEV_1 is a volume, it conveys information on obstruction because it is measured over a known time interval. FEV_1 depends on the volume of air within the lung and the effort during exhalation; therefore, it can be diminished by a decrease in TLC or by a lack of effort. A more sensitive way to measure obstruction is to express FEV_1 as a ratio of FVC. This ratio is independent of the patient's size or TLC; therefore, FEV_1/FVC is a specific measure of airway obstruction with or without restriction. Normally, this ratio is $\geq 75\%$, and any value $<70\%$ to 75% suggests obstruction.

Because *flow* is defined as the change in volume with time, forced expiratory flow can be determined graphically by dividing the volume change by the time change. The *forced expiratory flow* (FEF) during 25% to 75% of FVC ($FEF_{25\%-75\%}$) represents the mean flow during the middle half of the FVC. $FEF_{25\%-75\%}$, formerly called the *maximal midexpiratory flow*, is reported frequently in the assessment of small airways. The 95% confidence limit is so wide that $FEF_{25\%-75\%}$ has limited utility in the early diagnosis of small airways disease in an individual subject. The *peak expiratory flow* (PEF), also called *maximum forced expiratory flow* (FEF_{max}), is the maximum flow obtained during FVC. This measurement is used often in the outpatient management of asthma because it can be measured with inexpensive peak flowmeters.

All lung volumes and flows are compared to normal values obtained from healthy subjects. There are significant ethnic and racial variations in normal values, and all PFTs should report that race/ethnic adjustment factors have been used. The 2005 American Thoracic Society–European Respiratory Society (ATS–ERS) guidelines for interpretation of PFT results recommend that, for spirometry in the United States, the National Health and Nutrition Examination Survey (NHANES) III reference be used for subjects aged 8 to 80 years and the Wang equation used in subjects younger than 8 years.²

SPIROMETRY/FLOW–VOLUME LOOP

Spirometry is the most widely available and useful PFT. It takes only 15 to 20 minutes, carries no risks, and provides information about obstructive and restrictive disease. Spirometry allows for measurement of all lung volumes and capacities except RV, FRC, and TLC; it also allows assessment of FEV_1 and $FEF_{25\%-75\%}$. Spirometry measurements can be reported in two different formats—standard spirometry (Fig. 27–2) and the flow–volume loop (Fig. 27–3). In stan-

FIGURE 27-1. Lung volumes and capacities. (ERV, expiratory reserve volume; FRC, functional residual capacity; IC, inspiratory capacity; IRV, inspiratory reserve volume; RV, residual volume; TLC, total lung capacity; VC, vital capacity; V_T , tidal volume.)

FIGURE 27-2. Standard spirometry. Curve 1 is for a normal subject with normal FEV_1 ; curve 2 is for a patient with mild airways obstruction; curve 3 is for a patient with moderate airways obstruction; curve 4 is for a patient with severe airways obstruction. (BPTS, body temperature saturated with water vapor.)

FIGURE 27-3. Normal flow–volume loop. Flows are measured on the vertical (y) axis, and lung volumes are measured on the horizontal (x) axis. Forced vital capacity (FVC) can be read from the tracing as the maximal horizontal deflection. Instantaneous flow (\dot{V}_{\max}) at any point in FVC also can be measured directly. ($FEF_{50\%}$, forced expiratory flow at 50% of forced vital capacity; PEF, peak expiratory flow; PIF, peak inspiratory flow; RV, residual volume; TLC, total lung capacity.)

dard spirometry, the volumes are recorded on the vertical (y) axis and the time on the horizontal (x) axis. In flow–volume loops, volume is plotted on the horizontal (x) axis, and flow (derived from volume/time) is plotted on the vertical (y) axis. The shape of the flow–volume loop can be helpful in differentiating obstructive and restrictive defects and in diagnosing upper airway obstruction (Fig. 27–4). This curve gives a visual representation of obstruction because the expiratory descent becomes more concave with worsening obstruction.

LUNG VOLUMES

Spirometry measures three of the four basic lung volumes but cannot measure RV. RV must be measured to determine TLC. TLC should be measured anytime VC is reduced. In the setting of chronic obstructive pulmonary disease (COPD) and a low VC, measurement of TLC can help to determine the presence of a superimposed restrictive disorder. The four methods for measuring TLC are helium dilution, nitrogen washout, body plethysmography, and chest x-ray

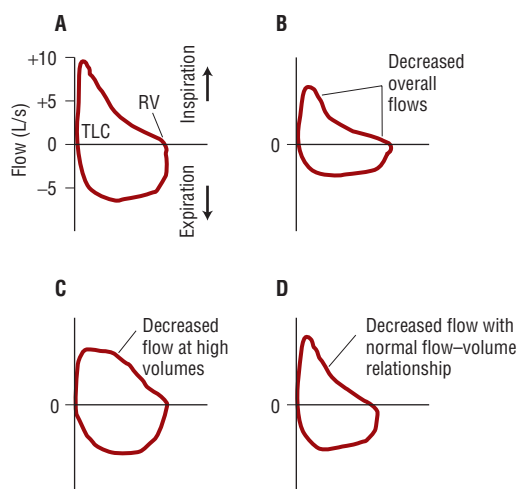

FIGURE 27-4. A. Flow–volume loop depicting mild obstruction characterized by decrease flow at low lung volumes. B. Moderate airflow obstruction characterized by a more concave curve. C. Variable intrathoracic obstruction in which peak flow is decreased at higher lung volumes with normalization of curve at lower lung volumes. D. Restrictive lung disease with a curve that is decreased in width but with a normal shape. (RV, residual volume; TLC, total lung capacity.)

measurement (planimetry). The first two methods are called *dilution techniques* and only measure lung volumes in communication with the upper airway. In patients with airway obstruction who have trapped air, dilution techniques will underestimate the actual volume of the lungs. Planimetry measures the circumference of the lungs on the posteroanterior view and lateral views of a chest x-ray film and estimates the total lung volume.

Body plethysmography, or body box, is the most accurate technique for lung volume determinations. It measures all the air in the lungs, including trapped air. The principle of the measurement of the body box is Boyle's gas law ($P_1V_1 = P_2V_2$): A volume of gas in a closed system varies inversely with the pressure applied to it. The changes in alveolar pressure are measured at the mouth, as well as pressure changes in the body box. The volume of the body box is known. Lung volumes can be determined measuring the changes in pressures caused by panting against a closed shutter.² Measurement of lung volumes provides useful information about elastic recoil of the lungs. If elastic recoil is increased (as in interstitial lung disease), lung volumes (TLC) are reduced. When elastic recoil is reduced (as in emphysema), lung volumes are increased.

CARBON MONOXIDE DIFFUSING CAPACITY

The diffusing capacity of the lungs (DL) is a measurement of the ability of a gas to diffuse across the alveolar–capillary membrane. Carbon monoxide is the usual test gas because normally it is not present in the lungs and is much more soluble in blood than in lung tissue. When the diffusing capacity is determined with carbon monoxide, the test is called the *diffusing capacity of lung for carbon monoxide* (DLCO). Because DLCO is directly related to alveolar volume (VA), it frequently is normalized to the value DL/VA, which allows for its interpretation in the presence of abnormal lung volumes (e.g., after surgical lung resection).

The diffusing capacity will be reduced in all clinical situations where gas transfer from the alveoli to capillary blood is impaired.³ Common conditions that reduce DLCO include lung resection, emphysema (loss of functioning alveolar–capillary units), and interstitial lung disease (thickening of the alveolar–capillary membrane). Normal PFTs with reduced DLCO should suggest the possibility of pulmonary vascular disease (e.g., pulmonary embolus) but also can be seen with anemia, early interstitial lung disease, and mild *Pneumocystis carinii* pneumonia (PCP) infection in patients with acquired immune deficiency syndrome.

OBSTRUCTIVE LUNG DISEASE

3 Obstructive lung disease implies a reduced capacity to get air through the conducting airways and out of the lungs. This reduction in airflow may be caused by a decrease in the diameter of the airways (bronchospasm), a loss of their integrity (bronchomalacia), or a reduction in elastic recoil (emphysema) with a resulting decrease in driving pressure. The most common diseases associated with obstructive pulmonary functions are asthma, emphysema, and chronic bronchitis; however, bronchiectasis, infiltration of the bronchial wall by tumor or granuloma, aspiration of a foreign body, and bronchiolitis also cause obstructive PFTs. The standard test used to evaluate airway obstruction is the forced expiratory spiogram.

Standard spirometry and flow–volume loop measurements include many variables; however, according to ATS guidelines, the diagnosis of obstructive and restrictive ventilatory defects should be made using the basic measurements of spirometry.³ A reduction in FEV_1 (with normal FVC) establishes the diagnosis of obstruction. When both FEV_1 and FVC are reduced, FEV_1 cannot be used to assess airway obstruction because such patients may have either obstruction or restriction. In restrictive lung disease, the patient has an inability to

get air into the lung, which results in a reduction of all expiratory volumes (FEV_1 , FVC, and SVC). In obstructed patients, a better measurement is the ratio FEV_1/FVC . Patients with restrictive lung disease have reduced FEV_1 and use of reduced FVC, but FEV_1/FVC remains normal. Although a normal FEV_1/FVC ratio is >70% to 75%, the ratio is age dependent, and slightly lower values may be normal in older patients. Younger children have increased lung elastic recoil and may have higher ratios. Children with asthma often have FEV_1/FVC >90% despite obstructive lung disease. In children, the improvement in FEV_1 after use of an inhaled bronchodilator often is the only way to document mild-to-moderate obstructive lung disease. Caution should be used in interpreting obstruction when FEV_1/FVC is below normal, but FEV_1 and FVC both are within the normal range because this pattern can be seen with healthy, athletic subjects. In screening spirometry performed in office practice, FEV_6 (forced expiratory volume in 6 seconds) can be used in place of FVC. FEV_6 is a more reproducible number when obtained by less skilled personnel. The measurement of $FEF_{25\%-75\%}$ also is abnormal in patients with obstructive airways disease. In general, this test has so much variability that it adds little to the measurement of FEV_1 and FEV_1/FVC . $FEF_{25\%-75\%}$ has been of value in monitoring lung transplant patients for graft rejection,⁴ and a reduced value may be an early indicator of acute rejection.

Although there is no standardization for interpretation of severity of obstruction, most pulmonary laboratories state that FEV_1/FVC <70% of the predicted value is diagnostic for obstruction, and the degree of obstruction then is based on the percent predicted of FEV_1 . FEV_1 <60% of the predicted value is moderate obstruction, and <40% of the predicted value is severe obstruction. In patients with obstruction, a dose of a bronchodilator (e.g., albuterol or isoproterenol) by metered-dose inhaler is given during the initial examination. An increase in FEV_1 of >12% and >0.2 L suggests an acute bronchodilator response.³ Because bronchodilator responsiveness is variable over time, the lack of an acute bronchodilator response should not preclude a 6- to 8-week trial of bronchodilators and/or corticosteroids.

Although all patients with obstructive lung disease of any etiology will have reduced flow rates on forced exhalation, the pattern on PFTs may be helpful in differentiating among the various etiologies (Table 27-1). Asthma is characterized by variable obstruction that often improves or resolves with appropriate therapy. Because asthma is an inflammatory disorder of the airways (predominantly large airways), DLCO is normal. Most patients with acute asthma have a bronchodilator response >15% to 20%; however, this response is also seen in 20% of patients with COPD. These patients are said to have asthmatic bronchitis. Chronic bronchitis may be limited to the airways, but the vast majority of patients with chronic bronchitis and airway obstruction have a mixture of bronchitis and emphysema and have a reduction in DLCO. Therefore, DLCO is the best PFT for separating asthma from COPD.

TABLE 27-1 Specific Patterns of Pulmonary Function in Patients with Chronic Obstructive Pulmonary Disease

	COPD		
	Asthma	Chronic Bronchitis	Emphysema
Decreased FEV_1	++++	++++	++++
Decreased FEV_1/FVC	++++	++++	++++
Increased airway resistance	++++	++++	+
Decreased D_{LCO}	—	—/+ ^a	++++
Response to bronchodilators	++++	+ ^b	— ^b

D_{LCO} , diffusing capacity of carbon monoxide; FEV_1 , forced expiratory volume in the first second of expiration; FVC, forced vital capacity.

^aMost smokers with chronic bronchitis have reduced D_{LCO} .

^bTwenty percent of patients with chronic obstructive pulmonary disease (COPD) have a large (++++) bronchodilator response.

After the diagnosis of obstructive airways disease is established, the course and response to therapy are best followed by serial spirometry. The multicenter Lung Health Study demonstrated an abnormally rapid decline (90–150 mL/y) in patients with COPD who continue to smoke.⁵ Smoking cessation often resulted in an increase in FEV_1 during the first year and a near-normal rate of decline (30–50 mL/y) in subsequent years.

AIRWAY HYPERREACTIVITY

4 *Airway hyperreactivity* or *hyperresponsiveness* is defined as an exaggerated bronchoconstrictor response to physical, chemical, or pharmacologic stimuli. Individuals with asthma, by definition, have hyperresponsive airways. The Lung Health Study Group observed nonspecific hyperresponsiveness in a significant number of patients with COPD. This group of patients with airway hyperreactivity appears to have a worse prognosis and an accelerated rate of decline in FEV_1 .⁶

Some patients with asthma (especially cough-variant asthma) present with no history of wheezing and normal PFTs. The diagnosis of asthma still can be established by demonstrating hyperresponsiveness to provocative agents. The two agents used most widely in clinical practice are methacholine and histamine. Other agents used for bronchial provocation include distilled water, cold air, and exercise. During a typical bronchoprovocation test, baseline FEV_1 is measured after inhalation of isotonic saline, then increasing doses of methacholine are given at set intervals. Hyperresponsiveness is defined as a decline in FEV_1 ≥20% and reversibility of obstruction to bronchodilators. The result can best be expressed as the provocative concentration needed to cause a 20% fall in FEV_1 (PC_{20}). A test is considered positive if either methacholine or histamine demonstrates a PC_{20} for FEV_1 ≤8 mg/mL or <60 to 80 cumulative breath units.⁷ This test is used most frequently to establish a diagnosis of asthma in patients with normal PFTs, but it also may be useful in following patients with occupational asthma, establishing the severity of asthma, and assessing the response to treatment.

UPPER AIRWAY OBSTRUCTION

Obstruction of airflow by abnormalities in the upper airway often goes undiagnosed or misdiagnosed because of improper interpretation of PFTs. Patients have obstructive physiology and often are misclassified as having asthma or COPD. The shape of the flow-volume loop, which includes inspiratory and expiratory flow-volume curves, and the ratio of forced expiratory and inspiratory flow at 50% of vital capacity ($FEF_{50\%}/FIF_{50\%}$) may be useful in the diagnosis of upper airway obstruction.⁸

The shape of the flow-volume curve differs depending on whether the obstruction is fixed or variable (Fig. 27-5). Fixed lesions, as in strictures from previous intubations or tracheostomy, cause a uniform caliber of airway during inspiration and expiration. With variable lesions, the airway caliber changes with changes in intrathoracic pressure. Variable lesions are subclassified into variable intrathoracic and variable extrathoracic. If the lesion is intrathoracic, as with tumors of the trachea, the negative pressure generated during inspiration opens the obstruction, whereas the positive pressure during expiration worsens the obstruction. If the lesion is a variable extrathoracic obstruction, as with vocal cord dysfunction, the negative pressure within the airways will pull the vocal cord toward the midline and potentiate the obstruction. In this case, there will be a plateau on the inspiratory limb of the flow-volume loop, and $FEF_{50\%}/FIF_{50\%}$ will be >1. Typical flow-volume curves from upper airway obstruction are shown in Fig. 27-4.

Another test used to distinguish upper airway obstruction from COPD and asthma is $FEV_1/FEV_{0.5}$ (FEV at 0.5 second). This ratio

FIGURE 27-5. Maximum expiratory flow–volume curves from patients with fixed obstruction, variable extrathoracic obstruction, and variable intrathoracic obstruction. (RV, residual volume; TLC, total lung capacity.)

usually is >1.5 in patients with upper airway obstruction.⁹ This is so because $FEV_{0.5}$ is proportionately more reduced in upper airway obstruction because forced expiration measured at 0.5 second better reflects obstruction at high lung volumes. The abnormality seen on the flow–volume loop has been referred to as “straightening” of the curve during early expiration.

RESTRICTIVE LUNG DISEASE

5 Restrictive lung disease is defined as an inability to get air into the lungs and to maintain normal lung volumes. Restrictive lung disease reduces all the subdivisions of lung volumes (IRV, VT, ERV, and RV) without reducing airflow. Patients have normal airway resistance and $FEV_1/FVC >75\%$.

Although *restriction* could be defined as a reduction in vital capacity (VC or FVC) with normal FEV_1/FVC , poor effort also will reduce FVC with normal FEV_1/FVC . A reduction in TLC is the most accurate measurement of restrictive lung function. TLC can be measured by various techniques. The gas dilution methods (e.g., helium dilution and nitrogen washout) are unable to measure gas trapped in cysts or bullae and may underestimate the true lung volume. Therefore, TLC is best measured by plethysmography. Most restrictive lung disease is associated with impairment or destruction of the alveolar–capillary membrane; therefore, DLCO is reduced in most patients with restrictive lung disease. The reduction in DLCO may occur prior to a reduction in lung volumes and is used as a marker of early interstitial (restrictive) lung disease. DLCO may be abnormal even with a normal chest x-ray film, and thin-cut computed tomographic scans of the chest may be required to diagnose early interstitial lung disease. Because peribronchiolar inflammation and fibrosis occur in patients with restrictive parenchymal lung disease, $FEF_{25\%-75\%}$ may be reduced and fail to respond to bronchodilators.

The severity of restrictive disease has not been standardized; however, many laboratories classify patients with reduced TLC as mild ($TLC \leq 80\%$), moderate ($TLC \leq 65\%$), or severe ($TLC \leq 50\%$). These definitions are completely arbitrary because a patient with obstructive lung disease may start with TLC 120% and subsequently

develop a moderately severe restrictive lung disease while maintaining TLC within the normal range. On flow–volume loop, patients with restrictive disease have normal-shaped curves with a reduction in the height and width of the curve because peak expiratory flow rate and VC both depend on the amount of air within the lung prior to performance of expiratory maneuvers (Fig. 27–3).

6 Restrictive lung function can be produced by increased elastic recoil of the lung parenchyma (interstitial lung disease), respiratory muscle weakness, mechanical restrictions (chest wall deformities), and/or poor effort. Table 27–2 lists common causes of restrictive lung disease.

Restrictive lung function from parenchymal lung disease usually can be differentiated from processes causing mechanical restriction as a result of chest bellows malfunction (Table 27–3). Restrictive parenchymal diseases are associated with a reduction in alveolar volume and an increase in lung elastic recoil. All lung volumes, as well as DLCO, are reduced. RV/TLC (normal $\leq 30\%$) and measurements of maximal inspiratory pressure (normal = -75 cm H₂O in males, -50 cm H₂O in females) remain normal. In addition, patients exhibit mild resting hypoxemia that worsens with exercise. Monitoring gas exchange during exercise may be the most sensitive test for detecting progression of interstitial lung disease.¹⁰

Mechanical restriction caused by chest bellows malfunction may result from chest wall or skeletal deformity, loss of neuromuscular function, fibrosis of the pleural space, and abdominal overdistension causing upward displacement of the diaphragm, as well as decreased diaphragm movement. The most common pulmonary function pattern seen in these patients is a decrease in TLC and VC with only a slight decrease in RV. RV is maintained in these diseases because lung compliance remains normal. DLCO is normal or only minimally reduced, and $DLCO/VA$ (corrected for alveolar volume) is normal. RV/TLC often is increased in patients with restrictive chest bellows disease. Patients with neuromuscular disease have reduced respiratory muscle function with a reduction in maximal inspiratory pressure.

PULMONARY GAS EXCHANGE

The essential function of the lungs is to maintain blood gas homeostasis. Arterial blood gas measurement plays an important role in

TABLE 27-2 Causes of Restrictive Lung Disease

the diagnosis and management of patients with pulmonary disease and should be ordered whenever hypoxemia, hypercapnia (CO_2 retention), and/or acid–base disorders are suspected clinically. Every time arterial blood gas determinations are ordered, the A–a gradient (difference between partial pressure of oxygen in the alveolus and partial pressure of oxygen in arterial blood) should be calculated. This is accomplished by computer on all automated blood gas machines, and a normal $P(\text{A} - \text{a})\text{O}_2$ can be approximated for sea-level breathing room air by multiplying the age by 0.3. The presence of hypoxemia with a normal A–a gradient usually implies alveolar hypoventilation (e.g., sedative overdose). Most patients develop hypoxemia secondary to mismatching of ventilation and perfusion, and $P(\text{A} - \text{a})\text{O}_2$ will be significantly elevated.

Oxygen saturation as measured by pulse oximetry (SpO_2) is widely used in clinical practice for monitoring arterial saturation. A pulse oximeter is a small battery-operated device that is placed on the finger or the earlobe. The device emits and reads the reflected light from capillary blood, and estimates the saturation. Although SpO_2 is clinically very useful, SpO_2 is only an estimate of arterial saturation. Actual arterial oxygen saturation (SaO_2) can be $\pm 2\%$ to 4% of the oximetric reading. The error may be even greater with saturation $<88\%$. Pulse oximeters do not measure carboxyhemoglobin, and SpO_2 may be overestimated significantly in patients with smoke inhalation or in recent smokers. An initial validation of pulse oximetry with direct measurement of SaO_2 is recommended in any critically ill patient.

EXERCISE TESTING

Cardiopulmonary exercise testing allows for assessment of multiple organs involved in exercise and has benefits over assessment of either the cardiac system or pulmonary system alone. The major indications for exercise testing are dyspnea on exertion, evaluation of exercise-induced bronchospasm, and suspected arterial desaturation during exercise.^{11–14} Exercise testing also can be useful in the evaluation of ventilatory or cardiovascular limitations to work, assessment of general fitness or conditioning, evaluation of disability, establishment of safe levels for exercise, evaluation of drug therapy, determining the need and liter flow for supplemental oxygen therapy during exercise, assessment of the effects of a rehabilitation program, and preoperative assessment before lung resection.^{11–14}

Tests for general fitness include the 6-minute walking distance and the Harvard step test.^{11,13–15} For the 6-minute walking distance, the subject simply walks a predetermined route or circuit as fast as possible for 6 minutes. The subject is allowed to stop and rest, but the clock continues to run. The greater the distance covered, the better are the patient's general fitness and exercise tolerance. For the Harvard step test, the subject steps up and down on a 20-inch step at a set rate for 5 minutes. A 1-minute rest period is followed by measurement of the subject's recovery heart rate. The lower the recovery heart rate, the better is the subject's general fitness.

Exercise testing sometimes is performed to determine if exercise results in arterial oxygen desaturation ($\text{SaO}_2 <90\%$).^{12,13} The test may be useful for quantifying the level of exertion the patient can perform during the activities of daily living as well as determining appropriate levels of supplemental oxygen therapy. Typically, this test is done using a treadmill or cycle ergometer. A baseline measurement of arterial blood gas values or pulse oximetry is followed by up to 6 minutes of exercise, during which time the patient is monitored for oxygen desaturation using pulse oximetry. If significant desaturation occurs (saturation $\leq 88\%$ – 90%), the test is terminated. In the event of oxygen desaturation, the test can be repeated to determine the level of supplemental oxygen therapy needed to compensate for the desaturation that otherwise would occur.

When more formal exercise testing is needed for some of the indications previously listed (e.g., dyspnea evaluation, evaluation of ventilatory or cardiovascular limitations to work, evaluation of disability and preoperative assessment before lung resection), exercise tolerance tests or cardiopulmonary stress testing can be performed. Tests include measurement of oxygen consumption ($\dot{V}\text{O}_2$), carbon dioxide production ($\dot{V}\text{CO}_2$), minute volume ($\dot{V}\text{E}$), VT, respiratory rate, SpO_2 , heart rate, blood pressure, and recording or monitoring of the electrocardiogram. During exercise, $\dot{V}\text{O}_2$ increases with workload in a linear fashion until a maximum oxygen consumption level ($\dot{V}\text{O}_{2\text{max}}$) is reached. Consequently, $\dot{V}\text{O}_{2\text{max}}$ is a measure of an individual's muscular work capacity.^{11–13} Normal $\dot{V}\text{O}_{2\text{max}}$ is approximately 1,700 mL/min for a sedentary person and up to 5,800 mL/min for a trained athlete.¹³ This compares with a resting $\dot{V}\text{O}_2$ of approximately 250 mL/min. Ventilatory equivalents for oxygen, carbon dioxide, and O_2 pulse are often calculated. Ventilatory equivalent for oxygen is a measure of the efficiency of the ventilatory pump at various workloads^{11,13,14} and is calculated as follows:

$$\text{Ventilatory equivalent for } \text{O}_2 = \dot{V}\text{E} / \dot{V}\text{O}_2.$$

A normal ventilatory equivalent for oxygen is 20 to 30.^{11,13}

O_2 pulse is an estimate of oxygen consumption per cardiac cycle and can be decreased with cardiac problems. O_2 pulse can be calculated as follows:

$$\text{O}_2 \text{ pulse} = (\dot{V}\text{O}_2 [\text{in L/min}] \times 1,000) / \text{Heart rate.}$$

TABLE 27-4 Indications and Contraindications for Exercise Testing

Indications

- Dyspnea upon exertion
- Exercise-induced bronchospasm
- Suspected arterial desaturation with exercise
- Evaluation of ventilatory limitations to exercise
- Evaluation of cardiac limitations to exercise
- Assessment of general fitness or conditioning
- Evaluation of cardiopulmonary disability
- Establishment of safe levels for exercise
- Evaluation of drug therapy
- Determining appropriate use of supplemental oxygen therapy
- Establishing an exercise prescription for a rehabilitation program
- Assessment of the effect of a rehabilitation program
- Evaluation of specific disease states or conditions (e.g., asthma, chronic obstructive pulmonary disease [COPD], interstitial lung disease, pulmonary vascular disorders, coronary artery disease, other vascular disorders, neuromuscular disorders, obesity, anxiety-induced hyperventilation)
- Assessment before resection
- Assessment before lung volume reduction surgery or lung transplantation

Contraindications

- $\text{PaO}_2 <40$ mm Hg on room air
- $\text{PaCO}_2 >70$ mm Hg
- $\text{FEV}_1 <30\%$ of predicted
- Recent (within 4 weeks) myocardial infarction
- Unstable angina pectoris
- Second- or third-degree heart block
- Rapid ventricular/atrial arrhythmias
- Orthopedic impairment
- Severe aortic stenosis
- Congestive heart failure
- Uncontrolled hypertension
- Limiting neurologic disorders
- Dissecting/ventricular aneurysms
- Severe pulmonary hypertension
- Thrombophlebitis or intracardiac thrombi
- Recent systemic or pulmonary embolus
- Acute pericarditis

TABLE 27-5 Typical Findings during Maximum Exercise with Poor Conditioning, Pulmonary Limitations to Exercise, and Cardiac Limitations to Exercise

Test Parameter	Poor Conditioning	Pulmonary Limitation	Cardiac Limitation
$\dot{V}O_2\text{max}$	↓	↓	↓
SpO_2	N	↓	N
O_2 pulse	N or ↓	N or ↓	↓
Anaerobic threshold	↓ or N	↓ or N	↓
Ventilatory reserve ^a (MVV – $\dot{V}E_{\text{max}}$)	N	↓	N or ↑

^aVentilatory reserve = Maximum voluntary ventilation (MVV) – Minute volume during maximum exercise ($\dot{V}E_{\text{max}}$).

N, normal.

Adapted from Madama VE. *Pulmonary Function Testing and Cardiopulmonary Stress Testing*. Albany, NY: Delmar, 1993.

A normal O_2 pulse is 2.5 to 4.0 mL per beat at rest and increases to 10 to 15 mL per beat during strenuous exercise.^{11,13}

The anaerobic threshold is the point during strenuous exercise at which anaerobic metabolism and lactic acid production begin.^{11,13,14} $\dot{V}CO_2\text{max}$ increases with exercise at about the same rate as $\dot{V}O_2$ until the subject's anaerobic threshold is reached. From that point on, $\dot{V}CO_2$ increases faster than $\dot{V}O_2$, and this change can be used to estimate the anaerobic threshold. A breath-by-breath plot of the ventilatory equivalents for O_2 and CO_2 also can be used to determine the anaerobic threshold. Anaerobic threshold is a measure of fitness in normal subjects, and aerobic training can delay the anaerobic threshold.^{11,13}

For exercise tolerance testing, the patient typically is subjected to either a constant workload (steady-state tests) or an increasing workload (progressive multistage tests) using a cycle ergometer or treadmill.^{11,13} With progressive multistage tests, the patient exercises to exhaustion or the occurrence of an adverse reaction, at which point the test is stopped. Safety during exercise testing is of major importance, and rigorous guidelines for termination of the test should be followed. Both types of tests can be used to determine $\dot{V}O_2\text{max}$. A limit to exercise, as indicated by a decrease in $\dot{V}O_2\text{max}$, can result from (1) poor conditioning, (2) pulmonary limitation, (3) cardiac limitation, or (4) poor effort. In the case of poor conditioning, SpO_2 and O_2 pulse will be normal. With a pulmonary limitation to exercise, SpO_2 will be reduced, and O_2 pulse will be normal. With a cardiac limitation to exercise, SpO_2 will be normal, and O_2 pulse will be reduced. Table 27-4 summarizes the indications and contraindications for exercise testing. Table 27-5 summarizes the findings during maximum exercise associated with poor conditioning, pulmonary limitations to exercise, and cardiac limitations to exercise.

ABBREVIATIONS

COPD: chronic obstructive pulmonary disease

DL: diffusing capacity of lung

DLCO: diffusing capacity of lung for carbon monoxide

ERV: expiratory reserve volume

FEF: forced expiratory flow

FEF_{25%–75%}: forced expiratory flow during 25% to 75% of forced vital capacity

FEF_{50%}: forced expiratory flow at 50% of forced vital capacity

FEFmax: maximum forced expiratory flow

FEV_{0.5}: forced expiratory volume at 0.5 second

FEV₁: forced expiratory volume in first second of expiration

FEV₆: forced expiratory volume in 6 seconds

FIF_{50%}: forced inspiratory flow at 50% of forced vital capacity

FRC: functional residual capacity

FVC: forced vital capacity

IC: inspiratory capacity

IRV: inspiratory reserve volume

$P_1V_1 = P_2V_2$: Boyle's gas law

$P(A-a)O_2$: alveolar–arterial difference in partial pressure of oxygen

$PaCO_2$: arterial partial pressure of carbon dioxide

PaO_2 : arterial partial pressure of oxygen

PC₂₀: provocative concentration needed to cause a 20% fall in FEV₁

PCP: *Pneumocystis carinii* pneumonia

PFT: pulmonary function test

PO₂: partial pressure of oxygen

RV: residual volume

SaO₂: arterial oxygen saturation

SpO₂: oxygen saturation as measured by pulse oximetry

SVC: slow vital capacity

TLC: total lung capacity

VA: alveolar volume

VC: vital capacity

VT: tidal volume

KEY CONCEPTS

- 1 Asthma is a disease of increasing prevalence that is a result of genetic predisposition and environmental interactions; it is one of the most common chronic diseases of childhood.
- 2 Asthma is primarily a chronic inflammatory disease of the airways of the lung for which there is no known cure or primary prevention; the immunohistopathologic features include cell infiltration by neutrophils, eosinophils, T-helper type 2 lymphocytes, mast cells, and epithelial cells.
- 3 Asthma is characterized by either the intermittent or persistent presence of highly variable degrees of airflow obstruction from airway wall inflammation and bronchial smooth muscle constriction; in some patients, persistent changes in airway structure occur.
- 4 The inflammatory process in asthma is treated most effectively with corticosteroids, with the inhaled corticosteroids having the greatest efficacy and safety profile for long-term management.
- 5 Bronchial smooth muscle constriction is prevented or treated most effectively with inhaled β_2 -adrenergic receptor agonists.
- 6 Variability in response to medications requires individualization of therapy within existing evidence-based guidelines for management.
- 7 Ongoing patient education, for a partnership in asthma care, is essential for optimal patient outcomes and includes trigger avoidance and self-management techniques.

Asthma has been known since antiquity, yet it is a disease that still defies precise definition. The word *asthma* is of Greek origin and means “panting.” More than 2,000 years ago, Hippocrates used the word *asthma* to describe episodic shortness of breath; however, the first detailed clinical description of the asthmatic patient was made by Aretaeus in the second century.¹ An expert panel of the National Institutes of Health, the National Asthma Education and Prevention Program (NAEPP), has provided the following working definition of asthma²:

Asthma is a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role: in particular,

mast cells, eosinophils, T-lymphocytes, macrophages, neutrophils, and epithelial cells. In susceptible individuals, this inflammation causes recurrent episodes of wheezing, breathlessness, chest tightness, and coughing, particularly at night or in the early morning. These episodes are usually associated with widespread but variable airflow obstruction that is often reversible either spontaneously or with treatment. The inflammation also causes an associated increase in the existing bronchial hyperresponsiveness (BHR) to a variety of stimuli. Reversibility of airflow limitation may be incomplete in some patients with asthma.

This definition encompasses the important heterogeneity of the clinical presentation of asthma by describing the scientific and clinically accepted characteristics of asthma.

EPIDEMIOLOGY

- 1 An estimated 20.5 million persons in the United States have asthma (approximately 7% of the population).³ Asthma is the most common chronic disease among children in the United States, with approximately 6.5 million children affected. The prevalence of asthma in the United States and worldwide has continued to increase. The prevalence rate is highest in children 5–17 years at 9.6%.³ In the United States, as in other Western industrialized countries, the prevalence of asthma has reached epidemic proportions. Asthma accounts for 1.6% of all ambulatory care visits (13.7 million physician office visits and 1.0 million hospital outpatient visits) and results in more than 497,000 hospitalizations and 1.8 million emergency department visits per year.³ Although asthma is the third leading cause of preventable hospitalization in the United States, hospitalizations for asthma have decreased only slightly over the past 10 years to 17 per 10,000 population.⁴ Children younger than 15 years of age have the highest rate of hospitalization at 31 per 10,000 population. Asthma accounts for more than 10 million missed school days per year.³ The prevalence of disabling asthma in children has increased 232% over the past 20 years compared with a 113% increase from all other chronic conditions in childhood.⁴ In young children (0 to 10 years of age), the risk of asthma is greater in boys than in girls, becomes about equal during puberty, and then is greater in women than in men.³

Ethnic minorities continue to share the burden of asthma disproportionately. African Americans have a higher prevalence than whites, but this appears to be a result of urbanization and not race or socioeconomic status.⁴ African Americans are three times as likely to be hospitalized and approximately 2.5 times more likely to die from asthma.³ In addition, African Americans and Puerto Ricans living in inner cities are four times more likely to experience emergency department visits than whites.³ These patterns are likely a result of poor access to care as Hispanics in general have a lower prevalence than African Americans or whites.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

The estimated direct medical cost of asthma in the United States in 2004 was \$11.5 billion.³ The societal burden of asthma (indirect medical expenditures) in the United States was \$4.6 billion. Prescription drugs were the largest single direct medical expenditure at \$5 billion, however, the combined costs of emergency care of acute asthma exacerbations makes up 36% of direct medical costs.³ Almost \$1.5 billion of indirect costs were a result of school days lost, and lost productivity secondary to asthma mortality cost \$1.7 billion.

The natural history of asthma is still not well defined. Although asthma can occur at any time, it is principally a pediatric disease, with most patients being diagnosed by 5 years of age and up to 50% of children having symptoms by 2 years of age.² Between 30% and 70% of children with asthma will improve markedly or become symptom-free by early adulthood; chronic disease persists in approximately 30% to 40% of patients, and generally 20% or less develop severe chronic disease.² Atopic status is the strongest indicator of persistence into adulthood, although initial severity also predicts severity as an adult.⁵ Other predictors of persistent adult asthma include onset during school age and presence of BHR. Diminished lung growth may occur in children with uncontrolled severe asthma but does not appear to occur in children with mild to moderate asthma.⁶ Most of the deficits in lung function growth occur in children whose symptoms begin during the first 3 years of life.⁶

In adults, most longitudinal studies have suggested a more rapid rate of decline in lung function in asthmatics than in normal volunteers, primarily reflected in forced expiratory volume in 1 second (FEV₁).⁵ However, the annual decline in FEV₁ is less than in smokers or in patients with a diagnosis of emphysema. In general, individuals with less-frequent asthma attacks and normal lung function on initial assessment have higher remission rates, whereas smokers have the lowest remission and highest relapse rates.⁵ The level of BHR tends to predict the rate of decline in FEV₁, with a greater decline with high levels of BHR.⁶ Thus airways obstruction in asthma not only may become irreversible but also may worsen over time owing to airway remodeling (see below Remodeling of the Airway section).⁷ Many elderly patients with asthma have irreversible airways obstruction.⁵ However, most patients do not die from long-term progression of their disease and their life span is not different from that of the general population.⁵

Although the prevalence of asthma is increasing in the United States, measures of significant morbidity (hospital admissions) and mortality from acute exacerbations of asthma have reached plateaus and have been slightly decreasing the past few years.³ Asthma results in a little more than 4,000 deaths per year.³ Despite the relatively low number of asthma deaths, 80% to 90% are preventable.^{2,8} Most deaths from asthma occur outside the hospital, and death is rare after hospitalization. The most common cause of death from asthma is inadequate assessment of the severity of airways obstruction by the patient or physician and inadequate therapy. The most common cause of death in hospitalized patients is also inadequate or inappropriate therapy. Thus the key to prevention of death from asthma, as advocated by the NAEPP, is education.⁶

ETIOLOGY

1 Asthma is at least a partially heritable complex syndrome that requires a gene-by-environment interaction for phenotypic expression. Epidemiologic studies strongly support the concept of a genetic predisposition to the development of asthma, yet the picture remains complex and incomplete.⁹ Genetic factors account for 35% to 70% of the susceptibility. Asthma represents a complex genetic disorder in that the asthma phenotype is likely a result of polygenic inheritance or different combinations of genes. Initial searches focused on establishing links between atopy (genetically determined state of hypersensitivity to environmental allergens) and asthma,

but more recent genome-wide searches have found linkages with genes for metalloproteinases (e.g., ADAM33).^{10,11} Thus, although genetic predisposition to atopy is a significant risk factor for developing asthma, not all atopic individuals develop asthma, nor do all asthmatics exhibit atopy.

1 Environmental risk factors for the development of asthma include socioeconomic status, family size, exposure to secondhand tobacco smoke in infancy and in utero, allergen exposure, urbanization, and decreased exposure to common childhood infectious agents.¹² The “hygiene hypothesis” proposes that genetically susceptible individuals develop allergies and asthma by allowing the allergic immunologic system (T-helper cell type 2 [TH₂]-lymphocytes) to develop instead of the immunologic system used to fight infections (T-helper cell type 1 [TH₁]-lymphocytes), and is being used to explain the increase of asthma in Western countries.^{6,12} The first 2 years of life appear to be most important for the exposures to produce an alteration in the immune response system. Support for the hygiene hypothesis for asthma comes from studies demonstrating a lower risk for asthma in children who live on farms and are exposed to high levels of bacteria, in those with a large number of siblings, in those with early enrollment into child care, in those with exposure to cats and dogs early in life, or in those with exposure to fewer antibiotics.^{10,12}

Risk factors for early (<3 years of age) recurrent wheezing associated with viral infections include low birth weight, male gender, and parental smoking. However, this early pattern is a result of smaller airways, and these risk factors are not necessarily risk factors for asthma in later life.⁷ Atopy is the predominant risk factor for children to have continued asthma.⁷ Asthma can occur in adults later in life. Occupational asthma in previously healthy individuals emphasizes the effect of environment on the development of asthma.¹³ The heterogeneity of the asthma phenotype appears most obvious when listing the diverse triggers of bronchospasm in asthmatic subjects (Table 28-1).^{2,6} The various triggers have relative degrees of importance from patient to patient. This variety should serve as ample evidence that asthma is likely to be as complex genetically.

Environmental exposures are the most important precipitants of severe asthma exacerbations (see Table 28-1).^{2,6} Epidemics of severe asthma in cities have followed exposures to high concentrations of aeroallergens.² Viral respiratory tract infections remain the single most significant precipitant of severe asthma in children, and are an important trigger in adults as well.^{2,6} Other possible factors include air pollution, sinusitis, food preservatives, and drugs.

TABLE 28-1 List of Agents and Events Triggering Asthma

Respiratory infection
Respiratory syncytial virus (RSV), rhinovirus, influenza, parainfluenza, <i>Mycoplasma pneumonia</i>
Allergens
Airborne pollens (grass, trees, weeds), house-dust mites, animal danders, cockroaches, fungal spores
Environment
Cold air, fog, ozone, sulfur dioxide, nitrogen dioxide, tobacco smoke, wood smoke
Emotions
Anxiety, stress, laughter
Exercise
Particularly in cold, dry climate
Drugs/preservatives
Aspirin, nonsteroidal antiinflammatory drugs (cyclooxygenase inhibitors), sulfites, benzalkonium chloride, nonselective β -blockers
Occupational stimuli
Bakers (flour dust); farmers (hay mold); spice and enzyme workers; printers (arabic gum); chemical workers (azo dyes, anthraquinone, ethylenediamine, toluene diisocyanates, polyvinyl chloride); plastics, rubber, and wood workers (formaldehyde, western cedar, dimethylethanolamine, anhydrides)

FIGURE 28-1. Representative illustration of the pathology found in the asthmatic bronchus compared with a normal bronchus (*upper right*). Each section demonstrates how the lumen is narrowed. Hypertrophy of the basement membrane, mucus plugging, smooth muscle hypertrophy, and constriction contribute (*lower section*). Inflammatory cells infiltrate, producing submucosal edema, and epithelial desquamation fills the airway lumen with cellular debris and exposes the airway smooth muscle to other mediators (*upper left*).

PATHOPHYSIOLOGY

2 The major characteristics of asthma include a variable degree of airflow obstruction (related to bronchospasm, edema, and hypersecretion), BHR, and airways inflammation (Fig. 28–1). Evidence of inflammation arose from the studies of nonspecific BHR, bronchoalveolar lavage, bronchial biopsies, and induced sputum, as well as from postmortem observations of patients with asthma who died from an attack of asthma or from other causes. To understand the pathogenetic mechanisms that underlie the many variants of asthma, it is critical to identify factors that initiate, intensify, and modulate the inflammatory response of the airways and to determine how these immunologic and biologic processes produce the characteristic airways abnormalities. Immune responses mediated by immunoglobulin (Ig) E antibodies are of foremost importance.

ACUTE INFLAMMATION

Inhaled allergen challenge models contribute most to our understanding of acute inflammation in asthma.¹⁴ Inhaled allergen challenge in allergic patients leads to an early phase allergic reaction that, in some cases, may be followed by a late-phase reaction. The activation of cells bearing allergen-specific IgE initiates the early phase reaction. It is characterized primarily by the rapid activation of airway mast cells and macrophages. The activated cells rapidly release proinflammatory mediators such as histamine, eicosanoids, and reactive oxygen species that induce contraction of airway smooth muscle, mucus secretion, and vasodilation.¹⁴ The bronchial microcirculation has an essential role in this inflammatory process. Inflammatory mediators induce microvascular leakage with exudation of plasma in the airways.¹⁴ Acute plasma protein leakage induces a thickened, engorged, and edematous airway wall and a consequent narrowing of the airway lumen. Plasma exudation may compromise epithelial integrity, and the presence of plasma in the lumen may reduce mucus clearance.¹⁴ Plasma proteins also may promote the formation of exudative plugs mixed with mucus and inflammatory and epithelial cells. Together these effects contribute to airflow obstruction (see Fig. 28–1).

The late-phase inflammatory reaction occurs 6 to 9 hours after allergen provocation and involves the recruitment and activation of eosinophils, CD4+ T cells, basophils, neutrophils, and macrophages.¹⁴ There is selective retention of airway T cells, the expression of adhesion molecules, and the release of selected proinflammatory mediators and cytokines involved in the recruitment and activation of inflammatory cells.¹⁴ The activation of T cells after allergen challenge leads to the release of TH₂-like cytokines that may be a key mechanism of the late-phase response.¹⁴ The release of preformed cytokines by mast cells is the likely initial trigger for the early recruitment of cells. This cell type may recruit and induce the more persistent involvement by T cells.¹⁴ The enhancement of nonspecific BHR usually can be demonstrated after the late-phase reaction but not after the early phase reaction following allergen or occupational challenge.

CHRONIC INFLAMMATION

Airways inflammation has been demonstrated in all forms of asthma, and an association between the extent of inflammation and the clinical severity of asthma has been demonstrated in selected studies.^{7,15} It is accepted that both central and peripheral airways are inflamed.

In asthma, all cells of the airways are involved and become activated (Fig. 28–2). Included are eosinophils, T cells, mast cells, macrophages, epithelial cells, fibroblasts, and bronchial smooth muscle cells. These cells also regulate airway inflammation and initiate the process of remodeling by the release of cytokines and growth factors.¹⁵

Epithelial Cells

Bronchial epithelial cells traditionally have been considered as a barrier, participating in mucociliary clearance and removal of noxious agents. However, epithelial cells also participate in inflammation by the release of eicosanoids, peptidases, matrix proteins, cytokines, and nitric oxide (NO). Epithelial cells can be activated by IgE-dependent mechanisms, viruses, pollutants, or histamine. In asthma, especially fatal asthma, extensive epithelial shedding occurs. The functional consequences of epithelial shedding may include heightened airways responsiveness, altered permeability of the airway mucosa, depletion of epithelial-derived relaxant factors, and loss of enzymes responsible for degrading proinflammatory neuropeptides. The integrity of airway epithelium may influence the sensitivity of the airways to various provocative stimuli. Epithelial cells also may be important in the regulation of airway remodeling and fibrosis.^{15,16}

Eosinophils

Eosinophils play an effector role in asthma by release of proinflammatory mediators, cytotoxic mediators, and cytokines.¹⁵ Circulating eosinophils migrate to the airways by cell rolling, through interactions with selectins, and eventually adhere to the endothelium through the binding of integrins to adhesion proteins (vascular cell adhesion molecule 1 [VCAM-1] and intercellular adhesion molecule 1 [ICAM-1]). As eosinophils enter the matrix of the membrane, their survival is prolonged by interleukin (IL)-5 and granulocyte-macrophage colony-stimulating factor (GM-CSF). On activation, eosinophils release inflammatory mediators such as leukotrienes and granule proteins to injure airway tissue.¹⁵

Lymphocytes

Mucosal biopsy specimens from patients with asthma contain lymphocytes, many of which express surface markers of inflammation. There are two types of T-helper CD4+ cells. TH₁ cells produce IL-2 and interferon- γ (INF- γ), both essential for cellular defense mechanisms. TH₂ cells produce cytokines (IL-4, -5, and -13)

FIGURE 28-2. Diagrammatic presentation of the relationship between inflammatory cells, lipid and preformed mediators, inflammatory cytokines, and proposed pathogenesis and clinical presentation in asthma. See text for details. (ECP, eosinophil cationic protein; GM-CSF, granulocyte-macrophage colony-stimulating factor; IAR, immediate asthmatic reaction; IFN, interferon; IL, interleukin; LAR, late asthmatic response; LT, leukotriene; MBP, major basis protein; PAF, platelet-activating factor; PG, prostaglandin.)

that mediate allergic inflammation. It is known that TH_1 cytokines inhibit the production of TH_2 cytokines, and vice versa. It is hypothesized that allergic asthmatic inflammation results from a TH_2 -mediated mechanism (an imbalance between TH_1 and TH_2 cells).¹⁵

TH_1 and TH_2 Cell Imbalance

It has been postulated that the TH_1/TH_2 imbalance contributes to the cause and evolution of atopic diseases, including asthma. The T-cell population in the cord blood of newborn infants is skewed toward a TH_2 phenotype.^{7,15} The extent of the imbalance between TH_1 and TH_2 cells (as indicated by diminished $INF-\gamma$ production) during the neonatal phase may predict the subsequent development of allergic disease, asthma, or both. It has been suggested that infants at high risk of asthma and allergies should be exposed to stimuli that upregulate TH_1 -mediated responses in order to restore the balance during a critical time in the development of the immune system and the lung.⁷

The basic premise of the hygiene hypothesis is that the newborn's immune system is skewed toward TH_2 cells and needs timely and appropriate environmental stimuli to create a balanced immune response. Factors that enhance TH_1 -mediated responses include infection with *Mycobacterium tuberculosis*, measles virus, and hepatitis A virus; increased exposure to infections through contact with older siblings; attendance at day care during the first 6 months of life; and a reduction in the production of $INF-\gamma$. Restoration of the balance between TH_1 and TH_2 cells may be impeded by frequent administration of oral antibiotics, with concomitant alterations in gastrointestinal flora. Other factors favoring the TH_2 phenotype include Western lifestyle, urban environment, diet, and sensitization to house-dust mites and cockroaches. Immune "imprinting" may begin in utero by transplacental transfer of allergens and cytokines.

Mast Cells

Mast cell degranulation is important in the initiation of immediate responses following exposure to allergens.² Mast cells are found throughout the walls of the respiratory tract, and increased numbers of these cells (three- to fivefold) have been described in the airways of asthmatics with an allergic component. Once binding of allergen to cell-bound IgE occurs, mediators such as histamine; eosinophil and neutrophil chemotactic factors; leukotrienes (LTs) C_4 , D_4 , and E_4 ; prostaglandins; platelet-activating factor; and others are released from mast cells (see Fig. 28-2). Histologic examination has revealed decreased numbers of granulated mast cells in the airways of patients who have died from acute asthma attacks, suggesting that mast cell degranulation is a contributing factor in the progression of the disease. Sensitized mast cells also may be activated by osmotic stimuli to account for exercise-induced bronchospasm (EIB).¹⁵

Alveolar Macrophages

The primary function of alveolar macrophages in the normal airway is to serve as "scavengers," engulfing and digesting bacteria and other foreign materials. They are found in large and small airways, ideally located for affecting the asthmatic response. A number of mediators produced and released by macrophages have been identified, including platelet-activating factor, LTB_4 , LTC_4 , and LTD_4 .¹⁵ Additionally, alveolar macrophages are able to produce neutrophil chemotactic factor and eosinophil chemotactic factor, which, in turn, amplify the inflammatory process.

Neutrophils

The role of neutrophils in the pathogenesis of asthma remains somewhat unclear because they normally may be present in the airways and usually do not infiltrate tissues showing chronic allergic

inflammation despite the potential to participate in late-phase inflammatory reactions. However, high numbers of neutrophils have been reported to be present in the airways of patients who died from sudden-onset fatal asthma⁷ and in those with severe disease.¹⁶ This suggests that neutrophils may play a pivotal role in the disease process, at least in some patients with long-standing or corticosteroid-dependent asthma.¹⁶ The neutrophil also can be a source for a variety of mediators, including platelet-activating factor, prostaglandins, thromboxanes, and leukotrienes, that contribute to BHR and airway inflammation.

Fibroblasts and Myofibroblasts

Fibroblasts are found frequently in connective tissue. Human lung fibroblasts may behave as inflammatory cells on activation by IL-4 and IL-13. The myofibroblast may contribute to the regulation of inflammation via the release of cytokines and to tissue remodeling. In asthma, myofibroblasts are increased in numbers beneath the reticular basement membrane, and there is an association between their numbers and the thickness of the reticular basement membrane.¹⁶

Inflammatory Mediators

Associated with asthma for many years, histamine is capable of inducing smooth muscle constriction and bronchospasm and is thought to play a role in mucosal edema and mucus secretion.² Lung mast cells are an important source of histamine. The release of histamine can be stimulated by exposure of the airways to a variety of factors, including physical stimuli (such as exercise) and relevant allergens.² Histamine is involved in acute bronchospasm following allergen exposure; however, other mediators, such as leukotrienes, are also involved.

Besides histamine release, mast cell degranulation releases interleukins, proteases, and other enzymes that activate the production of other mediators of inflammation. Several classes of important mediators, including arachidonic acid and its metabolites (i.e., prostaglandins, LTs, and platelet-activating factor), are derived from cell membrane phospholipids.

Once arachidonic acid is released, it can be metabolized by the enzyme cyclooxygenase to form prostaglandins. Although prostaglandin D₂ is a potent bronchoconstricting agent, it is unlikely to produce sustained effects and its role in asthma remains to be determined. Similarly, prostaglandin F_{2α} is a potent bronchoconstrictor in patients with asthma and can enhance the effects of histamine.² However, its pathophysiologic role in asthma is unclear. Another cyclooxygenase product, prostacyclin (prostaglandin I₂), is known to be produced in the lung and may contribute to inflammation and edema owing to its effects as a vasodilator.

Thromboxane A₂ is produced by alveolar macrophages, fibroblasts, epithelial cells, neutrophils, and platelets within the lung.¹⁵ Indirect evidence from animal models suggests that thromboxane A₂ may have several effects, including bronchoconstriction, involvement in the late asthmatic response, and involvement in the development of airway inflammation and BHR.

The 5-lipoxygenase pathway of arachidonic acid metabolism is responsible for the production of the *cysteinyl leukotrienes*.¹⁵ LTC₄, LTD₄, and LTE₄ are released during inflammatory processes in the lung. LTD₄ and LTE₄ share a common receptor (LTD₄ receptor) that, when stimulated, produces bronchospasm, mucus secretion, microvascular permeability, and airway edema, whereas LTB₄ is involved with granulocyte chemotaxis.

Thought to be produced by macrophages, eosinophils, and neutrophils within the lung, platelet-activating factor is involved in the mediation of bronchospasm, sustained induction of BHR, edema formation, and chemotaxis of eosinophils.¹⁵

Adhesion Molecules

An important step in the inflammatory process is the adhesion of the various cells to each other and the tissue matrix to facilitate infiltration and migration of these cells to the site of inflammation. To promote this, cell membranes express a number of glycoproteins, or adhesion molecules. Adhesion molecules have additional functions involved in the inflammatory process aside from promoting cell adhesion, including activation of cells and cell-cell communication, and promoting cellular migration and infiltration.² The many adhesion molecules are divided into families on the basis of their chemical structure. These families are the integrins, cadherins, immunoglobulin supergene family, selectins, vascular adreins, and carbohydrate ligands.¹⁵ Those thought to be important in inflammation include the integrins, immunoglobulin supergene family, selectins, and carbohydrate ligands, including ICAM-1 and VCAM-1.¹⁵ Adhesion molecules are found on a variety of cells, such as neutrophils, monocytes, lymphocytes, basophils, eosinophils, granulocytes, platelets, endothelial cells, and epithelial cells, and can be expressed or activated by the many inflammatory mediators present in asthma.¹⁵

CLINICAL CONSEQUENCES OF CHRONIC INFLAMMATION

Chronic inflammation is associated with nonspecific BHR and increases the risk of asthma exacerbations. Exacerbations are characterized by increased symptoms and worsening airways obstruction over a period of days or even weeks, and rarely hours. Hyperresponsiveness of the airways to physical, chemical, and pharmacologic stimuli is a hallmark of asthma.² BHR also occurs in some patients with chronic bronchitis and allergic rhinitis.² Normal healthy subjects also may develop a transient BHR after viral respiratory infections or exposure to ozone. However, the degree of BHR is quantitatively greater in asthmatic patients than in other groups. Bronchial responsiveness of the general population fits a unimodal distribution that is skewed toward increased reactivity. Patients with clinical asthma represent the extreme end of the distribution. The degree of BHR within asthmatics correlates with the clinical course of their disease and medication requirement necessary to control symptoms.² Patients with mild symptoms or in remission demonstrate lower levels of responsiveness, although still greater than the normal population.

Our current understanding recognizes that the increased BHR seen in asthma is at least in part owing to an inflammatory response within the airways. Early investigations found correlations with inflammatory cells in bronchoalveolar lavage fluids and degree of BHR.² Newer evidence suggests that airways remodeling, subepithelial fibrosis, or collagen deposition also correlates with BHR.¹⁶ Although the precise link is unknown, BHR is in part related to the extent of inflammation in the airways.

REMODELING OF THE AIRWAYS

Acute inflammation is a beneficial, nonspecific response of tissues to injury and generally leads to repair and restoration of the normal structure and function. In contrast, asthma represents a chronic inflammatory process of the airways followed by healing. The end result may be an altered structure referred to as a *remodeling of the airways*.¹⁶ Repair involves replacement of injured tissue by parenchymal cells of the same type and replacement by connective tissue and its maturation into scar tissue. In asthma, the repair process can be followed by complete or altered restitution of airways structure and function, presenting as fibrosis and an increase in smooth muscle and mucus gland mass.¹⁶

The precise mechanisms of remodeling of the airways are under intense study. Airways remodeling is of concern because it may

represent an irreversible process that can have more serious sequelae such as the development of chronic obstructive pulmonary disease.² Observations in children with asthma indicate that some loss of lung function may occur during the first 5 years of life.⁷ Of greatest concern is that no current therapies have been shown to alter either early decreased lung growth or later increased loss of lung function.

MUCUS PRODUCTION

The mucociliary system is the lung's primary defense mechanism against irritants and infectious agents. Mucus, composed of 95% water and 5% glycoproteins, is produced by bronchial epithelial glands and goblet cells.⁷ The lining of the airways consists of a continuous aqueous layer controlled by active ion transport across the epithelium in which water moves toward the lumen along the concentration gradient. Catecholamines and vagal stimulation enhance the ion transport and fluid movement. Mucus transport depends on the viscoelastic properties of the mucus. Mucus that is either too watery or too viscous will not be transported optimally. The exudative inflammatory process and sloughing of epithelial cells into the airway lumen impair mucociliary transport. The bronchial glands are increased in size and the goblet cells are increased in size and number in asthma. Expectoed mucus from patients with asthma tends to have a high viscosity. The mucus plugs in the airways of patients who died in status asthmaticus are tenacious and tend to be connected by mucous strands to the goblet cells. Asthmatic airways also may become plugged with casts consisting of epithelial and inflammatory cells. Although it is tempting to speculate that death from asthma attacks is a result of the mucus plugging resulting in irreversible obstruction, there is no direct evidence for this. Autopsies of asthmatics who died from other causes have shown similar pathology. In addition, some subjects who have died of sudden severe asthma did not show the characteristic mucus plugging on necropsy.⁷

AIRWAY SMOOTH MUSCLE

The smooth muscle of the airways does not form a uniform coat around the airways but is wrapped around in a connecting network best described as a spiral arrangement.¹⁵ The muscle contraction displays a sphincteric action that is capable of completely occluding the airway lumen. The airway smooth muscle extends from the trachea through the respiratory bronchioles. When expressed as a percentage of wall thickness, the smooth muscle represents 5% of the large central airways and up to 20% of the wall thickness in the bronchioles. Total smooth muscle mass decreases rapidly past the terminal bronchioles to the alveoli, so the contribution of smooth muscle tone to airway diameter in this region is relatively small. In the large airways of asthmatics, smooth muscle may account for 11% of the wall thickness. It is possible that the increased smooth muscle mass of the asthmatic airways is important in magnifying and maintaining BHR in chronic asthma. However, it appears that the hypertrophy and hyperplasia are secondary processes caused by chronic inflammation and are not the primary cause of BHR.⁷

NEURAL CONTROL/NEUROGENIC INFLAMMATION

The airway is innervated by parasympathetic, sympathetic, and nonadrenergic inhibitory nerves.² Parasympathetic innervation of the smooth muscle consists of efferent motor fibers in the vagus nerves and sensory afferent fibers in the vagus and other nerves.¹⁵ The normal resting tone of human airway smooth muscle is maintained by vagal efferent activity. Maximum bronchoconstriction mediated by vagal stimulation occurs in the small bronchi and is

absent in the small bronchioles. The nonmyelinated C fibers of the afferent system lie immediately beneath the tight junctions between epithelial cells lining the airway lumen.¹⁵ These endings probably represent the irritant receptors of the airways. Stimulation of these irritant receptors by mechanical stimulation, chemical and particulate irritants, and pharmacologic agents such as histamine produces reflex bronchoconstriction.¹⁵

The nonadrenergic noncholinergic (NANC) nervous system has been described in the trachea and bronchi. Substance P, neurokinin A, neurokinin B, and vasoactive intestinal peptide are the best-characterized neurotransmitters in the NANC nervous system.¹⁵ Vasoactive intestinal peptide is an inhibitory neurotransmitter in the system. Inflammatory cells in asthma can release peptidases that can degrade vasoactive intestinal peptide, producing exaggerated reflex cholinergic bronchoconstriction. NANC excitatory neuropeptides such as substance P and neurokinin A are released by stimulation of C-fiber sensory nerve endings. The NANC system may play an important role in amplifying inflammation in asthma by releasing NO.

NITRIC OXIDE

NO is produced by cells within the respiratory tract. It has been thought to be a neurotransmitter of the NANC nervous system.¹⁷ Endogenous NO is generated from the amino acid L-arginine by the enzyme NO synthase.¹⁷ There are three isoforms of NO synthase. One isoform is induced in response to proinflammatory cytokines, inducible NO synthase, in airway epithelial cells and inflammatory cells of asthmatic airways.¹⁷ NO produces smooth muscle relaxation in the vasculature and bronchials; however, it appears to amplify the inflammatory process and is unlikely to be of therapeutic benefit. Recent investigations measuring the fraction of exhaled NO (FeNO) concentrations have suggested that it may be a useful measure of ongoing lower airways inflammation in patients with asthma and for guiding asthma therapy.¹⁷

CLINICAL PRESENTATION

CHRONIC ASTHMA

3 Classic asthma is characterized by episodic dyspnea associated with wheezing; however, the clinical presentation of asthma is as diverse as the number of triggering events (see Clinical Presentation: Chronic Ambulatory Asthma). Although wheezing is the characteristic symptom of asthma, the medical literature is replete with the warning that “not all that wheezes is asthma.” A wheeze is a high-pitched, whistling sound created by turbulent airflow through an obstructed airway, so any condition that produces significant obstruction can result in wheezing as a symptom. In addition, “all of asthma does not wheeze” is an equally justifiable warning. Patients may present with a chronic persistent cough as their only symptom.²

CLINICAL PRESENTATION: CHRONIC AMBULATORY ASTHMA

General

- Asthma is a disease of exacerbation and remission, so the patient may not have any signs or symptoms at the time of examination.

Symptoms

- The patient may complain of episodes of dyspnea, chest tightness, coughing (particularly at night), wheezing, or a whistling sound when breathing. These often occur in association with exercise, but also occur spontaneously or in association with known allergens.

Signs

- Expiratory wheezing on auscultation, dry hacking cough, or signs of atopy (allergic rhinitis and/or eczema) may occur.

Laboratory

- Spirometry demonstrates obstruction (reduced FEV₁/FVC) with reversibility following inhaled β_2 -agonist administration (at least a 12% improvement in FEV₁).

Other Diagnostic Tests

- A fall in FEV₁ of at least 15% following 6 minutes of near maximal exercise. Elevated eosinophil count and IgE concentration in blood. Elevated FeNO (greater than 20 parts per billion in children younger than 12 years of age, and greater than 25 parts per billion in adults). Positive methacholine challenge (PC₂₀ FEV₁ less than 12.5 mg/mL).

There is no single test that can diagnose asthma. The diagnosis is based primarily on a good history (Table 28–2).^{2,6} The patient may have a family history of allergy or asthma or have symptoms of allergic rhinitis.² Reversibility of airways obstruction following administration of an inhaled short-acting β_2 -agonist provides confirmation but is not by itself diagnostic. Patients with normal values of spirometry can be challenged by exercise or substances that produce bronchoconstriction, such as methacholine, to determine if they have hyperresponsive airways, but again, positive challenges are not diagnostic. Newer tests of inflammation in the airways such as induced sputum eosinophil counts and FeNO measurements are consistent with but not diagnostic of asthma.

Asthma has a widely variable presentation from chronic daily symptoms to only intermittent symptoms. The intervals between symptoms can be days, weeks, months, or years. Asthma also can vary as to its severity, the intrinsic intensity of the disease process. Severity is most easily and directly measured in a patient who is not currently receiving asthma treatment. The NAEPP has provided a means of classifying asthma severity that is broken down into two domains: impairment and risk.⁶ This classification system is individualized for three age groups (0 to 4 years, 5 to 11 years, and ≥ 12 years) and summarized in Table 28–3. The intermittent and/or chronic nature of symptoms does not necessarily determine the severity of symptoms during exacerbations. The severity is determined by lung function, symptoms, nighttime awakenings, and interference with normal activity prior to therapy. Patients can present with a range from intermittent symptoms that require no medications or only occa-

sional use of short-acting inhaled β_2 -agonists to severe persistent asthma symptoms despite receiving multiple medications.

SEVERE ACUTE ASTHMA

Uncontrolled asthma, with its inherent variability, can progress to an acute state where inflammation, airways edema, excessive accumulation of mucus, and severe bronchospasm result in a profound airways narrowing that is poorly responsive to usual bronchodilator therapy (see Clinical Presentation: Severe Acute Asthma).^{2,6} Although this progression is the most common scenario, some patients experience rapid onset or hyperacute attacks.^{2,6} Hyperacute attacks are associated with neutrophilic as opposed to eosinophilic infiltration and resolve rapidly with bronchodilator therapy, suggesting that smooth muscle spasm is the major pathogenic mechanism.⁶ In most cases, emergency department visits for severe acute asthma represent the failure of an adequate therapeutic regimen for persistent asthma. Underuse of antiinflammatory drugs and excessive reliance on short-acting inhaled β_2 -agonists are the major risk factors for severe exacerbations.² A blunted perception of airway obstruction may predispose certain individuals to fatal asthma attacks.²

**CLINICAL PRESENTATION:
SEVERE ACUTE ASTHMA****General**

- An episode can progress over several days or hours (usual scenario) or can progress rapidly over 1 to 2 hours.

Symptoms

- The patient is anxious in acute distress and complains of severe dyspnea, shortness of breath, chest tightness, or burning. The patient is only able to say a few words with each breath. Symptoms are unresponsive to usual measures (inhaled short-acting β_2 -agonist administration).

Signs

- Signs include expiratory and inspiratory wheezing on auscultation (breath sounds may be diminished with very severe obstruction), dry hacking cough, tachypnea, tachycardia, pale or cyanotic skin, hyperinflated chest with intercostal and supraclavicular retractions, and hypoxic seizures if very severe.

Laboratory

- PEF and/or FEV₁ less than 50% of normal predicted values. Decreased arterial oxygen (PaO₂), and O₂ saturations by pulse oximetry (SaO₂ less than 90% on room air is severe). Decreased arterial or capillary CO₂ if mild, but in the normal range or increased in moderate to severe obstruction.

Other Diagnostic Tests

- Blood gases to assess metabolic acidosis (lactic acidosis) in severe obstruction. Complete blood count if there are signs of infection (fever and purulent sputum). Serum electrolytes as therapy with β_2 -agonist and corticosteroids can lower serum potassium and magnesium and increase glucose. Chest radiograph if signs of consolidation on auscultation.

TABLE 28-2 Sample Questions^a for the Diagnosis and Initial Assessment of Asthma

A “yes” answer to any question suggests that an asthma diagnosis is likely. In the past 12 months...
Have you had a sudden severe episode or recurrent episodes of coughing, wheezing (high-pitched whistling sounds when breathing out), chest tightness, or shortness of breath?
Have you had colds that “go to the chest” or that take more than 10 days to get over?
Have you had coughing, wheezing, or shortness of breath during a particular season or time of the year?
Have you had coughing, wheezing, or shortness of breath in certain places or when exposed to certain things (e.g., animals, tobacco smoke, perfumes)?
Have you used any medications that help you breathe better? How often?
Are your symptoms relieved when the medications are used?
In the past 4 weeks, have you had coughing, wheezing, or shortness of breath...
At night that has awakened you?
Upon awakening?
After running, moderate exercise, or other physical activity?

^aThese questions are recommended by the National Asthma Education and Prevention Program but have not been formally validated.

EXERCISE-INDUCED BRONCHOSPASM

During vigorous exercise, pulmonary functions (FEV₁ and peak expiratory flow [PEF]) in patients with asthma increase during the first few minutes but then begin to decrease after 6 to 8 minutes (Fig. 28–3).² EIB is defined as a drop in FEV₁ of greater than 15% of baseline (preexercise value).² Most studies suggest that many patients with persistent asthma experience EIB.² The exact pathogenesis of EIB is unknown, but heat loss and/or water loss from the central airways

TABLE 28-3 Classifying Asthma Severity for Patients Who Are Not Currently Taking Long-Term Control Medications					
Children 0–4 Years and 5–11 Years of Age					
		Persistent			
	Components	Intermittent	Mild	Moderate	Severe
Impairment	Symptoms	≤2 days/week	>2 days/week but not daily	Daily	Throughout the day
	Nighttime awakenings (0–4 years)	0	Once or twice per month	Three to four times per month	> once per week
	(5–11 years)	≤ twice per month	Three to four times per month	> once per week, but not nightly	Often seven times per week
	SABA use for symptom control	≤2 days/week	>2 days/week but not daily	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function (5–11 years)	FEV ₁ >80% FEV ₁ /FVC >85%	FEV ₁ >80% FEV ₁ /FVC >80%	FEV ₁ 60%–80% FEV ₁ /FVC 75%–80%	FEV ₁ <60% FEV ₁ /FVC <75%
Risk	Exacerbations	Intermittent	Persistent		
	(0–4 years)	0–1/year	≥2 in 6 months or ≥4 wheezing episodes/1 year lasting >1 day		
	(5–11 years)	0–2/year	>2 in 1 year →		
	Recommended step for initiating treatment	Step 1	Step 2	Step 3 and consider short course of systemic oral corticosteroids	
Youths ≥12 Years of Age and Adults					
		Persistent			
	Components	Intermittent	Mild	Moderate	Severe

FEV₁, force expiratory volume in the first second of expiration; FVC, forced vital capacity; SABA, short-acting β -antagonist.

appears to play an important role.¹⁸ EIB is provoked more easily in cold, dry air, and warm, humid air can blunt or block it.¹⁸ A number of studies have demonstrated increased plasma histamine, cysteinyl leukotrienes, prostaglandins, and tryptase concentrations during EIB, suggesting a role for mast cell degranulation.¹⁸

FIGURE 28-3. Typical responses to exercise in a normal subject and an asthmatic subject. Note the initial bronchodilation. (PEFR, peak expiratory flow rate.)

A refractory period following EIB lasts up to 3 hours after exercise. During this period, repeat exercise of the same intensity produces either no decrease in pulmonary function or a drop of less than 50% of the initial response.¹⁸ This refractory period is thought to be caused by an acute depletion of mast cell mediators and time required for their repletion. Patients with known refractoriness to exercise will still respond to histamine, so acute hyporesponsiveness of airway smooth muscle does not appear to be a factor.¹⁸

Exercise-induced bronchospasm is believed to be a reflection of the increased BHR of asthmatics. A correlation, though not perfect, exists between EIB and reactivity to histamine and methacholine.¹⁸ Other patient groups with BHR (e.g., after viral infection, cystic fibrosis, or allergic rhinitis) show bronchoconstriction after exercise to a lesser degree (5% to 10% drop) than patients with asthma (20% to 40% drops).¹⁸ Patients will not always demonstrate the same sensitivity. During periods of remission, they often have a decreased sensitivity to the same degree of exercise. Finally, a number of children and adults with EIB are otherwise normal, without symptoms or abnormal pulmonary function except in association with exercise.² Elite athletes have a higher prevalence of EIB than the general population.¹⁸

NOCTURNAL ASTHMA

3 Worsening of asthma during sleep is referred to as *nocturnal asthma*. Patients with nocturnal asthma exhibit significant falls in pulmonary function between bedtime and awakening.^{2,8} Typically, their lung function reaches a nadir at 3 to 4 AM. Although the pathogenesis of this phenomenon is unknown, it is associated with

diurnal patterns of endogenous cortisol secretion and circulating epinephrine.⁸ Direct evidence for an inflammatory component to nocturnal asthma includes increased circulating histamine and activated eosinophils and leukotriene excretion at night associated with increased hyperresponsiveness to methacholine.⁸

Numerous other factors that may affect nocturnal worsening of asthma, including allergies and improper environmental control, gastroesophageal reflux, obstructive sleep apnea, and sinusitis, also must be considered when evaluating these patients.^{2,6} Most experts consider nocturnal asthma to be a sign of inadequately treated persistent asthma.^{2,8} Awakening from nocturnal asthma is a sensitive indicator of both severity and asthma control.⁶

FACTORS CONTRIBUTING TO ASTHMA SEVERITY

VIRAL RESPIRATORY INFECTIONS

Viral respiratory infections are primarily responsible for exacerbations of asthma, particularly in children younger than age 10 years.⁶ Infants are particularly susceptible to airways obstruction and wheezing with viral infections because of their small airways. The most common cause of exacerbations in both children and adults is the common rhinovirus.⁶ Other viruses isolated include respiratory syncytial virus, parainfluenza virus, coronavirus, and influenza viruses. The inflammatory response to viral infection is thought to be associated directly with the increasing BHR. Certain viruses (respiratory syncytial virus and parainfluenza virus) are capable of inducing specific IgE antibodies, and rhinovirus can activate eosinophils directly in asthmatics. The increase in asthma symptoms and BHR that occurs may last for days or weeks following resolution of the symptoms of the viral infection. Recent evidence does not support a beneficial effect of influenza vaccine for preventing asthma exacerbations from subsequent influenza infections.¹⁹

ENVIRONMENTAL AND OCCUPATIONAL FACTORS

Table 28–1 lists the agents, events, and mechanisms that are known to trigger asthma.^{2,8} The general mechanisms are unknown but presumably are the result of epithelial damage and inflammation in the airway mucosa. Ozone and sulfur dioxide, common components of air pollution, have been used to induce BHR in animals. Exposure to 0.2 parts per million ozone for 2 to 3 hours can induce bronchoconstriction and increase BHR in asthmatics.^{2,8} Sulfur dioxide in the ambient atmosphere is highly irritating. It presumably induces bronchoconstriction through mast cell or irritant-receptor involvement.⁸ Asthma produced by repeated prolonged exposure to industrial inhalants is a significant health problem. It has been estimated that occupational asthma accounts for 2% of all asthmatic persons.¹³ Persons with occupational asthma have the typical symptoms of asthma with cough, dyspnea, and wheeze. Typically, the symptoms are related to work and improve on weekends and during vacations.¹³ In some instances, symptoms may persist even after termination of exposure.¹³

STRESS, DEPRESSION, AND PSYCHOSOCIAL FACTORS IN ASTHMA

Observational studies demonstrate an association between increased stress and worsening asthma, but the role is not clearly defined.⁶ Bronchoconstriction from psychological factors appears to be mediated primarily through excess parasympathetic input. Atropine has been shown to block experimental psychogenic bronchoconstriction. It is most important to emphasize to both patients and

parents that asthma is not an emotional disease; however, coping skills may benefit the patient who becomes emotionally distraught during an asthma attack.

RHINITIS AND SINUSITIS

Disorders of the upper respiratory tract, particularly rhinitis and sinusitis, have been linked with asthma for many years. As many as 40% to 50% of asthmatics have abnormal sinus radiographs.² However, chronic sinusitis may just represent a nonbacterial coexisting condition with allergic asthmatics because the histologic changes in the paranasal sinuses are similar to those seen in the lung and nose.² Treatment of upper airway disease may optimize overall asthma control. The mechanism by which sinusitis aggravates asthma is unknown. The treatment of allergic rhinitis with inhaled corticosteroids and cromolyn but not antihistamines will reduce BHR in asthmatic patients.² It has been postulated that transport of mucus chemotactic factors and inflammatory mediators from nasal passages during allergic rhinitis into the lung may accentuate BHR.

GASTROESOPHAGEAL REFLUX DISEASE

Symptoms of gastroesophageal reflux disease are common in both children and adults who have asthma.⁶ Nocturnal asthma may be associated with nighttime reflux.⁸ Reflux of acidic gastric contents into the esophagus is thought to initiate a vagally mediated reflex bronchoconstriction.⁸ Also of concern is that most medications that decrease airways smooth muscle tone also have a relaxant effect on gastroesophageal sphincter tone. Although a systematic review concluded there was no significant improvement in asthma symptoms from medical management of gastroesophageal reflux disease, the standard approach is to initiate standard antireflux therapy in those patients who are exhibiting symptoms of reflux (particularly with nocturnal asthma) and observe the asthma symptoms.^{2,20}

FEMALE HORMONES AND ASTHMA

Premenstrual worsening of asthma has been reported in as many as 30% to 40% of women in some studies, whereas worsening of pulmonary functions has been reported even in women who are unaware of worsening symptoms.²¹ The pathophysiology is uncertain because estrogen replacement in postmenopausal women worsens asthma, whereas estradiol and progesterone administration have been variably reported to improve or have no effect on asthma in women with premenstrual asthma.²¹ The clinical significance of menstruation-related asthma is still unclear because some studies report that up to 50% of emergency department visits by women were premenstrual, whereas others report no association with menstrual phase.^{21,22} Studies indicate that, in general, BHR and symptoms improve in asthmatics during pregnancy.^{8,21}

FOODS, DRUGS, AND ADDITIVES

There is no documentation in the literature of food allergens as triggers for asthma.⁸ However, additives, specifically sulfites used as preservatives, can trigger life-threatening asthma exacerbations. Beer, wine, dried fruit, and open salad bars in particular have high concentrations of metabisulfites.² Severe oral corticosteroid-dependent patients should be warned about ingesting foods processed with sulfites. Another additive producing bronchospasm is benzalkonium chloride, which is found as a preservative in some nebulizer solutions of antiasthmatic drugs.²³

Aspirin and other nonsteroidal antiinflammatory drugs can precipitate an attack in up to 20% of adults and 5% of children with asthma.²⁴ The mechanism is related to cyclooxygenase inhibition, and

5-lipoxygenase inhibition can alter dose–response but cannot completely block the symptoms.²⁴ The prevalence increases with age and severity of asthma.⁶ The greatest frequency occurs in severe corticosteroid-dependent asthmatics in their fourth and fifth decades who also have perennial rhinitis and nasal polyposis (presence of several polyps).²⁴ Other drugs that do not precipitate bronchospasm but which prevent its reversal are the nonselective β -blocking agents.^{2,6}

TREATMENT

Asthma

AEROSOL THERAPY FOR ASTHMA

4 5 Aerosol delivery of drugs for asthma has the advantage of being site-specific and thus enhancing the therapeutic ratio.^{2,25} Inhalation of short-acting β_2 -agonists provides more rapid bronchodilation than either parenteral or oral administration, as well as the greatest degree of protection against EIB and other challenges.² Inhaled corticosteroids have been developed with rapid oral and systemic clearance to enhance lung activity and reduce systemic activity. Specific agents (e.g., cromolyn, nedocromil, formoterol, salmeterol, and ipratropium) are only effective by inhalation.²⁵ The international ban on the production and use of chlorofluorocarbons, has resulted in the ongoing development of new devices for delivering topically active medication.^{2,25} Consequently, an understanding of aerosol drug delivery is essential to optimal asthma therapy. Table 28–4 lists the factors determining lung deposition of therapeutic aerosols.

Device Determinants of Delivery

Devices used to generate therapeutic aerosols include jet nebulizers, ultrasonic nebulizers, metered-dose inhalers (MDIs), and dry-

powder inhalers (DPIs). The single most important device factor determining the site of aerosol deposition is particle size.²⁵ Devices for delivering therapeutic aerosols generate particles with aerodynamic diameters from 0.5 to 35 microns.²⁵ Particles larger than 10 microns deposit in the oropharynx, particles between 5 and 10 microns deposit in the trachea and large bronchi, particles 1 to 5 microns in size reach the lower airways, and particles smaller than 0.5 microns act as a gas and are exhaled. In asthma, the airways, not the alveoli, are the target for delivery. Respirable particles are deposited in the airways by three mechanisms: (a) inertial impaction, (b) gravitational sedimentation, and (c) Brownian diffusion.²⁵ The first two mechanisms are the most important for therapeutic aerosols and probably are the only factors that can be manipulated by patients.

Each delivery device within a classification generates specific aerosol characteristics, so extrapolation of delivery data from one device cannot be done for the other devices in the class. For instance, MDIs can deliver 5% to 50% of the actuated dose; DPIs, 10% to 30% of the labeled dose; and nebulizers, 2% to 15% of the starting dose.²⁵ Unlike nebulizers, MDIs and DPIs are portable and convenient. MDIs consist of a pressurized canister with a metering valve; the canister contains active drug, low-vapor-pressure propellants such as chlorofluorocarbon or hydrofluoroalkane (HFA), cosolvents, and/or surfactants.²⁵ With any change in these components, the Food and Drug Administration (FDA) considers it to be a new drug that requires stability, safety, and efficacy studies prior to approval. The drug is either in solution or a suspended micronized powder. To disperse the suspension for accurate delivery, the canister must be shaken. The metering chamber measures a liquid volume; consequently, the device must be held with the valve stem facing downward so that the chamber is covered with liquid (Fig. 28–4).²⁵ When the canister is actuated, the device releases the propellant and drug in a forceful spray whose particles are large (mass median aerodynamic diameter [MMAD] = 45 microns; Fig. 28–4).²⁵ As evaporation occurs, the particle size is reduced to a final MMAD of 0.5 to 5.5 microns depending on the MDI. The aerosol cloud of a chlorofluorocarbon-propelled MDI extends at least 10 inches beyond the MDI at the lowest MMAD, and that of an HFA-propelled MDI extends about 6 inches.²⁵

The breath-actuated MDI Autohaler, is cocked with a lever to “load” the dose of medication, a baffle is opened by inspiratory pressure, and the dose is expelled from the canister metering chamber.²⁵ Although the need for hand–lung coordination for proper actuation is reduced significantly with breath-actuated MDIs, these devices do not allow the use of a spacer device.

Spacer devices are used frequently with a MDI to decrease oropharyngeal deposition and enhance lung delivery.^{2,6} However, not all spacer devices produce similar effects. The design of spacers varies from simple, open-ended tubes that separate the MDI from the mouth to holding chambers with one-way valves (valved hold-

TABLE 28-4 Factors Determining Lung Deposition of Aerosols		
Device	Device Factors	Patient Factors
Metered-dose inhaler (MDI)	Canister held inverted	Inspiratory flow (slow, deep)
	Formulation (CFC, HFA, solution, suspension)	Breath-holding
	Actuator cleanliness	Coordinating actuation with inhalation
Dry-powder inhaler (DPI)	Addition of a spacer device	Priming and shaking the device
	Device cleanliness	Inspiratory flow (deep, forceful)
	Resistance to inhalation	Tilting head back
Jet nebulizer (small volume)	Humidity	Maintaining parallel to ground once activated
	Volume fill (3–6 mL)	Inspiratory flow (slow, deep)
	Gas flow (6–12 L/min)	Breath-holding
Ultrasonic nebulizer	Dead-space volume	Tapping nebulizer
	Open versus closed system	
	Thumb-activating valve	
Spacer device	Mouthpiece versus face mask	Inspiratory flow (slow, deep)
	Volume (≥ 650 mL)	Breath-holding
	One-way valves	Tapping nebulizer
	Holding chamber versus open-ended	Inspiratory flow (slow, deep)
	Metal versus plastic	Time between actuation and inhalation (<5 s)
	Mouthpiece versus face mask	Cleaning with detergent to reduce static
		Multiple actuations decrease delivery
		Coordination of actuation and inhalation for the simple open-tube spacers

CFC, chlorofluorocarbon; HFA, hydrofluoroalkane.

FIGURE 28-4. Illustration of a metered-dose inhaler demonstrating the particle size difference as the aerosol cloud extends outward.

ing chambers [VHCs]) that open during inhalation (the preferred system). A VHC allows evaporation of the propellant prior to inhalation permitting a greater number of drug particles to achieve a respirable droplet size. It also allows inhalation after actuation of the device, obviating the need for good hand–lung coordination.²⁵ Additionally, the large particles that normally would deposit in the oropharynx “rain out” in the spacer.²⁵ All the available spacers significantly reduce oropharyngeal deposition from MDIs, with the VHCs being superior to the open-ended tubes.²⁵ This reduction in oropharyngeal deposition is an important factor in reducing local adverse effects (i.e., hoarseness and thrush) from inhaled corticosteroids.²⁵ The change in lung delivery depends on both the MDI and the drug, where one spacer device may enhance delivery with one MDI preparation and decrease delivery with others.²⁵ The use of VHCs is less likely to enhance delivery from HFA propelled MDIs. Finally, over time, holding chambers can build up static electricity that attracts small particles to the sides of the chamber, significantly reducing aerosol availability. It is recommended that some spacers be washed weekly with household detergent, with a single rinse, and allowed to drip dry.²⁵

Dry, micronized powders can be inhaled directly into the lung. A number of DPIs are now available for use in the United States, and others are under development.²⁵ Currently, there are no generic DPIs as each drug plus device has its own patent. Each DPI has unique characteristics with advantages and disadvantages (Table 28–5). The primary advantage of DPIs is that they are breath-actuated and require minimal hand–lung coordination, making it easier to teach patients proper technique.²⁵ Some DPIs are more flow-dependent than others.²⁵ Thus, similar to MDIs and spacers, delivery data from one DPI cannot be extrapolated to another.

Nebulizers come in two basic types: the jet nebulizer and the ultrasonic nebulizer. Jet nebulizers produce an aerosol from a liquid solution or suspension placed in a cup. A tube connected to a stream of compressed air or oxygen flows up through the bottom and draws the liquid up an adjacent open-ended tube.²⁵ The air and liquid strike a baffle, creating a droplet cloud that is then inhaled.²⁵ Ultrasonic nebulizers produce an aerosol by vibrating liquid lying

above a transducer at speeds of about 1 MHz.²⁵ Both produce similar degrees of lung deposition, with the exception that ultrasonic nebulizers are ineffective for nebulizing micronized suspensions.²⁵ The aerosol output and lung delivery vary significantly among the commercially available jet nebulizers even when operated in the same manner.²⁵ Increasing fill volume will increase the total amount of drug delivered; however, it also will take longer for the patient to nebulize the dose.²⁵ The MMAD of the droplets is related directly to the gas flow, with flows of 5 to 12 L/min providing an aerosol cloud with a MMAD of 4 to 8 microns for most jet nebulizers.²⁵ Each jet nebulizer comes with its optimal operating instructions.

Patient Determinants of Delivery (See Table 28–4)

6 7 The most important patient factor determining aerosol deposition is inspiratory flow.^{2,25} High inspiratory flows increase the degree of deposition owing to impaction of particles of any size, thereby increasing deposition centrally (i.e., throat and large airways) and decreasing peripheral deposition. Use of a VHC will enhance the clinical efficacy in patients with poor hand–lung coordination but may offer no advantage in patients who can use an MDI optimally alone.²⁵ Optimal inspiratory flow for most MDIs is slow and deep (approximately 30 L/min or 5 seconds for a full inhalation).² In general, DPIs require higher inspiratory flows (≥60 L/min) and a change in inhalation technique (i.e., deep, forceful inspiration) for optimal dispersion of the powder, which, in turn, increases the amount of drug delivered to the larger central airways.²⁵ However, this difference in delivery may not produce clinically significant differences.²⁵ Patients should be cautioned not to exhale into DPIs because this causes loss of dose and moistens the dry powder, causing aggregation into larger particles. Patient factors that cannot be controlled include interpatient variability in airway geometry (particularly the differences between children and adults)²⁵ and the effects of bronchospasm, edema, and mucus hypersecretion. Mild obstruction increases aerosol deposition; however, severe obstruction probably leads to increased central deposition from impac-

TABLE 28-5 Characteristics of Various Inhalation Devices

Device	Drugs	Breath-Activated	Dose Counter	Other Excipients	Disadvantages
CFC MDI	All classes	No	No	Propellants, surfactants	Requires coordination of actuation and inhalation Large pharyngeal deposition Difficult to teach
HFA MDI	Albuterol	No	No/Yes	Propellants, surfactants, cosolvents	Same as CFC MDI
	Levalbuterol	No	No		
	Corticosteroids	No	No		
Autohaler MDI	Pirbuterol	Yes	No	CFC propellant, surfactant	Requires rapid inhalation to activate
MDI plus holding chamber	All classes	No	No		More expensive than MDI alone; less portable; some payers will not pay; inconsistent effect on delivery
Jet nebulizers	All classes	No	—	Preservatives in some solutions	Significant interbrand variability; expensive and time-consuming; less efficient than MDIs; contamination possible; preparations may be light- and temperature-sensitive (short shelf-life)
Ultrasonic nebulizer	Cromolyn solution short-acting β_2 -agonist solutions	No	—	Preservatives in some solutions	Same as for jet nebulizers plus cannot be used for suspensions
Turbuhaler	Budesonide	Yes	Indicator for last 20 doses	No	Requires high inspiratory flow (60 L/min). Pharyngeal deposition; not approved for <6 years of age
Diskus	Fluticasone	Yes	Yes	Lactose filler	Not approved for <4 years of age
	Salmeterol				
	Fluticasone/salmeterol				
Aerolizer	Formoterol	Yes	—	Lactose filler	Single-dose capsules; not approved for <5 years of age
Twisthaler	Mometasone	Yes	Yes	Lactose filler	Requires high inspiratory flow (≥60 L/min) Not approved for <12 years of age

CFC, chlorofluorocarbon; HFA, hydrofluoroalkane; MDI, metered-dose inhaler.

Steps for Using Your Inhaler

Please demonstrate your inhaler technique at every visit.

1. Remove the cap and hold inhaler upright.
2. Shake the inhaler.
3. Tilt your head back slightly and breathe out slowly.
4. Position the inhaler in one of the following ways (A or B is optimal, but C is acceptable for those who have difficulty with A or B. C is required for breath-activated inhalers):

A Open mouth with inhaler 1 to 2 inches away.

B Use spacer/holding chamber (that is recommended especially for young children and for people using corticosteroids).

C In the mouth. Do not use for corticosteroids.

D NOTE: Inhaled dry powder capsules require a different inhalation technique. To use a dry powder inhaler, it is important to close the mouth tightly around the mouthpiece of the inhaler and to inhale rapidly.

5. Press down on the inhaler to release medication as you start to breathe in slowly.
6. Breathe in slowly (3 to 5 seconds).
7. Hold your breath for 10 seconds to allow the medicine to reach deeply into your lungs.
8. Repeat puff as directed. Waiting 1 minute between puffs may permit second puff to penetrate your lungs better.
9. Spacers/holding chambers are useful for all patients. They are particularly recommended for young children and older adults and for use with corticosteroids.

Avoid common inhaler mistakes. Follow these inhaler tips:

- Breathe out *before* pressing your inhaler.
- Inhale *slowly*.
- Breathe in through your mouth, not your nose.
- Press down on your inhaler at the *start* of inhalation (or within the first second of inhalation).
- Keep inhaling as you press down on inhaler.
- Press your inhaler only *once* while you are inhaling (one breath for each puff).
- Make sure you breathe in evenly and deeply.

NOTE: Other inhalers are becoming available in addition to those illustrated above. Different types of inhalers require different techniques.

FIGURE 28-5. Instructions for inhaler use from the National Asthma Education and Prevention Program Expert Panel Report 2. (Adapted from reference 2.)

tion.²⁵ The absolute delivery to the lung is not as important as consistency of delivery, assuming that a sufficient dose to produce the desired therapeutic effect is achieved. No single inhalation device is the best for all patients. Table 28–5 lists the differing characteristics of inhalation devices.

Appropriate inhalation technique is essential to achieve optimal drug delivery and therapeutic effect.^{2,8} Figure 28–5 illustrates the components of appropriate technique. Approximately 50% to 80% of a dose from MDIs and DPIs impacts on the oropharynx and is then swallowed; the rest is either left in the device or exhaled.²⁵ It is important that actuation occurs during inhalation, although the time during inspiration is unimportant.^{2,25} Although radiolabeled studies with chlorofluorocarbon-propelled MDIs indicate improved delivery by holding the actuator 2 to 3 cm in front of an open mouth to allow more evaporation and less impaction, physiologic studies with bronchodilators have failed to document an advantage for this method.^{2,25} Many patients do not use their MDIs optimally, and patient instruction with demonstration is the most effective means of improving inhaler technique.^{2,25} Even with instruction, up to 30% of patients, particularly young children and the elderly, cannot master the use of an MDI. For these patients, attachment of a VHC to the MDI or use of a breath-actuated MDI can improve efficacy significantly.^{2,25} Mouth rinsing following treatment with MDI- and DPI-inhaled corticosteroids is important to minimize local effects and oral absorption.^{2,25}

Delivery from high-resistance DPIs is more flow-dependent than from low-resistance DPIs. Thus younger children, and possibly

elderly adults, will have more variability in delivery from high-resistance devices.²⁵ Most children who are younger than 4 years of age cannot generate a sufficient inspiratory flow to use DPIs. Young children (age <4 years) and infants generally require the use of a face mask attached to either an MDI plus VHC or to a nebulizer. The use of a face mask results in a reduction in lung delivery because of the portion of the aerosol inhaled nasally so the doses of drugs used in these patients is often not decreased from that of older children.

TREATMENT

Severe Acute Asthma

The primary goal is prevention of life-threatening asthma by early recognition of signs of deterioration and early intervention. As such, the principal goals of treatment include²

- Correction of significant hypoxemia
- Rapid reversal of airflow obstruction
- Reduction of the likelihood of relapse of the exacerbation or future recurrence of severe airflow obstruction
- Development of a written asthma action plan in case of a further exacerbation

These goals are best achieved by early initiation or intensification of treatment and close monitoring of objective measures of oxygen-

ation and lung function.² Early response to treatment as measured by the improvement in FEV₁ at 30 minutes following inhaled β_2 -agonists is the best predictor of outcome.^{2,8} Providing adequate oxygen supplementation to maintain oxygen (O₂) saturations above 90% (or above 95% in pregnant women and those who have coexistent heart disease) is essential. In children younger than 6 years of age, in whom lung function measures are difficult to obtain, a combination of objective (e.g., oxygen saturation, capillary CO₂, respiratory rate, and heart rate) and subjective measures may be used to assess severity.^{2,8}

The primary therapy of acute exacerbations is pharmacologic, which includes inhaled short-acting β_2 -agonists and, depending on the severity, systemic corticosteroids, inhaled ipratropium and O₂ (Figs. 28–6 and 28–7).⁶ It is important that therapy not be delayed, so the history and physical examination should be obtained while initial therapy is being provided. Patients at risk for life-threatening exacerbations require special attention. Risk factors include a history of previous severe asthma exacerbations (e.g., hospitalizations, intubations, or hypoxic seizures); difficulty perceiving asthma symptoms or severity of exacerbations; comorbidities (e.g., cardiac disease, other chronic lung disease, illicit drug use, or major psychosocial/psychiatric history); use of more than two canisters per month of short-acting inhaled β_2 -agonists; and current intake of oral corticosteroids or recent withdrawal from oral corticosteroids.⁶

A complete blood count may be appropriate for patients with fever or purulent sputum, but modest leukocytosis is common in asthma exacerbations as a consequence of viral infection or secondary to corticosteroid administration. Chest radiography is not recommended for routine assessment but should be obtained for patients suspected of a complicating cardiopulmonary process or another pulmonary process (pneumothorax or pulmonary consolidation).² Serum electrolytes should be monitored if high-dose continuous-

inhaled or systemic β_2 -agonists are to be used because they can produce transient decreases in potassium, magnesium, and phosphate.²⁶ Measurement of serum electrolytes is also prudent in patients who take diuretics regularly, and in patients with coexistent cardiovascular disease. The combination of high-dose β_2 -agonists and systemic corticosteroids occasionally may result in excessive elevations of glucose.²⁶

Initial response should be achieved within minutes, and most patients experience significant improvement within the first 30 to 60 minutes of therapy, with most patients doubling their FEV₁ or PEF.²⁷ In patients ultimately admitted to the hospital, only a 10% to 20% predicted improvement is seen within the first 2 hours. Hypoxemia, primarily a result of ventilation–perfusion mismatch, is immediately correctable by low-flow oxygen.² While reversal of lung function into the normal range may take 12 to 24 hours, complete restoration takes much longer—up to 3 to 7 days.^{8,26} A strategy to prevent recurrence, such as systemic corticosteroids and symptom or PEF monitoring, should be used.^{2,8} It is essential to provide the patient with a self-management plan that includes a written action plan for dealing with exacerbations. Patients who are at risk for severe exacerbations should be taught how to use a peak-flow meter and to monitor morning peak flows at home.^{2,8} In young children, an increased respiratory rate, increased heart rate, and inability to speak more than one or two words between breaths are signs of severe obstruction.² Oxygen saturations by pulse oximetry and peak flows should be measured in all patients who are not completely responding to initial intensive inhaled β_2 -agonist therapy. Initially, on admission, the peak flows or clinical symptoms should be monitored every 2 to 4 hours. Prior to discharge from the emergency department or hospital, the patient should be given a sufficient supply of prednisone, taught the purpose of the medications and proper inhaler technique, and referred to

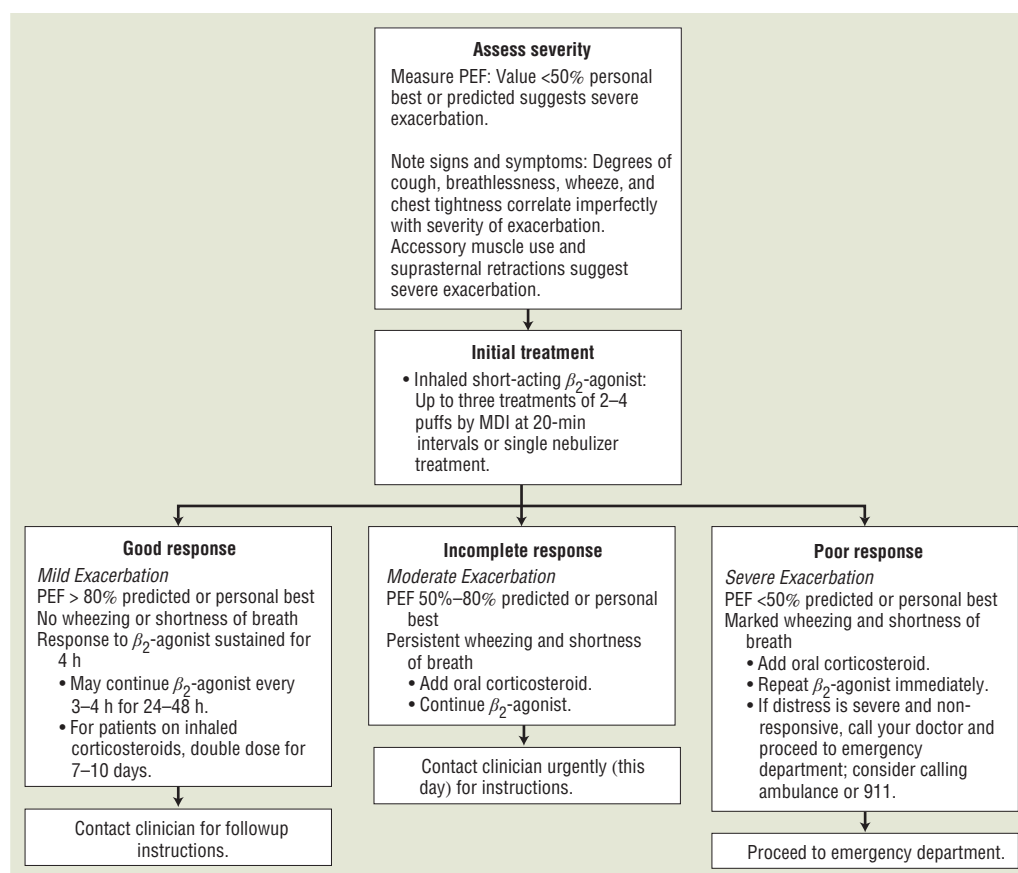

FIGURE 28-6. Home management of acute asthma exacerbation. Patients at risk for asthma-related death should receive immediate clinical attention after initial treatment. Additional therapy may be required. (MDI, metered-dose inhaler; PEF, peak expiratory flow.) (Adapted from reference 2.)

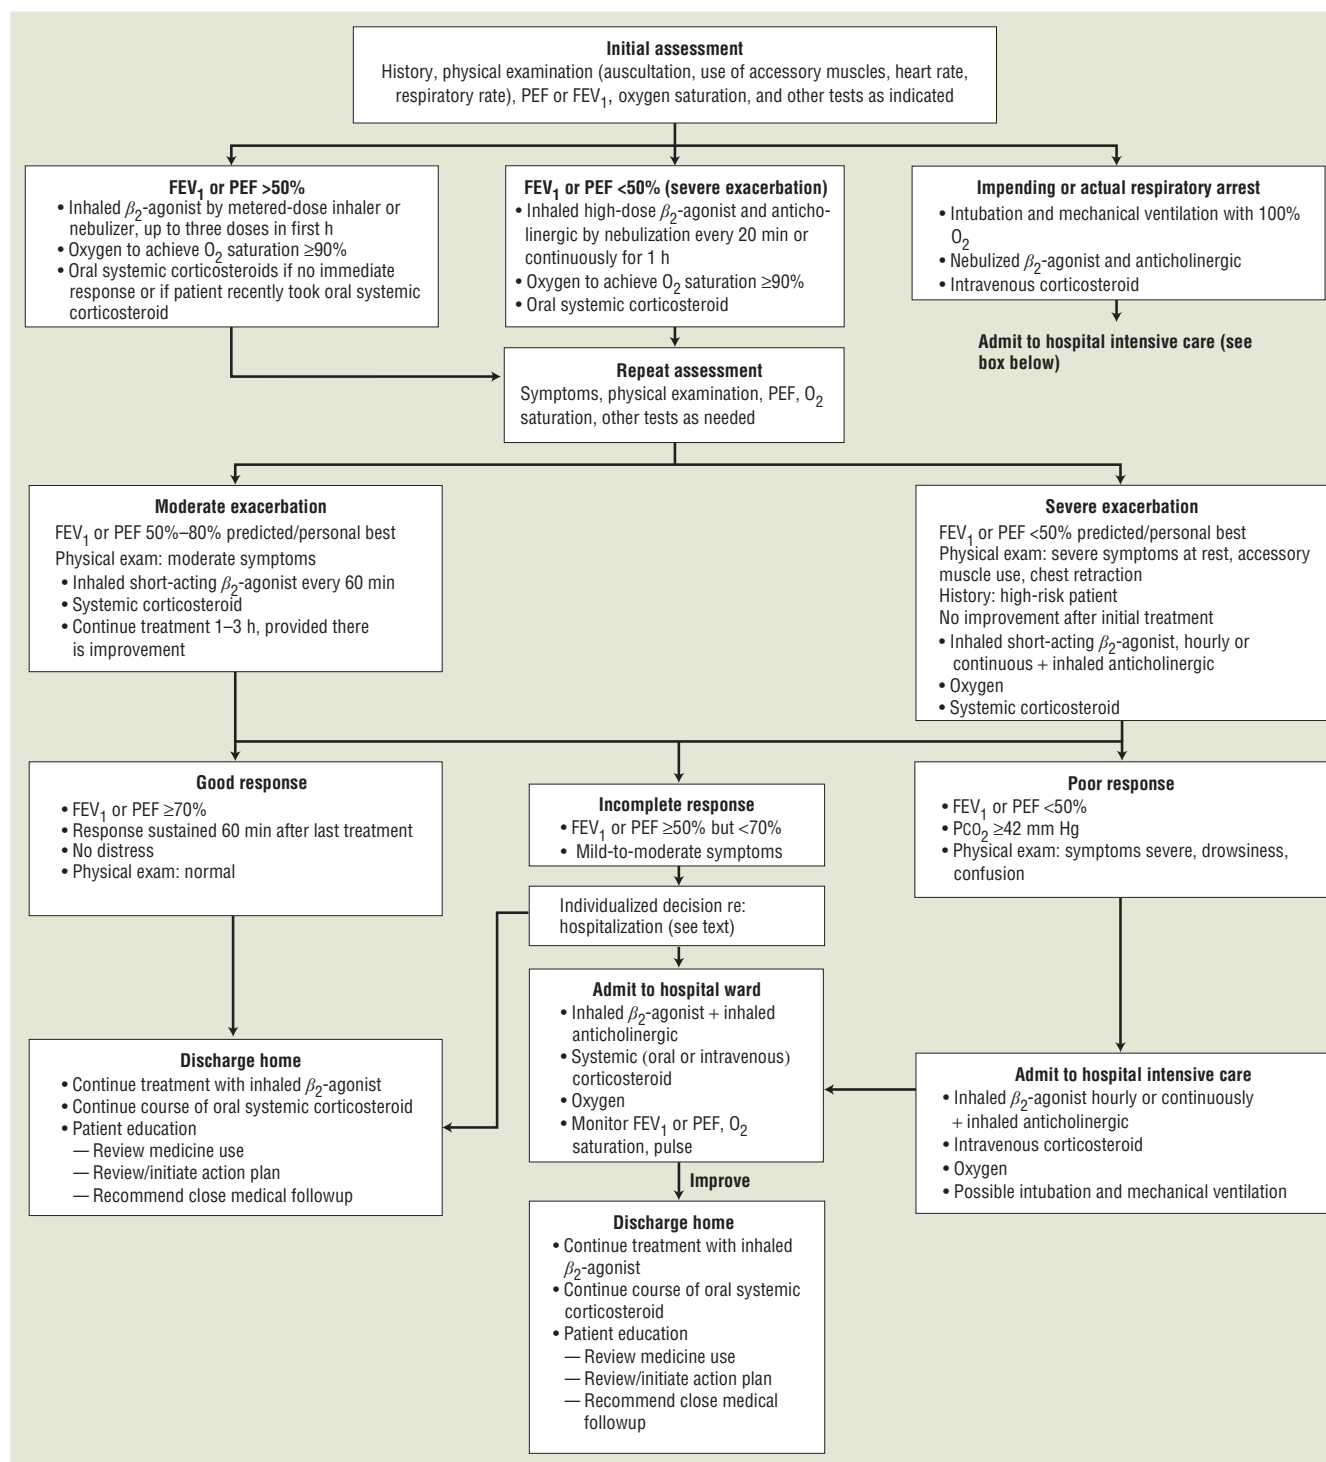

FIGURE 28-7. Emergency department and hospital care of acute asthma exacerbations. (FEV₁, forced expiratory volume in the first second of expiration; PEF, peak expiratory flow.) (Adapted from reference 2.)

followup asthma care within 1 to 4 weeks; initiation of inhaled corticosteroids (ICSs) should also be considered.⁶

7 Early recognition of deterioration and aggressive treatment are the keys to successful treatment of acute asthma exacerbations. Thus patient and/or parent education teaching self-management skills and written action plans for early institution of therapy for acute exacerbations improve outcomes.^{2,6,8} For more moderate to severe patients, this therapeutic plan also may include the availability of oral prednisone to begin at home.² Easy access by telephone to healthcare providers is also needed. Because of the rapid progression to severe asthma that can occur, patients and parents should be

encouraged to communicate promptly with their asthma care provider during an exacerbation. Systemic corticosteroids and aggressive use of inhaled β_2 -agonists continue to be the cornerstones of therapy for severe acute asthma exacerbations.^{2,6}

Figures 28-6 and 28-7 illustrate the recommended therapies for the treatment of acute asthma exacerbations in home and emergency department/hospital settings, respectively.² Table 28-6 lists the dosages of the drugs for acute severe asthma.^{2,6} Institutions should strongly consider developing critical pathways/treatment algorithms for their emergency departments because their implementation improves outcomes and decreases the cost of care.²⁸

TABLE 28-6 Dosages of Drugs of Acute Severe Exacerbations of Asthma in the Emergency Department or Hospital

	Dosages		
Medications	>6 Years Old	≤6 Years Old	Comments
Inhaled β-agonists			
Albuterol nebulizer solution (5 mg/mL)	2.5–5 mg every 20 min for 3 doses, then 2.5–10 mg every 1–4 h as needed, or 10–15 mg/h continuously	0.15 mg/kg (minimum dose 2.5 mg) every 20 min for 3 doses, then 0.15–0.3 mg/kg up to 10 mg every 1–4 h as needed, or 0.5 mg/kg/h by continuous nebulization	Only selective β_2 -agonists are recommended; for optimal delivery, dilute aerosols to minimum of 4 mL at gas flow of 6–8 L/min
Albuterol MDI (90 mcg/puff)	4–8 puffs every 30 min up to 4 h, then every 1–4 h as needed	4–8 puffs every 20 min for 3 doses, then every 1–4 h as needed	In patients in severe distress, nebulization is preferred; use holding-chamber-type spacer
Levalbuterol nebulizer solution	Give at one-half the mg dose of albuterol above	Give at one-half the mg dose of albuterol above	The single isomer of albuterol is likely to be twice as potent on a mg basis
Levalbuterol MDI (45 mcg/puff)	Give at one-half the mg dose of albuterol above	Give at one-half the mg dose of albuterol above	
Pirbuterol MDI (200 mcg/puff)	See albuterol dose	See albuterol dose; one-half as potent as albuterol on a mcg basis	Has not been studied in acute severe asthma
Systemic β-agonists			
Epinephrine 1:1000 (1 mg/mL)	0.3–0.5 mg every 20 min for 3 doses subcutaneously	0.01 mg/kg up to 0.5 mg every 20 min for 3 doses subcutaneously	No proven advantage of systemic therapy over aerosol
Terbutaline (1 mg/mL)	0.25 mg every 20 min for 3 doses subcutaneously	0.01 mg/kg every 20 min for 3 doses, then every 2–6 h as needed subcutaneously	Not recommended
Anticholinergics			
Ipratropium bromide nebulizer solution (0.25 mg/mL)	500 mcg every 30 min for 3 doses, then every 2–4 h as needed	250 mcg every 20 min for 3 doses, then 250 mcg every 2–4 h	May mix in same nebulizer with albuterol; do not use as first-line therapy; only add to β_2 -agonist therapy
Ipratropium bromide MDI (17 mcg/puff)	4–8 puffs as needed every 2–4 h	4–8 puffs as needed every 2–4 h	Not recommended because dose in inhaler is low and has not been studied in acute asthma
Corticosteroids			
Prednisone, methylprednisolone, prednisolone	60–80 mg in 3 or 4 divided doses for 48 h, then 30–40 mg/day until PEF reaches 70% of personal best	1 mg/kg every 6 h for 48 h, then 1–2 mg/kg/day in 2 divided doses until PEF is 70% of normal predicted	For outpatient “burst” use 1–2 mg/kg/day, maximum 60 mg, for 3–7 days; it is unnecessary to taper course

FEV₁, forced expiratory volume in the first second of expiration; MDI, metered-dose inhaler; PEF, peak expiratory flow.

Note: No advantage has been found for very-high-dose corticosteroids in acute severe asthma, nor is there any advantage for intravenous administration over oral therapy. The usual regimen is to continue the frequent multiple daily dosing until the patient achieves an FEV₁ or PEF of 50% of personal best or normal predicted value and then lower the dose to twice-daily dosing. This usually occurs within 48 hours. The final duration of therapy following a hospitalization or emergency department visit may be from 7 to 14 days. If patient is then started on inhaled corticosteroids, studies indicate there is no need to taper the systemic steroid dose. If the followup therapy is to be given once daily, studies indicate there may be an advantage to giving the single daily dose in the afternoon at around 3 pm.

■ NONPHARMACOLOGIC AND ANCILLARY THERAPY

Infants and young children may be mildly dehydrated owing to increased insensible loss, vomiting, and decreased intake.² Unless dehydration has occurred, increased fluid therapy is not indicated in acute asthma management because the capillary leak from cytokines and increased negative intrathoracic pressures may promote edema in the airways.² Correction of significant dehydration is always indicated, and the urine specific gravity may help to guide therapy in young children, in whom the state of hydration may be difficult to determine.² Chest physical therapy and mucolytics are not recommended in the therapy of acute asthma.⁶ Sedatives should not be given because anxiety may be a sign of hypoxemia, which could be worsened by central nervous system depressants. Antibiotics also are not indicated routinely because viral respiratory tract infections are the primary cause of asthma exacerbations.^{2,8} Antibiotics should be reserved for patients who have signs and symptoms of pneumonia (e.g., fever, pulmonary consolidation, and purulent sputum from polymorphonuclear leukocytes). *Mycoplasma* and *Chlamydia* are infrequent causes of severe asthma exacerbations but should be considered in patients with high oxygen requirements.⁸

Respiratory failure or impending respiratory failure as measured by rising PaCO₂ (>45 mm Hg) or failure to correct hypoxemia with supplemental oxygen therapy is treated with intubation and mechanical ventilation. To prevent barotrauma and pneumothoraces from excess positive pressure, it is recommended that controlled hyperventilation or permissive hypercapnia be used (correcting the hypoxemia, PaO₂ >60 mm Hg, but allowing the PaCO₂ to rise to the high 60 mm Hg range).

■ PHARMACOTHERAPY

β_2 -Agonists

④ The short-acting inhaled β_2 -agonists are the most effective bronchodilators and the treatment of first choice for the management of severe acute asthma.^{2,8,26} Up to 66% of adults presenting to an emergency department require only three doses of 2.5-mg nebulized albuterol to be discharged.²⁷ Most well-controlled clinical trials have demonstrated equal to greater efficacy and greater safety of aerosolized β_2 -agonists over systemic administration regardless of the severity of obstruction.^{2,26} Systemic adverse effects, hypokalemia, hyperglycemia, tachycardia, and cardiac dysrhythmias are more pronounced in patients receiving systemic β_2 -agonist therapy. Children younger than 2 years of age achieve clinically significant responses from nebulized albuterol.^{2,29} Effective doses of aerosolized β_2 -agonists can be delivered successfully through mechanical ventilator circuits to infants, children, and adults in respiratory failure secondary to severe airways obstruction.²⁹

Frequent administration of inhaled β_2 -agonists (every 20 minutes or continuous nebulization) is superior to the same dosage administered at 1-hour intervals.³⁰ In the subset of more severely obstructed patients, continuous nebulization decreases the hospital admission rate, provides greater improvement in the FEV₁ and PEF, and reduces duration of hospitalization when compared with intermittent (hourly) nebulized albuterol in the same total dose.³⁰ Thus continuous nebulization is recommended for patients having an unsatisfactory response (achieving less than 50% of normal FEV₁ or PEF) following the initial three doses (every 20 minutes) of aerosolized β_2 -agonists and potentially for patients presenting initially with PEF or FEV₁ values of less than 30% of predicted normal.^{2,30}

The doses of inhaled β_2 -agonists for severe acute asthma (see Table 28–6) have been derived empirically. The β_2 -agonists follow a log-linear dose–response curve.³¹ In addition, the dose–response curve is shifted to the right by more severe bronchospasm or by increased concentrations of bronchospastic mediators, which is characteristic of functional antagonists.³¹ The ability to increase the dose of the short-acting aerosolized β_2 -agonists by as much as 5- to 10-fold over doses producing adequate bronchodilation in chronic stable asthmatics is what contributes to their efficacy in reversing the bronchospasm of acute severe asthma. The nebulizer dose of inhaled β_2 -agonists for children often is listed on a weight basis (milligrams per kilogram). However, a fixed minimal dose (2.5 mg albuterol or equivalent), as opposed to a weight-adjusted dose, is more appropriate in younger children because children younger than 5 years of age receive a lower lung dose.²⁵ Adults dosed on a weight basis demonstrate excessive cardiac stimulation, so they have fixed maximal doses (see Table 28–6).²⁹ Initial doses of inhaled β_2 -agonists can produce vasodilation, worsening ventilation–perfusion mismatch, slightly lowering oxygen saturation or PaO_2 .²⁶ High-doses of inhaled β_2 -agonists can produce a decrease in serum potassium concentration, an increase in heart rate, and an increase in serum glucose concentration. However, both children and adults receiving continuously nebulized β_2 -agonists have demonstrated decreased heart rates as their lung function improves.³⁰ Thus, an elevated heart rate is not an indication to use lower doses or to avoid using inhaled β_2 -agonists.

Some controversy exists concerning the most cost-effective delivery system (MDI plus VHC vs. nebulization) to be used in treating severe acute asthma in the emergency department and hospital (see Clinical Controversies below).^{25,29} The DPIs are currently not indicated for the treatment of severe acute asthma exacerbations because of the higher inspiratory flows required for adequate delivery.²⁵

Corticosteroids

Systemic corticosteroids are indicated in all patients with acute severe asthma not responding completely to initial inhaled β_2 -agonist administration (every 20 minutes for three to four doses).² Intravenous therapy offers no therapeutic advantage over oral administration.^{26,32} This therapy usually is continued until hospital discharge. Tapering the dose in acute asthma following discharge from the hospital appears unnecessary, provided that patients are prescribed inhaled corticosteroids for outpatient therapy.² Most patients achieve 70% of predicted normal FEV_1 within 48 hours and 80% of predicted by 6 days after plateauing by day 3. Thus maintaining systemic corticosteroid courses for 10 to 14 days may be unnecessarily long in some patients. Indeed, many patients not admitted to the hospital respond to 3- to 5-day courses of systemic corticosteroids. Short courses of oral prednisone (3 to 10 days) have been effective in preventing hospitalizations in infants and young children.² It is recommended that a full dose of the corticosteroid be continued until the patient's peak flow reaches 70% of predicted normal or personal best.²

Multiple daily dosing of systemic corticosteroids for the initial therapy of acute asthma exacerbations appears warranted because receptor-binding affinities of lung corticosteroid receptors are decreased in the face of airway inflammation.³² However, patients with less-severe exacerbations may be treated adequately with once-daily administration. High-dose and very-high-pulse-dose corticosteroid regimens do not enhance the outcomes in severe acute asthma but are associated with a higher likelihood of side effects.³²

Studies of ICSs in acute exacerbations of asthma have provided conflicting results. Studies have demonstrated both greater and lesser efficacy than standard doses of oral corticosteroids.³² Currently, there is insufficient evidence supporting efficacy in the emergency department setting, although continued research appears warranted.³² There is evidence that prescribing ICSs on discharge from the emergency department reduces the risk of relapse.³² This policy seems like

a reasonable recommendation because inflammation is the underlying cause of deterioration in most cases.⁶

Anticholinergics

Inhaled ipratropium bromide produces a further improvement in lung function of 10% to 15% over inhaled β_2 -agonists alone. In children and adults, multiple-dose ipratropium bromide added to initial therapy also produced a reduced hospitalization rate in the subset of patients with an FEV_1 of less than 30% of predicted at baseline.³³ Ipratropium bromide, a quaternary amine, is poorly absorbed and produces minimal or no systemic effects. Care should be used when administering ipratropium bromide by nebulizer. If a tight mask or mouthpiece is not used, the ipratropium bromide that deposits in the eyes may produce pupillary dilation and difficulty in accommodation. Ipratropium bromide is not a vasodilator, so unlike β_2 -agonists it will not worsen ventilation–perfusion mismatch.²⁶

Alternative Therapies

The emergency department use of aminophylline, a moderate bronchodilator, for acute asthma has not been recommended for a number of years.² Clinical trials of aminophylline in adults and children hospitalized with acute asthma have not reported sufficient evidence of efficacy (improvement in lung function and reduced hospital stay) but have reported an increased risk of adverse effects.³⁴ Adverse effects of theophylline include nausea and vomiting and potentiation of the cardiac effects of the inhaled β_2 -agonists.

Magnesium sulfate is a moderately potent bronchodilator, producing relaxation of smooth muscle and central nervous system depression.³⁵ The use of intravenous magnesium sulfate in patients presenting to the emergency department is controversial (see Clinical Controversies below).^{35,36} The adverse effects of magnesium sulfate include hypotension, facial flushing, sweating, nausea, loss of deep tendon reflexes, and respiratory depression.³⁵ Some patients have required dopamine to treat the hypotension.

Helium is an inert gas of low density with no pharmacologic properties that can lower resistance to gas flow and increase ventilation because the low density decreases the pressure gradient needed to achieve a given level of turbulent flow, converting turbulent flow to laminar flow.² Helium is given as a mixture of helium and oxygen (heliox), usually 60% to 70% helium with 30% to 40% oxygen.³⁷ As with a number of experimental approaches, heliox was reported to be efficacious in initial nonrandomized clinical trials. However, the small number of randomized, controlled trials completed to date have failed to document efficacy.³⁷ Although heliox is free of adverse effects, its use is limited to patients with a low inspired oxygen requirement because the decrease in density generally is insignificant clinically with less than 60% helium.³⁷

The inhalational anesthetics halothane, isoflurane, and enflurane all have been reported to have a positive effect in children and adults with severe asthma that is unresponsive to standard medical therapy.² The proposed mechanisms for inhalational anesthetics include direct action on bronchial smooth muscle, inhibition of airway reflexes, attenuation of histamine-induced bronchospasm, and interaction with β_2 -adrenergic receptors.² Well-controlled trials with these agents have not been completed. Potential adverse effects include myocardial depression, vasodilation, arrhythmias, and depression of mucociliary function. In addition, the practical problem of delivery and scavenging these agents in the intensive care environment as opposed to the operating room is a concern. The use of volatile anesthetics cannot be recommended based on insufficient evidence of efficacy.

Ketamine has been recommended for rapid induction of anesthesia in patients with asthma who require intubation and mechanical ventilation.² Ketamine is thought to produce bronchodilation from a combination of an increase in circulating catecholamines, direct

TABLE 28-7 Pharmacologic Responses to Sympathomimetic Agonists

Tissue	Receptor Type	Response
Airways	β_2	Smooth muscle relaxation (bronchodilation), increased ciliary beat, increased serous secretion, and inhibition of mast cell degranulation
Heart	α	Smooth muscle contraction (bronchoconstriction?)
	β_1	Inotropic and chronotropic
	β_2	Chronotropic
Vasculature	β_2	Vasodilation, decrease microvascular leakage
	α	Vasoconstriction
Skeletal	β_2	Increased neuromuscular transmission (tremor and increased strength of contraction)
Uterus	β_2	Relaxation (tocolysis)
Metabolic	α, β_1	Glycogenolysis, lipolysis
	β_2	Gluconeogenesis, hypokalemia, increased lactate production

smooth muscle relaxation, and inhibition of vagal flow.² Anecdotal reports have suggested that ketamine is useful as a short-term adjunct in severe acute asthma; controlled trials have not provided sufficient evidence of efficacy, however. Ketamine has several significant adverse effects, including the anesthesia emergence reaction, which can alter mood and cause delirium. These emergence phenomena occur in at least 25% of patients older than 16 years of age; the incidence seems to be much lower in younger patients.² Other risks include an increase in heart rate, arterial blood pressure, and cerebral blood flow because of its sympathetic effects.²⁶

■ SPECIAL POPULATIONS

6 Infants and children younger than 4 years of age may be at greater risk of respiratory failure than older children and adults. Although treated with the same drugs, these younger children require the use of a facemask as opposed to a mouthpiece for delivery of aerosolized medication. Use of the facemask reduces delivery of drug to the lung by one-half so that a minimal dose is recommended as opposed to a weight-adjusted dose.^{25,29} The facemask should be sized appropriately and should fit snugly over the nose and mouth. Use of the “blow-by” method, where the respiratory therapist or parent places the mask or extension tubing near the child’s nose and mouth, should be discouraged because holding the mask as few as 2 cm from the patient’s face reduces lung delivery of the aerosol by 80%.²⁵

■ DRUG CLASS INFORMATION

Short-Acting β_2 -Agonists

5 **6** The β_2 -agonists are the most effective bronchodilators available. The β_2 -adrenergic receptors are transmembrane proteins con-

sisting of clusters of seven helices of amino acids that form the ligand-binding core.³¹ The human β_2 -adrenergic receptors are polymorphic in structure, with the most common polymorphisms in the amino terminus of the receptor at amino acid positions 16 (encoding either arginine [Arg] or glycine [Gly]) and 27 (encoding either glutamine [Gln] or glutamic acid [Glu]).³⁸ Some of the polymorphisms determine responsiveness to β_2 -agonists, whereas others may act as disease modifiers (see Treatment section on Chronic Asthma, Clinical Controversy below).³⁸ Stimulation of β_2 -adrenergic receptor activates cytoplasmic G proteins, which, in turn, activate adenylyl cyclase to produce cyclic adenosine monophosphate (cAMP), generally thought to be responsible for the bulk of activity through activation of various proteins by cAMP-dependent protein kinase A.³¹ This activation, in turn, decreases unbound intracellular calcium, producing smooth muscle relaxation, mast cell membrane stabilization, and skeletal muscle stimulation.³¹ Despite the fact that β_2 -agonists are potent inhibitors of mast cell degranulation in vitro, they do not inhibit the late asthmatic response to allergen challenge or the subsequent bronchial hyperresponsiveness.^{2,31} Long-term administration of β_2 -agonists does not reduce BHR, confirming a lack of significant antiinflammatory activity.³¹ β_2 -Adrenergic stimulation also activates Na^+/K^+ -ATPase, produces gluconeogenesis, and enhances insulin secretion, resulting in a mild to moderate decrease in serum potassium concentration by driving potassium intracellularly.³¹ The chronotropic response to β_2 -agonists is mediated in part by baroreceptor reflex mechanisms as a result of the drop in blood pressure from vascular smooth muscle relaxation, as well as by direct stimulation of cardiac β_2 -receptors and some β_1 stimulation at high concentrations.³¹ Table 28–7 lists the pharmacologic effects of adrenergic receptor stimulation. Because β_1 -receptor stimulation produces excessive cardiac stimulation, resulting in cardiac arrhythmias, and because the inotropic effect enhancing myocardial oxygen consumption leads to myocardial necrosis, there is no rationale for using non- β_2 -selective agonists in the treatment of asthma.³¹

Table 28–8 compares the various β -adrenergic agonists used in asthma in terms of selectivity, potency, oral activity, and duration of action. The β_2 -agonists are functional or physiologic antagonists in that they relax airway smooth muscle regardless of the mechanism for constriction.³¹ When administered in equipotent doses, all the short-acting drugs produce the same intensity of response; the only differences are in duration of action and cardiac toxicity.^{2,31} The catecholamine derivatives all have the disadvantage of rapid inactivation of their 3,4-hydroxyl catechol group from catechol-O-methyltransferase found in the gastrointestinal tract, rendering them orally inactive. In addition, catecholamines are taken up rapidly into tissues by secondary uptake mechanisms that limit their receptor occupancy and thus have a shorter duration of action.³¹ All the β_2 -agonists are more bronchoselective when administered by the aerosol route. Aerosol administration of the short-acting β_2 -agonists provides more rapid response and greater protection against

TABLE 28-8 Relative Selectivity, Potency, and Duration of Action of the β -Adrenergic Agonists

Agent	Selectivity		Potency, β_2^a	Duration of Action ^b

^cProtection refers to the prevention of bronchoconstriction induced by exercise or nonspecific bronchial challenges.

provocations that induce bronchospasm such as exercise and allergen challenges than does systemic administration.²⁵ Differences in myocardial effects are discernible between selective and nonselective agents even when administered as aerosols, particularly at the higher doses used for severe acute asthma. The β_2 -agonists also differ in efficacy or ability to activate the β_2 -adrenergic receptors. Full agonists include the catecholamines, metaproterenol, and formoterol.³¹ Partial agonists include albuterol, terbutaline, pirbuterol, and salmeterol.³¹ The principal differences between full and partial agonists are that full agonists require a lower fraction of receptor occupancy to produce their maximum effect and more easily produce receptor desensitization.³⁸ However, these differences have not been proven to be clinically significant.

All synthetic β_2 -agonists are 1:1 racemic mixtures of two mirror images (enantiomers) owing to an asymmetric or chiral carbon.³⁸ Because most physiologic functions (receptor occupancy and activation and enzymatic metabolism) are stereoselective, the (*R*)-enantiomers of the β_2 -agonists are the most pharmacologically active isomer.³⁸ Although it was initially thought that the (*S*)-enantiomers were essentially inactive owing to the 100- to 1,000-fold potency difference between the enantiomers, studies in animal models and isolated in vitro tissue preparations have suggested that the (*S*)-enantiomer of albuterol may be proinflammatory and could induce BHR.³⁸ However, evidence that this occurs consistently in humans or is clinically relevant is lacking.³⁸ The pharmacokinetics also are stereoselective, although not predictable. (*R*)-Albuterol is metabolized more rapidly than (*S*)-albuterol, which could lead to accumulation of (*S*)-albuterol with continued dosing.³⁸ This accumulation is more exaggerated with oral dosing, as would be expected from a drug with a high first-pass effect.³¹ On the other hand, (*S*)-terbutaline is eliminated more rapidly than (*R*)-terbutaline.³⁸

Both the intensity and duration of response are dose-dependent, and more importantly, the dose-response relationship is dynamic.³¹ At increasing levels of baseline bronchoconstriction (irrespective of the stimulus), the dose-response curve is shifted to the right, and the duration of bronchodilation is decreased.³¹ This shift is reflected in the need for higher, more frequent doses in acute asthma exacerbations; the duration of protection against significant provocation is much less than the duration of bronchodilation in chronic stable asthma (see Table 28–8).³¹

Chronic administration of β_2 -agonists leads to downregulation (decreased number of β_2 -receptors) and a decreased binding affinity for these receptors.³¹ Systemic corticosteroid therapy can both prevent and partially reverse this phenomenon.^{2,31} However, the use of inhaled corticosteroids appears to have minimal ability to prevent tolerance to β_2 -agonists.³¹ The homozygous Gly-16 form of the receptor downregulates to a much greater extent compared with the homozygous Arg-16 form of the receptor with heterozygous Arg-16/Gly-16 intermediately desensitized.³⁸ On the other hand, glutamate substitution at codon 27 (Glu-27) protects against downregulation compared with the glutamine form (Gln-27) of the receptor.³⁸ However, the Gly-16 overcomes any protective effect of Glu-27.³⁸ Tolerance primarily reduces duration of bronchodilation as opposed to peak response although that can occur as well. A significantly greater tolerance develops in other tissues (e.g., lymphocytes and cardiac and skeletal muscle) compared with the lung primarily as a result of the surplus β_2 receptors found in respiratory smooth muscle.³¹ Tolerance to the extrapulmonary effects (cardiac stimulation and hypokalemia) may account for a lack of significant cardiac effects with retention of the bronchodilator response despite chronic inhaled β_2 -agonist therapy, whereas tolerance to mast cell stabilization may be a drawback to chronic use.³¹ Thus, chronic β_2 -agonist administration produces a tolerance of minimal clinical significance that is overcome easily by increasing the dose or by administering corticosteroids.^{2,31,38} Most of the tolerance occurs within a week of

regular administration and does not worsen with continued administration. As would be expected from a receptor phenomenon, tolerance is a cross-tolerance to all β_2 -agonists.³¹ Whether or not regular use of short-acting inhaled β_2 -agonists produces worsening of asthma in a subset of patients remains controversial (see Treatment section on Chronic Asthma, Clinical Controversy below), but it does not appear to occur in the entire population.³⁸ Regular treatment with short-acting β_2 -agonists can increase BHR and in homozygous Arg-16 patients reduced morning PEF and increased exacerbations.³⁸ Regular treatment (four times daily) does not improve symptom control over as-needed use.^{2,8}

In conclusion, the inhaled short-acting selective β_2 -agonists are indicated for the treatment of intermittent episodes of bronchospasm. They are the first treatment of choice for acute severe asthma and exercise-induced bronchospasm.^{2,8,31} They inhibit EIB in a dose-dependent fashion and provide complete protection for a 2-hour period following inhalation with varying levels of patient-dependent protection over 4 hours.³¹ Although the regular administration of β_2 -agonists slightly decreases the effect, two inhalations prior to exercise still essentially blocks exercise-induced bronchospasm completely (1% versus 5% drop in FEV₁).³⁸

Systemic Corticosteroids

4 The corticosteroids are the most effective antiinflammatories available to treat asthma.^{2,6,8} Actions useful in treating asthma include (a) increasing the number of β_2 -adrenergic receptors and improving the receptor responsiveness to β_2 -adrenergic stimulation, (b) reducing mucus production and hypersecretion, (c) reducing BHR, and (d) reducing airway edema and exudation.^{7,8} The glucocorticoid receptor is found in the cytoplasm of most cells throughout the body, explaining the multiple effects of systemic corticosteroids. Although there is no difference between the glucocorticoid receptors found throughout the body, genetic differences between glucocorticoid receptors from different individuals may determine some of the variations in response.³⁹ The corticosteroids are lipophilic, readily cross the cell membrane, and combine with the glucocorticoid receptor. The activated complex then enters the nucleus, where it acts as a transcription factor leading to gene activation or suppression.⁴⁰ This leads to specific messenger ribonucleic acid (mRNA) production, resulting in increased production of antiinflammatory mediators; suppression of several proinflammatory cytokines such as IL-1, GM-CSF, IL-3, IL-4, IL-5, IL-6, and IL-8, reducing inflammatory cell activation, recruitment, and infiltration; and decreasing vascular permeability.⁴⁰ In addition, the activated glucocorticoid receptor complex can act directly with cytoplasmic transcription factors, nuclear factor κ B, and activating protein 1 to prevent the action of proinflammatory cytokines on the cell.⁴⁰

Owing to the mechanism that modifies gene expression, the time required to see the particular effect depends on the time required for new protein synthesis, decreased formation of the particular mediator, and resolution of the inflammatory response.⁴⁰ Generally, the cellular and biochemical effects are immediate, but varying amounts of time are required to produce a clinical response. β_2 -Receptor density increases within 4 hours of corticosteroid administration.⁴⁰ Improved responsiveness to β_2 -agonists occurs within 2 hours.⁴⁰ In severe acute asthma, 4 to 12 hours may be required before any clinical response is noted.^{32,40} Reversal of seasonally increased BHR requires at least 1 week of therapy.⁴⁰ The chronic use of corticosteroids does not induce a state of corticosteroid dependence. Nor is there evidence of tolerance produced by chronic administration.

Table 28–9 compares the corticosteroids used in asthma.^{39–41} Besides acute severe asthma, systemic corticosteroids are also recommended for the treatment of impending episodes of severe asthma unresponsive to bronchodilator therapy.^{2,6,8} The effects of corticosteroids in asthma

^bBDP and CIC are prodrugs that are activated in the lung to their active metabolites BMP and des-CIC respectively.

are dose and duration dependent. This pattern is true for the adverse effects as well (Table 28–10). The clinician must continually balance the toxicity of chronic systemic corticosteroid therapy with control of asthma symptoms. Because short-term (1 to 2 weeks) high-dose corticosteroids (1 to 2 mg/kg per day of prednisone) do not produce serious toxicities, the ideal use is to administer the systemic corticosteroids in a short “burst” and then to maintain the patient on appropriate long-term control therapy with ICSs (discussed below under Inhaled Corticosteroids).^{2,8} In general, therapy for more than 5 days at doses that exceed the usual physiologic endogenous cortisol production will cause temporary aberration in adrenal cortisol release.³⁹ However, this hypothalamic–pituitary–adrenal axis suppression is short-lived (1 to 3 days) and readily reversible following short bursts (10 days or less) of pharmacologic doses.⁴⁰ A maximum number of short bursts that a patient can receive probably exists, after which chronic corticosteroid side effects occur. Patients receiving at least eight bursts (≥10 days each) have a similar decrease in trabecular bone density as patients on daily or alternate-day corticosteroids over 1 year.⁴⁰ Children who received four or more bursts of prednisone exhibited a subnormal response to hypoglycemic stress or adrenocorticotrophic hormone administration.⁴⁰ Very short courses (3 to 5 days) have been effective in reducing hospitalization from acute exacerbations.^{2,8} Use of the shorter-acting corticosteroids, such as prednisone, produces less adrenal suppression than the longer-acting dexamethasone.⁴⁰

Anticholinergics

The anticholinergic agents have a long history of use for asthma, but they do not have an FDA-approved indication for asthma.^{2,42} Anti-

cholinergics are competitive inhibitors of muscarinic receptors.⁴² Unlike β_2 -agonists, they are not functional antagonists; they only reverse cholinergic-mediated bronchoconstriction. Normal bronchial tone is maintained through parasympathetic innervation of the airways via the vagus nerve.⁴² A number of the triggers and mediators of asthma (i.e., histamine, prostaglandins, sulfur dioxide, exercise, and allergens) produce bronchoconstriction in part through vagal reflex mechanisms.⁴² Studies of asthmatics consistently demonstrate that anticholinergics are effective bronchodilators, although not as effective as β_2 -agonists. Anticholinergics attenuate but do not block allergen-induced asthma in a dose-dependent fashion and have no effect on BHR.⁴² Anticholinergics attenuate but do not block EIB.⁴³

Ipratropium bromide is a nonselective muscarinic receptor blocker, and blockade of inhibitory muscarinic receptors theoretically could result in an increased release of acetylcholine and overcome the block on the smooth muscle receptors (M_3).⁴² Only the quaternary ammonium derivatives such as ipratropium bromide should be used because they have the advantage of poor absorption across mucosae and the blood–brain barrier. This results in negligible systemic effects with a prolonged local effect (i.e., bronchodilation). In addition, the quaternary compounds do not appear to produce a decrease in mucociliary clearance.⁴² Ipratropium bromide has a duration of action of 4 to 8 hours. Both intensity and duration of action are dose-dependent. Tiotropium bromide, a new long-acting inhaled anticholinergic, has a duration of 24 hours. Time to reach maximum bronchodilation for ipratropium is considerably slower than from aerosolized short-acting β_2 -agonists (30 to 60 minutes vs. 5 to 10 minutes). However, this is of little clinical consequence because some bronchodilation is seen within 30 seconds, 50% of maximum response occurs within 3 minutes.⁴² Ipratropium bromide is only indicated as adjunctive therapy in severe acute asthma not completely responsive to β_2 -agonists alone because it does not improve outcomes in chronic asthma.^{2,8} Tiotropium has not been studied in asthma.

Hypokalemia/hyperglycemia	

PHARMACOECONOMICS

The number of emergency department visits for asthma exceeds the number of hospitalizations by approximately four times, yet the annual expenditure for emergency department visits (\$518 million) is significantly less than the estimated \$2.7 billion spent on inpatient hospital services for patients with acute severe asthma.³ Thus,

reducing the number of patients requiring hospitalizations is a primary goal of therapy. Because the primary drugs used to treat severe acute asthma are available generically, drug costs account for only a small portion of the overall costs of care. Few of the therapies used in the management of acute severe asthma have been evaluated formally for their pharmacoeconomic impact. One evaluation based on a meta-analysis of inhaled anticholinergics added to short-acting inhaled β_2 -agonists in children with acute severe asthma suggested that this approach was cost-effective and would reduce overall costs by reducing hospitalizations.⁴⁴ In children with acute severe asthma admitted to an intensive care unit, the use of continuously nebulized albuterol resulted in a decreased cost of care compared with intermittent nebulization.³⁰

CLINICAL CONTROVERSIES

Some clinicians believe that intravenous magnesium sulfate is effective for the treatment of severe acute asthma unresponsive to standard doses of inhaled β_2 -agonists in the emergency department. This is based on subset analyses of two studies showing that patients with the most severe obstruction following initial inhaled β_2 -agonists decreased hospitalizations with magnesium treatment compared with placebo.³⁵ However, the subset with severe obstruction is the one demonstrating an improved response to the addition of ipratropium bromide and continuous nebulization of inhaled β_2 -agonists. In addition a large, randomized trial failed to confirm a decreased hospitalization even in the severe group. The new NAEPP⁶ and the Global Initiative for Asthma guidelines state that it can be considered for use in patients with severe episodes with a poor response to initial inhaled β_2 -agonists.⁸

Numerous studies show that the inhaled β_2 -agonists administered by MDI plus VHC provide a similar outcome in severe acute asthma as administration by jet nebulizers.²⁹ Proponents of administration by MDI plus VHC argue that it is more cost-effective and so should replace nebulizer therapy. However, appropriate cost analyses have yet to be performed.²⁵ Nor have there been comparisons in the most severe subsets, where combination therapy and continuous nebulization are recommended.²⁵ Current practice should be based on the comfort level of the clinical staff until sufficient data are available to warrant a wholesale recommendation of one method.²⁹

EVALUATION OF THERAPEUTIC OUTCOMES

Figures 28–6 and 28–7 provide the monitoring parameters for severe acute asthma. Lung function, either spirometry or peak flows, should be monitored 5 to 10 minutes after each treatment.² Oxygen saturations can be easily monitored continuously with pulse oximetry. For young children and infants, pulse oximetry, lung auscultation, and observation of the presence of supraclavicular retractions is useful.^{2,26} The majority of patients will respond within the first hour of initial inhaled β_2 -agonists regardless of history of home administration of drug.²⁶ Patients not achieving an initial response should be monitored every 0.5 to 1 hour. Depending on whether there is a standard emergency department or a special unit for severe acute asthma, the decision to admit to the hospital should be made within 4 to 6 hours of entry to the emergency department.²⁶ The mean duration of hospitalization following admission is 2 to 3 days. Frequency of monitoring depends on the severity of the exacerbation. With mild exacerbations, monitor lung function every 2 to 3 hours; with severe exacerbations, monitor every 30 minutes to 1 hour.

TREATMENT

Chronic Asthma

The diagnosis of chronic asthma is made primarily by history and confirmatory spirometry (see Clinical Presentation above).^{2,6} The NAEPP has provided a list of questions that would lead to the diagnosis of asthma (see Table 28–2).^{2,6} In the older child and adult patient in whom spirometric evaluations can be performed, failure of pulmonary functions to improve acutely does not necessarily rule out asthma. Patients with long-standing disease or substantial inflammation may require an intensive, prolonged course of bronchodilators and glucocorticoids before reversibility is detected.^{2,8} If baseline spirometry is normal, challenge testing with exercise, histamine, or methacholine can be used to elicit BHR.² Patients with significant symptoms and/or an FEV₁ of less than 65% of predicted normal should not be challenged. Studies for atopy, such as serum IgE and sputum and blood eosinophil determinations, are unnecessary to make the diagnosis of asthma, but they may help differentiate asthma from chronic bronchitis in adults. Clinically, this distinction is often difficult to make. Some patients with chronic bronchitis may have a reversible component, and some patients with long-standing severe chronic asthma may have significant irreversible damage and obstruction. Very high peripheral blood eosinophil counts may point to the diagnosis of allergic bronchopulmonary aspergillosis or other hypereosinophilic syndromes.⁸ Skin testing is of no value in diagnosing asthma but is useful in identifying triggers.² In small infants unable to perform spirometry, the diagnosis is more difficult. They may demonstrate hyperinflation on the chest roentgenogram.² Radiologic examination is helpful in ruling out other causes of wheezing (e.g., foreign-body aspiration, parenchymal lung disease, cardiac disease, and congenital anomalies).² In place of pulmonary functions, the parents should be given a diary card to record symptoms and precipitating events.

GOALS FOR MANAGING ASTHMA LONG TERM

The NAEPP has provided key points for managing asthma long term.⁶ The goal for therapy is to control asthma by:

Reducing impairment

1. Prevent chronic and troublesome symptoms (e.g., coughing or breathlessness in the daytime, in the night, or after exertion)
2. Require infrequent use (≤ 2 days a week) of inhaled short-acting β_2 -agonist for quick relief of symptoms² (not including prevention of EIB)
3. Maintain (near-) normal pulmonary function
4. Maintain normal activity levels (including exercise and other activity and attendance at work or school)
5. Meet patients' and families' expectations of and satisfaction with care

Reducing risk

1. Prevent recurrent exacerbations of asthma and minimize the need for visits or hospitalizations
2. Prevent loss of lung function; for children, prevent reduced lung growth
3. Minimal or no adverse effects of therapy

NONPHARMACOLOGIC THERAPY

Although the mainstay of the management of asthma is pharmacologic therapy, it is likely to fail without concurrent attention to

relevant environmental control and management of comorbid conditions. Figure 28–8 depicts the stepwise approach for managing asthma recommended in the newest update by the NAEPP.⁶ It is important to note that the nonpharmacologic aspects of therapy are incorporated into the steps. The guidelines were designed to

give primary healthcare providers a framework with which to develop the proper approach to the individualized therapy of patients. The heterogeneity of asthma demands an individualized approach to therapy with the basic goals of therapy as primary outcome measures.^{2,6}

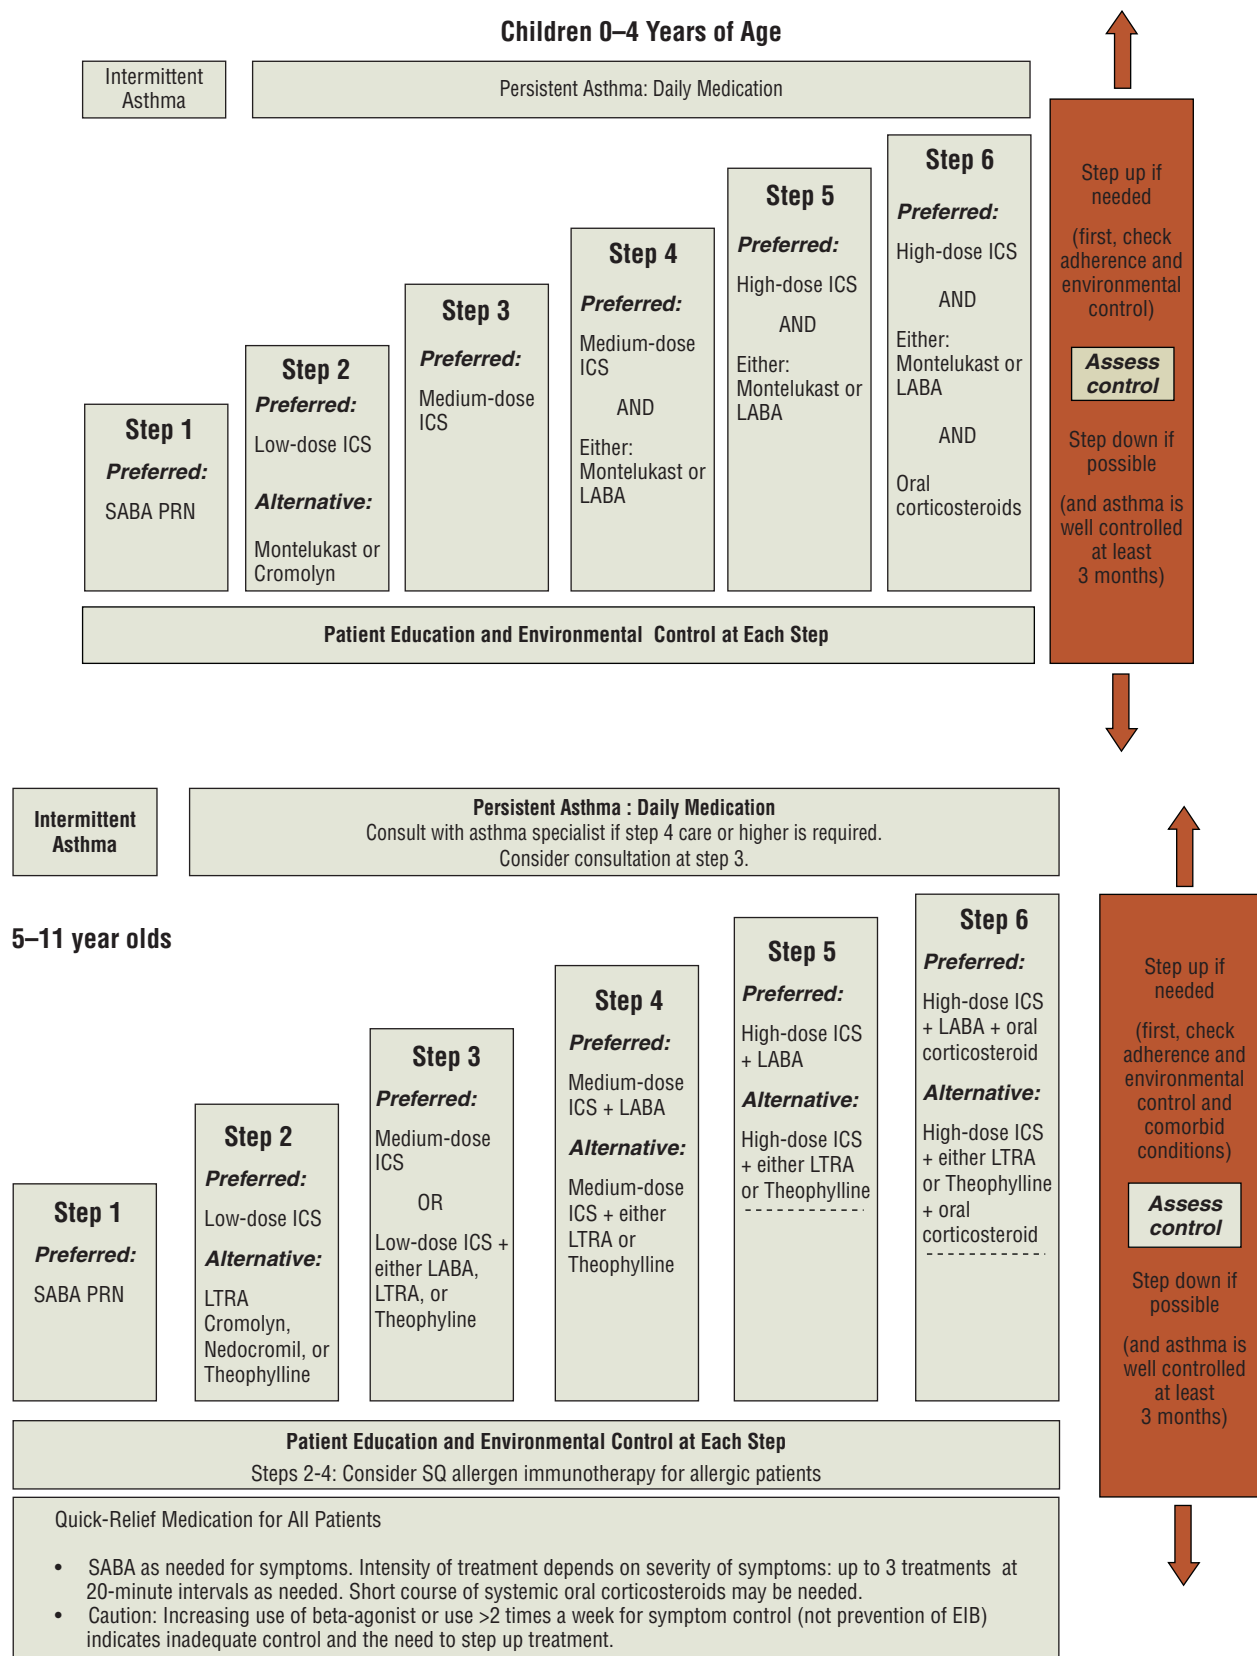

FIGURE 28-8. Stepwise approach for managing asthma in adults and children. (ICS, inhaled corticosteroid; LABA, long-acting β -agonist; LTRA, leukotriene receptor antagonist; PRN, as needed; SABA, short-acting β -agonist.) (Adapted from reference 6.)

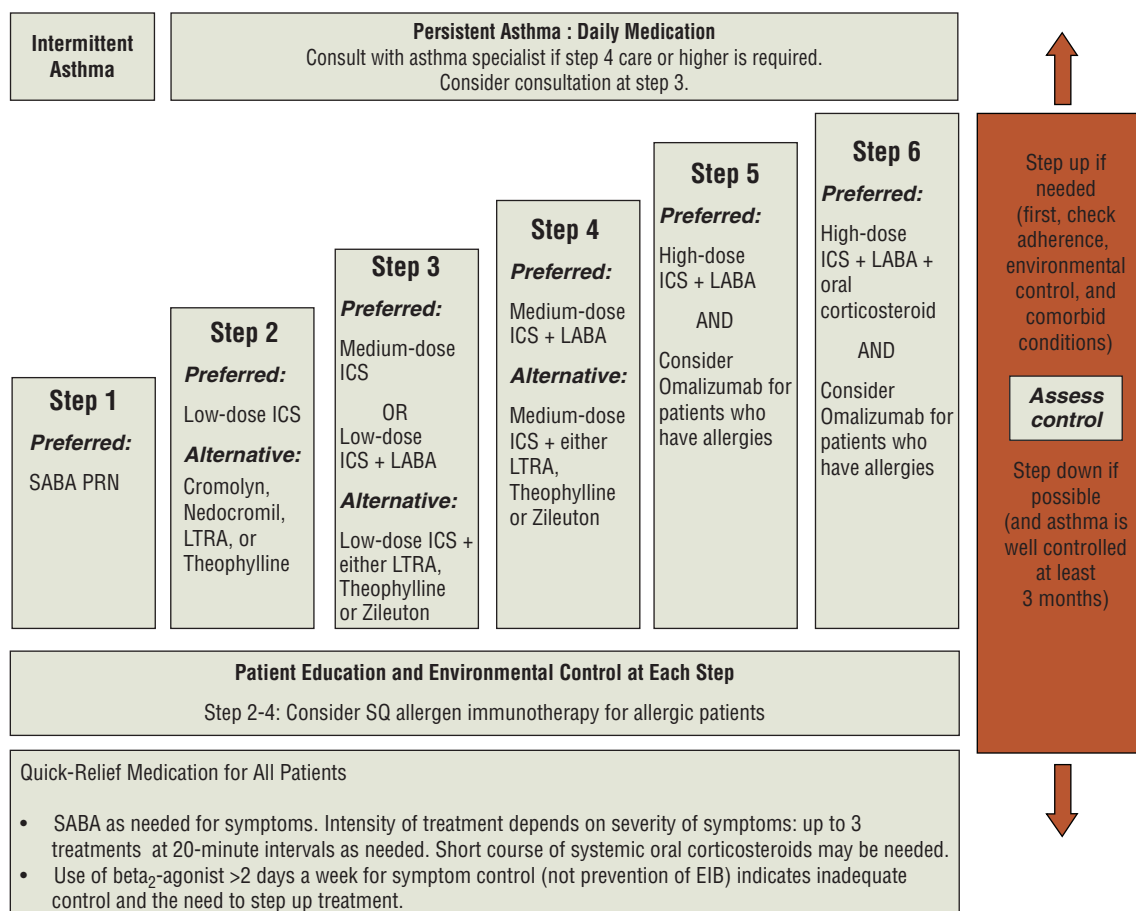

FIGURE 28-8. (continued)

The knowledge that inflammation plays a primary role in the pathogenesis of asthma has led to the conviction that the focus of therapy is the prevention and suppression of the underlying inflammation.^{2,6,8} Thus current therapeutic options in asthma consist of acute reliever medications used for acute exacerbations and long-term control medications used for the prevention of symptoms and exacerbations and the suppression of inflammation.² The currently accepted approach is to use drugs that suppress the inflammatory response as primary long-term control therapy, thereby reducing the degree of BHR and improving long-term control and outcomes in asthma.^{2,6,8}

7 The development of a partnership in care through patient education and the teaching of patient self-management skills should be the cornerstone of any treatment program.^{2,6,8} There are a number of published self-management programs for children and adults available through local American Lung Association chapters, as well as asthma treatment centers, and nationally through the NAEPP and the Asthma and Allergy Foundation of America.^{2,6,8} Asthma self-management programs have been shown to improve patient adherence to medication regimens, improve self-management skills, and improve use of healthcare services.^{2,6,8} The objective of these programs is to develop a partnership relationship between the patient and the healthcare provider. Table 28-11 lists the key educational messages recommended by the NAEPP.⁶

Self-management programs instruct patients in the pathogenesis of asthma and the appropriate use of their medications but focus principally on teaching patients to recognize triggers for their asthma and how to recognize early signs of deterioration. Home PEF monitoring is part of some programs.^{2,8} However, routine PEF monitoring in and of itself does not improve patient outcomes.⁶

The NAEPP advocates the use of PEF monitoring only for patients with severe persistent asthma who have difficulty perceiving airway obstruction.² The NAEPP also has recommended a system based on a traffic light scenario (based on percentage of normal predicted values or personal best values): the green zone is

equal to 80% to 100%, the yellow zone is equal to 50% to 79%, and the red zone is less than 50%. The yellow zone is cautionary and requires increasing as-needed bronchodilator use and possibly beginning prednisone if not improved, whereas the red zone warrants contacting the patient's healthcare provider.²

Patient education is essential before monitoring can be effective. Patient education has proved successful regardless of the health professional who provided the information (physician, nurse, or pharmacist). The NAEPP advocates significant involvement of all points of patient care in the educational process. The provision of written action plans enhances the success of education and is considered an essential component of care.^{2,6} Samples of clinically tested written action plans are available from the NAEPP guidelines and other sources.^{2,6}

In patients with known allergic triggers for their asthma, allergen avoidance has resulted in an improvement in symptoms, a reduction in medication use, and a decrease in BHR.^{2,6} A comprehensive approach to environmental control is advocated. For example, for patients with house-dust mite allergy, removing carpeting from bedrooms, washing sheets in hot water (>54.4°C [130°F]), and using special dust-proof pillow and mattress covers can reduce symptoms and need for medications.^{2,6} Obvious environmental triggers (e.g., animal dander, cockroaches), if the patient is sensitive, should be avoided. Evidence for home air-filtering systems and chemicals for killing house-dust mites is limited.⁶ Immunotherapy (allergy shots) with single antigens particularly, has been beneficial and may be considered in patients with persistent asthma with documented sensitivity.⁶ Immunotherapy with multiple antigens has been less effective.

Patients who smoke should be encouraged to stop. Parents of children with asthma should stop or at least not smoke around their children.^{2,6,8}

■ PHARMACOLOGIC THERAPY

Figure 28–8 illustrates the current NAEPP recommendations for therapy of persistent asthma.⁶ Therapy should be adjusted based on

control status of the patient (refer to Evaluation of Asthma Control section). Regardless of the long-term therapy, all patients need to have quick-relief medication in the form of short-acting inhaled β_2 -agonists available for acute symptoms. The ICSs are considered the preferred long-term control therapy for persistent asthma in all patients because of their potency and consistent effectiveness.^{6,8} Low- to medium-dose ICSs reduce BHR, improve lung function, and reduce severe exacerbations leading to emergency department visits and hospitalizations. They are more effective than cromolyn, nedocromil, theophylline, or the leukotriene receptor antagonists.⁶ In addition, the ICSs are the only therapy that reduces the risk of dying from asthma.⁴⁵ In the low to medium doses recommended by the NAEPP guidelines (Table 28–12), ICSs are safe for long-term administration (see Drug Class Information, Inhaled Corticosteroids below).^{6,39} The ICSs do not appear to reduce airway remodeling and loss of lung function found in some patients with persistent asthma. The ICSs do not enhance lung growth in children with asthma, prevent the development of asthma in high risk infants, or induce remission of asthma as BHR and other measures of inflammation return to pretreatment levels on discontinuation of therapy.^{46,47} The sensitivity and consequent clinical response to ICSs can vary among patients.⁶

Although studies of the alternative long-term control therapies (e.g., cromolyn, leukotriene receptor antagonists, nedocromil, and theophylline) demonstrate improvement in symptoms, lung function, and as-needed short-acting inhaled β_2 -agonist use, they do not reduce BHR, suggesting minimal antiinflammatory activity.⁶ The evidence suggests minimal to no differences in efficacy between these alternatives. Consequently, the NAEPP lists them in alphabetical order to show no preference for one over the other.⁶

For those patients who are inadequately controlled on low-dose ICSs, either an increased dose of the ICS or the combination of ICS and long-acting inhaled β_2 -agonist (LABA) is the next step to gain control of more moderate persistent asthma.^{6,8} Alternatives could be the addition of leukotriene modifiers or theophylline to ICSs.^{6,8} The addition of theophylline or leukotriene modifiers to ICSs is no more

TABLE 28-12 Available Inhaled Corticosteroid Products, Lung Delivery, and Comparative Daily Dosages

Inhaled Corticosteroids	Product	Lung Delivery ^a
Beclomethasone dipropionate (BDP)	40 and 80 mcg/actuation HFA MDI, 120 actuations	55–60%

CFC, chlorofluorocarbon; DPI, dry-powder inhaler; HFA, hydrofluoroalkane; MDI, metered-dose inhaler; UK, unknown.

effective than doubling the dose of the ICS.⁶ The combination of ICS/LABA is more effective at reducing severe asthma exacerbations than doubling the dose of ICS in moderate persistent asthma; increasing the dose of ICSs fourfold also will result in a significant reduction in exacerbations.^{48–50} However, doses of ICSs in the high range significantly enhance the risk of toxicity. Thus, high doses of ICSs plus LABA are reserved for patients with severe persistent asthma.⁶

Although the addition of a third controller medication is often used clinically in patients with severe, persistent asthma uncontrolled on high-dose ICS/LABA, there are few studies evaluating this practice.⁶ Leukotriene receptor antagonists or theophylline added to high-dose combination ICS/LABA do not improve outcomes.⁶ Omalizumab, a recombinant anti-IgE has demonstrated significant activity in these severe, uncontrolled patients.⁵¹ Thus adult patients with severe, persistent, uncontrolled asthma and atopy would be candidates for omalizumab therapy.

■ SPECIAL POPULATIONS

6 Children 4 years of age and younger have not been studied adequately. Thus, many of the recommendations in this age group are based on extrapolation of data from older children and adults.⁶ The studies of ICSs in this younger group demonstrate improvement in symptoms, as needed bronchodilator use and exacerbations. The nebulized suspension of budesonide gained FDA approval from three pivotal efficacy and safety trials.⁶ The FDA approval for montelukast in children younger than age 6 years was based on safety and pharmacokinetic studies establishing doses but not on efficacy although improvement in symptoms and as needed bronchodilators was noted.⁶ Cromolyn nebulizer solution was approved down to 2 years based upon efficacy, however, not all trials of cromolyn, particularly when administered by MDI plus VHC, in this younger group have demonstrated efficacy.⁶ Theophylline has not been evaluated adequately, except for pharmacokinetics.⁶ Combination therapy of any kind has not been studied except for a small number of patients down to 4 years of age on ICS/LABA.⁶

The FDA approval of the fluticasone/salmeterol DPI 100/50 in patients 4 to 11 years of age was largely based on extrapolation of efficacy data from patients older than 12 years of age and by a single safety and efficacy study in children with asthma aged 4 to 11 years. In children 5 to 11 years old, the ICS/LABA combination has not been shown to decrease exacerbations compared to medium-dose ICS as in adults although impairment domains improved. The only study of the addition of montelukast to ICS showed minimal improvement in PEF and as-needed albuterol use. Thus combination therapy has been inadequately studied in this population.

Owing to the increased risk of osteoporosis in the elderly, patients requiring high doses of ICSs should have their bone mineral density determinations followed and appropriate therapies for prevention of osteoporosis instituted.³⁹

Asthma affects 7% of pregnant women, making it potentially the most common serious medical condition to complicate pregnancy.⁵² Maternal asthma has been reported to increase the risk of perinatal mortality, preeclampsia, preterm birth, and low-birth-weight infants.⁵² More severe asthma is associated with increased risks, whereas better-controlled asthma is associated with decreased risks. A systematic review of the evidence on the safety of asthma medications has been conducted by drug class.⁵² This review concluded that it is safer for pregnant women with asthma to be treated with effective medications than for them to have exacerbations.⁵² Proper monitoring and control of asthma should enable a woman with asthma to maintain a normal pregnancy with little or no risk to mother or her fetus.

A stepwise approach to managing asthma during pregnancy and lactation has been published, with low-dose ICSs recommended as preferred treatment for mild persistent asthma with the addition of

a LABA if not adequately controlled.⁵² Budesonide is considered the preferred ICS to initiate because it has the greatest amount of safety data.⁵² Albuterol is considered the preferred rescue therapy.⁵²

■ DRUG CLASS INFORMATION

Inhaled Corticosteroids

The mechanism of action of the corticosteroids was reviewed under Systemic Corticosteroids above. The principal advantage of the ICSs is their high topical potency to reduce inflammation in the lung and low systemic activity.^{39–41} The ICSs have high antiinflammatory potency, approximately 1,000-fold greater than endogenous cortisol, and differ from each other by as much as 4- to 6-fold.⁴¹ However, potency differences, which are simply a measure of binding affinity to the receptor, can be overcome simply by giving different microgram dosages of drug. Aerosol delivery of the preparations is remarkably variable, ranging from 10% to 60% of the nominal dose (i.e., that dose which leaves an actuator for an MDI or, in the case of a DPI, that which is released on actuation of the inhaler).^{25,41} Different devices for the same chemical entity may result in twofold differences in delivery, such as with fluticasone propionate and budesonide, or as much as eightfold with beclomethasone dipropionate preparations.³⁹ Thus the delivery method can make a significant difference in the relative comparable dose.^{2,6}

Table 28–12 lists and compares the ICSs, beclomethasone dipropionate, budesonide, flunisolide, fluticasone propionate, mometasone furoate, and triamcinolone acetonide, which are currently available for use, and ciclesonide, which is undergoing clinical trials. The ICSs have pharmacokinetic differences that result in different topical/systemic activity.^{44,45} Most evidence is consistent with log-linear dose–response curves for both indirect and direct responses.³⁹ The log-linear nature of the dose–response curve for corticosteroid activity raises the issue of how much of a difference in dose (or lung delivery) or potency is detectable. The measures used to assess efficacy (lung function, BHR, symptoms, and as-needed, short-acting, inhaled β_2 -agonist use) are downstream events from the antiinflammatory activity.³⁹ In general, it takes a fourfold difference in potency or dose to detect clinically significant differences in efficacy. The table of comparable doses (see Table 28–12) is based on extensive clinical trial data.⁶ Clinically comparable doses take into consideration drug potency differences as well as device delivery differences.

Because the glucocorticoid receptors within the various tissues are the same, differences in the pharmacokinetic profile are required to produce differences in the topical–systemic effect ratio (therapeutic index).³⁹ Pharmacokinetic properties that enhance improved topical selectivity include rapid systemic clearance, poor oral bioavailability, and long residence time in the lung.^{39,41} Owing to their high lipophilicity, systemic clearance of the available ICSs is very rapid, approaching the rate of liver blood flow, with the exception of ciclesonide, which is inactivated by blood esterases.⁴¹ However, the ICSs differ markedly in their oral bioavailability, although they all undergo rather extensive first-pass metabolism to less active substances when absorbed (see Table 28–9).⁴¹ The ICSs produce dose-dependent systemic effects from a combination of the orally absorbed fraction and the fraction absorbed from the lung (Table 28–13).^{39,41} Essentially all the drug that reaches the lung is absorbed systemically; thus a slow absorption from the lung results in an apparent long elimination half-life and enhances topical selectivity by lowering the systemic concentration.⁴¹ The potential advantage of the drugs with low oral bioavailability is obviated by using a spacer device with the MDI for the drugs with higher oral bioavailability because appropriate spacers reduce the oral dose by 80%.²⁵ The use of VHCs also can increase systemic activity by increasing lung delivery of drugs not absorbed significantly orally.³⁹ If this increase in lung deposition is twofold or less, it will increase systemic activity without producing a clinically important

TABLE 28-13 Effects of Inhaled Corticosteroids

Beneficial Effects	Potential Adverse Effects
Decrease eosinophil numbers	Growth retardation, skeletal muscle myopathy
Decrease mast cell numbers	Osteoporosis, fractures, and aseptic necrosis of hip
Decrease T-lymphocyte cytokine production	Posterior subcapsular cataract formation and glaucoma
Inhibit transcription of inflammatory genes in airway epithelium	Adrenal axis suppression, immunosuppression
Reduce endothelial cell leak	Impaired wound healing, easy bruising, skin striae
Upregulate β_2 -receptor production	Hyperglycemia/hypokalemia, hypertension
Reduce airway epithelial subbasement membrane thickening	Psychiatric disturbances

increase in efficacy, thus decreasing the therapeutic index.³⁹ Mouth rinsing and spitting also will reduce the oral availability and are particularly useful for DPI devices.^{2,25}

The response to ICSs is somewhat delayed. Most patients' symptoms will improve in the first 1 to 2 weeks of therapy and will reach maximum improvement in 4 to 8 weeks.⁵³ Improvement in baseline FEV₁ and PEFs may require 3 to 6 weeks for maximum improvement, whereas improvement in BHR requires 2 to 3 weeks and approaches maximum in 1 to 3 months but may continue to improve over 1 year.⁵³ Most of the improvement in these parameters occurs at low to medium doses, and there is a large variability in response, with 10% of patients not demonstrating an improvement in either parameter.⁵³ Whether these nonresponders also show no improvement in rates of exacerbations is unknown. Maximum decrease in FeNO occurs within 2 to 3 weeks.⁵⁴ Sensitivity to exercise challenge decreases after 4 weeks of therapy.^{18,53} Although single doses do not inhibit the immediate asthmatic response to antigen challenge, continued therapy for 1 week partially suppresses the response. These two latter effects are likely caused by a reduction in mucosal mast cells.⁵³

Local adverse effects from ICSs include oropharyngeal candidiasis and dysphonia that are dose-dependent. The dysphonia (reported in 5% to 50% of patients) appears to be caused by a local corticosteroid-induced myopathy of the vocal cords.² The use of a spacer device with MDIs can decrease oropharyngeal deposition and thus decrease the incidence and severity of local side effects.^{25,53} There is less data on the use of spacers with ICS HFA MDIs. In infants who require delivery through a facemask, the parent should clean the nasal-perioral area with a damp cloth following each treatment to prevent topical candidal infections.

Systemic adverse effects can occur with any of the ICSs given in a sufficiently high dose.³⁹ Long-term adverse effects of greatest concern include growth suppression in children, osteoporosis, cataracts, dermal thinning, and adrenal insufficiency and crisis.^{39,53} Of these, only growth retardation occurs in low to medium doses. However, the growth reduction appears to be transient in that growth velocity is reduced in the first 6 months to 1 year of therapy and then returns to normal.^{6,39} The effect is small (1 to 2 cm total) and not cumulative, and current studies suggest that attainment of predicted adult height is not affected.^{6,39} The suppression of the hypothalamic–pituitary–adrenal axis and decreased bone mineralization are dose-dependent and do not appear to be significant clinically except at high doses.³⁹ The risks of these adverse effects are all dose-dependent and depend on the therapeutic index of each ICS and its delivery device. The effect of delivery device is illustrated by fluticasone propionate, which has both the greatest therapeutic index when administered by DPI and the lowest therapeutic index when administered by MDI plus VHC.³⁹ Some of the ICSs including fluticasone propionate, budesonide and mometasone are metabolized in the gastrointestinal tract and liver by cytochrome P450 (CYP) 3A4 isoenzymes. Potent inhibitors of CYP3A4, such as ritonavir and ketoconazole, have the

potential for increasing systemic concentrations of these ICSs by increasing oral availability and decreasing systemic clearance. Some cases of clinically significant Cushing syndrome and secondary adrenal insufficiency have been reported.⁴¹

Most patients with moderate disease can be controlled with twice-daily dosing of most ICSs.^{6,8,53} Twice-daily dosing produces less thrush than three- to four-times-daily dosing regimens. In milder asthma, once-daily dosing is often sufficient to maintain control.⁵³ Some of the newer products have gained once-daily dosing indications, particularly in mild asthma once initial control is established.⁴¹ There does not appear to be any specific pharmacologic or pharmacokinetic aspect of the ICSs that allows for once-daily dosing because all the agents studied (both the older low-potency and newer high-potency ICSs) have been effective, provided that patients had relatively mild to moderate asthma.^{39,53} Patients with more severe asthma require multiple daily dosing. The inflammatory response of asthma inhibits steroid-receptor binding.⁵³ This provides strong theoretical evidence for initially beginning patients on higher and more frequent doses and then tapering down once control has been achieved. Once asthma is controlled, many patients are able to reduce the ICS dose and maintain control.⁵³

Long-Acting Inhaled β_2 -Agonists

The two LABAs, formoterol and salmeterol, provide long-lasting bronchodilation (12 or more hours) when administered as aerosols (see Table 28-8).³⁰ Unlike the more water-soluble short-acting β_2 -agonists, the long-acting agents are lipid soluble, readily partitioning into the outer phospholipid layer of the cell membrane.³⁰ Salmeterol is more β_2 -selective than albuterol and more bronchoselective by virtue of its property of remaining in the lung tissue cell membrane, which produces its longer duration.³⁰ However, both formoterol and salmeterol will produce dose-dependent systemic β_2 -agonist effects.³⁰

The principal differences between formoterol and salmeterol are that formoterol has a more rapid onset of action (similar to that of albuterol) and formoterol is a full agonist, whereas salmeterol is a partial agonist. These differences are unlikely to produce clinically significant differences because both are recommended for chronic therapy only in combination with ICSs.⁶ They are available singly and as fixed-dose combinations with ICSs. Patients should be warned to not use salmeterol for acute relief of asthma because it can take up to 20 minutes for onset and 1 to 4 hours for maximum bronchodilation following inhalation.^{2,6} Formoterol also does not have approved FDA labeling for acute relief. Patients need to be counseled to continue to use their short-acting inhaled β_2 -agonists for acute exacerbations while receiving the LABAs.

The LABAs are the preferred adjunctive therapy to ICSs in children ≥ 12 years of age and in adults for step 3, and in children 5 to 11 years of age for steps 4 and 5.⁶ Combination treatment with ICS/LABA provides greater asthma control than increasing the dose of ICS alone while at the same time reducing the frequency and perhaps the severity of exacerbations.⁴⁸⁻⁵⁰ Because they are devoid of antiinflammatory activity, LABAs should not be used as monotherapy for asthma. Recent evidence suggests that patients treated with LABA monotherapy added to usual therapy are at an increased risk for severe, life-threatening exacerbations and asthma-related death.^{55,56} This risk may be greater in African American patients. Whether this risk is obviated by concomitant ICS use is unknown at this time but preliminary evidence does not support an increased risk of severe, life-threatening exacerbations in patients receiving LABAs in combination with ICSs.^{57,58}

As with short-acting β_2 -agonists, tolerance is produced with chronic administration of LABAs. Long-term trials show no diminution in bronchodilator response, but do show a partial loss of the bronchoprotective effect against methacholine, histamine, and

exercise challenge.⁵⁸ In particular, the duration of protection against EIB following a single dose of salmeterol is up to 9 hours but is reduced to less than 4 hours following regular treatment.⁵⁸ Following regular treatment with salmeterol and formoterol, decreased protection against nonspecific bronchoprovocation with methacholine also occurs, although it provides greater protection than placebo.⁵⁸ Responsiveness to short-acting β_2 -agonists is reported to be slightly decreased but easily overcome by increasing the dose (by approximately 1 puff) following chronic therapy with LABAs.⁵⁸

There is ample evidence that the use of a LABA in combination with ICS therapy does not mask inflammation.⁵⁷ A meta-analysis of studies comparing the addition of salmeterol to ICS therapy versus at least a doubling of ICS dose demonstrates that rather than increasing asthma exacerbations, the number of these events was reduced.⁴⁸ As stated previously LABAs added to ICS in children improve impairment but have yet to be adequately studied for reducing exacerbations over ICS alone.⁵⁹

Methylxanthines

Methylxanthines have been used for asthma therapy for more than 50 years but their use in recent years has declined markedly owing to the high risk of severe life-threatening toxicity and numerous drug interactions, as well as decreased efficacy when compared with ICSs and LABAs. Theophylline, the primary methylxanthine of interest, is a moderately potent bronchodilator with mild anti-inflammatory properties.^{2,8} Like the β_2 -agonists, the methylxanthines are functional antagonists of bronchospasm; however, their clinical usefulness is limited by their low therapeutic index.² Theophylline as a sustained-release product is the preferred oral preparation, whereas its complex with ethylenediamine (aminophylline) is the preferred injectable product because of increased solubility.⁶⁰

The mechanism by which theophylline produces bronchodilation appears to be through nonselective phosphodiesterase inhibition.⁶⁰ Inhibition of phosphodiesterase results in increased cAMP and cyclic guanosine monophosphate concentrations. The phosphodiesterase isoenzymes currently thought to be important for theophylline's clinical effects are isoenzymes III, predominant in airway smooth muscle, and IV, important in inflammatory cell regulation such as mast cells, neutrophils, eosinophils, and T lymphocytes.⁶⁰ Selective phosphodiesterase isoenzyme IV inhibitors, however, have no significant effects in clinical asthma. Theophylline is a competitive antagonist of adenosine and stimulates endogenous catecholamine release.⁶⁰ These latter two effects are important determinants of toxic symptoms of excess theophylline.⁶⁰

Theophylline has a log-linear dose-response curve.⁶⁰ Most chronic stable asthmatics will obtain significant bronchodilation when the serum theophylline concentration reaches 5 mcg/mL, and most patients will have no toxic symptoms with serum concentrations of less than 15 mcg/mL.^{6,60} The percentage of patients experiencing adverse effects increases sharply as concentrations exceed 15 mcg/mL. As with the β_2 -agonists, the dose-response curves for smooth muscle relaxation by theophylline are dynamic and shifted to the right in the face of increasing contractile stimuli.⁶⁰ This probably explains theophylline's relative lack of bronchodilatory effect in acute severe asthma.^{6,60} The severity of theophylline's toxicity precludes even doubling the usual dosage. Toxicities include caffeine-like effects of nausea, vomiting, tachycardia, jitteriness, and difficulty sleeping to more severe toxicities such as cardiac tachyarrhythmias and seizures. Death has occurred in children receiving their usual doses of theophylline during acute systemic viral illnesses.⁶⁰

Routine monitoring of serum concentrations is essential for the safe and effective use of theophylline.⁶ Theophylline is eliminated primarily by metabolism via the hepatic cytochrome P450 mixed-function oxidase microsomal enzymes (primarily the CYP1A2 and CYP3A3 isozymes), with 10% or less excreted unchanged in the

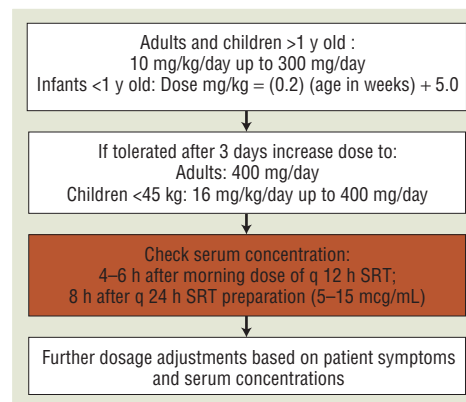

FIGURE 28-9. Algorithm for slow titration of theophylline dosage and guide for final dosage adjustment based on serum theophylline concentration measurement. For infants younger than 1 year of age, the initial daily dosage can be calculated by the following regression equation: Dose (mg/kg) = (0.2) (age in weeks) + 5.0. Whenever side effects occur, dosage should be reduced to a previously tolerated lower dose. (SRT, sustained-release theophylline.)

kidney.⁶⁰ Theophylline clearance is age-dependent, with 1- to 9-year-olds having the highest systemic clearances and therefore requiring the largest dosages (on a weight basis). However, even within the same age groups, theophylline clearance can vary two- to threefold.⁶⁰ Figure 28-9 gives a dosing and monitoring schedule for theophylline. Table 28-14 lists factors that affect theophylline's hepatic metabolism.² Only drugs or diseases that produce a 20% or greater inhibition or a 50% or greater induction of theophylline metabolism are likely to result in clinically significant interactions.⁶⁰

Sustained-release theophylline is less effective than ICSs and no more effective than oral sustained-release β_2 -agonists, cromolyn, or leukotriene antagonists.⁶ The addition of theophylline to ICSs is similar to doubling the dose of the ICS and is less effective overall than the LABAs as adjunctive therapy.⁶

Cromolyn Sodium and Nedocromil Sodium

Cromolyn sodium and nedocromil sodium are pharmacologically similar.² They are classified as mast cell stabilizers, and the principal difference appears to be potency, with 4 mg nedocromil by MDI equivalent to 10 mg cromolyn.^{2,61} However, there is no apparent difference in the clinical efficacy between these two drugs.² They inhibit the early and late asthmatic response to allergen challenge, as well inhibit EIB.^{2,8} Treatment prevents the usual rise in bronchial hyperresponsiveness with specific pollen seasons, but long-term treatment produces minimal to no change in baseline bronchial

TABLE 28-14 Factors Affecting Theophylline Clearance

Decreased Clearance	% Decrease	Increased Clearance	% Increase
Cimetidine	-25 to -60	Rifampin	+53
Macrolides: erythromycin, clarithromycin	-25 to -50	Carbamazepine	+50
		Phenobarbital	+34
		Phenytoin	+70
Allopurinol	-20	Charcoal-broiled meat	+30
Propranolol	-30		
Quinolones: ciprofloxacin, enoxacin, pefloxacin	-20 to -50	High-protein diet	+25
		Smoking	+40
Interferon	-50	Sulfipyrazone	+22
Thiabendazole	-65	Moricizine	+50
Ticlopidine	-25	Aminoglutethimide	+50
Zileuton	-35		
Systemic viral illness	-10 to -50		

hyperresponsiveness.^{6,61} They inhibit neurally mediated bronchoconstriction, through C-fiber sensory nerve stimulation in the airways, although neither drug has a bronchodilatory effect.⁶¹

Cromolyn and nedocromil are only effective by inhalation and are available as MDIs, whereas cromolyn also is available as a nebulizer solution. The pharmacokinetics of both drugs are very similar. They are not bioavailable orally, but the portion of the dose that reaches the lung is absorbed completely.⁶¹ Absorption from the airway is significantly slower than elimination (hours versus minutes). The short duration in the lung likely limits their efficacy. Both the intensity and duration of protection against various challenges are dose-dependent.⁶¹ Higher doses produce greater and more prolonged protection.

Both drugs are remarkably nontoxic. No evidence of mutagenesis or teratogenesis has been found for cromolyn. Cough and wheeze have been reported following inhalation of each, and bad taste and headache following nedocromil are reported.² The taste from nedocromil is sufficiently bad in some patients (approximately 20%) to preclude them from taking the drug.⁶¹ Tolerance to cromolyn or nedocromil has not been demonstrated. Neither are ICS-sparing agents.

Cromolyn and nedocromil are no more or less effective than theophylline or the leukotriene antagonists for persistent asthma.⁶ Neither cromolyn nor nedocromil is as effective as the ICSs for controlling persistent asthma.^{6,46} Neither is as effective as the inhaled β_2 -agonists for preventing EIB but can be used in conjunction for patients not responding completely to the inhaled β_2 -agonists.⁴³

Most patients will experience an improvement in 1 to 2 weeks, but it may take longer to achieve maximum benefit. Patients initially should receive cromolyn or nedocromil four times daily, and then only after stabilization of symptoms may the frequency be reduced to two times daily for nedocromil and three times daily for cromolyn. Only the nebulizer solution should be used for children younger than 5 years of age.⁶

Leukotriene Modifiers

Two clinically distinct cysteinyl leukotriene receptor antagonists (zafirlukast and montelukast) and one 5-lipoxygenase inhibitor (zileuton) have been available in the United States since 1996 for both children and adults with persistent asthma.⁶² In challenge studies, they reduce allergen-, exercise-, cold air hyperventilation-, irritant-, and aspirin-induced asthma.⁶³ Clinical use of zileuton is limited because of the potential for elevated liver enzymes (especially in the first 3 months of therapy), and the potential inhibition of drugs metabolized by the CYP3A4 isoenzymes.^{62,63}

In clinical trials, the LTD₄ receptor antagonists (zafirlukast and montelukast) have demonstrated efficacy in adults and children with persistent asthma. These drugs improve pulmonary function tests (FEV₁ and PEF), decrease nocturnal awakenings and β_2 -agonist use, and improve asthma symptoms.^{62,63} A major advantage is that they are effective orally, administered once or twice a day, and contribute to patient adherence and satisfaction with therapy.⁶² However, they are less effective in asthma than low doses of ICSs.^{64,65} It is not yet possible to predict which patients respond best to leukotriene modifiers, although there is some evidence that patients with aspirin-sensitive asthma do well, as predicted by studies showing increased cysteinyl leukotriene production in these patients.⁶³ It is possible that genetic polymorphisms in the 5-lipoxygenase or LTC₄ synthase pathways or in cys-LT₁ receptors might predict better responders in the future.⁶³ Antileukotrienes also have modest efficacy in allergic rhinitis.

In general, the LTD₄ receptor antagonists are well tolerated and do not appear to have serious class-specific effects.⁶ An idiosyncratic syndrome similar to the Churg-Strauss syndrome, with marked circulating eosinophilia, heart failure, and associated eosinophilic vasculitis, has been reported in a small number of patients treated with zafirlukast or montelukast.⁶ The majority of these patients had

been receiving high-dose inhaled or oral corticosteroids and were able to reduce the dose as a consequence of the LTD₄ receptor antagonists. It is unclear whether the increased reports are a result of increased case findings among patients with asthma prescribed a new drug or whether the syndrome is related to corticosteroid dose reduction or an idiosyncratic effect of leukotriene modifiers in general. Whatever the cause, it appears to be a rare syndrome, with an estimated incidence of fewer than 1 case per 15,000 to 20,000 patient-years of treatment.⁶ Montelukast has been prescribed widely worldwide owing to its approval for use in young children. Churg-Strauss syndrome has not been reported in children, and the drug has been very well tolerated and palatable.⁶ Recent reports of fatal hepatic failure associated with zafirlukast have prompted a warning for patients to be made aware of signs and symptoms of hepatic dysfunction.

Zileuton can be administered four times daily or twice daily as controlled release tablets.⁶ Efficacy data is more limited, liver function monitoring is recommended, and drug interactions are reported with warfarin and theophylline.

Combination Controller Therapy: ICS/LABA versus ICS/Leukotriene Receptor Agonists

Whereas ICS therapy is considered the most effective antiinflammatory treatment, in cases of moderate to severe persistent asthma, the addition of a second long-term control medication to ICS therapy is one recommended treatment option. Single inhaler combination products containing fluticasone propionate and salmeterol or budesonide and formoterol are commercially available and there likely will be more in the future. The inhalers, both DPIs and MDIs, contain varied doses of the ICSs and a fixed dose of the respective LABAs. The pivotal trials for gaining FDA approval of fixed-dose combinations require that the combination demonstrate greater efficacy than either component alone. Importantly, the addition of a LABA allows reduction in ICS dosage by 50% in most patients with persistent asthma.^{48,50} Furthermore, combination therapy is more effective than higher-dose ICS alone in reducing asthma exacerbations in patients with persistent asthma.^{6,50} The ability to detect deteriorating asthma and the severity of exacerbation were similar between groups. Leukotriene receptor agonists also are successful as additive therapy in patients inadequately controlled on ICS alone and as ICS-sparing therapy.⁶ However, the magnitude of these benefits is less than those reported with the addition of LABAs.^{6,49}

Anti-IgE (Omalizumab)

Omalizumab is a recombinant anti-IgE antibody approved for the treatment of allergic asthma not well controlled by oral corticosteroids or ICSs.⁶⁶ Omalizumab is a composite of 95% human and 5% antihuman murine IgE sequences. The mouse protein becomes part of the receptor complex and thus is shielded from exposure to the immune system, lowering the risk for an anaphylactic response.⁶⁶ Omalizumab binds to the Fc portion of the IgE antibody, preventing the binding of IgE to its high-affinity receptor (FcεRI) on mast cells and basophils. The decreased binding of IgE on the surface of mast cells leads to a decrease in the release of mediators in response to allergen exposure. Omalizumab also decreases FcεRI expression on basophils and airway submucosal cells.

Omalizumab is administered subcutaneously and has a slow absorption rate; peak serum concentration is achieved in 3 to 14 days.⁶⁶ It is eliminated primarily through the reticuloendothelial system and has an elimination half-life of 17 to 22 days; serum free IgE levels return to baseline in about 3 weeks.⁶⁶ It should be administered under medical observation with drugs for treating anaphylaxis available.

The dosage of omalizumab is determined by the patient's baseline total serum IgE level (international units per milliliter) and body weight (kilograms).⁶⁶ Doses range from 150 to 375 mg and are given at

either 2- or 4-week intervals. No further adjustments for variations in total serum IgE are required, and patients receive a consistent dose for the duration of treatment.⁶⁶ Omalizumab is approved for patients older than 12 years of age who have allergic asthma.⁶⁶ Clinical trials in 5- to 12-year-olds are ongoing. Because of its significant cost, it is only indicated as step 5 or 6 care for patients who have allergies and severe persistent asthma that is inadequately controlled with the combination of high-dose ICS/LABA.⁶ It is the only adjunctive therapy that has demonstrated improved outcomes in patients uncontrolled on ICS/LABA and has allowed oral corticosteroid reduction in a number of studies.^{6,66} However, recent postmarketing surveillance suggests that omalizumab therapy is associated with a 0.1% rate of anaphylaxis, prompting an FDA warning that patients should remain in the physician's office for a reasonable period of time past the injection because 70% of reactions occur within 2 hours. In addition, patients should be counseled on the signs and symptoms of anaphylaxis because some reactions have occurred up to 24 hours following an injection.⁶

■ MISCELLANEOUS THERAPIES (IMMUNOMODULATORS)

The following therapies have been loosely categorized by the NAEPP with omalizumab as immunomodulators because they either affect the immune system or have antiinflammatory properties. Many have been used experimentally in severe persistent uncontrolled asthma for years to try to avoid or lower oral corticosteroid dosages.

Low-dose methotrexate (15 mg/week) used for inflammatory diseases, psoriatic and rheumatoid arthritis, and polymyositis has been used to reduce the systemic steroid dose in patients with severe steroid-dependent asthma.⁶⁷ Double-blind, placebo-controlled trials have given decidedly mixed results, with half the studies showing no effect.⁶⁸ A recent meta-analysis determined that there was insufficient evidence to support its use, particularly in light of the risk for severe side effects.⁶⁷ Methotrexate inhibits chemotaxis of neutrophils, inhibits leukotriene B₄-induced adherence to endothelium, and inhibits the proinflammatory activity of IL-1. Low-dose weekly methotrexate is associated with hepatotoxicity and pulmonary fibrosis.⁶⁷ The NAEPP has concluded that it should not be used chronic asthma.⁶

A number of the drugs with antiinflammatory or immunomodulatory activity such as hydroxychloroquine, dapsone, gold, intravenous γ -globulin, cyclosporine, and colchicine have been studied in severe steroid-dependent asthma with mixed and limited results.^{6,68} Routine use is not recommended.⁶

■ FUTURE THERAPIES

Agents that are now in development for asthma focus on the treatment of allergic inflammation.^{68,69} Examples include inhibitors of eosinophilic inflammation, drugs that may inhibit allergen presentation, and inhibitors of TH₂ cells. Multiple cytokines have been implicated in allergic inflammation, and several possible inhibiting approaches are being explored. These range from drugs that inhibit cytokine synthesis (cyclosporine A and tacrolimus), humanized blocking antibodies to cytokines or their receptors, soluble receptors to mop up secreted cytokines, receptor antagonists, and drugs that block the signal-transduction pathways activated by cytokines.⁶⁸ Specifically, humanized monoclonal antibodies to IL-5 and nebulized soluble IL-4 receptors have been tested but have been disappointing to date.^{68,69}

PHARMACOECONOMIC CONSIDERATIONS

Of the estimated \$11.5 billion cost of asthma in the United States in 2004, direct medical expenditure accounted for 60% of the total, with emergency care (emergency department and inpatient hospital care) reaching \$2.5 billion.³ A cost-of-illness approach takes in all

measurable costs; both indirect costs or costs to society and direct medical costs are considered. Using this approach, indirect costs, such as lost work and death, accounted for two-thirds of total expenditures per patient. Although prescription drugs were the largest single direct medical expenditure at \$5 billion, an increase in these costs secondary to improved patient adherence could significantly reduce other costs because of school days lost and lost productivity secondary to asthma morbidity and mortality.

The medication cost increase over the past 10 years resulted from a doubling of prescribed medications, as well as a 169% increase in unit cost per medication, presumably as a result of a shift to more expensive antiinflammatory drugs consistent with the recommendations of the NAEPP guidelines.² Asthma severity obviously has an impact on cost of care. Studies from health maintenance organizations suggest that up to 45% of the cost of asthma is accrued by 10% of the patients, primarily as a result of emergency care.⁷⁰

Numerous studies demonstrate the cost-effectiveness of patient education programs for asthma, particularly those providing guided self-management.⁷⁰ Several studies report positive results from pharmacist interventions reducing overall cost of care.⁷⁰ Similar studies demonstrate the cost-effectiveness of specialist care compared with generalist care. However, the results of these trials may be confounded by changes in prescribing as part of the overall program. Indeed, use of ICSs reduces both morbidity, particularly hospitalizations, and mortality in asthma patients.^{6,53,71}

The NAEPP recommendations provide numerous alternatives for long-term controllers in mild to moderate persistent asthma, and few studies have compared their relative cost-effectiveness. This is important because outside the realm of randomized clinical trials that evaluate efficacy, other factors such as concern about adverse effects and adherence to therapy may alter the overall clinical effectiveness. Use of ICSs in children has produced a cost of \$9.45 per symptom-free day gained, and in adults a cost of \$5.00 per symptom-free day.⁷⁰ Retrospective analyses of large managed-care-linked pharmacy claims and healthcare utilization databases has allowed direct comparisons of the various long-term controllers in a general population to assess clinical effectiveness and cost-effectiveness. These studies have confirmed comparative randomized clinical trials showing ICSs to be significantly more cost-effective than leukotriene antagonists despite slightly better compliance with the leukotriene antagonists.^{72,73} In addition, the combination of ICSs/LABA lowers healthcare use and total healthcare costs compared with the combination of a leukotriene antagonist and an ICS.⁷⁴

CLINICAL CONTROVERSY

The potential for chronic use of inhaled β_2 -agonists to worsen asthma has been a concern for more than 30 years. Large multicenter, double-blind, placebo-controlled trials with both mild and moderate persistent asthma did not show that regular administration of short-acting inhaled β_2 -agonists worsened asthma. However, studies that have genotyped patients at the β -receptor suggest that homozygous Arg-16 patients (who make up approximately 16% of the population) are predisposed to worsening asthma with regular administration as measured by lower morning PEFs.⁵⁸ This phenomenon does not appear to occur with as-needed therapy with short-acting β_2 -agonists. It is yet unknown if regular treatment with LABAs produces similar effects as retrospective analyses have not shown worsening of asthma or whether concurrent use of ICS is protective. These patients still respond acutely to the β_2 -agonists, so whether they should avoid all β_2 -agonists is speculative. Because the regular use of short-acting inhaled β_2 -agonists does not improve control of symptoms, they should be used only as needed for symptoms.^{6,58}

EVALUATION OF ASTHMA CONTROL

Control of asthma is defined as reducing both impairment and risk domains. The stepwise approach to therapy should be used to achieve and maintain this control. Figure 28–8 outlines the steps of care appropriate to the three age ranges of asthma. Depending on the severity of the patient's asthma, compromises from the ideal control are made, and the best possible outcome, balancing disease control and possible adverse effects from the drugs, is attempted. Regular followup contact is essential (at 1- to 6-month intervals, depending on control). A 3-month interval of well-controlled asthma should be considered if a step-down is anticipated.

Components of evaluations control include symptoms, nighttime awakenings, interference with normal activities, pulmonary function, quality of life, exacerbations, adherence, treatment-related adverse effects, and satisfaction with care. The categories of well-controlled, not well-controlled, and very poorly controlled are recommended.⁶ Validated questionnaires such as the Asthma Therapy Assessment Questionnaire (ATAQ), the Asthma Control Questionnaire (ACQ), and the Asthma Control Test (ACT) can be regularly administered. The NAEPP minimally recommends spirometric tests at initial assessment, after treatment is initiated, and then every 1 to 2 years. In moderate to severe persistent asthma, peak-flow monitoring is recommended. Peak flow monitoring should also be considered for patients who are poor symptom perceivers and for those with a history of severe exacerbations. Patients also should be asked about exercise tolerance. All patients on inhaled drugs should have their inhalation delivery technique evaluated periodically—monthly initially, and then every 3 to 6 months. Before step-up in therapy, adherence, environmental control, and comorbid conditions should be reviewed.

Following initiation of antiinflammatory therapy or an increase in dosage, most patients should begin experiencing a decrease in symptoms in 1 to 2 weeks and achieve maximum symptomatic improvement within 4 to 8 weeks. The use of higher doses or more potent ICS agents may accelerate the process. Improvement in FEV₁ and PEF should follow a similar time frame; however, a decrease in BHR, as measured by morning PEF, PEF variability, and exercise tolerance, may take longer and improve over 1 to 3 months.² Patients should be informed that following a viral respiratory infection, they may experience increased exercise intolerance for up to 4 weeks.

Initial visits with the patient should focus on the patient's concerns, expectations, and goals of treatment. Basic education should focus on asthma as a chronic lung disease, the types of medications, and how they are to be used. Inhaler technique is taught, as is when to seek medical advice. Written action plans should be provided. Either peak-flow-based or symptom-based self-monitoring can be effective, if taught and followed correctly.⁶ The first followup visit should be in 2 to 6 weeks, to evaluate control. At that time, the educational messages of the first visit should be repeated, as well as questions about the patient's current medications, adherence, and any difficulties related to the therapy.

CONCLUSIONS

Asthma is a complicated disease with a multitude of clinical presentations. The exact defect in asthma has not been defined, and it may be that asthma is a common presentation of a heterogeneous group of diseases. Asthma is defined and characterized by excessive reactivity of the bronchial tree to a wide variety of noxious stimuli. The reaction is characterized by bronchospasm, excessive mucus production, and inflammation. The central role of inflammation in inducing and maintaining BHR is now becoming widely appreciated and studied. The goal of asthma therapy is to normalize, as

much as possible, the patient's life and prevent chronic irreversible lung changes. Drugs are the mainstay of asthma therapy. The goal of drug therapy is to use the minimum amount of medications possible to completely control the disease. In chronic asthma, therapy should be aimed at both bronchospasm and inflammation so as to produce the best results. Patients should be followed and monitored diligently for toxicities. Although death from asthma is an uncommon event, the most common cause of death is underassessment of the severity of obstruction either by the patient or by the clinician; the next common cause is undertreatment. A cornerstone of any therapy is education and the realization that most asthma deaths are avoidable.

ABBREVIATIONS

Arg:	arginine
BHR:	bronchial hyperresponsiveness
cAMP:	cyclic adenosine monophosphate
CYP:	cytochrome P450
DPI:	dry-powder inhaler
EIB:	exercise-induced bronchospasm
FeNO:	fraction of exhaled nitric oxide
FEV ₁ :	forced expiratory volume in 1 second
Gln:	glutamine
Glu:	glutamic acid
Gly:	glycine
GM-CSF:	granulocyte-macrophage colony-stimulating factor
HFA:	hydrofluoroalkane
ICAM-1:	intercellular adhesion molecule 1
ICS:	inhaled corticosteroids
IgE:	immunoglobulin E
IL:	interleukin
LABA:	long-acting β -agonists
LT:	leukotriene
MDI:	metered-dose inhaler
MMAD:	mass median aerodynamic diameter
NAEPP:	National Asthma Education and Prevention Program
NANC:	nonadrenergic, noncholinergic
NO:	nitric oxide
PEF:	peak expiratory flow
VCAM-1:	vascular cell adhesion molecule 1

Chronic Obstructive Pulmonary Disease

DENNIS M. WILLIAMS AND SHARYA V. BOURDET

KEY CONCEPTS

- 1 Chronic obstructive pulmonary disease (COPD) is a progressive disease characterized by airflow limitation that is not fully reversible and is associated with an abnormal inflammatory response of the lungs to noxious particles or gases.
- 2 COPD is historically described as either *chronic bronchitis* or *emphysema*. Chronic bronchitis is defined in clinical terms, whereas emphysema is defined in terms of anatomic pathology. Because most patients exhibit some features of each disease, the appropriate emphasis of COPD pathophysiology is on small airway disease and parenchymal damage that contributes to chronic airflow limitation.
- 3 Mortality from COPD has increased steadily over the past three decades; it currently is the fourth leading cause of death in the United States.
- 4 The primary cause of COPD is cigarette smoking. Other risks include a genetic predisposition, environmental exposures (including occupational dusts and chemicals), and air pollution.
- 5 Smoking cessation is the only management strategy proven to slow progression of COPD.
- 6 Oxygen therapy has been shown to reduce mortality in selected patients with COPD. Oxygen therapy is indicated for patients with a resting PaO_2 (partial pressure alveolar oxygen) of less than 55 mm Hg or a PaO_2 of less than 60 mm Hg and evidence of right-sided heart failure, polycythemia, or impaired neurologic function.
- 7 Bronchodilators represent the mainstay of drug therapy for COPD. Pharmacotherapy is used to relieve patient symptoms and improve quality of life. Guidelines recommend short-acting bronchodilators as initial therapy for patients with mild or intermittent symptoms.
- 8 For the patient who experiences chronic symptoms, long-acting bronchodilators are appropriate. Either a β_2 -agonist or an anticholinergic offers significant benefits. Combining long-acting bronchodilators is recommended if necessary despite limited data.
- 9 The role of inhaled corticosteroid therapy in COPD is controversial. International guidelines suggest that patients with severe

COPD and frequent exacerbations may benefit from inhaled corticosteroids.

- 10 Acute exacerbations of COPD have a significant impact on disease progression and mortality. Treatment of acute exacerbations includes intensification of bronchodilator therapy and a short course of systemic corticosteroids.
- 11 Antimicrobial therapy should be used during acute exacerbations of COPD if the patient exhibits at least two of the following: increased dyspnea, increased sputum volume, and increased sputum purulence.

Chronic obstructive pulmonary disease (COPD) is a common chronic disease of the airways characterized by the gradual and progressive loss of lung function. The prevalence and mortality of COPD have increased substantially over the past two decades. Currently, COPD is the fourth leading cause of death in the United States.

Although national guidelines for COPD management have been available for nearly two decades, questions were raised concerning their quality and supporting evidence. To standardize the care of patients with COPD and present evidence-based recommendations, the National Heart, Lung, and Blood Institute and the World Health Organization launched the Global Initiative for Chronic Obstructive Lung Disease (GOLD) in 2001.¹ This report was updated most recently in 2006. The goals of the GOLD organization are to increase awareness of COPD and reduce morbidity and mortality associated with the disease. International guidelines have also been developed through a collaborative effort of the American Thoracic Society and the European Respiratory Society and are widely available.² These two guidelines are generally concordant in their recommendations.

1 A consensus definition recognizes COPD as a disease characterized by airflow limitation that is not fully reversible. The airflow limitation is usually both progressive and associated with an abnormal inflammatory response of the lungs to noxious particles or gases.² Although COPD primarily affects the lungs, it also is associated with significant consequences. Finally, COPD is preventable and treatable.

For many years, clinicians and researchers have exhibited a nihilistic attitude toward the value of treatments for COPD. This was based on the paucity of effective therapies, the destructive nature of the condition, and the fact that the common etiology is cigarette smoking, a modifiable health risk. Currently, there is renewed interest in evaluating the value of treatments and prevention based on the availability of new therapeutic options for pharmacotherapy and guidelines based on evidence.³ Support for renewed optimism is also reflected in the availability of research funding to improve understanding about this disease and its management. This includes National Heart, Lung, and Blood Institute funding of Specialized Centers of Clinically Oriented Research programs in COPD, whose objective is to promote multidisciplinary research on clinically rele-

Learning objectives, review questions,
and other resources can be found at
www.pharmacotherapyonline.com.

vant questions enabling basic science findings to be more rapidly applied to clinical problems.⁴

② The most common conditions comprising COPD are chronic bronchitis and emphysema. Chronic bronchitis is associated with chronic or recurrent excessive mucus secretion into the bronchial tree with cough that is present on most days for at least 3 months of the year for at least 2 consecutive years in a patient in whom other causes of chronic cough have been excluded.² Although chronic bronchitis is defined in clinical terms, emphysema is defined in terms of anatomic pathology. Emphysema historically was defined on histologic examination at autopsy. Because this histologic definition is of limited clinical value, emphysema also has been defined as abnormal permanent enlargement of the airspaces distal to the terminal bronchioles accompanied by destruction of their walls yet without obvious fibrosis.²

Current guidelines have moved away from chronic bronchitis and emphysema as descriptive subsets of COPD. This is based on the observation that the majority of COPD is caused by a common risk factor (cigarette smoking), and most patients exhibit features of both chronic bronchitis and emphysema. Therefore, emphasis is currently placed on the pathophysiologic features of small airways disease and parenchymal destruction as contributors to chronic airflow limitation. Most patients with COPD demonstrate features of both problems. Chronic inflammation affects the integrity of the airways and causes damage and destruction of the parenchymal structures. The underlying problem is persistent exposure to noxious particles or gases that sustain the inflammatory response. The airways of the lung and the parenchyma are both susceptible to inflammation and the result is chronic airflow limitation that characterizes COPD (Fig. 29–1).

EPIDEMIOLOGY

The true prevalence of COPD is likely underreported. Data from the National Health Interview Survey in 2001 indicate that 12.1 million people older than age 25 years in the United States have COPD.⁵ More than 9 million of these individuals have chronic bronchitis; the remainder have emphysema or a combination of both diseases. According to national surveys, the true prevalence of people with symptoms of chronic airflow obstruction may exceed 24 million.⁶ The burden may be even greater because more than one-third of adults in the United States reported respiratory complaints compatible with symptomatic COPD in some surveys.⁷

③ COPD is the fourth leading cause of death in the United States, exceeded only by cancer, heart disease, and cerebrovascular accidents. In 2004, COPD accounted for 123,884 deaths in the United

States.⁸ It is the only leading cause of death to increase over the last 30 years and is projected to be the third leading cause by 2020.⁹ Overall, the mortality rate is higher in males; however, the female death rate has doubled over the last 25 years, and the number of female deaths has exceeded male deaths since 2000. The mortality rate is higher in whites than in blacks.⁹

Cigarette smoking is the primary cause of COPD and although the prevalence of cigarette smoking has declined compared with 1965, approximately 25% of individuals in the United States currently smoke. The trend of increasing COPD mortality likely reflects the long latency period between smoking exposure and complications associated with COPD.

Although the mortality of COPD is significant, morbidity associated with the disease also has a significant impact on patients, their families, and the healthcare system. COPD represents the second leading cause of disability in the United States. In the last 20 years, COPD has been responsible for nearly 50 million hospital visits nationwide.¹⁰ In recent years, a diagnosis of COPD accounts for more than 15 million physician office visits, 1.5 million emergency room visits, and 700,000 hospitalizations annually. A survey by the American Lung Association revealed that among COPD patients, 51% reported that their condition limits their ability to work, 70% were limited in normal physical activity, 56% were limited in performing household chores, and 50% reported that sleep was affected adversely.¹¹

The economic impact of COPD continues to increase as well. It was estimated at \$23 billion in 2000 and rose to \$37.2 billion in 2004, including \$20.9 billion in direct costs and \$16.3 billion in indirect morbidity and mortality costs.^{9,12} By 2020, COPD will be the fifth most burdensome disease, as measured by disability-adjusted life years lost as a consequence of illness.

ETIOLOGY

④ Although cigarette smoking is the primary modifiable risk factor for the development of COPD, the disease can be attributed to a combination of risk factors that results in lung injury and tissue destruction. Smokers are 12 to 13 times more likely to die from COPD than nonsmokers.¹³ Risk factors can be divided into host factors and environmental factors (Table 29–1), and commonly, the interaction between these risks leads to expression of the disease. Host factors, such as genetic predisposition, may not be modifiable but are important for identifying patients at high risk of developing the disease.

Environmental factors, such as tobacco smoke and occupational dust and chemicals, are modifiable factors that, if avoided, may reduce the risk of disease development. Environmental exposures associated with COPD are particles that are inhaled by the individual and result in inflammation and cell injury. Exposure to multiple environmental toxins increases the risk of COPD. Thus, the total burden of inhaled particles (e.g., cigarette smoke as well as occupational and environmental particles and pollutants) can play a significant role in the development of COPD. In such cases, it is helpful to assess an individual's total burden of inhaled particles. For example, an individual who smokes and works in a textile factory has a higher total burden of inhaled particles than an individual who smokes and has no occupational exposure.

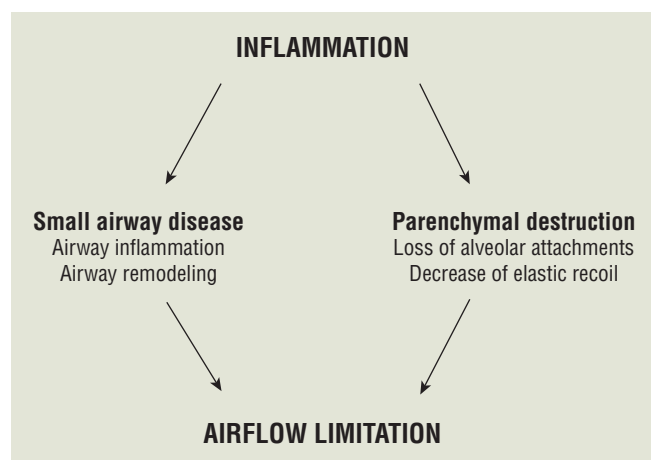

FIGURE 29-1. Mechanisms for developing chronic airflow limitation in chronic obstructive pulmonary disease. (From reference 1.)

TABLE 29-1 Risk Factors for Development of Chronic Obstructive Pulmonary Disease

Exposures	Host Factors
Environmental tobacco smoke	Genetic predisposition (α_1 -antitrypsin)
Occupational dusts and chemicals	Airway hyperresponsiveness
Air pollution	Impaired lung growth

Cigarette smoking is the most common risk factor and accounts for 85% to 90% of cases of COPD.¹ Components of tobacco smoke activate inflammatory cells, which produce and release the inflammatory mediators characteristic of COPD. Although the risk is lower in pipe and cigar smokers, it is still higher than in nonsmokers. Age of starting, total pack-years, and current smoking status are predictive of COPD mortality.

However, only 15% to 20% of all smokers go on to develop COPD, and not all smokers who have equivalent smoking histories develop the same degree of pulmonary impairment, suggesting that other host and environmental factors contribute to the degree of lung dysfunction. Nevertheless, the rate of loss of lung function is determined primarily by smoking status and history.² Children and spouses of smokers are also at increased risk of developing significant pulmonary dysfunction by passive smoking, also known as *environmental tobacco smoke* or *secondhand smoke*.

Occupational exposures are also important risk factors for COPD and, in nonindustrialized countries, may be more common than cigarette smoking. These exposures include dust and chemicals such as vapors, irritants, and fumes. Reduced lung function and deaths from COPD are higher for individuals who work in gold and coal mining, in the glass or ceramic industries with exposure to silica dust, and in jobs that expose them to cotton dust or grain dust, toluene diisocyanate, or asbestos. Other occupational risk factors include chronic exposure to open cooking or heating fires.

It is unclear whether or not air pollution alone is a significant risk factor for the development of COPD in smokers and nonsmokers with normal lung function. However, in individuals with existing pulmonary dysfunction, significant air pollution worsens symptoms. As evidence for this, emergency department visits are increased during higher-intensity periods of air pollution.

Individuals exposed to the same environmental risk factors do not have the same chance of developing COPD, suggesting that host factors play an important role in pathogenesis.^{1,2} While many not yet identified genes may influence the risk of developing COPD, the best documented genetic factor is a hereditary deficiency of α_1 -antitrypsin (AAT). AAT-associated emphysema is an example of a pure genetic disorder inherited in an autosomal recessive pattern. Some researchers sometimes describe inheritance as autosomal codominant because heterozygotes can also have decreased concentrations of AAT enzyme.¹⁴ The consequences of AAT deficiency are discussed in Pathophysiology below as protease-antiprotease imbalance. True AAT deficiency accounts for less than 1% of COPD cases.²

AAT is a 42-kDa plasma protein that is synthesized in hepatocytes. A primary role of AAT is to protect cells, especially those in the lung, from destruction by elastase released by neutrophils. In fact, AAT may be responsible for 90% of the inhibition of this destructive enzyme.¹⁵ In individuals with the most common allele (M), plasma levels of AAT are approximately 20 to 50 micromolars (100 to 350 mg/dL). The protective effect of AAT in the lungs is significantly diminished when plasma levels are less than 11 micromolars (80 mg/dL).¹⁵ AAT is an acute-phase reactant, and the serum concentration can be quite variable.

Several types of AAT deficiency have been identified and are caused by mutations in the AAT gene. Two main gene variants, S and Z, have been identified. In patients who are homozygous with the S variant, AAT levels are at least 60% of those of normal individuals. These patients usually do not have an increased risk of COPD compared with normal individuals. Patients with homozygous Z deficiency (ZZ), represent 95% of clinical cases of AAT-associated emphysema¹⁴ and have AAT levels that are 10% of those of normal individuals, whereas patients with heterozygous Z variant (SZ) have levels closer to 40% of those of normal individuals. Homozygous Z patients have a higher risk of developing COPD than do heterozygous Z patients. A history of cigarette smoking

increases this risk. A small number of patients have a null, null phenotype and are at high risk for developing emphysema because they produce virtually no AAT.

Patients with AAT deficiency develop COPD at an early age (20 to 50 years) primarily owing to an accelerated decline in lung function. Compared with an average annual decline in forced expiratory volume in 1 second (FEV₁) of 25 mL/year in healthy nonsmokers, patients with homozygous Z deficiency have been reported to have declines of 54 mL/year for nonsmokers and 108 mL/year for current smokers. Effective diagnosis is dependent on clinical suspicion, diagnostic testing of serum concentrations, and genotype confirmation.¹⁴ Patients developing COPD at an early age or those with a strong family history of COPD should be screened for AAT deficiency. If the concentration is low, genotype testing (DNA) should be performed.

Two additional host factors that may influence the risk of COPD include airway hyperresponsiveness and lung growth. Individuals with airway hyperresponsiveness to various inhaled particles may have an accelerated decline in lung function compared with those without airway hyperresponsiveness. Additionally, individuals who do not attain maximal lung growth owing to low birth weight, prematurity at birth, or childhood illnesses may be at risk for COPD in the future.¹

PATHOPHYSIOLOGY

COPD is characterized by chronic inflammatory changes that lead to destructive changes and the development of chronic airflow limitation. The inflammatory process is widespread and involves not only the airways but also extends to the pulmonary vasculature and lung parenchyma. The inflammation of COPD is often referred to as neutrophilic in nature, but macrophages and CD8+ lymphocytes also play major roles.^{16–18} The inflammatory cells release a variety of chemical mediators, of which tumor necrosis factor- α , interleukin (IL-8), and leukotriene (LT) B₄ play major roles.^{1,19} The actions of these cells and mediators are complementary and redundant, leading to the widespread destructive changes. The stimulus for activation of inflammatory cells and mediators is an exposure to noxious particles and gas through inhalation. The most common etiologic factor is exposure to environmental tobacco smoke, although other chronic inhalational exposures can lead to similar inflammatory changes.

Other processes that have been proposed to play a major role in the pathogenesis of COPD include oxidative stress and an imbalance between aggressive and protective defense systems in the lungs (proteases and antiproteases).¹⁶ These processes may be the result of ongoing inflammation or occur as a result of environmental pressures and exposures (Fig. 29–2).

An altered interaction between oxidants and antioxidants present in the airways is responsible for the increased oxidative stress present in COPD. Increases in markers (e.g., hydrogen peroxide and nitric oxide) of oxidants are seen in the epithelial lining fluid.¹ The increased oxidants generated by cigarette smoke react with and damage various proteins and lipids, leading to cell and tissue damage. Oxidants also promote inflammation directly and exacerbate the protease-antiprotease imbalance by inhibiting antiprotease activity.

The consequences of an imbalance between proteases and antiproteases in the lungs was described over 40 years ago when the hereditary deficiency of the protective antiprotease AAT was discovered to result in an increased risk of developing emphysema prematurely. This enzyme (AAT) is responsible for inhibiting several protease enzymes, including neutrophil elastase. In the presence of unopposed activity, elastase attacks elastin, a major component of alveolar walls.¹

In the inherited form of emphysema, there is an absolute deficiency of AAT. In cigarette smoking-associated emphysema, the

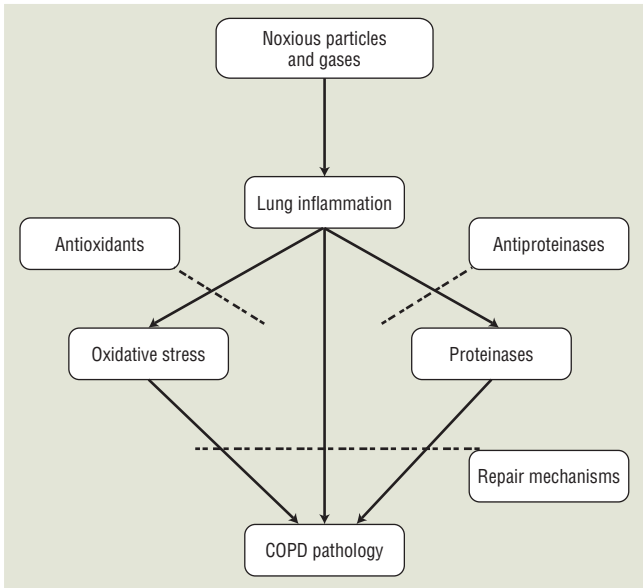

FIGURE 29-2. Pathogenesis of chronic obstructive pulmonary disease (COPD). (From reference 1.)

imbalance is likely associated with increased protease activity or reduced activity of antiproteases. Activated inflammatory cells release several proteases other than AAT, including cathepsins and metalloproteinases. In addition, oxidative stress reduces antiprotease (or protective) activity.

It is helpful to differentiate inflammation occurring in COPD from that present in asthma because the response to antiinflammatory therapy differs. The inflammatory cells that predominate differ between the two conditions, with neutrophils playing a major role in COPD and eosinophils and mast cells in asthma. Mediators of inflammation also differ with LTB₄, IL-8, and tumor necrosis factor- α predominating in COPD, compared with LTD₄, IL-4, and IL-5 among the numerous mediators modulating inflammation in asthma.¹ Table 29-2 summarizes the characteristics of inflammation for the two diseases.

Pathologic changes of COPD are widespread, affecting large and small airways, lung parenchyma, and the pulmonary vasculature.¹ An inflammatory exudate is often present that leads to an increase

in the number and size of goblet cells and mucus glands. Mucus secretion is increased, and ciliary motility is impaired. There is also a thickening of smooth muscle and connective tissue in the airways. Inflammation is present in central and peripheral airways. The chronic inflammation results in a repeated injury and repair process that leads to scarring and fibrosis. Diffuse airway narrowing is present and is more prominent in smaller peripheral airways. The decrease in FEV₁ is attributed to the presence of inflammation in the airways while the blood gas abnormalities result from impaired gas transfer due to parenchymal damage.

Parenchymal changes affect the gas-exchanging units of the lungs, including the alveoli and pulmonary capillaries. The distribution of destructive changes varies depending on the etiology. Most commonly, smoking-related disease results in centrilobular emphysema that primarily affects respiratory bronchioles. Panlobular emphysema is seen in AAT deficiency and extends to the alveolar ducts and sacs.

The vascular changes of COPD include a thickening of pulmonary vessels and often are present early in the disease. Increased pulmonary pressures early in the disease are caused by hypoxic vasoconstriction of pulmonary arteries. If persistent, the presence of chronic inflammation may lead to endothelial dysfunction of the pulmonary arteries. Later, structural changes lead to an increase in pulmonary pressures, especially during exercise. In severe COPD, secondary pulmonary hypertension leads to the development of right-sided heart failure.

Mucus hypersecretion is present early in the course of the disease and is associated with an increased number and size of mucus-producing cells. The presence of chronic inflammation perpetuates the process, although the resulting airflow obstruction and chronic airflow limitation may be reversible or irreversible. Table 29-3 summarizes the various causes of airflow obstruction.

Recently, there has been interest in the role of thoracic overinflation as it relates to the pathophysiology of COPD. Chronic airflow obstruction leads to air trapping which results in thoracic hyperinflation that can be detected on chest radiograph. This problem results in several dynamic changes in the chest, including flattening of diaphragmatic muscles. Under normal circumstances, the diaphragms are dome-shaped muscles tethered at the base of the lungs. When the diaphragm contracts, the muscle becomes shorter and flatter, which creates the negative inspiratory force through which air flows into the lung during inspiration. In the presence of thoracic hyperinflation, the diaphragmatic muscle is placed at a disadvantage and is a less-efficient muscle of ventilation. The increased work required by diaphragmatic contractions predisposes the patient to muscle fatigue especially during periods of exacerbations.

The other consequence of thoracic hyperinflation is a change in lung volumes. In patients with COPD who exhibit thoracic hyperinflation there is an increase in the functional residual capacity which is the amount of air left in the lung after exhalation at rest. Therefore, these patients are breathing at higher lung volumes which perturbs gas exchange. In addition, the increased functional residual capacity limits the inspiratory reserve capacity which is the amount of air that

TABLE 29-2 Features of Inflammation in Chronic Obstructive Pulmonary Disease (COPD) Compared with Asthma		
	COPD	Asthma
Cells	Neutrophils	Eosinophils
	Large increase in macrophages	Small increase in macrophages
	Increase in CD8+ T lymphocytes	Increase in CD4+ TH ₂ lymphocytes
Mediators	LTB ₄	Activation of mast cells
	IL-8	LTD ₄
	TNF- α	IL-4, IL-5 (Plus many others)
Consequences	Squamous metaplasia of epithelium	Fragile epithelium
	Parenchymal destruction	Thickening of basement membrane
	Mucus metaplasia	Mucus metaplasia
Response to treatment	Glandular enlargement	Glandular enlargement
	Glucocorticosteroids have variable effect	Glucocorticosteroids inhibit inflammation

the patient can inhale to fill the lungs. The increased functional residual capacity also limits the duration of inhalation time and this has been associated with an increase in dyspnea complaints by patients.²⁰ Drug therapy for COPD, especially bronchodilators, can reduce thoracic hyperinflation by reducing airflow obstruction. This may partially explain the improvement in symptoms reported by patients with COPD despite minimal improvements in lung function with drug therapy.

Airflow limitation is assessed through spirometry, which represents the “gold standard” for diagnosing and monitoring COPD. The hallmark of COPD is a reduction in the ratio of FEV₁ to forced vital capacity (FVC) to less than 70%.^{1,2} The FEV₁ generally is reduced, except in very mild disease, and the rate of FEV₁ decline is greater in COPD patients compared with normal subjects.

The impact of the numerous pathologic changes in the lung perturbs the normal gas-exchange and protective functions of the lung. Ultimately, these are exhibited through the common symptoms of COPD, including dyspnea and a chronic cough productive of sputum. As the disease progresses, abnormalities in gas exchange lead to hypoxemia and/or hypercapnia; although there often is not a strong relationship between pulmonary function and arterial blood gas results.

Significant changes in arterial blood gases usually are not present until the FEV₁ is less than 1 L.¹ In these patients, hypoxemia and hypercapnia can become chronic problems. Initially, when hypoxemia is present, it usually is associated with exercise. However, as the disease progresses, hypoxemia at rest develops. Patients with severe COPD can have a low arterial oxygen tension (PaO₂ = 45 to 60 mm Hg) and an elevated arterial carbon dioxide tension (PaCO₂ = 50 to 60 mm Hg). The hypoxemia is attributed to hypoventilation (\dot{V}) of lung tissue relative to perfusion (\dot{Q}) of the area. This low \dot{V}/\dot{Q} ratio will progress over a period of several years, resulting in a consistent decline in the PaO₂. Some COPD patients lose the ability to increase the rate or depth of respiration in response to persistent hypercapnia. Although this is not completely understood, the decreased ventilatory drive may be a result of abnormal peripheral or central respiratory receptors responses. This relative hypoventilation subsequently leads to hypercapnia. In this case, the central respiratory response to a chronically increased PaCO₂ can be blunted. These changes in PaO₂ and PaCO₂ are subtle and progress over a period of many years; as a result, the pH usually is nearly normal because the kidneys compensate by retaining bicarbonate. If acute respiratory distress develops, such as might be seen in pneumonia or a COPD exacerbation with impending respiratory failure, the PaCO₂ may rise sharply, and the patient presents with an uncompensated respiratory acidosis.

The consequences of long-standing COPD and chronic hypoxemia include the development of secondary pulmonary hypertension that progresses slowly if appropriate treatment of COPD is not initiated. Pulmonary hypertension is the most common cardiovascular complication of COPD and can result in cor pulmonale, or right-sided heart failure.²¹

The elevated pulmonary artery pressures are attributed to vasoconstriction (in response to chronic hypoxemia), vascular remodeling, and loss of pulmonary capillary beds. If elevated pulmonary pressures are sustained, cor pulmonale can develop, characterized by hypertrophy of the right ventricle in response to increases in pulmonary vascular resistance.

The risks of cor pulmonale include venous stasis with the potential for thrombosis and pulmonary embolism. Another important systemic consequence of COPD is a loss of skeletal muscle mass and general decline in the overall health status.

Although airway inflammation is prominent in patients with COPD, there is also evidence of systemic inflammation.²² The systemic manifestations can have devastating effects on overall health status and comorbidities. These include cardiovascular events associ-

ated with ischemia, cachexia, and muscle wasting. There is some interest in the role of measuring C-reactive protein as a parameter to assess systemic inflammation and its impact on COPD severity; however, it is premature to recommend this strategy currently.²³

PATHOPHYSIOLOGY OF EXACERBATION

The natural history of COPD is characterized by recurrent exacerbations associated with increased symptoms and a decline in overall health status. An exacerbation is defined as a change in the patient's baseline symptoms (dyspnea, cough, or sputum production) beyond day-to-day variability sufficient to warrant a change in management.^{1,2} Exacerbations have a significant impact on the natural course of COPD and occur more frequently in patients with more severe chronic disease. Because many patients experience chronic symptoms, the diagnosis of an exacerbation is based, in part, on subjective measures and clinical judgment. Repeated exacerbations, especially those requiring hospitalization, are associated with an increased mortality risk.

There are limited data about pathology during exacerbations owing to the nature of the disease and the condition of patients; however, inflammatory mediators including neutrophils and eosinophils are increased in the sputum. Chronic airflow limitation is a feature of COPD and may not change remarkably even during an exacerbation.¹ The lung hyperinflation present in chronic COPD is worsened during an exacerbation which contributes to worsening dyspnea and poor gas exchange.

The primary physiologic change is often a worsening of arterial blood gas results owing to poor gas exchange and increased muscle fatigue. In a patient experiencing a severe exacerbation, profound hypoxemia and hypercapnia can be accompanied by respiratory acidosis and respiratory failure.

CLINICAL PRESENTATION

The diagnosis of COPD is made based on the patient's symptoms, including cough, sputum production, and dyspnea, and a history of exposure to risk factors such as tobacco smoke and occupational exposures. Patients may have these symptoms for several years before dyspnea develops and often will not seek medical attention until dyspnea is significant. A diagnosis of COPD should be considered in any patient who presents with chronic cough, sputum production, or dyspnea and who has risk factors for the disease.

The presence of airflow limitation should be confirmed with spirometry. Spirometry represents a comprehensive assessment of lung volumes and capacities. The hallmark of COPD is an FEV₁:FVC ratio of less than 70%, which indicates airway obstruction, and a postbronchodilator FEV₁ of less than 80% of predicted confirms the presence of airflow limitation that is not fully reversible.¹ An improvement in FEV₁ of less than 12% following inhalation of a rapid-acting bronchodilator is considered to be evidence of irreversible airflow obstruction. Reversibility of airflow limitation is measured by a bronchodilator challenge, which is described in Table 29–4. Although a low peak expiratory flow is consistent with COPD, the use of peak expiratory flow measurements is inadequate for the diagnosis of COPD owing to low specificity and the high degree of effort dependence. Chapter 27 has a comprehensive discussion of spirometry.

Spirometry combined with a physical examination improves the diagnostic accuracy of COPD.⁷ Spirometry is also used to determine the severity of the disease, along with an assessment of symptoms and the presence of complications. A primary benefit of spirometry is to identify individuals who might benefit from pharmacotherapy to reduce exacerbations. Currently, the GOLD consensus guidelines suggest a four-stage classification system (Table 29–5).

TABLE 29-4 Procedures for Reversibility Testing**Preparation**

Tests should be performed when patients are clinically stable and free from respiratory infection.
Patients should not have taken inhaled short-acting bronchodilators in the previous 6 hours, long-acting β -agonists in the previous 12 hours, or sustained-release theophylline in the previous 24 hours.

Spirometry

FEV₁ should be measured before bronchodilator is given.
Bronchodilators can be given by either metered-dose inhaler or nebulization.
Usual doses are 400 mcg of β -agonist, up to 160 mcg of anticholinergic, or the two combined.
FEV₁ should be measured 10–15 minutes after the β -agonist or 30–45 minutes after combination is given.

Results

An increase in FEV₁ that is both greater than 200 mL and 12% above the prebronchodilator FEV₁ is considered significant.

FEV₁, forced expiratory volume in the first second of expiration.

From reference 1.

The 2006 GOLD guidelines were modified to remove the stage 0 category for COPD classification. Patients at risk (stage 0) have normal spirometry but experience chronic symptoms of cough or sputum production and a history of exposure to risk factors. This change was made because of inadequate evidence to identify patients who might progress to stage 1 disease. Patients in the remaining four stages of classification all exhibit the hallmark finding of airflow obstruction, that is, a reduction in the FEV₁:FVC ratio to less than 70%. FVC is the total amount of air exhaled after a maximal inhalation. The extent of reduction in FEV₁ further defines the patient with mild, moderate, severe, or very severe disease.¹

Spirometry is the primary tool in classifying COPD according to severity. However, two other factors that influence disease severity, survival, and health-related quality of life are body mass index (BMI) and dyspnea.² A low BMI is a systemic consequence of chronic COPD and a BMI of less than 21 kg/m² is associated with increased mortality.²⁴

Dyspnea is often the most troublesome complaint for the patient with COPD. Dyspnea can impair exercise performance and functional capacity and is frequently associated with depression and anxiety. Together, these have a significant effect on health related quality of life.²⁰ As a subjective symptom, dyspnea is often difficult for the clinician to assess. Various tools are available to evaluate the severity of dyspnea. A version of the Medical Research Council scale, modified by the American Thoracic Society, is commonly employed and categorizes dyspnea grades from 0 to 4 (Table 29–6).²⁵

TABLE 29-5 Classification of Chronic Obstructive Pulmonary Disease Severity**Stage I: mild**

FEV₁/FVC <70%
FEV₁ ≥80%
With or without symptoms

Stage II: moderate

FEV₁/FVC <70%
50% <FEV₁ <80%
With or without symptoms

Stage III: severe

FEV₁/FVC <70%
30% <FEV₁ <50%
With or without symptoms

Stage IV: very severe

FEV₁/FVC <70%
FEV₁ <30% or <50% with presence of chronic respiratory failure or right heart failure

FEV₁, forced expiratory volume in the first second of expiration; FVC, forced vital capacity.

From reference 1.

TABLE 29-6 Modified Medical Research Council (MRC) Dyspnea Scale

Grade 0	No dyspnea	Not troubled by breathlessness except with strenuous exercise
Grade 1	Slight dyspnea	Troubled by shortness of breath when hurrying on a level surface or walking up a slight hill
Grade 2	Moderate dyspnea	Walks slower than normal based on age on a level surface due to breathlessness or has to stop for breath when walking on level surface at own pace
Grade 3	Severe dyspnea	Stops for breath after walking 100 yards or after a few minutes on a level surface
Grade 4	Very severe dyspnea	Too breathless to leave the house or becomes breathless while dressing or undressing

From reference 2.

Although a physical examination is appropriate in the diagnosis and assessment of COPD, most patients who present in the milder stages of COPD will have a normal physical examination. In later stages of the disease, when airflow limitation is severe, patients may have cyanosis of mucosal membranes, development of “barrel chest” because of hyperinflation of the lungs, an increased respiratory rate and shallow breathing, and changes in breathing mechanics such as pursing of the lips to help with expiration or use of accessory respiratory muscles.

CLINICAL PRESENTATION**Symptoms**

- Chronic cough
- Sputum production
- Dyspnea

Exposure to Risk Factors

- Tobacco smoke
- α_1 -Antitrypsin deficiency
- Occupational hazards

Physical Examination

- Cyanosis of mucosal membranes
- Barrel chest
- Increased resting respiratory rate
- Shallow breathing
- Pursed lips during expiration
- Use of accessory respiratory muscles

Diagnostic Tests

- Spirometry with reversibility testing
- Radiograph of chest
- Arterial blood gas (not routine)

FEATURES OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE EXACERBATION**Symptoms**

- Increased sputum volume
- Acutely worsening dyspnea
- Chest tightness
- Presence of purulent sputum
- Increased need for bronchodilators
- Malaise, fatigue
- Decreased exercise tolerance

Physical Examination

- Fever
- Wheezing, decreased breath sounds

Diagnostic Tests

- Sputum sample for Gram stain and culture
- Chest radiograph to evaluate for new infiltrates

PROGNOSIS

For the patient with COPD, the combination of impaired lung function and recurrent exacerbations promote a clinical scenario characterized by dyspnea, reduced exercise tolerance and physical activity, and deconditioning. These factors lead to disease progression, poor quality of life, possible disability, and premature mortality.²⁶ COPD is ultimately a fatal disease if it progresses and advanced directives and end-of-life care options are appropriate to consider.

The FEV₁ is the most important prognostic indicator in a patient with COPD. The average rate of decline of FEV₁ is the most useful objective measure to assess the course of COPD. The average rate of decline in FEV₁ for healthy, nonsmoking patients owing to age alone is 25 to 30 mL/year. The rate of decline for smokers is steeper, especially for heavy smokers compared with light smokers. The decline in pulmonary function is a steady curvilinear path. The more severely diminished the FEV₁ at diagnosis; the steeper is the rate of decline. Greater numbers of years of smoking and number of cigarettes smoked also correlate with a steeper decline in pulmonary function.²⁷ Conversely, the rate of decline of blood gases has not been shown to be a useful parameter to assess progression of the disease. Patients with COPD should have spirometry performed at least annually to assess disease progression.

The survival rate of patients with COPD is highly correlated to the initial level of impairment in the FEV₁ and to age. Other, less-important factors include degree of reversibility with bronchodilators, resting pulse, perceived physical disability, diffusing capacity of lung for carbon monoxide (D_{LCO}), cor pulmonale, and blood gas abnormalities. A rapid decline in pulmonary function tests indicates a poor prognosis. Median survival is approximately 10 years when the FEV₁ is 1.4 L, 4 years when the FEV₁ is 1.0 L, and about 2 years when the FEV₁ is 0.5 L.

Although arterial blood gas (ABG) measurements are important, they do not carry the prognostic value of pulmonary function tests. Measurement of ABGs is more useful in patients with severe disease and is recommended for all patients with an FEV₁ of less than 40% of predicted or those with signs of respiratory failure or right-sided heart failure.¹

It is important to recognize that patients with COPD die from a variety of causes, not only respiratory failure. Cardiovascular complications, as well as lung cancer, are the leading causes of death in patients with COPD.^{28,29}

CLINICAL PRESENTATION OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE EXACERBATION

Because of the subjective nature of defining an exacerbation of COPD, the criteria used among clinicians varies widely; however, most rely on a change in one or more of the following clinical findings: worsening symptoms of dyspnea, increase in sputum volume, or increase in sputum purulence. Acute exacerbations have a significant impact of the economics of treating COPD as well, estimated at 35% to 45% of the total costs of the disease in some settings.³⁰

With an exacerbation, patients using rapid-acting bronchodilators may report an increase in the frequency of use. Exacerbations

TABLE 29-7 Staging Acute Exacerbations of Chronic Obstructive Pulmonary Disease^a

Mild (type 1)	One cardinal symptom ^a plus at least one of the following: URTI within 5 days, fever without other explanation, increased wheezing, increased cough, increase in respiratory or heart rate >20% above baseline
Moderate (type 2)	Two cardinal symptoms ^a
Severe (type 3)	Three cardinal symptoms ^a

URTI, upper respiratory tract infection.

^aCardinal symptoms include worsening of dyspnea, increase in sputum volume, and increase in sputum purulence.

are commonly staged as mild, moderate, or severe according to the criteria summarized in Table 29–7.³¹

An important complication of a severe exacerbation is acute respiratory failure. In the emergency department or hospital, an ABG usually is obtained to assess the severity of an exacerbation. The diagnosis of acute respiratory failure in COPD is made on the basis of an acute change in the ABGs. Defining acute respiratory failure as a PaO₂ of less than 50 mm Hg or a PaCO₂ of greater than 50 mm Hg often may be incorrect and inadequate because these values may not represent a significant change from a patient's baseline values. A more precise definition is an acute drop in PaO₂ of 10 to 15 mm Hg or any acute increase in PaCO₂ that decreases the serum pH to 7.3 or less. Additional acute clinical manifestations of respiratory failure include restlessness, confusion, tachycardia, diaphoresis, cyanosis, hypotension, irregular breathing, miosis, and unconsciousness.

PROGNOSIS

COPD exacerbations are associated with significant morbidity and mortality. While mild exacerbations may be managed at home, mortality rates are higher for patients admitted to the hospital. In one study of patients hospitalized with COPD exacerbations, in-hospital mortality was 6% to 8%.³² Many patients experiencing an exacerbation do not have a return to their baseline clinical status for several weeks, significantly affecting their quality of life. Additionally, as many as half the patients originally hospitalized for an exacerbation are readmitted within 6 months.³³

It is now evident that acute exacerbations of COPD have a tremendous impact on disease progression and ultimate mortality. For exacerbations requiring hospitalizations, mortality rates range from 22% to 43% after 1 year, and 36 to 49% in 2 years.^{32,34,35}

TREATMENT

Chronic Obstructive Pulmonary Disease

■ DESIRED OUTCOMES

Given the nature of COPD, a major focus in healthcare should be on prevention. However, in patients with a diagnosis of COPD, the primary goal is to prevent or minimize progression. Table 29–8 lists specific management goals. The primary goal of pharmacotherapy has been relief of symptoms, including dyspnea. More recently, however, there has been increased interest in the value of therapeutic interventions that reduce exacerbation frequency and severity, as well as reduce mortality.

Optimally, these goals can be accomplished with minimal risks or side effects. The therapy of the patient with COPD is multifaceted and includes pharmacologic and nonpharmacologic strategies. Appropriate measures of effectiveness of the management plan include continued smoking cessation, symptom improvement, reduction in FEV₁

TABLE 29-8	Goals of Chronic Obstructive Pulmonary Disease Management
Prevent disease progression	
Relieve symptoms	
Improve exercise tolerance	
Improve overall health status	
Prevent and treat exacerbations	
Prevent and treat complications	
Reduce morbidity and mortality	

decline, reduction in the number of exacerbations, improvements in physical and psychological well-being, and reduction in mortality, hospitalizations, and days lost from work.

Unfortunately, most treatments for COPD have not been shown to improve survival or to slow the progressive decline in lung function. However, many therapies do improve pulmonary function and quality of life and reduce exacerbations and duration of hospitalization. Several disease-specific quality-of-life measures are available to assess the overall efficacies of therapies for COPD, including the Chronic Respiratory Questionnaire and the St. George’s Respiratory Questionnaire. These questionnaires measure the impact of various therapies on such disease variables as severity of dyspnea and level of activity; they do not measure impact of therapies on survival. Whereas early studies of COPD therapies focused primarily on improvements in pulmonary function measurements such as FEV₁, there is a trend toward greater use of these disease-specific quality-of-life measures to evaluate the benefits of therapy on larger clinical outcomes.

■ GENERAL APPROACH TO TREATMENT

To be effective, the clinician should address four primary components of management: assess and monitor the condition; avoidance of or reduced exposure to risk factors; manage stable disease; and treat exacerbations. These components are addressed through a variety of nonpharmacologic and pharmacologic approaches.

■ NONPHARMACOLOGIC THERAPY

Patients with COPD should receive education about their disease, treatment plans, and strategies to slow progression and prevent complications.¹ Advice and counseling about smoking cessation are essential, if applicable. Because the natural course of the disease leads to respiratory failure, the clinician should address end-of-life decisions and advanced directives prospectively with the patient and family.³⁶

Smoking Cessation

5 A primary component of COPD management is avoidance of or reduced exposure to risk factors. Exposure to environmental tobacco smoke is a major risk factor, and smoking cessation is the most effective strategy to reduce the risk of developing COPD and to slow or stop disease progression. The cost-effectiveness of smoking-cessation interventions compares favorably with interventions made for other major chronic diseases.³⁷ The importance of smoking cessation cannot be overemphasized. Smoking cessation leads to decreased symptomatology and slows the rate of decline of pulmonary function even after significant abnormalities in pulmonary function tests have been detected (FEV₁:FVC <60%).²⁷ As confirmed by the Lung Health Study, smoking cessation is the only intervention proven at this time to affect long-term decline in FEV₁ and slow the progression of COPD.²⁸ In this 5-year prospective trial, smokers with early COPD were randomly assigned to one of three groups: smoking-cessation intervention plus inhaled ipratropium three times a day, smoking-cessation intervention alone, or no

intervention. During an 11-year followup, the rate of decline in FEV₁ among subjects who continued to smoke was more than twice the rate in sustained quitters. Smokers who underwent smoking-cessation intervention had fewer respiratory symptoms and a smaller annual decline in FEV₁ compared with smokers who had no intervention. However, this study also demonstrated the difficulty in achieving and sustaining successful smoking cessation.

Tobacco cessation has mortality benefits beyond those related to COPD. A followup analysis of the Lung Health Study data conducted more than 14 years later demonstrated an 18% reduction in all-cause mortality in patients who received the intervention compared to usual care.²⁹ Intervention patients had lower death rates as a consequence of coronary artery disease (the leading cause of mortality), cardiovascular diseases, and lung cancer, although no category reached clinical significance.

Every clinician has a responsibility to assist smokers in smoking-cessation efforts. A clinical practice guideline for treating tobacco dependence from the U.S. Public Health Service was updated in 2000.³⁸ Table 29-9 summarizes the major findings and recommendations of that report. In 2004, a report from the Surgeon General on the health consequences of smoking broadened the scope of the detrimental effects of cigarette smoking, indicating that “Smoking harms nearly every organ of the body, causing many diseases and reducing the health of smokers in general.”¹³

All clinicians should take an active role in assisting patients with tobacco dependence in order to reduce the burden on the individual, the individual’s family, and the healthcare system. It is estimated that more than 75% of smokers want to quit and that one-third have made a serious effort. Yet complete and permanent tobacco cessation is difficult.²⁸ Counseling that is provided by clinicians is associated with greater success rates than self-initiated efforts.³⁸

The U.S. Public Health Service guidelines recommend that clinicians take a comprehensive approach to smoking-cessation counseling. Advice should be given to smokers even if they have no symptoms of smoking-related disease or if they are receiving care for reasons unrelated to smoking. Clinicians should be persistent in their efforts because relapse is common among smokers owing to the chronic nature of dependence. Brief interventions (3 minutes) of counseling are proven effective. However, it must be recognized that the patient must be ready to stop smoking because there are several stages of decision making. Based on this, a five-step intervention program is proposed (Table 29-10).

TABLE 29-9	Treating Tobacco Use and Dependence: Public Health Service Report (2000) Major Findings and Recommendations
Tobacco dependence should be recognized as a chronic condition requiring repeated treatment until permanent abstinence is achieved.	
Effective treatments for tobacco dependence are available and should be offered to all tobacco users.	
Clinicians and healthcare systems should ensure mechanisms to identify, document, and treat all tobacco users in the system.	
Brief treatment interventions for tobacco dependence should be offered to all tobacco users at a minimum.	
There is a strong dose–response relationship between the intensity of tobacco dependence counseling and its effectiveness.	
The most effective types of counseling and behavioral therapies are (a) practical counseling employing problem-solving and skills training, (b) social support as part of treatment, and (c) social support outside of treatment.	
Numerous pharmacotherapies are effective for smoking cessation and should be offered in the absence of contraindications. These include sustained-release bupropion, nicotine gum, nicotine inhaler, nicotine nasal spray, nicotine patch, and varenicline.	
Tobacco dependence treatments are effective and cost-effective compared with other medical and disease-prevention measures.	

TABLE 29-10 Five-Step Strategy for Smoking-Cessation Program (5 A's)

Ask	Use systematic approach to identify all tobacco users.
Advise	Urge all tobacco users to quit.
Assess	Determine willingness to make a cessation attempt.
Assist	Provide support for the patient to quit smoking.
Arrange	Schedule followup and monitor for continued abstinence.

There is strong evidence to support the use of pharmacotherapy to assist in smoking cessation. In fact, it should be offered to most patients as part of a cessation attempt. In general, available therapies will double the effectiveness of a cessation effort. Table 29-11 lists first-line agents. The usual duration of therapy is 8 to 12 weeks, although some individuals may require longer courses of treatment. Precautions to consider before using bupropion include a history of seizures or an eating disorder. Nicotine-replacement therapies are contraindicated in patients with unstable coronary artery disease, active peptic ulcers, or recent myocardial infarction or stroke. Nicotine patch, bupropion, and the combination of bupropion and the nicotine patch were compared with placebo in a controlled trial.³⁹ The treatment groups that received bupropion had higher rates of smoking cessation than the groups that received placebo or the nicotine patch. The addition of the nicotine patch to bupropion slightly improved the smoking-cessation rate compared with bupropion monotherapy. Recently, a new agent became available to assist in tobacco cessation attempts. Varenicline is a nicotine acetylcholine receptor partial agonist that has shown benefit in tobacco cessation.⁴⁰ Varenicline relieves physical withdrawal symptoms and reduces the rewarding properties of nicotine. Nausea and headache are the most frequent complaints associated with varenicline. Currently, varenicline has not been studied in combination with other tobacco cessation therapies. Second-line agents, such as clonidine and nortriptyline, a tricyclic antidepressant, are less effective or associated with greater side effects; however, they may be useful in selected clinical situations.

Behavioral modification techniques or other forms of psychotherapy also may be helpful in assisting in smoking cessation. Programs that address the many issues associated with smoking (i.e., learned behaviors, environmental influences, and chemical dependence) using a team approach are more likely to be successful. The role of alternative medicine therapies in smoking cessation is controversial. Hypnosis may aid in improving abstinence rates when added to a smoking-cessation program but appears to give little benefit when used alone. Acupuncture has not been shown to contribute to smoking cessation and is not recommended.²

Pulmonary Rehabilitation

Exercise training is beneficial in the treatment of COPD to improve exercise tolerance and to reduce symptoms of dyspnea and fatigue.¹ Pulmonary rehabilitation programs are an integral component in the management of COPD and should include exercise training along with smoking cessation, breathing exercises, optimal medical treatment, psychosocial support, and health education. High-intensity training (70% maximal workload) is possible even in advanced

COPD patients, and the level of intensity improves peripheral muscle and ventilatory function. Studies have demonstrated that pulmonary rehabilitation with exercise three to seven times per week can produce long-term improvement in activities of daily living, quality of life, exercise tolerance, and dyspnea in patients with moderate to severe COPD.⁴¹ Improvements in dyspnea can be achieved without concomitant improvements in spirometry. Programs using less-intensive exercise regimens (two times per week) are not beneficial.⁴²

Immunizations

Vaccines can be considered as pharmacologic agents; however, their role is described here in reducing risk factors for COPD exacerbations. Because influenza is a common complication in COPD that can lead to exacerbations and respiratory failure, an annual vaccination with the inactivated intramuscular influenza vaccine is recommended. Immunization against influenza can reduce serious illness and death by 50% in COPD patients.⁴³ Influenza vaccine should be administered in the fall of each year (October and November) during regular medical visits or at vaccination clinics. There are few contraindications to influenza vaccine except for a patient with a serious allergy to eggs. An oral antiinfluenza agent (oseltamivir) can be considered for patients with COPD during an outbreak for patients who have not been immunized; however, this therapy is less effective and causes more side effects.⁴⁴

The polyvalent pneumococcal vaccine, administered one time, is widely recommended for people from 2 to 64 years of age who have chronic lung disease and for all people older than age 65 years. Thus COPD patients at any age are candidates for vaccination. Although evidence for the benefit of the pneumococcal vaccine in COPD is not strong, the argument for continued use is that the current vaccine provides coverage for 85% of pneumococcal strains causing invasive disease and the increasing rate of resistance of pneumococcus to selected antibiotics. Currently, administering the vaccine remains the standard of practice and is recommended by the Centers for Disease Control and Prevention and the American Lung Association. Repeated vaccination with the 23-valent product is not recommended for patients ages 2 to 64 years with chronic lung disease; however, revaccination is recommended for patients older than 65 years of age if the first vaccination was more than 5 years earlier and the patient was younger than age 65 years. The GOLD guidelines recommend pneumococcal vaccine for all COPD patients age 65 years and older and for patients younger than age 65 years only if the FEV₁ is less than 40% of predicted.^{45,46}

Long-Term Oxygen Therapy

6 The use of supplemental oxygen therapy increases survival in COPD patients with chronic hypoxemia. Although long-term oxygen has been used for many years in patients with advanced COPD, it was not until 1980 that data became available documenting its benefits. At that time, the Nocturnal Oxygen Therapy Trial Group published its data comparing nocturnal oxygen therapy (12 h/day) with continuous oxygen therapy (average of 20 h/day).⁴⁷ Among patients who were followed for at least 12 months, the results revealed a mortality rate in the nocturnal oxygen therapy group that

TABLE 29-11 First-Line Pharmacotherapies for Smoking Cessation

Agent	Usual Dose	Duration	Common Complaints
Bupropion SR	150 mg orally daily for 3 days, then twice daily	12 weeks, up to 6 months	Insomnia, dry mouth
Nicotine gum	2–4 mg gum prn, up to 24 pieces daily	12 weeks	Sore mouth, dyspepsias
Nicotine inhaler	6–16 cartridges daily	Up to 6 months	Sore mouth and throat
Nicotine nasal spray	8–40 doses daily	3 to 6 months	Nasal irritation
Nicotine patches	Various, 7–21 mg every 24 hours	Up to 8 weeks	Skin reaction, insomnia
Varenicline	0.5 mg daily for 3 days, then 0.5 mg twice daily for 4 days, then 1 mg twice daily	12 weeks	Nausea, sleep disturbances

was nearly double that of the continuous oxygen therapy group (51% versus 26%). Statistical estimates of the continuous oxygen therapy group suggest that continuous oxygen therapy may have added 3.25 years to a COPD patient's life. Additional data from the Nocturnal Oxygen Therapy Trial Group revealed that continuous oxygen therapy patients had fewer (but statistically insignificant) hospitalizations, improved quality of life and neuropsychological function, reduced hematocrit, and decreased pulmonary vascular resistance.⁴⁷

The decline in mortality with oxygen therapy was further substantiated in 1981 in a study by the British Medical Research Council that compared 15 h/day of oxygen versus no supplemental oxygen in COPD patients.⁴⁸ Patients receiving oxygen therapy for at least part of the day had lower rates of mortality than those not receiving oxygen. Long-term oxygen therapy provides even more benefit in terms of survival after at least 5 years of use, and it improves the quality of life of these patients by increasing walking distance and neuropsychological condition and reducing time spent in the hospital.⁴⁹ Before patients are considered for long-term oxygen therapy, they should be stabilized in the outpatient setting, and pharmacotherapy should be optimized. Once this is accomplished, long-term oxygen therapy should be instituted if either of two conditions exists: (a) a resting PaO_2 of less than 55 mm Hg or (b) evidence of right-sided heart failure, polycythemia, or impaired neuropsychiatric function with a PaO_2 of less than 60 mm Hg.

The most practical means of administering long-term oxygen is with the nasal cannula, at 1 to 2 L/min which provides 24% to 28% oxygen. The goal is to raise the PaO_2 above 60 mm Hg. Patient education about flow rates and avoidance of flames (i.e., smoking) is of the utmost importance.

There are three different ways to deliver oxygen, including (a) in liquid reservoirs, (b) compressed into a cylinder, and (c) via an oxygen concentrator. Although conventional liquid oxygen and compressed oxygen are quite bulky, smaller, portable tanks are available to permit greater patient mobility. Oxygen concentrator devices separate nitrogen from room air and concentrate oxygen. These are the most convenient and the least-expensive method of oxygen delivery. Oxygen-conservation devices are available that allow oxygen to flow only during inspiration, making the supply last longer. These may be particularly useful to prolong the oxygen supply for mobile patients using portable cylinders. However, the devices are bulky and subject to failure.

Adjunctive Therapies

In addition to supplemental oxygen, adjunctive therapies to consider as part of a pulmonary rehabilitation program are psychoeducational care and nutritional support. Psychoeducational care (such as relaxation) has been associated with improvement in the functioning and well-being of adults with COPD.^{1,2} The role of nutritional support in patients with COPD is controversial. Several studies have shown an association between malnutrition, low BMI, and impaired pulmonary status among patients with COPD. However, a meta-analysis suggests that the effect of nutritional support on outcomes in COPD is small and not associated with improved anthropometric measures, lung function, or functional exercise capacity.⁵⁰

■ PHARMACOLOGIC THERAPY

In contrast to the survival benefit conferred by supplemental oxygen therapy, there is no medication available for the treatment of COPD that has been shown to modify the progressive decline in lung function or prolong survival.¹ Thus a primary goal of pharmacotherapy is to control patient symptoms and reduce complications, including the frequency and severity of exacerbations and improving the overall health status and exercise tolerance of the patient.

International guidelines recommend a stepwise approach to the use of pharmacotherapy based on disease severity,^{1,2} which is determined by the extent of airflow limitation and degree of symptoms. The impact of recurrent exacerbations on disease progression is increasingly recognized as an important factor and should be considered. The primary goals of pharmacotherapy are to control symptoms (including dyspnea), reduce exacerbations, and improve exercise tolerance and health status. Currently, there is inadequate evidence to support the use of more aggressive pharmacotherapy early in the course of disease, although data from ongoing trials may provide answers.

7 Pharmacotherapy focuses on the use of bronchodilators to control symptoms. There are several classes of bronchodilators to choose from, and no single class has been proven to provide superior benefit over other available agents. The initial and subsequent choice of medications should be based on the specific clinical situation and patient characteristics. Medications can be used as needed or on a scheduled basis depending on the clinical situation, and additional therapies should be added in a stepwise manner depending on the response and severity of disease. Considerations should be given to individual patient response, tolerability, adherence, and economic factors. A stepwise approach to the management of COPD has been proposed based on the stage of disease severity (Fig. 29–3).

8 According to the guidelines, patients with intermittent symptoms should be treated with short-acting bronchodilators. When symptoms become more persistent, long-acting bronchodilators should be initiated. For patients with an FEV_1 less than 50% and who experience frequent exacerbations, inhaled corticosteroids should be considered. Short-acting bronchodilators relieve symptoms and increase exercise tolerance. Long-acting bronchodilators relieve symptoms, reduce exacerbation frequency, and improve quality of life and health status. Patients have a variety of choices in using inhalational therapies, including metered dose inhalers (MDIs), dry powder inhalers (DPIs), or nebulizers. There is not a clear advantage of one delivery method over another and it is recommended that patient-specific factors and preferences should be considered in selecting the device.⁵¹

Bronchodilators

Bronchodilator classes available for the treatment of COPD include β_2 -agonists, anticholinergics, and methylxanthines. There is no clear benefit to one agent or class over others, although inhaled therapy generally is preferred. In general, it can be more difficult for patients with COPD to use inhalation devices effectively compared with other populations owing to advanced age and the presence of other comorbidities. Clinicians should advise, counsel, and observe patient technique with the devices frequently and consistently.

Bronchodilators generally work by reducing the tone of airway smooth muscle (relaxation), thus minimizing airflow limitation. In patients with COPD, the clinical benefits of bronchodilators include increased exercise capacity, decreased air trapping in the lungs, and relief of symptoms such as dyspnea. However, use of bronchodilators may not be associated with significant improvements in pulmonary function measurements such as FEV_1 . In general, side effects of bronchodilator medications are related to their pharmacologic effects and are dose-dependent. Because COPD patients are older and more likely to have comorbid conditions, the risk for side effects and drug interactions is higher compared with patients with asthma.

Short-Acting Bronchodilators The initial therapy for COPD patients who experience symptoms intermittently are short-acting bronchodilators. Among these agents, the choices are a short-acting β_2 -agonist or an anticholinergic. Either class of agents has a relatively rapid onset on action, relieves symptoms, and improves exercise tolerance and lung function. In general, both classes are equally effective.

	0: At risk	I: Mild	II: Moderate	III: Severe	IV: Very severe
Characteristics	<ul style="list-style-type: none"> • Chronic symptoms • Exposure to risk factors • Normal spirometry 	<ul style="list-style-type: none"> • FEV₁:FVC <70% • FEV₁ ≥80% • With or without symptoms 	<ul style="list-style-type: none"> • FEV₁:FVC <70% • 50% > FEV₁ <80% • With or without symptoms 	<ul style="list-style-type: none"> • FEV₁:FVC <70% • 30% > FEV₁ <50% • With or without symptoms 	<ul style="list-style-type: none"> • FEV₁:FVC <70% • FEV₁ <30% or presence of chronic respiratory failure or right heart failure

FIGURE 29-3. Recommended therapy of stable chronic obstructive pulmonary disease. (FEV₁, forced expiratory volume in the first second of expiration; FVC, forced vital capacity.) (From reference 1.)

Short-Acting Sympathomimetics (β_2 -Agonists) A number of sympathomimetic agents are available in the United States. They vary in selectivity, route of administration, and duration of action. In COPD management, sympathomimetic agents with β_2 -selectivity, or β_2 -agonists, should be used as bronchodilators. β_2 -Agonists cause bronchodilation by stimulating the enzyme adenyl cyclase to increase the formation of cyclic adenosine monophosphate. Cyclic adenosine monophosphate is responsible for mediating relaxation of bronchial smooth muscle, leading to bronchodilation. In addition, it may improve mucociliary clearance. Although shorter-acting and less-selective β -agonists are still used widely (e.g., metaproterenol, isoetharine, isoproterenol, and epinephrine), they should not be used owing to their shorter duration of action and increased cardio-stimulatory effects. Short-acting, selective β_2 -agonists such as albuterol, levalbuterol, and pirbuterol, are preferred for therapy.

Sympathomimetics are available in inhaled, oral, and parenteral dosage forms. The preferred route of administration is by inhalation. The use of oral and parenteral β -agonists in COPD is discouraged because they are no more effective than a properly used MDI or DPI, and the incidence of systemic adverse effects such as tachycardia and hand tremor is greater. Administration of β_2 -agonists in the outpatient and emergency room settings via inhalers (MDIs or DPIs) is at least as effective as nebulization therapy and usually favored for reasons of cost and convenience.⁵¹ Chapter 28 includes a complete description of the devices used for delivering aerosolized medication and a comparison β_2 -agonist therapies.

Albuterol is the most frequently used β_2 -agonist. It is available as an oral and inhaled preparation. Albuterol is a racemic mixture of (R)-albuterol that is responsible for the bronchodilator effect and (S)-albuterol that has no therapeutic effect. (S)-Albuterol is considered by some clinicians to be inert, whereas others believe that it may be implicated in worsening airway inflammation and antagonizing the response to (R)-albuterol. Levalbuterol is a single-isomer formulation of (R)-albuterol. A retrospective evaluation of levalbuterol versus albuterol use in patients with asthma and COPD concluded that levalbuterol offered significant advantages over albuterol for hospitalized patients.⁵² Other clinicians feel that there are no significant differences between the products and that the use of levalbuterol is not justified owing to its higher acquisition cost.⁵³ The effects of a

single dose of levalbuterol have been compared with those of albuterol and ipratropium plus albuterol in patients with COPD. No significant differences in pulmonary function improvements or adverse effects were noted.⁵⁴

In COPD patients, β_2 -agonists exert a rapid onset of effect, although the response generally is less than that seen in asthma. Short-acting inhaled β_2 -agonists cause only a small improvement in FEV₁ acutely but may improve respiratory symptoms and exercise tolerance despite the small improvement in spirometric measurements.⁵⁵ Patients with COPD can use quick-onset β_2 -agonists as needed for relief of symptoms or on a scheduled basis to prevent or reduce symptoms. The duration of action of short-acting β_2 -agonists is 4 to 6 hours.

Short-Acting Anticholinergics When given by inhalation, anticholinergics such as ipratropium or atropine produce bronchodilation by competitively inhibiting cholinergic receptors in bronchial smooth muscle. This activity blocks acetylcholine, with the net effect being a reduction in cyclic guanosine monophosphate, which normally acts to constrict bronchial smooth muscle. Muscarinic receptors on airway smooth muscle include M₁, M₂, and M₃ subtypes. Activation of M₁ and M₃ receptors by acetylcholine results in bronchoconstriction; however, activation of M₂ receptors inhibits further acetylcholine release.

Ipratropium is the primary short-acting anticholinergic agent used for COPD in the United States. Atropine has a tertiary structure and is absorbed readily across the oral and respiratory mucosa, whereas ipratropium has a quaternary structure that is absorbed poorly. The lack of systemic absorption of ipratropium greatly diminishes the anticholinergic side effects such as blurred vision, urinary retention, nausea, and tachycardia associated with atropine. Ipratropium bromide is available as a MDI and a solution for inhalation. The MDI was recently reformulated with an hydrofluoroalkane propellant and delivers 17 mcg per puff. Ipratropium is also available as a MDI in combination with albuterol and as a solution for nebulization at 200 mcg/mL. It provides a peak effect in 1.5 to 2 hours and has a duration of effect of 4 to 6 hours. Ipratropium has a slower onset of action and a more prolonged bronchodilator effect compared with standard β_2 -agonists. Because of the slower onset of effect (15 to 20 minutes

compared with 5 minutes for albuterol), it may be less suitable for as-needed use; however, it is often prescribed in that manner. Although the role of inhaled anticholinergics in COPD is well established,^{56–58} results from the Lung Health Study showed that treatment with ipratropium did not affect the progressive decline in lung function.²⁸ Studies comparing ipratropium with inhaled β_2 -agonists have generally reported similar improvements in pulmonary function. Others report a modest benefit with ipratropium, including a lower incidence of side effects such as tachycardia.^{56,57}

Although the recommended dose of ipratropium is 2 puffs four times a day, there is evidence for a dose–response, so the dose can be titrated upward, often to 24 puffs a day. Ipratropium has been shown to increase maximum exercise performance in stable COPD patients with doses of 8 to 12 puffs prior to exercise but not with doses of 4 puffs or fewer.^{58,59} During sleep, ipratropium also has been shown to improve arterial oxygen saturation and sleep quality.⁶⁰ Ipratropium is well tolerated. The most frequent patient complaints are dry mouth, nausea, and an occasional metallic taste.

Clinicians differ about preference in choosing the initial short-acting bronchodilator therapy for the patient with COPD. Both a short-acting β_2 -agonist and ipratropium represent reasonable choices for initial therapy.

Long-Acting Bronchodilators For patients with moderate to severe COPD who experience symptoms on a regular and consistent basis, or in whom short-acting therapies do not provide adequate relief, long-acting bronchodilator therapies are the recommended treatment. Long-acting, inhaled bronchodilator therapy can be administered as a β_2 -agonist or an anticholinergic. Long-acting bronchodilators provide similar benefits to short-acting agents. In addition, they reduce exacerbation frequency and improve quality of life.

Long-Acting, Inhaled β_2 -Agonists Long-acting, inhaled β_2 -agonists offer the convenience and benefit of a long duration of action for patients with persistent symptoms. Both salmeterol and formoterol are dosed every 12 hours and provide sustained bronchodilation. Formoterol has an onset of action similar to albuterol (less than 5 minutes), whereas salmeterol has a slower onset (15 to 20 minutes); however, neither agent is recommended for acute relief of symptoms. The clinical benefits of long-acting inhaled β_2 -agonists compared to short-acting therapies include similar or superior improvements in lung function and symptoms, as well as reduced exacerbation rates.^{61–63} The use of the long-acting agents should be considered for patients with frequent and persistent symptoms. When patients require short-acting β_2 -agonists on a scheduled basis, long-acting agents, such as formoterol and salmeterol, are more convenient based on dosing frequency, but are also more expensive.

Long-acting β -agonists are also useful to reduce nocturnal symptoms and improve quality of life. When compared to short-acting bronchodilators or theophylline, both salmeterol and formoterol improve lung function, symptoms, exacerbation frequency and quality of life.⁶⁴ These benefits are apparent even in patients with poorly reversible lung function and are related to improvements in inspiratory capacity.⁶⁵ Both salmeterol and formoterol have been compared to ipratropium. In separate studies, each agent improved FEV₁ compared to ipratropium and, in addition, the long-acting bronchodilator was more effective for other selected outcomes (e.g., prolonged time to exacerbation for salmeterol while formoterol reduced symptoms and rescue inhaler use).^{66,67}

In 2007, two new long-acting, inhaled β -agonists became available in the United States. Formoterol and arformoterol are unique in that they are the first long-acting β -agonists available as nebulized solutions. When arformoterol was compared to salmeterol (administered by MDI) in a 12-week study, both treatments increased the trough FEV₁.⁶⁸ Arformoterol also improved peak flows

and reduced short-acting bronchodilator use. These two new products are the first long-acting bronchodilator therapies available for use by nebulization. They offer an important option for patients with COPD in whom nebulization therapy is warranted.

Long-Acting Anticholinergics Tiotropium bromide, a long-acting quaternary anticholinergic agent, has been available in the United States since 2004. This agent blocks the effects of acetylcholine by binding to muscarinic receptors in airway smooth muscle and mucus glands, blocking the cholinergic effects of bronchoconstriction and mucus secretion. Tiotropium is more selective than ipratropium at blocking important muscarinic receptors. Tiotropium dissociates slowly from M₁ and M₃ receptors, allowing prolonged bronchodilation. The dissociation from M₂ receptors is much faster, allowing inhibition of acetylcholine release. Binding studies of tiotropium in the human lung show that it is approximately 10-fold more potent than ipratropium and protects against cholinergic bronchoconstriction for greater than 24 hours.⁶⁹

When inhaled, tiotropium is minimally absorbed into the systemic circulation and results in bronchodilation within 30 minutes, with a peak effect in 3 hours. Bronchodilation persists for at least 24 hours, allowing for a once-daily dosing. In the United States, it is delivered via the HandiHaler, a single-load, dry-powder, breath-actuated device. Because it acts locally, tiotropium is well tolerated, with the most common complaint being a dry mouth. Other anticholinergic side effects that are reported include constipation, urinary retention, tachycardia, blurred vision, and precipitation of narrow-angle glaucoma symptoms.

The benefits of tiotropium have been evaluated in numerous trials of patients with COPD. Similar to long-acting β -agonists, tiotropium improves lung function and, dyspnea, exacerbation frequency, and health-related quality of life.⁷⁰ The tolerance that is demonstrated with chronic use of β -agonists does not occur with tiotropium therapy, as improvements in lung function are sustained with long-term therapy.⁷¹

There is a large body of evidence supporting the use of tiotropium as a long-acting bronchodilator for COPD patients. Benefits have been demonstrated compared to placebo⁷² and to ipratropium.⁷³ Equivalent or superior effects have been proven compared to long-acting β -agonist therapy.⁷² Tiotropium therapy is associated with a decreased risk of exacerbations compared to placebo or ipratropium, and equal or superior efficacy compared to long-acting β -agonists.⁷⁴

Tiotropium was evaluated as an addition to standard COPD medications in a 1-year, placebo-controlled, double-blind study involving more than 900 subjects. Tiotropium 18 mcg/day improved the FEV₁ response an average of 12% (trough) to 22% (peak) when added to standard therapy.⁷⁰

The efficacy and safety of tiotropium administered via a DPI was compared with ipratropium administered four times daily by MDI in a multicenter, double-blind study that followed patients for 1 year.⁷³ Patients who received once-daily tiotropium demonstrated significantly greater improvements in lung function and selected quality-of-life scores, decreased dyspnea, and fewer exacerbations compared with patients who received ipratropium. There were no differences in side effects between the two agents.

As a long-acting bronchodilator, tiotropium is an option to consider in addition to long-acting inhaled β_2 -agonists for COPD management. Once-daily tiotropium has been compared with twice-daily salmeterol in two placebo-controlled trials of 6 months' duration. Tiotropium reduced asthma exacerbations and hospital admissions and improved quality of life, whereas both active treatments improved lung function and reduced dyspnea.⁷² In another 6-month randomized, controlled trial of patients with COPD, patients were randomized to receive either tiotropium once daily by DPI, salmeterol twice daily by MDI, or placebo.⁷⁵ Patients receiving

tiotropium had greater improvements in trough FEV₁ and dyspnea scores than those receiving salmeterol. Patients also were more likely to have improvements in quality-of-life indicators with tiotropium than with salmeterol. However, no differences in frequency of exacerbations were noted among the three groups.

These data offer some promise about the long term benefit of tiotropium on slowing the progressive decline in lung function, although this claim is premature. A major clinical trial evaluating the benefit of long-term treatment is currently ongoing. This trial is evaluating the long-term benefits of tiotropium in the treatment of COPD, including the effects on FEV₁ decline, exacerbation frequency, and overall mortality. The results of the UPLIFT (Understanding the Potential Long-Term Impacts on Function with Tiotropium) trial are anticipated in 2008.⁷⁶

The potential benefit of tiotropium therapy in augmenting pulmonary rehabilitation has been evaluated. The basis for this combination is that tiotropium can improve ventilatory mechanics and allow greater participation in exercise and muscle training. Tiotropium therapy combined with pulmonary rehabilitation improved exercise endurance and health status, and reduced dyspnea compared to pulmonary rehabilitation alone.⁷⁷ The effects were sustained for three months after the pulmonary rehabilitation program was complete.

Combination Anticholinergics and β -Agonists Combination regimens of bronchodilators are used often in the treatment of COPD, especially as the disease progresses and symptoms worsen over time. Combining bronchodilators with different mechanisms of action allows the lowest possible effective doses to be used and reduces potential adverse effects from individual agents.¹ Combinations of both short- and long-acting β_2 -agonists with ipratropium have been shown to provide added symptomatic relief and improvements in pulmonary function.^{78–80}

A combination of albuterol and ipratropium (Combivent) is available as a MDI in the United States for chronic maintenance therapy of COPD. This product offers the obvious convenience of two classes of bronchodilators in a single inhaler.

Although clinical practice guidelines recommend that combinations of long-acting bronchodilators are appropriate in patients who do not receive adequate benefit from a single agent, data to support the use of these combinations have been lacking. These approaches have been the focus of more recent research. Future combination inhalation products may contain long-acting β_2 -agonists with tiotropium to reduce the need for frequent dosing. In a preliminary single-dose study, the combination of tiotropium and formoterol resulted in a faster and greater improvement in FEV₁ compared with either treatment alone.⁸¹ In another trial, 95 subjects received either tiotropium 18 mcg or tiotropium plus formoterol 12 mcg, either once or twice daily. All patients received each therapy for 2 weeks each in an open-label crossover design. Both combination regimens improved lung function and reduced rescue therapy use compared to tiotropium alone.⁸²

Methylxanthines Methylxanthines, including theophylline and aminophylline, have been available for the treatment of COPD for at least five decades and at one time were considered first-line therapy. However, with the availability of long-acting inhaled β_2 -agonists and inhaled anticholinergics, the role of methylxanthine therapy is significantly limited. Inhaled bronchodilator therapy is preferred for COPD. Because of the risk for drug interactions and the significant inpatient and outpatient variability in dosage requirements, theophylline therapy generally is considered in patients who are intolerant or unable to use an inhaled bronchodilator. Theophylline is still an alternative to commonly used inhaled therapies partially because of the potential for multiple mechanisms (bronchodilation and antiinflammatory) and the possible benefit that systemic administration may exert on peripheral airways.⁸³

The methylxanthines may produce bronchodilation through numerous mechanisms, including (a) inhibition of phosphodiesterase, thereby increasing cyclic adenosine monophosphate levels, (b) inhibition of calcium ion influx into smooth muscle, (c) prostaglandin antagonism, (d) stimulation of endogenous catecholamines, (e) adenosine receptor antagonism, and (f) inhibition of release of mediators from mast cells and leukocytes.⁸⁴

Chronic theophylline use in patients with COPD has been shown to exert improvements in lung function, including vital capacity, FEV₁, minute ventilation, and gas exchange.⁸³ Subjectively, theophylline has been shown to reduce dyspnea, increase exercise tolerance, and improve respiratory drive in COPD patients.^{83,84} Other nonpulmonary effects of theophylline that may contribute to improved overall functional capacity in patients with COPD include improved cardiac function and decreased pulmonary artery pressure.

Although theophylline is available in a variety of oral dosage forms, sustained-release preparations are most appropriate for the long-term management of COPD. These products have the advantages of improving patient compliance and achieving more consistent serum concentrations over rapid-release theophylline and aminophylline preparations. However, caution must be used in switching from one sustained-release preparation to another because there are considerable variations in sustained-release characteristics.⁸⁴ Aside from intravenous aminophylline, there is no need to use any of the various salts forms of theophylline.

Regular use of methylxanthines has not been shown to have either a beneficial or a detrimental effect on the progression of COPD. However, methylxanthines may be added to the treatment plan of patients who have not achieved an optimal clinical response to ipratropium and an inhaled β_2 -agonist. Studies suggest that adding theophylline to a combination of albuterol and ipratropium provides added benefit for stable COPD patients, supporting the hypothesis that there is a synergistic bronchodilator effect.^{85–87} The efficacy of combination therapy with salmeterol and theophylline for patients with COPD was reported to improve pulmonary function and reduce dyspnea better than either treatment alone.⁸⁸ Combination treatment also was associated with a reduced number of exacerbations only when compared with the theophylline group, suggesting that the salmeterol component was responsible for this beneficial effect.

As is the case with other bronchodilator therapy, parameters other than objective measurements, such as FEV₁, should be monitored to assess efficacy of theophylline in COPD. Subjective parameters, such as perceived improvements in symptoms of dyspnea, and exercise tolerance, become increasingly important in assessing the acceptability of methylxanthines for COPD patients. Although objective improvement may be minimal, patients may experience an improvement in clinical symptoms, and thus benefit to the individual may be meaningful.

Theophylline's role in COPD is as maintenance therapy in the nonacutely ill patient. Therapy can be initiated at 200 mg twice daily and titrated upward every 3 to 5 days to the target dose. Most patients required daily doses of 400 to 900 mg. Dosage adjustments generally should be made based on serum concentration results. Traditionally, the therapeutic range of theophylline was identified as 10 to 20 mcg/mL; however, because of the frequency of dose-related side effects and the relatively minor benefit of higher concentrations, a more conservative therapeutic range of 8 to 15 mcg/mL often is targeted. This is especially preferable in the elderly. When concentrations are measured, trough measurements are most appropriate.

Once a dose is established, serum concentrations should be monitored once or twice a year unless the patient's disease worsens, medications that interfere with theophylline metabolism are added to therapy, or toxicity is suspected. The most common side effects of theophylline therapy are related to the gastrointestinal system, the cardiovascular system, and the central nervous system. Side effects are dose-related; however, there is overlap in side effects

between the therapeutic and toxic ranges. Minor side effects include dyspepsia, nausea, vomiting, diarrhea, headache, dizziness, and tachycardia. More serious toxicities, especially at toxic concentrations, include arrhythmias and seizures.

Factors that decrease theophylline clearance and lead to reduced maintenance-dose requirements include advanced age, bacterial or viral pneumonia, left or right ventricular failure, liver dysfunction, hypoxemia from acute decompensation, and use of drugs such as cimetidine, macrolides, and fluoroquinolone antibiotics. Factors that may enhance theophylline clearance and result in the need for higher maintenance doses include tobacco and marijuana smoking, hyperthyroidism, and the use of such drugs as phenytoin, phenobarbital, and rifampin.

In summary, there are decades of experience with theophylline and other methylxanthine products in the management of patients with COPD. However, inhalation therapy is currently preferred based on superior efficacy and safety, as well as ease of use by the clinician. Theophylline is a challenging medication to dose, monitor, and manage because of the significant inpatient and outpatient variability in pharmacokinetics and the potential for drug interactions and toxicities.

Corticosteroids

9 Corticosteroid therapy has been studied and debated in COPD therapy for half a century; however, owing to the poor risk-to-benefit ratio, chronic systemic corticosteroid therapy should be avoided if possible.¹ Because of the potential role of inflammation in the pathogenesis of the disease, clinicians hoped that corticosteroids would be promising agents in COPD management. However, their use continues to be debated, especially in the management of stable COPD.

The antiinflammatory mechanisms whereby corticosteroids exert their beneficial effect in COPD include (a) reduction in capillary permeability to decrease mucus, (b) inhibition of release of proteolytic enzymes from leukocytes, and (c) inhibition of prostaglandins. Unfortunately, the clinical benefits of systemic corticosteroid therapy in the chronic management of COPD are often not evident, and the risk of toxicity is extensive and far-reaching. Currently, the appropriate situations to consider corticosteroids in COPD include (a) short-term systemic use for acute exacerbations and (b) inhalation therapy for chronic stable COPD.

The role of oral steroid use in chronic stable COPD patients was evaluated in a meta-analysis over a decade ago.⁸⁹ Investigators concluded that only a small fraction (10%) of COPD patients treated with steroids showed clinically significant improvement in baseline FEV₁ (increase of 20%) compared with those treated with placebo. While a small number of COPD patients are considered responders to oral steroids, many of these patients actually may have an asthmatic, or reversible, component to their disease. The best predictors for response to oral steroids is the presence of eosinophils on sputum examination ($\geq 3\%$) and a significant response on pulmonary function tests to sympathomimetics.⁹⁰ Both the presence of eosinophils in sputum and the responsiveness to sympathomimetics suggest an asthmatic component to the disease process and thus may explain the clinical benefit seen with steroids.

Long-term adverse effects associated with systemic corticosteroid therapy include osteoporosis, muscular atrophy, thinning of the skin, development of cataracts, and adrenal suppression and insufficiency. The risks associated with long-term steroid therapy are much greater than the clinical benefits. If a decision to treat with long-term systemic corticosteroids is made, the lowest possible effective dose should be given once per day in the morning to minimize the risk of adrenal suppression. If therapy with oral agents is required, an alternate-day schedule should be used.

Previously, a common clinical practice was to administer a short course (2 weeks) of oral corticosteroids as a trial to predict which patients would benefit from chronic oral or inhaled corticosteroids. There is now sufficient evidence suggesting that this practice is not effective in predicting a long-term response to inhaled corticosteroids and should not be recommended.⁹¹

The use of chronic inhaled corticosteroid therapy has been of interest for the past decade. Their use has been common despite the lack of firm evidence about significant clinical benefit until recently. Inhaled corticosteroids have an improved risk-to-benefit ratio compared with systemic corticosteroid therapy. Using the model for asthma, it was hoped that the inhalation of potent corticosteroid would result in high local efficacy and limited systemic exposure and toxicity. In the latter part of the 1990s, several large international trials were initiated to evaluate the effect on inhaled corticosteroids in COPD. Unfortunately, the results of these major clinical trials failed to demonstrate any benefit from chronic treatment with inhaled corticosteroids in modifying long-term decline in lung function that is characteristic of COPD. Therefore, the role of inhaled corticosteroids in COPD continues to be debated in the literature, unlike asthma, where their use is clearly advocated. Much of the debate centers on the appropriate outcome measures in this population of patients.

During the last decade, several studies of inhaled corticosteroids in COPD were designed to detect a benefit on slowing the progressive loss of lung function, but the results were disappointing.^{92–98} None of the large national or international trials were able to demonstrate a benefit of high-dose inhaled corticosteroid therapy on this primary outcome. However, inhaled corticosteroids are associated with other important benefits in some patients, including a decrease in exacerbation frequency and improvements in overall health status.^{94,98,99} Clinicians continue to debate the most appropriate and relevant outcome measure to evaluate in COPD studies. Based on the results of clinical trials, consensus guidelines suggest that inhaled corticosteroid therapy should be considered for symptomatic patients with stage III or IV disease (FEV₁ <50%) who experience repeated exacerbations.^{1,2} These are the patients who demonstrated benefit in clinical trials and in whom a trial of inhaled corticosteroid therapy is warranted. There are also data from epidemiologic studies that suggest that chronic treatment with inhaled corticosteroids is associated with a lower risk of rehospitalization for a broader group of patients with COPD. Thus the debate about the appropriate role for this antiinflammatory therapy continues.

A meta-analysis evaluating randomized clinical trials involving inhaled corticosteroids in patients COPD indicated that treatment was associated with a relative risk reduction in exacerbation frequency of 33%. The report indicated that 12 patients would require treatment for 20.8 months to prevent one exacerbation episode. The benefit was evident for patients with moderate to severe COPD.¹⁰⁰ This meta-analysis did not detect a mortality benefit.

Other investigators have reported a reduction in mortality in patients with COPD who were treated with inhaled corticosteroids. In an epidemiologic study of a Canadian database, patient mortality 3 months to 1 year following a hospitalization for a COPD exacerbation was evaluated in patients who received inhaled corticosteroids in the first 3 months compared to those who did not. For patients older than 65 years of age, inhaled corticosteroid therapy reduced mortality by 25%. Much of the mortality reduction was reflected in deaths from cardiovascular causes. Conversely, patients who received only bronchodilator therapy trended toward higher mortality rates, although not significant.¹⁰¹ A pooled analysis of seven large trials also concluded that inhaled corticosteroids reduced all-cause mortality in COPD patients.¹⁰²

Currently, the recommended role of inhaled corticosteroid therapy is for COPD patients with moderate to severe airflow obstruction

(FEV₁ <50% predicted), and who experience frequent exacerbations despite bronchodilator therapy. The initial hope that treatment with inhaled corticosteroids would prevent or slow the progressive decline in FEV₁ remains unproven; however, it is often argued that additional important outcomes in patients with COPD include relief of symptoms, fewer and less-severe exacerbations, and improved quality of life.¹⁰³ The role of inhaled corticosteroids in prolonging survival of patients with COPD has been widely debated in recent years. Investigators have reported mixed success and studies are confounded by small sample size and differences in study design.¹⁰⁴

Although a dose–response relationship for inhaled corticosteroids has not been demonstrated in COPD, the major clinical trials employed moderate to high doses for treatment. Side effects of inhaled corticosteroids are relatively mild compared with the toxicity from systemic therapy. Hoarseness, sore throat, oral candidiasis, and skin bruising have been reported in the clinical trials. Severe side effects, such as adrenal suppression, osteoporosis, and cataract formation, have been reported less frequently than with systemic corticosteroids, but clinicians should monitor patients who are receiving high-dose chronic therapy.^{105,106}

There is evidence supporting a dose relationship between inhaled corticosteroid use and the risk of fractures. In a cohort of more than 1,600 subjects with a diagnosis of asthma or COPD (mean age: 80 years), the risk of a fracture was 2.53 times higher (confidence interval: 1.65 to 3.89) in those receiving a mean daily dose of inhaled corticosteroid of 601 mcg or greater.¹⁰⁷ However, the data are conflicting about this issue. A meta-analysis found no evidence supporting an increased risk of fractures or decreased bone mineral density with chronic inhaled corticosteroid use.¹⁰⁸ It appears prudent to suggest that, to minimize the risk of fracture, patients should be treated with the lowest effective dose of inhaled corticosteroids.¹⁰⁹ It may also be helpful to recommend adequate intake of calcium and vitamin D, and possibly periodic bone mineral density testing.

Combination Therapy: Bronchodilators and Inhaled Corticosteroids

Following the disappointing results of chronic inhaled corticosteroid studies and the progressive decline in lung function, investigators became interested in the combination of potent antiinflammatory therapies and long-acting bronchodilators. Subsequently, several studies have shown an additive benefit with long-acting bronchodilators.^{110–113} In various studies, combination therapy with salmeterol plus fluticasone or formoterol plus budesonide was associated with greater improvements in clinical outcomes such as FEV₁, health status, and frequency of exacerbations compared with inhaled corticosteroids or long-acting bronchodilators alone. The availability of combination inhalers (e.g., salmeterol plus fluticasone) makes administration of both inhaled corticosteroids and long-acting bronchodilators more convenient for patients and decreases the total number of inhalations needed daily. Therefore, there is growing evidence that inhaled corticosteroid and long-acting β -agonist combinations improve lung function, as well as reduce symptoms of dyspnea and exacerbation frequency.^{112–114}

The combination of a long-acting β -agonist and inhaled corticosteroid has been compared to the long-acting β -agonist therapy alone. In a study involving nearly 1,000 patients with severe but stable COPD, subjects received either salmeterol 50 mcg/fluticasone 500 mcg twice daily or salmeterol 50 mcg twice daily for 44 weeks. Exacerbation frequency was significantly lower in the combination group (334 versus 464 episodes) which corresponded to a 35% reduction in the annualized rate. The time to the first exacerbation was also delayed with the combination therapy.¹¹⁵ One finding of concern reported in this trial was the increased number of pneumonia cases in patients receiving combination therapy compared to

salmeterol alone. There were 23 cases reported, compared with 7 in the salmeterol group.¹¹⁵ An increase in the risk for pneumonia was also reported in the Towards a Revolution in COPD Health (TORCH) study.¹¹⁶ This finding requires further investigation.

The largest prospective study to date is referred to as the TORCH study.¹¹⁶ This trial consisted of 6,112 patients who received one of four treatments for 3 years. Treatment groups were placebo, salmeterol 50 mcg twice daily, fluticasone 500 mcg twice daily, or the combination of salmeterol and fluticasone in a single inhaler. The primary outcome was death from any cause and secondary outcomes were exacerbation rates, lung function, and health status. None of the active treatments differed significantly from placebo, although the combination of salmeterol and fluticasone trended toward fewer deaths ($p = 0.052$). The combination also reduced exacerbation rates, and improved lung function and health status compared to the other treatments. Exacerbation rates were also significantly reduced with combination therapy compared to either single agent alone. Both treatment groups that included fluticasone had higher rates of pneumonia. Although this study did not reflect a mortality benefit, the authors indicated the risk of death was reduced by 17.5% with the combination and that the number needed to treat for 1 year to provide a benefit was 4.

Combinations of Long-Acting Bronchodilators Compared to Long-Acting Bronchodilators Plus Inhaled Corticosteroids

The combination of salmeterol and tiotropium has also been evaluated in a short-term crossover study involving only 22 subjects who received either salmeterol (50 mcg twice daily) plus fluticasone (500 mcg twice daily), fluticasone plus tiotropium (18 mcg once daily), or fluticasone, salmeterol, and tiotropium for 1 week. The triple combination provided a significant benefit of improved lung function compared to either of the dual treatments in subjects with moderate to severe COPD.¹¹⁷ The benefit of triple therapy was evaluated in a 1-year randomized, double-blind, placebo control study involving 449 subjects with moderate to severe COPD. Treatment consisted of either tiotropium, tiotropium plus salmeterol, or tiotropium, salmeterol and fluticasone.¹¹⁸ There was no difference between treatments for the primary outcome of percentage of patients experiencing an exacerbation requiring systemic corticosteroids or antibiotics. The triple-drug regimen improved lung function, quality of life, and reduced hospitalization compared to tiotropium alone, whereas two-drug therapy did not offer any benefit in lung function improvement or hospitalization rates compared to the single agent. Another small study evaluated the addition of tiotropium for 1 month to a regimen of an inhaled corticosteroid and a long-acting β -agonist.¹¹⁹ The addition of tiotropium improved lung function and quality-of-life scores, apparently by improving dynamics of lung capacity (inspiratory capacity). These effects were reversed when tiotropium therapy was discontinued. These data involving combinations of long acting bronchodilators are limited and preliminary. More research is required and should include other outcome parameters including relief of symptoms, exacerbation rates and quality of life. Larger sample sizes and longer durations will provide insight into the value of combinations.

α_1 -Antitrypsin Replacement Therapy

In patients with inherited AAT deficiency-associated emphysema, treatment focuses on reduction of risk factors such as smoking, symptomatic treatment with bronchodilators, and augmentation therapy with replacement AAT. Based on knowledge about the relationship between serum concentrations of AAT and the risk of developing emphysema, the rationale for augmentation therapy is to maintain serum concentrations above the protective threshold throughout the dosing interval.¹²⁰ Indirect evidence of AAT activity in the interstitium of the lung has been demonstrated by measuring

concentrations of the enzyme in epithelial lining fluid obtained during bronchoalveolar lavage. Augmentation therapy consists of weekly infusions of pooled human AAT to maintain AAT plasma levels greater than 10 micromolars. Much of the data supporting the use of AAT replacement is based on evidence of biochemical efficacy (e.g., administering the product and demonstrating protective serum concentrations of AAT).

Clinical evidence for slowing lung function decline or improving outcomes with augmentation therapy is sparse. Stated challenges to performing randomized clinical trials include the large sample size and long duration of followup required, and the expense of conducting such a trial. One observational study followed patients in the National Registry of Severe AAT Deficiency over a period of several years and documented clinical outcomes. In this study, patients who received weekly augmentation therapy with purified AAT had slower declines in FEV₁ and decreased mortality compared with patients who never received augmentation therapy.¹²¹ However, this was an observational study of patients, not a randomized, placebo-controlled trial, and so direct cause-and-effect relationships cannot be concluded. One randomized, placebo-controlled study of patients with severe AAT deficiency (ZZ phenotype) did show a significant reduction in lung tissue loss and destruction as measured by computed tomographic scan in patients receiving augmentation therapy.¹²² Other measures of lung function and mortality were not recorded.

The recommended dosing regimen for replacement AAT is 60 mg/kg administered intravenously once a week at a rate of 0.08 mL/kg per minute, adjusted to patient tolerance. It has been estimated that this form of augmentation therapy will cost more than \$54,000 annually.¹²³ In the absence of alternative treatments, it is difficult to assess cost-effectiveness using conventional criteria. There have been repeated problems with supply of this biologic replacement therapy (derived from pooled blood donors) related to production difficulty and contamination issues. Currently, there are three products available (Prolastin [Bayer], Aralast [Baxter], and Zemaira [ZLB Behring]), which should minimize this problem in the future. Drug development research continues in the area of recombinant products and inhalational therapy.

The safety of AAT replacement therapy has been recently evaluated in two large observational studies. In the most recent study, 174 patients (n = 747) reported 720 adverse events, classified as severe in 8.8% of cases and moderate in 72.4% of cases.¹²⁴ Common complaints included headache, dizziness, nausea, dyspnea, and fever. The overall rate of adverse events was low (i.e., two events over 5 years).

TREATMENT

Chronic Obstructive Pulmonary Disease Exacerbation

DESIRED OUTCOMES

10 The goals of therapy for patients experiencing exacerbations of COPD are (a) prevention of hospitalization or reduction in hospital stay, (b) prevention of acute respiratory failure and death, and (c) resolution of exacerbation symptoms and a return to baseline clinical status and quality of life. Acute exacerbations can range from mild to severe. Factors that influence the severity, and subsequently the level of care required, include the severity of airflow limitation, presence of comorbidities and the history of previous exacerbations. Table 29–12 includes factors that warrant treatment in the hospital.

Table 29–13 summarizes the various therapeutic options for exacerbation management. Pharmacotherapy consists of intensification of bronchodilator therapy and a short course of systemic corticosteroids. Antimicrobial therapy is indicated in the presence of selected symptoms. As the frequency and severity of exacerbations

TABLE 29-12 Factors Favoring Hospitalization for Treatment of Chronic Obstructive Pulmonary Disease Exacerbation

Presence of high risk comorbidity (e.g., pneumonia, arrhythmia, congestive heart failure, diabetes, renal or hepatic failure)
Suboptimal response to outpatient management
Marked worsening of dyspnea
Inability to eat or sleep because of symptoms
Worsening hypoxemia or hypercapnia
Mental status changes
Lack of home support for care
Uncertain diagnosis

Modified from the American Thoracic Society.
Adapted from reference 2.

tions are closely related to each patient's overall health status, all patients should receive optimal chronic treatment, including smoking cessation, appropriate pharmacologic therapy, and preventative therapy such as vaccinations.

NONPHARMACOLOGIC THERAPY

Controlled Oxygen Therapy

Oxygen therapy should be considered for any patient with hypoxemia during an exacerbation. Caution must be used, however, because many patients with COPD rely on mild hypoxemia to trigger their drive to breathe. In normal, healthy individuals, the drive to breathe is triggered by carbon dioxide accumulation. In patients with COPD who retain carbon dioxide as a result of their disease progression, hypoxemia rather than hypercapnia becomes the main trigger for their respiratory drive. Overly aggressive administration of oxygen to patients with chronic hypercapnia may result in respiratory depression and respiratory failure. Oxygen therapy should be used to achieve a PaO₂ of greater than 60 mm Hg or oxygen saturation of greater than 90%. However, an ABG should be obtained after oxygen initiation to monitor carbon dioxide retention owing to hypoventilation.

Noninvasive Mechanical Ventilation

Noninvasive positive-pressure ventilation (NPPV) provides ventilatory support with oxygen and pressurized airflow using a face or nasal mask with a tight seal but without endotracheal intubation. Numerous

TABLE 29-13 Therapeutic Options for Acute Exacerbations of Chronic Obstructive Pulmonary Disease

Therapy	Comments
Antibiotics	Recommended if two or more of the following are present: Increased dyspnea Increased sputum production Increased sputum purulence
Corticosteroids	Oral or intravenous therapy may be used. If intravenous is used, it should be changed to oral after improvement in pulmonary status. If continued longer than 14 days, then the dose should be tapered to avoid hypothalamic-pituitary-adrenal axis suppression.
Bronchodilators	Metered-dose inhalers and dry-powder inhalers equal in efficacy to nebulization. β -Agonists also may increase mucociliary clearance. Long-acting β -agonists should not be used for quick relief of symptoms or on an as-needed basis.
Controlled oxygen therapy	Titrate oxygen to desired oxygen saturation (>90%). Monitor arterial blood gas for development of hypercapnia.
Noninvasive mechanical ventilation	Consider for patients with acute respiratory failure. Not appropriate for patients with altered mental status, severe acidosis, respiratory arrest, or cardiovascular instability.

trials have reported the benefits of NPPV in patients with acute respiratory failure caused by COPD exacerbations. In one meta-analysis of eight studies, NPPV was associated with lower mortality, lower intubation rates, shorter hospital stays, and greater improvements in serum pH in 1 hour when compared with treatment with usual care alone.¹²⁵ The benefits seen with NPPV generally can be attributed to a reduction in the complications that often arise with invasive mechanical ventilation. Not all patients with COPD exacerbations are appropriate candidates for NPPV. Patients with altered mental status may not be able to protect their airway and thus may be at increased risk for aspiration. Patients with severe acidosis (pH <7.25), respiratory arrest, or cardiovascular instability should not be considered for NPPV. Patients failing a trial of NPPV or those considered poor candidates may be considered for intubation and mechanical ventilation.

■ PHARMACOLOGIC THERAPY

Bronchodilators

During exacerbations, intensification of bronchodilator regimens is used commonly. The doses and frequency of bronchodilators are increased to provide symptomatic relief. Short-acting β_2 -agonists are preferred owing to rapid onset of action. Anticholinergic agents may be added if symptoms persist despite increased doses of β_2 -agonists. In fact, combinations of these agents are employed often, although data are lacking about the benefit versus higher doses of one agent. Bronchodilators may be administered via MDIs or nebulization with equal efficacy. Nebulization may be considered for patients with severe dyspnea who are unable to hold their breath after actuation of an MDI. Clinical evidence supporting the use of theophylline during exacerbations is lacking, and thus theophylline generally should be avoided. However, addition of one of these agents may be considered for patients not responding to other therapies. The risk of adverse effects such as cardiac arrhythmias should be considered and serum levels monitored closely.

Corticosteroids

Until recently, the literature supporting the use of corticosteroids in acute exacerbations of COPD was sparse. However, since 1996, five studies have been performed that document the value of systemic corticosteroids in exacerbations of COPD.^{126–130} The Systemic Corticosteroids in Chronic Obstructive Pulmonary Disease Exacerbations (SCCOPE) trial evaluated three groups of patients hospitalized for exacerbations of COPD.¹²⁶ The first group received an 8-week course of corticosteroids given as methylprednisolone 125 mg intravenously every 6 hours for 72 hours, followed by once-daily oral prednisone (60 mg on days 4 through 7; 40 mg on days 8 through 11; 20 mg on days 12 through 43; 10 mg on days 44 through 50; and 5 mg on days 51 through 57). The second group received a 2-week course given as methylprednisolone 125 mg intravenously every 6 hours for 72 hours, followed by oral prednisone (60 mg on days 5 through 7; 40 mg on days 8 through 11; and 20 mg on days 12 through 15) and placebo on days 16 through 57. The third group received placebo for all 57 days of study. Rates of treatment failure and hospital stay were significantly higher in the placebo group than in either treatment group at 30 and 90 days. Groups randomized to corticosteroid treatment also had a significantly shorter length of hospital stay than did the placebo group. The 8-week regimen was not found to be superior to the 2-week regimen. Significant treatment benefits were no longer evident at 6 months.

Davies et al.¹²⁷ evaluated the oral use of corticosteroids in hospitalized patients with acute exacerbations of COPD. Patients received either 30 mg/day oral prednisolone or placebo for 14 days. Patients who were treated with corticosteroids had a significantly more rapid improvement in FEV₁ and a shorter hospital stay than did patients

who received placebo. There was no significant difference between groups at 6-week followup.

In total, results from these trials suggest that patients with acute exacerbations of COPD should receive a short course of intravenous or oral corticosteroids. However, because of the large variability in dosage ranges, the optimal dose and duration of corticosteroid treatment are not known. It appears that short courses (9 to 14 days) are as effective as longer courses and have a lower risk of associated adverse effects owing to less time of exposure. Several trials used high initial doses of steroids before tapering to a lower maintenance dose. Adverse effects such as hyperglycemia, insomnia, and hallucinations may occur at higher doses. Depending on the clinical status of the patient, treatment may be initiated at a lower dose or tapered more quickly if these effects occur. It appears that a regimen of prednisone 40 mg orally daily (or equivalent) for 10 to 14 days can be effective for most patients.¹³¹ If steroid treatment is continued for longer than 2 weeks, a tapering oral schedule should be employed to avoid signs of hypothalamic–pituitary–adrenal axis suppression.

Antimicrobial Therapy

Most acute exacerbations of COPD are thought to be caused by viral or bacterial infections. However, as many as 30% of exacerbations are caused by unknown factors.¹ A meta-analysis of nine studies evaluating the effectiveness of antibiotics in treating exacerbations of COPD determined that patients receiving antibiotics had a greater improvement in peak expiratory flow rate than those who did not.¹³²

This meta-analysis concluded that antibiotics are of most benefit and should be initiated if at least two of the following three symptoms are present: increased dyspnea, increased sputum volume, and increased sputum purulence. The utility of sputum Gram stain and culture is questionable because some patients have chronic bacterial colonization of the bronchial tree between exacerbations.

The emergence of drug-resistant organisms has mandated that antibiotic regimens be chosen judiciously. Selection of empirical antimicrobial therapy should be based on the most likely organism(s) thought to be responsible for the infection based on the individual patient profile. The most common organisms for any acute exacerbation of COPD are *Haemophilus influenzae*, *Moraxella catarrhalis*, *Streptococcus pneumoniae*, and *Haemophilus parainfluenzae*. More virulent bacteria may be present in patients with more complicated acute exacerbations of COPD, including drug-resistant pneumococci, β -lactamase-producing *H. influenzae* and *M. catarrhalis*, and enteric gram-negative organisms, including *Pseudomonas aeruginosa*. Table 29–14 summarizes recommended antimicrobial therapy for exacerbations of COPD and the most common organisms based on patient presentation.¹³³

Therapy with antibiotics generally should be continued for at least 7 to 10 days. Studies evaluating shorter treatment courses (usually 5 days) with the fluoroquinolones, second- and third-generation cephalosporins, and macrolide antimicrobials have demonstrated comparable efficacy with the longer treatment regimens.¹³⁴ If the patient deteriorates or does not improve as anticipated, hospitalization may be necessary, and more aggressive attempts should be made to identify potential pathogens responsible for the exacerbation.

■ COMPLICATIONS

Cor Pulmonale

Cor pulmonale is right-sided heart failure secondary to pulmonary hypertension. Long-term oxygen therapy and diuretics have been the mainstays of therapy for cor pulmonale. Increasing the PaO₂ above 60 mm Hg with supplemental oxygen therapy decreases pulmonary hypertension and thus decreases the force against which the right ventricle has to work. Although diuretics may help decrease fluid overload, caution should be used because patients with significant

TABLE 29-14 Recommended Antimicrobial Therapy in Acute Exacerbations of Chronic Obstructive Pulmonary Disease

Patient Characteristics	Likely Pathogens	Recommended Therapy
Uncomplicated exacerbations <4 exacerbations per year No comorbid illness FEV ₁ >50% of predicted	<i>Streptococcus pneumoniae</i> <i>Haemophilus influenzae</i> <i>Moraxella catarrhalis</i> <i>Haemophilus parainfluenzae</i> Resistance uncommon	Macrolide (azithromycin, clarithromycin) Second- or third-generation cephalosporin Doxycycline Therapies not recommended ^a : TMP-SMX, amoxicillin, first-generation cephalosporins, and erythromycin
Complicated exacerbations Age ≥65 years >4 exacerbations per year FEV ₁ <50% but >35% of predicted	As above plus drug-resistant pneumococci, <i>β</i> -lactamase-producing <i>H. influenzae</i> and <i>M. catarrhalis</i>	Amoxicillin/clavulanate Fluoroquinolone with enhanced pneumococcal activity (levofloxacin, gemifloxacin, moxifloxacin)
Complicated exacerbations with risk of <i>Pseudomonas aeruginosa</i> Chronic bronchial sepsis ^b Need for chronic corticosteroid therapy Resident of nursing home >4 exacerbations per year FEV ₁ >35% of predicted	Some enteric gram-negatives As above plus <i>P. aeruginosa</i>	Fluoroquinolone with enhanced pneumococcal and <i>P. aeruginosa</i> activity (levofloxacin) IV therapy if required: <i>β</i> -lactamase-resistant penicillin with antipseudomonal activity Third- or fourth-generation cephalosporin with antipseudomonal activity

FEV₁, forced expiratory volume in the first second of expiration; TMP-SMX, trimethoprim-sulfamethoxazole.

^aTMP-SMX should not be used because of increasing pneumococcal resistance; amoxicillin and first-generation cephalosporins are not recommended because of *β*-lactamase susceptibility; and erythromycin is not recommended because of insufficient activity against *H. influenzae*.

^bIn sepsis, double antipseudomonal coverage should be considered (e.g., addition of aminoglycoside).

Modified and updated from reference 1.

right-sided heart failure are highly dependent on preload for cardiac output. Consequently, the decision to use diuretics must be based on a risk-to-benefit ratio. Digitalis glycosides have no role in the treatment of cor pulmonale.

Other pharmacologic agents that have been investigated to treat cor pulmonale include hydralazine, calcium channel blockers, angiotensin-converting enzyme inhibitors, and angiotensin II antagonists. However, there is insufficient evidence to offer guidelines for the role of these agents in COPD patients with cor pulmonale.

Polycythemia

Polycythemia secondary to chronic hypoxemia in COPD patients can be improved by either oxygen therapy or periodic phlebotomy if oxygen therapy alone is not sufficient. Continuous oxygen therapy was shown by the Nocturnal Oxygen Therapy Trial Group to reduce hematocrit values in treated patients.³¹ Acute phlebotomy is indicated if the hematocrit is above 55% to 60% and the patient is experiencing central nervous system effects suggestive of sludging from high blood viscosity. Long-term oxygen then can be used to maintain a lower hematocrit.

OTHER PHARMACOLOGIC CONSIDERATIONS

A number of other treatments have been explored over the years. Among these therapies, there is either insufficient evidence to warrant recommending their use, or they have been proven to not be beneficial in the management of COPD. A brief summary is provided because the clinician likely will encounter patients who are receiving or inquire about these treatments.

Suppressive Antimicrobial Agents

Because COPD patients often are colonized with bacteria and experience recurrent exacerbations of their condition, a common practice employed in the past has been the use of low-dose antimicrobial therapy as preventative or prophylaxis against these acute exacerbations. However, clinical studies over the past 40 years have failed to demonstrate any benefit from this practice.¹ The role of antimicrobial therapy is limited to acute exacerbations of COPD meeting specific criteria.

Expectorants and Mucohydics

Adequate water intake generally is acceptable to maintain hydration and assist in the removal of airway secretions. Beyond this, the regular use of mucolytics or expectorants for COPD patients has no proven benefit.¹³⁵ This includes the use of saturated solutions of potassium iodide, ammonium chloride, acetylcysteine, and guaifenesin. In 2007, the FDA announced its intention to take action against several companies marketing unapproved timed-released formulations of guaifenesin. Two formulations are approved by the FDA (Humibid and Mucinex); however, data are lacking on their benefit.

Narcotics

Systemic (oral and parenteral) opioids, especially morphine, can relieve dyspnea in patients with endstage COPD. Nebulized therapy is sometimes used in clinical practice although data about clinical benefit are lacking.¹³⁶ Opioids should be used carefully, if at all, to avoid adverse effects on ventilatory drive.

Respiratory Stimulants

There is no role for respiratory stimulants in the long-term management of COPD.¹ Agents that have shown some usefulness in the acute setting include almitrine and doxapram. However, almitrine is available only in Europe, and its usefulness is limited by neurotoxicity. Doxapram is available for intravenous use only and may be no better than intermittent NPPV.

SURGICAL INTERVENTION

Various surgical options have been employed in the management of COPD. These include bullectomy, lung volume reduction surgery (LVRS), and lung transplantation. Bullectomy has been performed for many years and may be useful when large bullae (>1 cm) are noted on computed tomographic scan. The presence of bullae may contribute to complaints of dyspnea and their removal can improve lung function and reduce symptoms, although there is no evidence of a mortality benefit. Because of the prevalence of COPD, it is the most frequent indication for lung transplantation. Intervention is considered when predicted survival is less than 2 years, FEV₁ is <25% predicted, and hypoxemia, hypercapnia, and pulmonary hypertension exists despite medical management.² Experience to

date shows 2-year survival of 65% to 90%, and 5-year survival of 41% to 53%.

Recent trials have evaluated the effect of bilateral LVRS for management of severe COPD. Short-term trials comparing the effects of pulmonary rehabilitation plus LVRS with pulmonary rehabilitation alone reported that the combination of treatments resulted in greater improvements in lung function, gas exchange, and quality of life at 3 months. Only recently have data evaluating the long-term effect of LVRS compared with pulmonary rehabilitation been published. The National Emphysema Treatment Trial, a prospective, randomized trial evaluating the long-term effects of LVRS plus pulmonary rehabilitation compared with pulmonary rehabilitation alone, followed 1,218 patients for 3 years.¹³⁷ The primary end points for the study were mortality and maximal exercise capacity 2 years after randomization. Secondary end points included pulmonary function, distance walked in 6 minutes, and quality-of-life measurements. At an interim analysis, patients with an FEV₁ of less than 20% of predicted or a carbon monoxide diffusing capacity of less than 20% of predicted were noted to be at high risk of death after surgery and subsequently were excluded from the study. Results of the study showed no mortality benefit with LVRS compared with pulmonary rehabilitation alone. Patients undergoing surgery had improved exercise capacity, lung function, and quality of life at 2 years, but these patients also had a higher risk of short-term morbidity and mortality associated with the surgery. A subgroup analysis of the study noted that patients with predominately upper-lobe emphysema and low exercise capacity undergoing surgery had lower mortality rates at 2 years compared with patients treated with medical therapy alone. Because of the costs and risks associated with LVRS, more studies are needed to better determine the ideal surgical candidates and identify subgroups of patients who would benefit most from surgery.

■ DIETARY SUPPLEMENTS

There is increasing interest in the role of antioxidants, including vitamins E and C and β -carotene, in reducing the frequency of exacerbations. It is postulated that they may be beneficial in COPD as a result of an imbalance between oxidants and antioxidants that has been considered in the pathogenesis of smoking-induced lung disease. However, there is no good evidence that antioxidant therapies improve COPD symptoms or slow disease progression.

■ INVESTIGATIONAL THERAPIES

Based on the knowledge about the importance of neutrophilic inflammation in COPD and potential therapeutic benefit of inhibition of neutrophil activity, a number of antiinflammatory compounds are being explored. Specifically, agents inhibiting leukotriene B₄, neutrophil elastase, and phosphodiesterases currently are being evaluated. To date, studies evaluating leukotriene-modifying therapies have been disappointing. Further studies are needed to evaluate the clinical benefit of such inhibitors in patients with COPD.

Phosphodiesterase-4 is the major phosphodiesterase found in airway smooth muscle cells and inflammatory cells and is responsible for degrading cyclic adenosine monophosphate. Inhibition of phosphodiesterase-4 results in relaxation of airway smooth muscle cells and decreased activity of inflammatory cells and mediators such as tumor necrosis factor- α and interleukin-8. Two phosphodiesterase-4 inhibitors have reached clinical trials—cilomilast and roflumilast. Cilomilast has been evaluated in several human trials and has been shown to improve expiratory airflow as measured by FEV₁ in patients with COPD when given at a dose of 15 mg twice daily for 6 weeks. To date, the results of clinical trials investigating these agents have been modest. Future studies of these agents

should evaluate effects on other clinical outcomes such as health status, exacerbation frequency, and progression of disease.

Neutrophil elastase is implicated in the induction of bronchial disease, causing structural changes in lungs, impairment of mucociliary clearance, and impairment of host defenses. Protease inhibitors, namely, inhibitors of neutrophil elastase, are being investigated currently for the treatment of COPD.

Results have been disappointing in evaluating the benefit of infliximab, a tumor necrosis factor- α blocker, in treating COPD. A total of 234 patients with moderate to severe COPD received either infliximab 3 mg/kg or 5 mg/kg, or placebo at baseline, 2, 6, 12, 18, and 24 weeks. Subjects completed a quality-of-life questionnaire (Chronic Respiratory Questionnaire) during treatment and out to 44 weeks. There were no differences on the Chronic Respiratory Questionnaire, or on any secondary end points, including lung function, exercise capacity, or exacerbation rates. The discontinuation rate as a consequence of adverse events was high (20% to 27%) in the active-treatment group.¹³⁸

PHARMACOECONOMIC CONSIDERATIONS

The overall cost of therapy is an important consideration in contemporary medical practice. Meaningful cost analysis goes beyond the cost of the medication itself and incorporates the impact of a given therapeutic agent on overall healthcare cost. Because of the relative lack of benefit among objective outcome measures in COPD clinical trials, pharmacoeconomic studies can be useful in decision making about pharmacotherapy options. Pharmacoeconomic analyses in COPD, although limited, are available regarding antibiotic use in acute exacerbations and some therapies for management of chronic stable COPD.

The costs of managing an acute exacerbation of COPD in the ambulatory setting was evaluated in more than 2,400 patients. Subjects were followed for 1 month following the diagnosis of the exacerbation. The overall relapse rate was 21%, with 31% and 16% of subjects requiring care in the emergency department and hospital, respectively. The overall costs for exacerbation treatment averaged \$159, with 58% attributed to hospitalization.¹³⁹ These authors concluded that a significant cost savings would result from improving the successful ambulatory management of acute exacerbations.

Grossman et al. conducted a trial investigating the use of aggressive antimicrobial therapy (ciprofloxacin), comparing it with usual antibiotic therapy (defined as any nonquinolone) in the treatment of acute exacerbations of COPD.¹⁴⁰ Overall, the results indicated no preference for either treatment arm. However, in patients who were categorized as high risk (severe underlying lung disease, more than four exacerbations per year, duration of bronchitis longer than 10 years, elderly, significant comorbid illness), the use of aggressive antibiotic therapy was associated with improved clinical outcome, higher quality of life, and fewer costs. The results of this study are consistent with Table 29-14, which suggests that higher-risk patients are likely to have more resistant strains of organisms and thus require more aggressive antimicrobial treatment.

Friedman et al. conducted a post hoc pharmacoeconomic evaluation of two multicenter, randomized trials comparing the combination of ipratropium and albuterol with both drugs used as monotherapy.¹⁴¹ Patients who received a combination of ipratropium and albuterol had lower rates of exacerbations, lower overall treatment costs, and improved cost-effectiveness compared with either drug used alone. With the introduction of new bronchodilator therapies, and with no clearly consistent advantage of one class of agents over another, pharmacoeconomic analyses may be useful for clinicians in determining the most appropriate therapy for their patients.

CLINICAL CONTROVERSIES

Albuterol is one of the most commonly prescribed medications in the United States. Albuterol is a 50/50 racemic mixture of (*R*)-albuterol and (*S*)-albuterol, with the (*R*)-isomer responsible for all the therapeutic effect. A single-isomer product, levalbuterol, claims clinical superiority based on the absence of the (*S*)-isomer, which may have detrimental effects in the airway and antagonistic effects on the active isomer. However, the acquisition cost of levalbuterol is significantly higher than that of generic albuterol. The advantages of using the single-isomer product in clinical practice are not clear and require further investigation.

A combination product of a long-acting inhaled β -agonist (salmeterol) and an inhaled corticosteroid agent (fluticasone) is one of the most commonly prescribed medications for lung disease, including COPD. However, in expert guidelines, inhaled corticosteroids are indicated only for patients with more severe disease who experience frequent exacerbations. Many patients now receiving therapy with the combination inhaler may be candidates for bronchodilator therapy alone, although the benefit of inhaled corticosteroids continues to be a focus of clinical research, including the potential for a mortality benefit.

The role of systemic corticosteroids for acute exacerbations of COPD has been clarified in recent years. However, the appropriate dosage regimen is not well established. Regimens range from initial high doses (methylprednisolone 125 mg every 6 hours) to more conservative dosing (prednisone 40 to 60 mg/day). Consensus guidelines indicate that bronchodilator therapy is the focus of pharmacotherapy for COPD. However, there is no clear choice for the initial agent. For patients with daily but not persistent symptoms, either ipratropium or albuterol offers advantages as initial therapy. Both also have limitations if chosen as the initial therapy.

International guidelines recommend long-acting bronchodilator therapy in patients with moderate to very severe disease, or who when symptoms are not adequately managed with short-acting agents or as needed therapy. When response to a single long-acting bronchodilator is not optimal, guidelines recommend the use of combinations. However, data are lacking presently about the therapeutic benefit of combinations of long-acting bronchodilators and this approach is associated with substantial costs.

EVALUATION OF THERAPEUTIC OUTCOMES

To evaluate therapeutic outcomes of COPD effectively, the practitioner must first delineate between chronic stable COPD and acute exacerbations. In chronic stable COPD, pulmonary function tests should be assessed periodically and with any therapy addition, change in dose, or deletion of therapy. Because objective improvements often are minimal, subjective assessments are important. Other outcome parameters are commonly evaluated, including dyspnea score, quality-of-life assessments, and exacerbation rates, including visits to the emergency department or hospitalization. In acute exacerbations of COPD, white blood cell count, vital signs, chest radiography, and changes in frequency of dyspnea, sputum volume, and sputum purulence should be assessed at the onset and throughout treatment of an exacerbation. In more severe exacerbations, ABGs and oxygen saturation also should be monitored. As with any drug therapy, patient adherence to therapeutic regimens, side effects, potential drug interactions, and subjective measures of quality of life also must be evaluated.

END-OF-LIFE CARE

Based on the natural course of COPD, characterized by the progressive decline in lung function, and development of complications, consideration should be given to end-of-life decisions and advanced directives.¹⁴² Factors associated with expected mortality within 1 year have been identified and include older age, diagnosis of depression, declining overall health status, hypercapnia, an FEV₁ of less than 30% predicted, ability to walk only a few steps without resting, more than one emergent hospitalization in the past year, and the presence of comorbidities, including congestive heart failure. An effective strategy to discuss end-of-life care involves the patient's participation in identifying advanced directives. Patients should be assured that symptoms, including pain, will be managed, and their dignity will be preserved. Specific issues that should be addressed include location and provider for terminal care, desires to use or withhold mechanical ventilation, and involvement of other family members in decisions on behalf of the patient.

ROBERT L. TALBERT, REBECCA BOUDREAUX, AND REBECCA L. OWENS

KEY CONCEPTS

- 1 Pulmonary arterial hypertension (PAH) may be defined as a mean pulmonary artery pressure (PAPm) ≥ 25 mm Hg at rest with a pulmonary wedge pressure (also known as pulmonary artery occlusion pressure) ≤ 15 mm Hg measured by cardiac catheterization.
- 2 Idiopathic PAH (IPAH) is one of the most common forms of PAH. Fortunately, it is generally more responsive to therapy than secondary forms of PAH.
- 3 PAH is uncommon but increasing in prevalence.
- 4 The underlying cause of PAH is a complicated amalgam of endothelial cell dysfunction, a procoagulant state, platelet activation, constricting factors, loss of relaxing factors, cellular proliferation, hypertrophy, fibrosis and inflammation
- 5 PAH presents with exertional dyspnea, fatigue, weakness, complaints of general exertion intolerance, dyspnea at rest as the disease progresses, anginal chest pain, syncope.
- 6 Right-heart catheterization provides important prognostic information and can be used to assess pulmonary vasoreactivity prior to initiating therapy.
- 7 The goals of treatment are alleviation of symptoms, improvement in the quality of life, prevention of disease progression, and improvement in survival.
- 8 The general principle of PAH treatment is to attempt to correct the imbalance between vasoconstriction and vasodilation and prevent adverse thrombotic events to improve oxygenation and quality of life.
- 9 Nonpharmacologic therapy is frequently used to address comorbid conditions that often accompany PAH.
- 10 General care interventions in PAH include oral anticoagulants, diuretics, oxygen, and digoxin.
- 11 A small number of patients with IPAH who demonstrate a favorable response to acute vasodilator testing will do well with calcium channel blockers.

- 12 Sildenafil is a potent and highly specific phosphodiesterase-5 inhibitor that has been shown to reduce PAPm and improve functional class.
- 13 Prostacyclin analogs such as epoprostenol, treprostinil and iloprost induce potent vasodilation of all vascular beds.
- 14 Endothelin antagonists, bosentan and ambrisentan, improve exercise capacity, hemodynamics, and functional class in PAH.
- 15 Combination therapy in PAH may address more than one mechanism causing this disease. Combination therapy in uncontrolled trials has provided additional benefit (but at the risk of increased side effects).

1 Pulmonary arterial hypertension (PAH) may be defined as a mean pulmonary artery pressure (PAPm) ≥ 25 mm Hg at rest with a pulmonary wedge pressure (also known as pulmonary artery occlusion pressure) ≤ 15 mm Hg measured by cardiac catheterization.¹ PAH is a disorder that may occur either in the setting of a variety of underlying medical conditions or as a disease that uniquely affects the pulmonary circulation. Historically, medical treatment of PAH has been difficult. Idiopathic PAH (IPAH) was formerly known as primary pulmonary hypertension and carried a poor prognosis (median survival 2.8 years) through the mid-1980s.² Prior to the availability of disease-specific or targeted drug therapy for IPAH, survival rates for 1, 3, and 5 years were 68%, 48%, and 34%, respectively.³ Others have found similar survival rates in registry studies.^{4,5} Since then a number of new therapeutic options have been developed which address this difficult to treat disease. 2 PAH may be classified into several types depending on etiology and diseases. Several sets of guidelines exist to aid clinicians in diagnosis and management of PAH.^{1,2,6-9}

EPIDEMIOLOGY

3 The prevalence of PAH is estimated to be 50,000 to 100,000 individuals in the United States.⁶ Unfortunately, only 15,000 to 20,000 of the afflicted patients have an established diagnosis of PAH and are currently receiving treatment. In a French registry study of more than 600 patients with PAH, Humbert et al. found that the most common cause of PAH was IPAH (approximately 40%) followed by PAH associated with connective tissue diseases (15.3%), congenital heart disease (11.3%), portal hypertension (10.4%), and familial PAH (FPAH) (3.9%).⁵ Based on autopsy findings, PAH was found to occur in 0.13% of all patients autopsied and was more commonly found if patients had cirrhosis (0.73%).⁷ (Through extrapolation of these autopsy findings to the entire U.S. population, there may be well over 1 million individuals with PAH in this country.)

Drug-Induced Pulmonary Diseases

HENGAMEH H. RAISSY, MICHELLE HARKINS, AND PATRICIA L. MARSHIK

KEY CONCEPTS

- 1 Select populations may be more susceptible to toxicities associated with specific agents.
- 2 Primary treatment is discontinuation of the offending agent and supportive care.

The manifestations of drug-induced pulmonary diseases span the entire spectrum of pathophysiologic conditions of the respiratory tract. As with most drug-induced diseases, the pathologic changes are nonspecific. Therefore, the diagnosis is often difficult and, in most cases, is based on exclusion of all other possible causes. In addition, the true incidence of drug-induced pulmonary disease is difficult to assess as a result of the pathologic nonspecificity and the interaction between the underlying disease state and the drugs.

Considering the physiologic and metabolic capacity of the lung, it is surprising that drug-induced pulmonary disease is not more common. The lung is the only organ of the body that receives the entire circulation. In addition, the lung contains a heterogeneous population of cells capable of various metabolic functions, including *N*-alkylation, *N*-dealkylation, *N*-oxidation, reduction of *N*-oxides, and *C*-hydroxylation.

Evaluation of epidemiologic studies on adverse drug reactions provides a perspective on the importance of drug-induced pulmonary disease. In a 2-year prospective survey of a community-based general practice, 41% of 817 patients experienced adverse drug reactions.¹ Four patients, or 0.5% of the total respondents, experienced adverse respiratory symptoms. Respiratory symptoms occurred in 1.2% of patients experiencing adverse drug reactions. In a recent retrospective analysis of clinical case series in France, 898 patients had reported drug allergy, with a bronchospasm incidence of 6.9%. When these patients were rechallenged with the suspected drug, only 241 (17.6%) tested positive. The incidence of bronchospasm in patients with positive provocation test was 7.9%.²

Adverse pulmonary reactions are uncommon in the general population but are among the most serious reactions, often requiring intervention. In a study of 270 adverse reactions leading to hospitalization from two populations, 3.0% were respiratory in nature.³ Of the reactions considered to be life-threatening, 12.3% were respiratory. An early report on death caused by drug reactions from the Boston Collaborative Drug Surveillance Program indicated that 7 of 27 drug-induced deaths were respiratory in nature.⁴

This was confirmed in a followup study in which 6 of 24 drug-induced deaths were respiratory in nature.⁵

DRUG-INDUCED APNEA

Apnea may be induced by central nervous system depression or respiratory neuromuscular blockade (Table 31-1). Patients with chronic obstructive airway disease, alveolar hypoventilation, and chronic carbon dioxide retention have an exaggerated respiratory depressant response to narcotic analgesics and sedatives. In addition, the injudicious administration of oxygen in patients with carbon dioxide retention can worsen ventilation-perfusion mismatching, producing apnea.⁶ Although the benzodiazepines are touted as causing less respiratory depression than barbiturates, they may produce a profound additive or synergistic effect when taken in combination with other respiratory depressants. Combining intravenous diazepam with phenobarbital to stop seizures in an emergency department frequently results in admissions to an intensive care unit for a short period of assisted mechanical ventilation, regardless of the drug administration rate. Too rapid intravenous administration of any of the benzodiazepines, even without coadministration of other respiratory depressants, will result in apnea. The risk appears to be the same for the various available agents (diazepam, lorazepam, and midazolam). Respiratory depression and arrests resulting in death and hypoxic encephalopathy have occurred following rapid intravenous administration of midazolam for conscious sedation prior to medical procedures. 1 This has been reported more commonly in the elderly and the chronically debilitated or in combination with opioid analgesics. Concurrent use of inhibitors of cytochrome P450 3A4 with benzodiazepines are likely to lead to greater risk of respiratory depression.

1 Prolonged apnea may follow administration of any of the neuromuscular blocking agents used for surgery, particularly in patients with hepatic or renal dysfunction. In addition, persistent neuromuscular blockade and muscle weakness have been reported in critically ill patients who are receiving neuromuscular blockers continuously for more than 2 days to facilitate mechanical ventilation.⁷ This has resulted in delayed weaning from mechanical ventilation and prolonged intensive care unit stays. The prolonged neuromuscular blockade has been confined principally to pancuronium and vecuronium in patients with renal disease. Both agents have pharmacologic active metabolites that are excreted renally. The persistent muscular weakness is less well defined but appears to represent an acute myopathy.⁷ High-dose corticosteroids appear to produce a synergistic effect, supported by animal studies showing that corticosteroids at dosages ≥ 2 mg/kg per day of prednisone produce atrophy in denervated muscle.⁸ The fluorinated corticosteroids (e.g., triamcinolone) appear to be more myopathic.⁹ Dose-dependent respiratory muscle weakness has been reported in chronic obstructive pulmonary disease (COPD) and asthma patients receiving repeated short courses of oral prednisone in the previous 6 months.¹⁰

Diuretics	I
Aminocaproic acid	R
Clofibrate	R

F, Frequent; I, infrequent; R, rare.

Respiratory failure has been known to occur following local spinal anesthesia. Apnea from respiratory paralysis and rapid respiratory muscle fatigue has followed the administration of polymyxin and aminoglycoside antibiotics.⁶ The mechanism appears to be related to the complexation of calcium and its depletion at the myoneural junction. Intravenous calcium chloride has been variably effective in reversing the paralysis.⁶ The aminoglycosides competitively block neuromuscular junctions. This has resulted in life-threatening apnea when neomycin, gentamicin, streptomycin, or bacitracin has been ① administered into the peritoneal and pleural cavities.⁶ The aminoglycosides will produce an additive blockade and ventilatory paralysis with curare or succinylcholine and in patients with myasthenia gravis or myasthenic syndromes.⁶ Intravenous administration of aminoglycosides has resulted in respiratory failure in babies with infantile ② botulism. Treatment consists of ventilatory support and administration of an anticholinesterase agent (neostigmine or edrophonium).⁶

DRUG-INDUCED BRONCHOSPASM

Bronchoconstriction is the most common drug-induced respiratory problem. Bronchospasm can be induced by a wide variety of drugs through a number of disparate pathophysiologic mechanisms ① (Table 31-2). Regardless of the pathophysiologic mechanism, drug-induced bronchospasm is almost exclusively a problem of patients with preexisting bronchial hyperreactivity (e.g., asthma, chronic obstructive lung disease).¹¹ By definition, all patients with nonspecific bronchial hyperreactivity will experience bronchospasm if given sufficiently high doses of cholinergic or anticholinesterase agents. Severe asthmatics with a high degree of bronchial reactivity may wheeze following the inhalation of a number of particulate substances, such as the lactose in dry-powder inhalers and inhaled corticosteroids, presumably through direct stimulation of the central airway irritant receptors. Other pharmacologic mechanisms for inducing bronchospasm include β_2 -receptor blockade and nonim-

munologic histamine release from mast cells and basophils.¹¹ A large number of agents are capable of producing bronchospasm through immunoglobulin (Ig) E-mediated reactions.¹¹ These drugs can become a significant occupational hazard for pharmacists, nurses, and pharmaceutical industry workers.¹¹

Epidemiologic studies demonstrate an increase in the prevalence of asthma and COPD with increased use of acetaminophen. The use

of aspirin or ibuprofen is not associated with asthma or COPD. The acetaminophen–asthma/COPD association may be explained by reduction of glutathione, an endogenous antioxidant enzyme in the airway epithelial lining fluid, with high doses of acetaminophen resulting in oxidant damage in the lung.¹²

ASPIRIN-INDUCED BRONCHOSPASM

Aspirin sensitivity or intolerance occurs in 4% to 20% of all asthmatics.¹³ The frequency of aspirin-induced bronchospasm increases with age. Patients older than age 40 years have a frequency approximately four times that of patients younger than 20 years.¹³ The frequency increases to 14% to 23% in patients with nasal polyps.¹³ Women predominate over men, and there is no evidence for a genetic or familial predisposition.¹⁴

The classic description of the aspirin-intolerant asthmatic includes the triad of severe asthma, nasal polyps, and aspirin intolerance. The typical patient experiences intense vasomotor rhinitis, which may or may not be associated with aspirin exposure, beginning during the third or fourth decade of life.¹⁵ Over a period of months, nasal polyps begin to appear, followed by severe asthma exacerbated by aspirin. Bronchospasm typically begins within minutes to hours following ingestion of aspirin and is associated with rhinorrhea, flushing of the head and neck, and conjunctivitis.¹⁵ The reactions are severe and often life-threatening.

All aspirin-sensitive asthmatics do not fit the classic “aspirin triad” picture, and not all patients with asthma and nasal polyps develop sensitivity to aspirin.¹⁴ In most cases, aspirin-sensitive asthmatics are clinically indistinguishable from the general population of asthmatics except for their intolerance to aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs). Aspirin-induced asthmatics are not at higher risk of having fatal asthma if aspirin and other NSAIDs are avoided.¹⁶

Diagnosis of aspirin-induced asthma requires a detailed medical history. The definitive diagnosis is made by aspirin provocation tests, which may be done via different routes.^{14,17} An oral provocation test is used commonly where threshold doses of aspirin induce a positive reaction measured by a drop in forced expiratory volume in the first second of expiration (FEV₁) and/or the presence of symptoms.^{17,18} A nasal provocation test is done by the application of one dose of lysine-aspirin, and aspirin sensitivity is manifested with clinical symptoms of watery discharge and a significant fall in inspiratory nasal flow.^{17,18} When lysine-aspirin bronchoprovocation was compared with oral aspirin provocation, both methods were equally sensitive.¹⁹

PATHOGENESIS

Aspirin-induced asthma is correctly classified as an idiosyncratic reaction in that the pathogenesis is still unknown. Patients with aspirin intolerance have increased plasma histamine concentrations after ingestion of aspirin and elevated peripheral eosinophil counts.^{14,15} All attempts to define an immunologic mechanism have been unsuccessful. Chemically similar drugs such as salicylamide and choline salicylate do not cross-react, whereas a large number of chemically dissimilar NSAIDs do produce reactions.^{14,15} Table 31–3 lists the analgesics that do and do not cross-react with aspirin.

The currently accepted hypothesis of aspirin-induced asthma is that aspirin intolerance is integrally related to inhibition of cyclooxygenase. This is supported by the following evidence: (a) All NSAIDs that inhibit cyclooxygenase produce reactions, (b) the degree of cross-reactivity is proportional to the potency of cyclooxygenase inhibition, and (c) each patient with aspirin sensitivity has a threshold dose for precipitating bronchospasm that is specific for the degree of cyclooxygenase inhibition produced, and once established, the dose of another cyclooxygenase inhibitor needed to induce bronchospasm can be estimated.¹⁵

TABLE 31-3 Tolerance of Antiinflammatory and Analgesic Drugs in Aspirin-Induced Asthma

Cross-Reactive Drugs	Drugs with No Cross-Reactivity
Diclofenac	Acetaminophen ^a

^aA very small percentage (5%) of aspirin-sensitive patients react to acetaminophen and phenacetin.

The mechanism by which cyclooxygenase inhibition produces bronchospasm in susceptible individuals is unknown. Arachidonic acid metabolism through the 5-lipoxygenase pathway may lead to the excess production of leukotrienes C₄ and D₄.¹⁶ Leukotrienes C₄, D₄, and E₄ produce bronchospasm and promote histamine release from mast cells.¹⁵ The precise mechanism by which augmented leukotriene production occurs is unknown, and available hypotheses do not explain why only a small number of asthmatic patients react to aspirin and NSAIDs.

DESENSITIZATION

Patients with aspirin sensitivity can be desensitized. The ease of desensitization correlates with the sensitivity of the patient.¹⁵ Highly sensitive patients who react initially to less than 100 mg aspirin require multiple rechallenges to produce desensitization.¹⁴ Desensitization usually persists for 2 to 5 days following discontinuance, with full sensitivity reestablished within 7 days.¹⁴ Cross-desensitization has been established between aspirin and all NSAIDs tested to date. Because patients may experience life-threatening reactions, desensitization should be attempted only in a controlled environment by personnel with expertise in handling these patients. In addition, there are reports of patients who have failed to maintain a desensitized state despite continued aspirin administration.¹⁴ In one open followup trial in 172 aspirin-sensitive asthmatics who had undergone desensitization and continued daily aspirin treatment (1,300 mg/day) an improvement in nasal-sinus and asthma symptoms occurred after 6 months of treatment, which persisted up to 5 years.²⁰

CROSS-SENSITIVITY WITH FOOD AND DRUG ADDITIVES

1 Up to 80% of aspirin-sensitive asthmatics will have an adverse reaction to the yellow azo dye tartrazine (FD&C Yellow No. 5), which is used widely for coloring foods, drinks, drugs, and cosmetics.¹³ However, the studies reporting high cross-reactivity were poorly controlled and often used only subjective criteria.^{13,21} In double-blind, placebo-controlled trials using pulmonary function testing, sensitivity to tartrazine has proved to be a rare event.²¹ Tartrazine sensitivity appears to occur only in aspirin-intolerant patients at a prevalence of 2%.²¹ Although rare, owing to the severity of reaction and widespread use of tartrazine, the U.S. Food and Drug Administration (FDA)

requires labeling for the products containing this dye.²² The likely mechanism is dose-related histamine release, and the clinical presentation is the same as the reaction to aspirin in aspirin-sensitive patients.²²

Reactions to other azo dyes, monosodium glutamate, parabens, and nonazo dyes have been reported much less frequently than reactions to tartrazine and have been equally difficult to confirm with controlled challenges.²¹ Positive reactions to sodium benzoate, a food preservative, have been reported in as many as 23% of aspirin-sensitive individuals.¹³ Acetaminophen is a weak inhibitor of cyclooxygenase. As such, approximately 5% of aspirin-sensitive asthmatics will experience reactions to acetaminophen.¹³ Most aspirin-sensitive asthmatics can use acetaminophen as a safe alternative to aspirin. There is a growing body of evidence that selective cyclooxygenase-2 inhibitors may be used safely in aspirin-sensitive patients,^{23–26} but long-term studies with these agents should be undertaken to confirm their safe use in aspirin-sensitive patients. At this point, the package inserts of these agents state that they are contraindicated for aspirin-sensitive asthmatics.^{23–26} Sporadic cases of worsening bronchospasm and anaphylaxis have been reported in aspirin-sensitive asthmatics receiving intravenous hydrocortisone succinate, but such reactions have not been reported with use of other corticosteroids.¹⁴ It is not known whether it is the hydrocortisone or the succinate that is the problem.

TREATMENT

Aspirin-Sensitive Asthma

② Therapy of aspirin-sensitive asthmatics takes one of two general approaches: desensitization or avoidance. Avoidance of triggering substances seldom alters the clinical course of patients' asthma. The therapy of asthma has been nonspecific; however, in theory, 5-lipoxygenase inhibitors such as zileuton or leukotriene antagonists should provide specific therapy. A few studies have investigated use of leukotriene modifiers to prevent aspirin-induced bronchospasm in aspirin-sensitive asthmatic patients.^{27–29} Pretreatment with zileuton in eight aspirin-sensitive asthmatic patients protected them from the same threshold-provoking doses of aspirin.²⁷ However, larger, escalating doses of aspirin above the threshold challenge doses were not examined in this study. Furthermore, when doses of aspirin were escalated above the threshold provocative doses, zileuton did not prevent formation of leukotrienes.²⁸ In a similar study, pretreatment with montelukast 10 mg/day did not protect patients when aspirin doses were increased above their threshold doses.²⁹ In another study, the mean provoking dose of aspirin did not differ in the asthmatics who were taking leukotriene modifiers and the control group (60.4 mg vs. 70.3 mg, respectively).³⁰ Although initial studies suggested that leukotriene modifiers blocked aspirin-induced reactions, it is now apparent that they merely shift the dose–response curve to the right, leaving the patient at risk at higher doses. Thus even patients who might benefit from leukotriene modifiers should avoid aspirin and all NSAIDs. A case of ibuprofen 400-mg–induced asthma was reported in an asthmatic patient on zafirlukast 20 mg twice daily.³¹ Furthermore, most of the challenge studies are based on incremental doses of aspirin or NSAIDs, and exposure of patients to full clinical doses of aspirin or NSAIDs can overcome the antagonistic effect of leukotriene modifiers. The respiratory symptoms can be decreased but not prevented by pretreatment with antihistamines, cromolyn, and nedocromil.^{14,32} The long-term asthma control of patients with aspirin sensitivity does not differ from that for other asthmatics. There is no evidence to support that aspirin-sensitive asthmatics respond better to leukotriene modifiers. In a double-blind, randomized, placebo-controlled study, aspirin-sensitive asthmatic patients on montelukast showed a 10% improvement in FEV₁ compared with the placebo group.³³ Similar results were reported when montelukast was compared with placebo in patients with intermittent or persistent asthma.³⁴

β-BLOCKERS

① β-Adrenergic receptor blockers comprise the other large class of drugs that can be hazardous to a person with asthma. Even the more cardioselective agents such as acebutolol, atenolol, and metoprolol have been reported to cause asthma attacks.¹¹ Patients with asthma may take nonselective and β₁-selective blockers without incident for long periods; however, the occasional report of fatal asthma attacks resistant to therapy with β-agonists should provide ample warning of the dangers inherent in β-blocker therapy.¹¹

If a patient with bronchial hyperreactivity requires β-blocker therapy, one of the selective β₁-blockers (e.g., acebutolol, atenolol, metoprolol, or pindolol) should be used at the lowest possible dose. Celiprolol and betaxolol appear to possess greater cardioselectivity than currently marketed drugs.^{35,36} Fatal status asthmaticus has occurred with the topical administration of the nonselective timolol maleate ophthalmic solution for the treatment of open-angle glaucoma.³⁷ Early investigations with ophthalmic betaxolol suggest that it is well tolerated even in timolol-sensitive asthmatics.^{38,39}

SULFITES

Severe, life-threatening asthmatic reactions following consumption of restaurant meals and wine have occurred secondary to ingestion of the food preservative potassium metabisulfite.²¹ Sulfites have been used for centuries as preservatives in wine and food. As antioxidants, they prevent fermentation of wine and discoloration of fruits and vegetables caused by contaminating bacteria.⁴⁰ Previously, sulfites had been given “generally recognized as safe” status by the FDA. Sensitive patients react to concentrations ranging from 5 to 100 mg, amounts that are consumed routinely by anyone eating in restaurants. Consumption of sulfites in U.S. diets is estimated to be 2 to 3 mg/day in the home with 5 to 10 mg per 30 mL of beer or wine consumed.²¹ Anaphylactic or anaphylactoid reactions to sulfites in nonasthmatics are extremely rare. In the general asthmatic population, reactions to sulfites are ① uncommon. Approximately 5% of steroid-dependent asthmatics demonstrate sensitivity to sulfiting agents, but the prevalence is only around 1% in non-steroid-dependent asthmatic patients.⁴⁰

MECHANISM

Three different mechanisms have been proposed to explain the reaction to sulfites in asthmatic patients.⁴⁰ The first is explained by the inhalation of sulfur dioxide, which produces bronchoconstriction in all asthmatics through direct stimulation of afferent parasympathetic irritant receptors. Furthermore, inhalation of atropine or the ingestion of doxepin protects sulfite-sensitive patients from reacting to the ingestion of sulfites. The second theory, IgE-mediated reaction, is supported by reported cases of sulfite-sensitive anaphylaxis reaction in patients with positive sulfite skin test. Finally, a reduced concentration of sulfite oxidase enzyme (the enzyme that catalyzes oxidation of sulfites to sulfates) compared with normal individuals has been demonstrated in a group of sulfite-sensitive asthmatics.

A number of pharmacologic agents contain sulfites as preservatives and antioxidants. The FDA now requires warning labels on drugs containing sulfites. Most manufacturers of drugs for the treatment of asthma have discontinued the use of sulfites. In addition, labeling is required on packaged foods that contain sulfites at 10 parts per million or more, and sulfiting agents are no longer allowed on fresh fruits and vegetables (excluding potatoes) intended for sale.

Pretreatment with cromolyn, anticholinergics, and cyanocobalamin have protected sulfite-sensitive patients.^{40,41} Presumably, pharmacologic doses of vitamin B₁₂ catalyze the nonenzymatic oxidation of sulfite to sulfate.

OTHER PRESERVATIVES

Both ethylenediamine tetraacetic acid (EDTA) and benzalkonium chloride, used as stabilizing and bacteriostatic agents, respectively, can produce bronchoconstriction.⁴² In addition to producing bronchoconstriction, EDTA potentiates the bronchial responsiveness to histamine.⁴² These effects presumably are mediated through calcium chelation by EDTA. Benzalkonium chloride is more potent than EDTA, and its mechanism appears to be a result of mast cell degranulation and stimulation of irritant C fibers in the airways.⁴²

The bronchoconstriction from benzalkonium chloride can be blocked by cromolyn but not the anticholinergic ipratropium bromide.⁴³ Benzalkonium chloride is found in the commercial multiple-dose nebulizer preparations of ipratropium bromide and beclomethasone dipropionate marketed in the United Kingdom and Europe and is presumed to be in part responsible for paradoxical wheezing following administration of these agents.^{42–44} Benzalkonium chloride is also found in albuterol nebulizer solutions marketed in the United States and has been implicated as a possible cause of paradoxical wheezing in infants receiving this preparation.⁴² The effect of these agents on FEV₁ when used in the amount administered for treatment of acute asthma was evaluated in subjects with stable asthma.⁴⁵ Patients were assigned randomly to inhale up to four 600-mcg nebulized doses of EDTA and benzalkonium chloride and normal saline. The change in FEV₁ was not different between EDTA and the placebo group; however, benzalkonium chloride was associated with a statistically significant decrease in FEV₁ compared with placebo. It is important to consider that these agents are always used in combination with bronchodilators and β_2 -agonists, which are potent mast cell stabilizers, and the anecdotal reports have not yet been confirmed with controlled investigations.^{42,43}

CONTRAST MEDIA

Iodinated radiocontrast materials are the most common cause of anaphylactoid reactions producing bronchospasm.⁴⁶ Chapter 91 discusses this topic.

NATURAL RUBBER LATEX ALLERGY

Allergy to natural rubber latex, first reported in 1989 in the United States, is a common cause of occupational allergy for healthcare workers.⁴⁷ Natural rubber is a processed plant product from the commercial rubber tree, *Hevea brasiliensis*.⁴⁸ Latex allergens are proteins found in both raw latex and the extracts used in finished rubber products. Latex gloves are the largest single source of exposure to the protein allergens.⁴⁸

1 The reported prevalence of latex allergy depends on the sample population. In the general population, latex allergy is less than 1%; however, the prevalence increases in healthcare workers to 5% to 15%.⁴⁸ Risk factors for latex allergy include frequent exposure to rubber gloves, history of atopic disease, and presence or history of hand dermatitis. Patients with spina bifida are at an increased risk of latex allergy, with an incidence of 24% to 60% as a result of early and repeated exposure to rubber devices during the surgical procedures.⁴⁸

Clinical manifestations of latex allergy range from contact dermatitis and urticaria, rhinitis and asthma, and reported cases of anaphylaxis.^{47,48} The early manifestation of rubber allergy is contact urticaria, which is an IgE-mediated reaction to rubber proteins following direct contact with the medical devices: mainly rubber gloves.⁴⁸ Contact dermatitis may occur within 1 to 2 days. Contact dermatitis is a cell-mediated delayed-type hypersensitivity reaction to the additive chemical component of rubber products.⁴⁸ Rhinitis and asthma may follow

inhalation of allergens by cornstarch powder used to coat the latex gloves. Asthma caused by occupational exposure is seen mostly in atopic patients with histories of seasonal and perennial allergies and asthma.⁴⁸ Isolated cases of wheezing secondary to latex exposure in patients without a history of asthma have also been reported.⁴⁸

The diagnosis of latex allergy is based on the presence of latex-specific IgE, as well as symptoms consistent with IgE-mediated reactions.⁴⁹ The mainstay of therapy for latex allergy is avoidance. The FDA requires appropriate labeling for all medical devices containing natural rubber latex to ensure avoidance and a latex-free environment. The role of pretreatment with antihistamines, corticosteroids, and allergen immunotherapy remains to be determined.^{48,49} Two randomized, placebo-controlled clinical trials have evaluated the role of specific immunotherapy in the treatment of latex allergy.^{50,51} Although both studies showed an improvement of cutaneous and rhinitis reactions, systemic reactions were observed, and bronchoconstriction did not improve. At this time, immunotherapy remains investigational for the treatment of latex allergy.

ANGIOTENSIN-CONVERTING ENZYME INHIBITOR-INDUCED COUGH

1 Cough has become a well-recognized side effect of angiotensin-converting enzyme (ACE) inhibitor therapy. According to spontaneous reporting by patients, cough occurs in 1% to 10% of patients receiving ACE inhibitors, with a preponderance of females. In a retrospective analysis, 14.6% of women had cough compared with 6.0% of the men on ACE inhibitors. It is suggested that women have a lower cough threshold, resulting in their reporting this adverse effect more commonly than men.⁵² Studies specifically evaluating cough caused by ACE inhibitors report a prevalence of 19% to 25%.^{53,54} Patients receiving ACE inhibitors had a 2.3 times greater likelihood of developing cough than a similar group of patients receiving diuretics.⁵³ Patients with hyperreactive airways do not appear to be at greater risk.⁵⁴ African Americans and Chinese have a higher incidence of cough.⁵² When different disease states were compared, 26% of patients with heart failure had ACE inhibitor-induced cough compared with 14% of those with hypertension.⁵² Cough can occur with all ACE inhibitors.⁵⁵

The cough typically is dry and nonproductive, persistent, and not paroxysmal.⁵⁵ The severity of cough varies from a “tickle” to a debilitating cough with insomnia and vomiting. The cough can begin within 3 days or have a delayed onset of up to 12 months following initiation of ACE inhibitor therapy.⁵⁵ The cough remits within 1 to 4 days of discontinuing therapy but (rarely) can last up to 4 weeks and recur with rechallenge.⁵⁵ Patients should be given a 4-day withdrawal to determine if the cough is induced by ACE inhibitors. The chest radiograph is normal, as are pulmonary function tests (spirometry and diffusing capacity). Bronchial hyperreactivity, as measured by histamine and methacholine provocation, may be worsened in patients with underlying bronchial hyperreactivity such as asthma and chronic bronchitis. However, bronchial hyperreactivity is not induced in others.^{55,56} The cough reflex to capsaicin is enhanced but not to nebulized distilled water or citric acid.⁵⁵

The mechanism of ACE inhibitor-induced cough is still unknown. ACE is a nonspecific enzyme that also catalyzes the hydrolysis of bradykinin and substance P (see Chap. 15) that produce or facilitate inflammation and stimulate lung irritant receptors.⁵⁵ ACE inhibitors also may induce cyclooxygenase to cause the production of prostaglandins. NSAIDs, benzonatate, inhaled bupivacaine, theophylline, baclofen, thromboxane A₂ synthase inhibitor,^{52,57} and cromolyn sodium all have been used to suppress or inhibit ACE inhibitor-induced cough.^{55,58} The cough generally is unresponsive to cough suppressants or bronchodilator therapy. No long-term trials evaluating

different treatment options for ACE inhibitor-induced cough exist. Cromolyn sodium may be considered first because it is the **2** most studied agent and has minimal toxicity.⁵² The preferred therapy is withdrawal of the ACE inhibitor and replacement with an alternative antihypertensive agent. Owing to their decrease in ACE inhibitor-induced side effects, angiotensin II receptor antagonists often are recommended in place of an ACE inhibitor; however, there are rare reports of this agent inducing bronchospasm.⁵⁹ The clinical trials suggest that angiotensin II receptor antagonists have the same incidence of cough as placebo. Furthermore, when angiotensin II receptor antagonists were compared with ACE inhibitors, cough occurred much less frequently. Reduction in the incidence of cough with angiotensin II receptor antagonists is likely caused by the lack of effect on clearance of bradykinin and substance P.⁶⁰ The use of alternative therapies to treat ACE inhibitor-induced cough generally is not recommended.⁵⁵

PULMONARY EDEMA

Pulmonary edema may result from the failure of any of a number of homeostatic mechanisms. The most common cause of pulmonary edema is an increase in capillary hydrostatic pressure because of left ventricular failure. Excessive fluid administration in compensated and decompensated heart failure patients is the most frequent cause of iatrogenic pulmonary edema. Besides hydrostatic forces, other homeostatic mechanisms that may be disrupted include the osmotic and oncotic pressures in the vasculature, the integrity of the alveolar epithelium, interstitial pulmonary pressure, and the interstitial lymph flow.⁶ The edema fluid in cardiogenic pulmonary edema contains a low amount of protein, whereas noncardiogenic pulmonary edema fluid has a high protein concentration.⁶ This indicates that noncardiogenic pulmonary edema results primarily from disruption of the alveolar epithelium.

The clinical presentation of pulmonary edema includes persistent cough, tachypnea, dyspnea, tachycardia, rales on auscultation, hypoxemia from ventilation-perfusion imbalance and intrapulmonary shunting, widespread fluffy infiltrates on chest roentgenogram, and decreased lung compliance (stiff lungs). Noncardiogenic pulmonary edema may progress to hemorrhage; cellular debris collects in the alveoli, followed by hyperplasia and fibrosis with a residual restrictive mechanical defect.⁶

NARCOTIC-INDUCED PULMONARY EDEMA

The most common drug-induced noncardiogenic pulmonary edema is produced by the narcotic analgesics (Table 31-4).⁶ Narcotic-induced pulmonary edema is associated most commonly with intravenous heroin use but also has occurred with morphine, methadone, meperidine, and propoxyphene use.^{6,61} There also have been a few reported cases associated with the use of the opiate antagonist naloxone and nalmefene, a long-acting opioid antagonist.^{62,63} The mechanism is unknown but may be related to hypoxemia similar to the neurogenic pulmonary edema associated with cerebral tumors or trauma or a direct toxic effect on the alveolar capillary membrane.⁶¹ Initially thought to occur only with overdoses, most evidence now supports the theory that narcotic-induced pulmonary edema is an idiosyncratic reaction to moderate as well as high narcotic doses.⁶¹

Patients with pulmonary edema may be comatose with depressed respirations or dyspnea and tachypnea. They may or may not have other signs of narcotic overdose. Symptomology varies from cough and mild crepitations on auscultation with characteristic radiologic findings to severe cyanosis and hypoxemia, even with supplemental oxygen. Symptoms may appear within minutes of intravenous administration but may take up to 2 hours to occur, particularly following oral methadone.⁶¹ Hemodynamic studies in the first 24

hours have demonstrated normal pulmonary capillary wedge pressures in the presence of pulmonary edema.

Clinical symptoms generally improve within 24 to 48 hours and radiologic clearing occurs in 2 to 5 days, but abnormalities in pulmonary function tests may persist for 10 to 12 weeks. Therapy consists of naloxone administration, supplemental oxygen, and ventilatory support if required. Mortality is less than 1%.⁶¹

Cough has been reported with intravenous administration of fentanyl.⁶⁴ A cohort of 1,311 adult patients undergoing elective surgery had 120 patients with vigorous cough within 20 seconds after administration of fentanyl.⁶⁴ The cough was associated with young age and absence of cigarette smoking.⁶⁴ Among anesthetic factors, it was associated with the absence of epidurally administered lidocaine and the absence of a priming dose of vecuronium.⁶⁴ A history of asthma or COPD had no predictive effect.⁶⁴ Further clinical trials are required to understand the mechanism of paradoxical cough with fentanyl and to identify the means to prevent it.

OTHER DRUGS THAT CAUSE PULMONARY EDEMA

A paradoxical pulmonary edema has been reported in a few patients following hydrochlorothiazide ingestion but not any other benzthiazide diuretic.⁶ Acute pulmonary edema rarely has followed the injection of high concentrations of contrast medium into the pulmonary circulation during angiocardiology.⁶ Rare occur-

rences of pulmonary edema have followed the intravenous administration of bleomycin, cyclophosphamide, and vinblastine.⁶

The selective β_2 -adrenergic agonists terbutaline and ritodrine have been reported to induce pulmonary edema when used as tocolytics.⁶ This disorder commonly occurs 48 to 72 hours after tocolytic therapy.⁶³ This has never occurred with their use in asthma patients, even in inadvertent overdosage. This reaction may result from excess fluid administration used to prevent the hypotension from β_2 -mediated vasodilation or the particular hemodynamics of pregnancy. In a review of 330 patients who received tocolytic therapy and were monitored closely for their fluid status, no episode of pulmonary edema was reported.⁶³

Interleukin-2, a cytokine used alone or in combination with cytotoxic drugs, has been reported to induce pulmonary edema. Although other cytokines have been associated with pulmonary edema, the problem is most significant with interleukin-2. A weight gain of 2 kg has been reported after treatment with interleukin-2.⁶³

Pulmonary edema has occurred occasionally with salicylate overdoses. The serum salicylate concentrations are often greater than 45 mg/dL, and the patients have other signs of toxicity, although some cases have been associated with concentrations in the usual therapeutic range.⁶¹

PULMONARY EOSINOPHILIA

Pulmonary infiltrates with eosinophilia (Loeffler syndrome) are associated with nitrofurantoin, *para*-aminosalicylic acid, methotrexate, sulfonamides, tetracycline, chlorpropamide, phenytoin, NSAIDs, and imipramine (Table 31-5).^{6,65} The disorder is characterized by fever, nonproductive cough, dyspnea, cyanosis, bilateral pulmonary infiltrates, and eosinophilia in the blood.⁶ Lung biopsy has revealed perivascularitis with infiltration of eosinophils, macrophages, and proteinaceous edema fluid in the alveoli. The symptoms and eosinophilia generally respond rapidly to withdrawal of the offending drug.

Sulfonamides were first reported as causative agents in users of sulfanilamide vaginal cream.⁶ *para*-Aminosalicylic acid frequently produced the syndrome in tuberculosis patients being treated with this agent.⁶ There are nine reported cases associated with sulfasalazine use in inflammatory bowel disease.⁶⁵ The drug associated most frequently with this syndrome is nitrofurantoin.^{6,61} Nitrofurantoin-induced lung disorders appear to be more common in postmenopausal women.⁶¹ Lung reactions made up 43% of 921 adverse reactions to nitrofurantoin reported to the Swedish Adverse Drug Reaction Committee between 1966 and 1976.⁶⁵ No apparent correlation exists between duration of drug exposure and severity or reversibility of the reaction.⁶⁵ Most cases occur within 1 month of therapy. Typical symptoms include fever, tachypnea, dyspnea, dry cough, and,

less commonly, pleuritic chest pain. Radiographic findings include bilateral interstitial infiltrates, predominant in the bases and pleural effusions 25% of the time. Although there are anecdotal reports that steroids are beneficial, the usual rapid improvement following discontinuation of the drugs brings the usefulness of steroids into question. Complete recovery usually occurs within 15 days of withdrawal.

A few cases of pulmonary eosinophilia have been reported in asthmatics treated with cromolyn.^{6,65} The significance of this is unknown in light of the occasional spontaneous occurrence of pulmonary eosinophilia in asthmatic patients. Cases of acute pneumonitis and eosinophilia have been reported to occur with phenytoin and carbamazepine therapy.⁶⁵ Patients have had other symptoms of hypersensitivity, including fever and rashes. The symptoms of dyspnea and cough subside following discontinuation of the drug.

OXYGEN TOXICITY

Because of the similarity to pulmonary fibrosis, oxygen-induced lung toxicity is reviewed briefly. More extensive reviews on this topic have been published.^{66,67}

The earliest manifestation of oxygen toxicity is substernal pleuritic pain from tracheobronchitis.⁶⁷ The onset of toxicity follows an asymptomatic period and presents as cough, chest pain, and dyspnea. Early symptoms usually are masked in ventilator-dependent patients. The first noted physiologic change is a decrease in pulmonary compliance caused by reversible atelectasis. Then decreases in vital capacity occur, followed by progressive abnormalities in carbon monoxide diffusing capacity.⁶⁷ Decreased inspiratory flow rates, reflected in the need for high inspiratory pressures in ventilator-dependent patients, occur as the fractional concentration of inspired oxygen requirement increases. The lungs become progressively stiffer as the ability to oxygenate becomes more compromised.

The fraction of inspired oxygen and duration of exposure are both important determinants of the severity of lung damage. Normal human volunteers can tolerate 100% oxygen at sea level for 24 to 48 hours with minimal to no damage.⁶⁶ Oxygen concentrations of less than 50% are well tolerated even for extended periods. Inspired oxygen concentrations between 50% and 100% carry a substantial risk of lung damage, and the duration required is inversely proportional to the fraction of inspired oxygen.⁶⁶ Underlying disease states may alter this relationship. Lung damage may not be lasting and may improve months to years after the exposure.^{68,69}

Oxygen-induced lung damage generally is separated into the acute exudative phase and the subacute or chronic proliferative phase. The acute phase consists of perivascular, peribronchiolar, interstitial, and alveolar edema with alveolar hemorrhage and necrosis of pulmonary endothelium and type I epithelial cells.⁶⁶ The proliferative phase consists of resorption of the exudates and hyperplasia of interstitial and type II alveolar lining cells. Collagen and elastin deposition in the interstitium of alveolar walls then leads to thickening of the gas-exchange area and the fibrosis.⁶⁶

The biochemical mechanism of the tissue damage during hyperoxia is the increased production of highly reactive, partially reduced oxygen metabolites (Fig. 31-1).⁶⁷ These oxidants normally are produced in small quantities during cellular respiration and include the superoxide anion, hydrogen peroxide, the hydroxyl radical, singlet oxygen, and hypochlorous acid.⁶⁷ Oxygen free radicals normally are formed in phagocytic cells to kill invading microorganisms, but they also are toxic to normal cell components. The oxidants produce toxicity through destructive redox reactions with protein sulfhydryl groups, membrane lipids, and nucleic acids.⁶⁷

The oxidants are products of normal cellular respiration that are normally counterbalanced by an antioxidant defense system that prevents tissue destruction. The antioxidants include superoxide dismutase, catalase, glutathione peroxidase, ceruloplasmin, and

α -tocopherol (vitamin E). Antioxidants are ubiquitous in the body. Hyperoxia produces toxicity by overwhelming the antioxidant system. There is experimental evidence that a number of drugs and chemicals produce lung toxicity through increasing production of oxidants (e.g., bleomycin, cyclophosphamide, nitrofurantoin, and paraquat) and/or by inhibiting the antioxidant system (e.g., carmustine, cyclophosphamide, and nitrofurantoin).^{70,71}

PULMONARY FIBROSIS

A large number of drugs are associated with chronic pulmonary fibrosis with or without a preceding acute pneumonitis (Table 31-6). The cancer chemotherapeutic agents make up the largest group and have been the subject of numerous reviews.^{70,71} Although the mech-

anisms by which all the drugs produce pneumonitis and/or fibrosis are not known, the clinical syndrome, pulmonary function abnormalities, and histopathology present a relatively homogeneous pattern.⁷⁰ The histopathologic picture closely resembles oxidant lung damage, and in some experimental cases, oxygen enhances the pulmonary injury.⁶¹ Although the terms *pulmonary fibrosis* or *interstitial pneumonitis* have been used widely to describe pneumonia after bone marrow transplantation, in 1991, a National Institutes of Health workshop recommended that the term *idiopathic pneumonia syndrome* (IPS) should be used to avoid histopathologic terms and to define the inherent heterogeneity of this disorder.⁷² IPS accounts for more than 40% of deaths related to bone marrow transplantation.⁷² Suggested causes of IPS include radiation or chemotherapy regimens prior to transplantation, graft-versus-host disease, unrecognized infections, and other inflammation-related lung injuries.^{73,74} IPS is characterized by dyspnea, hypoxemia, nonproductive cough, diffuse alveolar damage, and interstitial pneumonitis in the absence of lower respiratory infection. IPS has been reported early and late, up to 24 months after bone marrow transplantation.⁷⁴

The lung damage following ingestion of the contact herbicide paraquat classically resembles hyperoxic lung damage. Hyperoxia accelerates the lung damage induced by paraquat. Lung toxicity from paraquat occurs following oral administration in humans and aerosol administration and inhalation in experimental animals.⁷¹ The pulmonary specificity of paraquat results in part from its active uptake into lung tissue. Paraquat readily accepts an electron from reduced nicotinamide-adenine dinucleotide phosphate and then is reoxidized rapidly, forming superoxide and other oxygen radicals.⁷¹ The toxicity may be a result of nicotinamide-adenine dinucleotide phosphate depletion (see Fig. 31-1) and/or excess oxygen free radical generation with lipid peroxidation. Treatment with exogenous superoxide dismutase has had limited and conflicting results.⁷¹

A number of furans have been shown to produce oxidant injury to lungs.⁷¹ Occasionally, patients with acute nitrofurantoin lung toxicity will progress to a chronic reaction leading to fibrosis, and rarely, a patient may develop chronic toxicity without an antecedent acute reaction. Like paraquat, nitrofurantoin undergoes cyclic reduction and reoxidation that may produce superoxide radicals or deplete nicotinamide-adenine dinucleotide phosphate. In addition, nitrofurantoin inhibits glutathione reductase, an enzyme involved in the glutathione antioxidant system (see Fig. 31-1). Table 31-7 lists possible nondrug causes of pulmonary fibrosis.

TABLE 31-7 Possible Causes of Pulmonary Fibrosis
Idiopathic pulmonary fibrosis (fibrosing alveolitis)
Pneumoconiosis (asbestosis, silicosis, coal dust, talc berylliosis)
Hypersensitivity pneumonitis (molds, bacteria, animal proteins, toluene diisocyanate, epoxy resins)
Smoking
Sarcoidosis
Tuberculosis
Lipoid pneumonia
Systemic lupus erythematosus
Rheumatoid arthritis
Systemic sclerosis
Polymyositis/dermatomyositis
Sjögren syndrome
Polyarteritis nodosa
Wegener granuloma
Byssinosis (cotton workers)
Siderosis (arc welders' lung)
Radiation
Oxygen
Chemicals (thioureas, trialkylphosphorothioates, furans)
Drugs (see Tables 31-5, 31-6, and 31-8)

DRUGS ASSOCIATED WITH PULMONARY FIBROSIS

ANTINEOPLASTICS

A number of cancer chemotherapeutic agents produce pulmonary fibrosis. In an excellent review,⁷⁰ six predisposing factors for the development of cytotoxic drug-induced pulmonary disease were described: (a) cumulative dose, (b) increased age, (c) concurrent or previous radiotherapy, (d) oxygen therapy, (e) other cytotoxic drug therapy, and (f) preexisting pulmonary disease. Drugs that are directly toxic to the lung would be expected to show a dose–response relationship. Dose–response relationships have been established for bleomycin, busulfan, and carmustine (BCNU).⁷⁰ Bleomycin and busulfan exhibit threshold cumulative doses below which a very small percentage of patients exhibit toxicity, but carmustine shows a more linear relationship.⁷¹ Older patients appear to be more susceptible, possibly as a result of a decrease in the antioxidant defense system.

Excessive irradiation produces a pneumonitis and fibrosis thought to be caused by oxygen free radical formation.⁷⁰ Evidence for synergistic toxicity with radiation exists for bleomycin, busulfan, and mitomycin.⁷⁰ Hyperoxia has shown synergistic toxicity with bleomycin, cyclophosphamide, and mitomycin.⁷⁰ Carmustine, mitomycin, cyclophosphamide, bleomycin, and methotrexate all appear to show increased lung toxicity when they are part of multiple-drug regimens.

NITROSOUREAS

BCNU is associated with the highest incidence of pulmonary toxicity (20% to 30%).⁷⁰ The lung pathology generally resembles that produced by bleomycin and busulfan. Unique to BCNU is the finding of fibrosis in the absence of inflammatory infiltrates. BCNU preferentially inhibits glutathione reductase, the enzyme required to regenerate glutathione, thus reducing glutathione tissue stores.^{70,71} The patients present with dyspnea, tachypnea, and nonproductive cough that may begin within a month of initiation of therapy but may not develop for as long as 3 years.⁷⁰ Most patients receiving BCNU develop fibrosis that may remain asymptomatic or become symptomatic any time up to 17 years after therapy.⁷⁵ The cumulative dose has ranged from 580 to 2,100 mg/m².⁷¹ The disease is usually slowly progressive with a mortality rate from 15% to greater than 90% depending on the study and period of followup. In a retrospective study, the risk factors for development of IPS and prognostic factors for outcomes were evaluated in 94 patients with relapsed Hodgkin disease treated with BCNU containing high-dose chemotherapy and hematopoietic support. The risk factors for pulmonary fibrosis and mortality were female sex and dose of BCNU, with all deaths reported in those who received BCNU at doses of more than 475 mg/m².⁷⁶ Rapid progression and death within a few days occur in a small percentage of patients.⁷⁰ Corticosteroids do not appear to be effective in reducing damage.⁷⁰ Other nitrosoureas, lomustine, and semustine also have been reported to produce lung damage in patients receiving unusually high doses.⁷⁰

BLEOMYCIN

Bleomycin is the best-studied cytotoxic pulmonary toxin. Because of its lack of bone marrow suppression, pulmonary toxicity is the dose-limiting toxicity of bleomycin therapy. The incidence of bleomycin lung toxicity is approximately 4%, which may be affected by the following risk factors: bleomycin cumulative dose, age, high concentration of inspired oxygen, radiation therapy, and multidrug regimens, particularly those with cyclophosphamide.⁶³ Age at the time of treatment with bleomycin also may be a risk factor; patients younger than 7 years of age at the time of receiving bleomycin therapy are

more likely to develop pulmonary toxicity compared with older subjects.⁶³ The cumulative dose above which the incidence of toxicity significantly increases is 450 to 500 units.⁷⁰ However, rapidly fatal pulmonary toxicity has occurred with doses as low as 100 units.⁷⁰

Experimentally, bleomycin generates superoxide anions, and the lung toxicity is increased by radiation and hyperoxia.⁷⁰ Pretreatment with superoxide dismutase and catalase reduces toxicity in experimental animals.⁷⁰ Bleomycin also oxidizes arachidonic acid, which may account for the marked inflammation. Bleomycin also may affect collagen deposition by its stimulation of fibroblast growth.⁷⁰ Combination of bleomycin with other cytotoxic agents, particularly regimens containing cyclophosphamide, may predispose patients to pulmonary damage.

There are two distinct clinical patterns of bleomycin pulmonary toxicity. Chronic progressive fibrosis is the most common; acute hypersensitivity reactions occur infrequently. Patients present with cough and dyspnea. The first physiologic abnormality seen is a decreased diffusing capacity of carbon monoxide.⁷⁰ Chest radiographs show a bibasilar reticular pattern, and gallium scans show marked uptake in the involved lung.⁷⁰ Chest radiographic changes lag behind pulmonary function abnormalities. Spirometry tests before each bleomycin dose are not predictive of toxicity. The single-breath diffusing capacity of carbon monoxide is the most sensitive indicator of bleomycin-induced lung disease. Although it is not absolutely predictive, a drop of 20% or greater in the diffusing capacity of carbon monoxide is an indication for using alternative therapies.⁷⁰ The prognosis of bleomycin lung toxicity has improved as a consequence of early detection, but the mortality rate is approximately 25%. Mild cases respond to discontinuation of bleomycin therapy.⁶³ Corticosteroid therapy appears to be helpful in patients with acute pneumonitis, although there have been no controlled trials. Patients with chronic fibrosis are less likely to respond. Although corticosteroids have been used for a number of drug-induced pulmonary problems, a study in mice showing a potential for worsening of lung damage when administered early during the repair stage should sound a word of caution against their indiscriminate use.⁷⁷

MITOMYCIN

Mitomycin is an alkylating antibiotic that produces pulmonary fibrosis at a frequency of 3% to 12%.⁷⁰ The mechanism is unknown, but oxygen and radiation therapy appear to enhance the development of toxicity.⁷⁰ The clinical presentation and symptoms are the same as for bleomycin. The mortality rate is approximately 50%. Early withdrawal of the drug and administration of corticosteroids appear to improve the outcome significantly.

ALKYLATING AGENTS

A number of alkylating agents are associated with pulmonary fibrosis (see Table 31–5). The incidence of clinical toxicity is around 4%, although subclinical damage is apparent in up to 46% of patients at autopsy. The mechanism of toxicity is unknown; however, epithelial cell damage that triggers the arachidonic acid inflammatory cascade may be the initiating event.⁷⁰ The clinical presentation is insidious, with 4 years being the average duration of therapy before the onset of symptoms.⁷⁰ Patients present with low-grade fever, weight loss, weakness, dyspnea, cough, and rales.⁷⁰ Pulmonary function tests initially show abnormal diffusion capacity followed by a restrictive pattern (low vital capacity). The histopathologic findings are nonspecific. The prognosis is one of slow progression with a mean survival of 5 months following diagnosis.⁷⁰ Although there is no direct dose-dependent correlation, patients receiving less than 500 mg of busulfan do not develop the syndrome without concomitant radiation or use of other pulmonary toxic chemotherapeutic agents.⁷⁰ There are anecdotal

reports of beneficial responses to corticosteroids, but no controlled studies have been done.

Cyclophosphamide infrequently produces pulmonary toxicity. More than 20 well-documented cases have been reported to date. In animal models, cyclophosphamide produces reactive oxygen radicals. High oxygen concentrations produce synergistic toxicity with cyclophosphamide. The duration of therapy before the onset of symptoms is highly variable, and there may be a delay of several months between the onset of symptoms and discontinuation of the drug.⁷⁰ Cyclophosphamide may potentiate carmustine lung toxicity.⁷⁰ Clinical symptoms usually consist of dyspnea on exertion, cough, and fever. Inspiratory crackles and the bibasilar reticular pattern typical of cytotoxic drug-induced radiographic changes are present. Histopathologic changes are also nonspecific. Approximately 60% of patients recover. Corticosteroid therapy has been reported to be beneficial; however, death despite corticosteroid administration also has been reported.

Chlorambucil, melphalan, and uracil mustard also are associated with pulmonary fibrosis. Of the alkylating agents, only nitrogen mustard and thiotepea have not been reported to cause fibrotic pulmonary toxicity.⁷⁰

ANTIMETABOLITES

Methotrexate was first reported to induce pulmonary toxicity in 1969.⁷⁰ The pulmonary toxicity to methotrexate is unique in that discontinuation is not always necessary, and reinstitution of the drug may not produce recurrence of symptoms.⁶ Methotrexate pulmonary toxicity most commonly appears to result from hypersensitivity,⁶⁵ and it can occur 3 or more years following methotrexate therapy.⁷⁸ Age, sex, underlying pulmonary disease, duration of therapy, or smoking is not associated with an increased risk of pneumonitis with methotrexate.⁷⁸ Serial pulmonary function tests did not help to identify pneumonitis in patients receiving methotrexate before the onset of clinical symptoms.⁷⁸ Reductions in diffusing capacity of carbon monoxide and lung volumes are the most common manifestations of methotrexate lung toxicity.⁶³ Pulmonary edema and eosinophilia are common, and fibrosis occurs in only 10% of the patients who develop acute pneumonitis.⁷⁰ Systemic symptoms of chills, fever, and malaise are common before the onset of dyspnea, cough, and acute pleuritic chest pain. Methotrexate also is associated with granuloma formation.⁷⁰

The prognosis of methotrexate-induced pulmonary toxicity is good, with a 1% or less mortality rate.⁶⁵ Pulmonary toxicity has followed intrathecal as well as oral administration and has occurred after single doses as well as long-term daily and intermittent administration.⁷⁰ Pneumonitis has been reported to occur up to 4 weeks following discontinuation of therapy.⁷⁰ Numerous anecdotal reports have claimed dramatic benefit from corticosteroid therapy. It is unknown whether intermittent (weekly) dosing, as is done for rheumatoid arthritis, decreases the risk of methotrexate-induced pulmonary toxicity because pneumonitis has occurred with this form of dosing.

Rarely, azathioprine and its major metabolite 6-mercaptopurine have been reported to produce an acute restrictive lung disease. Procarbazine, a methylhydrazine associated more commonly with Loeffler syndrome, rarely has been associated with pulmonary fibrosis.⁶⁵ The vinca alkaloids vinblastine and vindesine have been reported to produce severe respiratory toxicity in association with mitomycin. The incidence with the combination is 39% and may represent a true synergistic effect between these agents.⁷⁰

NONCYTOTOXIC DRUGS

Pulmonary fibrosis associated with the ganglionic-blocking agent hexamethonium was first reported in 1954 (see Table 31–6).⁶

Patients developed extreme dyspnea after several months on the drug. Pathologic findings were consistent with bronchiectasis, bronchiolectasis, and fibrosis.⁶ This phenomenon has occurred occasionally with use of the other ganglionic blockers (i.e., mecamylamine and pentolinium).⁶

In 1959, radiographic changes characteristic of diffuse pulmonary fibrosis were reported in 27 (87%) of 31 patients who had taken phenytoin for 2 years or more.⁶¹ Since then, studies have been conflicting. If phenytoin does produce chronic fibrosis, it would appear to be a relatively rare event.

Gold salts (sodium aurothiomalate) used in the treatment of rheumatoid arthritis have produced pulmonary fibrosis with cough, dyspnea, and pleuritic pain 5 to 16 weeks following institution of therapy.⁶¹ Pulmonary function tests show a restrictive defect, and patients generally have an eosinophilia. The reactions improve on discontinuation of the gold therapy and recur promptly on reexposure. The pulmonary deficit may not resolve completely.

AMIODARONE

Amiodarone, a benzofuran derivative, produces pulmonary fibrosis when used for supraventricular and ventricular arrhythmias (see Table 31–6).⁷⁹ The duration of amiodarone therapy before the onset of symptoms has ranged from 4 weeks to 6 years.^{61,79} The estimated incidence is 1 in 1,000 to 2,000 treated patients per year. The clinical course is variable, ranging from acute onset of dyspnea with rapid progression into severe respiratory failure and death caused by slowly developing exertional dyspnea over a few months. Patients generally improve on discontinuation of the drug.⁷⁹ The majority of patients develop reactions while taking maintenance doses greater than 400 mg daily for more than 2 months or smaller doses for more than 2 years. The risk of amiodarone pulmonary toxicity is higher during the first 12 months of therapy even at a low dosage.⁸⁰ Other risk factors include cardiopulmonary surgery combined with the administration of high concentrations of oxygen.⁸⁰ Routine spirometry does not appear to be predictive of patients at risk.⁸¹ Carbon monoxide diffusing capacity studies are sensitive indicators of amiodarone pulmonary toxicity but have only a 21% positive predictive value.⁸¹ Clinical findings include exertional dyspnea, nonproductive cough, weight loss, and occasionally low-grade fever.^{61,81} Radiographic changes are nondiagnostic and consist of diffuse bilateral interstitial changes consistent with a pneumonitis. Pulmonary function abnormalities include hypoxia, restrictive changes, and diffusion abnormalities.

The mechanism of amiodarone-induced pulmonary toxicity is multifactorial. Amiodarone and its metabolite can damage lung tissue directly by a cytotoxic process or indirectly by immunologic reactions.⁸⁰ Amiodarone is an amphiphilic molecule that contains both a highly apolar aromatic ring system and a polar side chain with a positively charged nitrogen atom.⁷⁹ Amphiphilic drugs characteristically produce a phospholipid storage disorder in the lungs of experimental animals and humans.⁷¹ Chlorphentermine, an anorectic, is the prototype amphiphilic compound. The mechanism is currently believed to be the inhibition of lysosomal phospholipases.⁷¹ The inflammation and fibrosis are thought to be a late finding resulting from nonspecific inflammation following the breakdown of phospholipid-laden macrophages.⁷⁹

In a review of 39 cases, 9 patients died, and the remaining 30 patients had resolution of abnormalities after withdrawal of the drug.⁷⁹ Some patients have had resolution with lowering of the dosage, and therapy has been reinstituted at lower doses without problems in others. Of the patients who died, one-half had received corticosteroids. There are reports of a protective effect with prophylactic corticosteroids and other reports of patients developing amiodarone lung toxicity while on corticosteroids.⁷⁹ At this time, any benefit of corticosteroids is unclear because most patients improve after stopping the drug.

PULMONARY HYPERTENSION

Pulmonary hypertension is a rare disorder, occurring with an approximate incidence of 1 to 2 cases per 1 million in the general population.⁸² With progression of the disease, right ventricular afterload increases, and the ability to increase cardiac output with activity decreases. This progresses to right-sided heart failure and death.⁸³

Patients with pulmonary hypertension often complain of exertional dyspnea, chest pain, and syncope. Because of the nonspecific nature of these symptoms and lack of a noninvasive diagnostic test for detecting pulmonary hypertension, there are often delays in the diagnosis of the disease, frequently up to a year after the onset of symptoms.⁸³

The factors leading to the development of pulmonary hypertension are unclear, although associations with portal hypertension and pregnancy have been detected. Obesity by itself may double the risk of pulmonary hypertension.⁸⁴ Additionally, the use of cocaine or oral contraceptives, infection with the human immunodeficiency virus (HIV), the use of anorexic agents,⁸⁵ hepatic cirrhosis, genetic susceptibility, and female sex in the third to fourth decades of life also are implicated as predisposing factors.⁸⁴ Exposure of patients to fenfluramine or dexfenfluramine is associated with 20% of all diagnosed cases of pulmonary hypertension.⁸⁴

The first reports of the association between pulmonary hypertension and the use of anorexic agents occurred in the late 1960s and early 1970s in Western Europe when the drug aminorex was used for weight reduction.⁸⁶ The incidence of pulmonary hypertension returned to baseline after the drug was removed from the market. In the early 1990s, an association between fenfluramine use and pulmonary hypertension was established.⁸⁷ Shortly thereafter, the International Primary Pulmonary Hypertension Study Group investigated the potential role of anorexic agents in causing pulmonary hypertension.⁸⁵ Included in this multinational case-control study were 95 patients with pulmonary hypertension and 355 controls from general practices matched for gender and age. The use of anorexic agents, primarily fenfluramine and dexfenfluramine, within the last year was associated with an increased risk of pulmonary hypertension with an odds ratio of 10:1. When anorexic drugs were used for a total of more than 3 months, the odds ratio increased to 23:1.

In a 12-year observational study, 62 patients with fenfluramine-associated pulmonary hypertension were compared with 125 sex-matched patients with pulmonary hypertension unrelated to the use of fenfluramine derivatives. In most of the cases (81%), fenfluramine derivatives were used for at least 3 months. The time frame between the initiation of the therapy and the onset of dyspnea ranged from 27 days to 23 years. Both the fenfluramine-associated pulmonary hypertension group and the control group had similar levels of New York Heart Association functional class and symptoms, as well as an overall survival rate of 50% in 3 years.⁸⁸

The mechanism by which anorexic agents cause pulmonary hypertension is unknown. Studies show that fenfluramine, dexfenfluramine, and aminorex inhibit potassium channels in isolated pulmonary artery smooth muscle cells in rats, which results in vasoconstriction. Potassium channel activity is altered in pulmonary artery smooth muscle cells obtained from patients with pulmonary hypertension, leading to speculation that anorexic agents may cause vasoconstriction followed by vascular growth and remodeling.⁸³ Another potential mechanism involves serotonin, which has been found in increased levels in patients with pulmonary hypertension.⁸³ Serotonin can be stored in the platelet when serotonin plasma concentration is high. Serotonin acts as a pulmonary vasoconstrictor when it is released from the platelets.⁸⁴

Patients with pulmonary hypertension associated with anorexic use may experience a considerable improvement in their condition or possibly even remission within 1 to 3 months following discontinuation of the drug.^{84,89}

Pharmacologic agents used in the treatment of pulmonary hypertension include high dosage of calcium channel blockers and anticoagulants.⁸² Epoprostenol, also known as *prostacyclin*, a strong vasodilator of all vascular beds was approved for the long-term therapy of pulmonary hypertension in 1995.⁹⁰ Additionally, lung and heart-lung transplantations have played a role in the treatment of pulmonary hypertension. However, the 4-year survival rate is less than 60% in pulmonary hypertension patients receiving any transplant.⁹⁰ Bosentan, an endothelin receptor antagonist indicated for primary pulmonary hypertension, also may have a role, but no studies currently exist describing its use.

In September 1997, the FDA requested the manufacturers of fenfluramine and dexfenfluramine to voluntarily withdraw their products from the market. This was done following case reports of valvular heart disease in patients taking either medication as monotherapy or in combination with another anorexic agent, phentermine. Because no association has been found between phentermine alone and valvular heart disease, it is still available. Isolated case reports of pulmonary hypertension and phentermine monotherapy have been reported,^{91,92} but present data do not support an association. Although fenfluramine and phentermine were both approved by the FDA to be used as anorectic agents, the combination therapy, “fen-phen,” was never approved.

MISCELLANEOUS PULMONARY TOXICITY

Drugs may produce serious pulmonary toxicity as part of a more generalized disorder. The pleural thickening, effusions, and fibrosis that occur as an extension of the retroperitoneal fibrotic reactions of methysergide and practolol or as part of a drug-induced lupus syndrome are the most common examples (Table 31-8).

Methysergide therapy for prophylaxis of poorly controlled migraine headache occasionally results in pulmonary toxicity associated with pleural effusions. The patients develop pleural pain, dyspnea, and fever. Chest radiography reveals a uniform hazy shadowing over the lower lung fields, and a loud pleural rub is heard on auscultation.⁶ The mechanism is unknown, and most patients improve with discontinuation of the drug. Pleural and pulmonary fibrosis has been reported in one patient taking pindolol, a β -blocker structurally similar to practolol.

TABLE 31-8 Drugs That May Induce Pleural Effusions and Fibrosis

	Relative Frequency of Reactions
Idiopathic	
Methysergide	F
Practolol	F
Pindolol	R
Methotrexate	R
Nitrofurantoin	R
Drug-induced lupus syndrome	
Procainamide	F
Hydralazine	F
Isoniazid	R
Phenytoin	R
Mephenytoin	R
Griseofulvin	R
Trimethadione	R
Sulfonamides	R
Phenylbutazone	R
Streptomycin	R
Ethosuximide	R
Tetracycline	R
Pseudolymphoma syndrome	
Cyclosporine	R
Phenytoin	R

F, frequent; I, infrequent; R, rare.

tolol, an agent known to produce fibrosis.⁶¹ Acute pleuritis with pleural effusions and fibrosis is a prominent manifestation of drug-induced lupus syndrome. Procainamide is associated with the largest number of pulmonary reactions, with 46% of patients with the lupus syndrome developing pulmonary complications.⁶ Symptoms include pleuritic pain and fever with muscle and joint pain. Chest radiographs show bilateral pleural effusions and linear atelectasis. Patients have a positive antinuclear antibody test. Symptoms usually resolve within 6 weeks of drug withdrawal.⁶

Hydralazine is the next most common cause of lupus syndrome. Most patients who develop pleuropulmonary manifestations have antecedent symptoms of generalized lupus.⁶ Other drugs that produce the lupus syndrome include isoniazid and phenytoin. Phenytoin also can produce hilar lymphadenopathy as part of a generalized pseudolymphoma or lymphadenopathy syndrome.⁶

MONITORING THERAPEUTIC OUTCOMES

Monitoring for drug-induced pulmonary diseases consists primarily of having a high index of suspicion that a particular syndrome may be drug-induced. Most hypersensitivity or allergic reactions (bronchospasm) occur rapidly, within the first 2 weeks of therapy with the offending agent, and reverse rapidly with appropriate therapy (e.g., withdrawal of the offending agent and administration of corticosteroids and bronchodilators). Dyspnea associated with Loeffler syndrome and acute pulmonary edema syndromes also improve rapidly in 1 to 2 days. However, some residual defect in diffusion capacity and the roentgenogram may persist for a few weeks. It is probably unnecessary to do followup spirometry or diffusion capacity determinations in these patients unless there is some concern that the syndrome will progress to pulmonary fibrosis (through the use of bleomycin or nitrofurantoin).

The routine monitoring of patients receiving known pulmonary toxins with dose-dependent toxicity such as amiodarone, bleomycin, or carmustine is still controversial. For chronic fibrosis, the diffusing capacity of carbon monoxide is the most sensitive test and may be useful in patients receiving bleomycin for detecting and preventing further deterioration of lung function with continued administration. Carmustine lung toxicity may be delayed up to 10 years following administration, and routine monitoring has not proved preventive. Monitoring patients receiving amiodarone in doses greater than 400 mg/day every 4 to 6 months may prove useful in detecting early disease that requires lowering the amiodarone or stopping the drug. Because there is no evidence of a cumulative dose effect once it has been established that the patient can tolerate the elevated dose, continued routine monitoring past the first year is unnecessary.

ABBREVIATIONS

ACE: angiotensin-converting enzyme

COPD: chronic obstructive pulmonary disease

EDTA: ethylenediamine tetraacetic acid

FDA: Food and Drug Administration

FEV₁: forced expiratory volume in the first second of expiration

IPS: idiopathic pneumonia syndrome

NSAIDs: nonsteroidal antiinflammatory drugs

GARY MILAVETZ

KEY CONCEPTS

- 1 Cystic fibrosis is a disorder of the chloride ion transport in epithelial cells. It especially affects the cells that line the pulmonary and gastrointestinal systems, although the functions of other exocrine glands are altered.
- 2 The chloride ion transport dysfunction is multifaceted and results in thickened secretions that typically lead to obstruction, infection and inflammation in the affected systems. These in turn lead to the morbidity and mortality associated with cystic fibrosis.
- 3 Thickened secretions from the pancreas lead to deficiencies of digestive enzymes and bicarbonate, which leads to malabsorption of foodstuffs; malabsorption leads to maldigestion and malnutrition.
- 4 Treatment of the gastrointestinal component includes pancreatic enzyme and vitamin supplementation aimed at providing adequate nutritional needs.
- 5 Airway obstruction and pulmonary infection occur as a result of bacterial colonization and infection, thickened secretions and inflammation.
- 6 Acute antibiotic treatment is aimed at bacterial eradication while prophylactic treatment reduces the progression of the disease. *Pseudomonas aeruginosa* is the most common pathogen found in patients with cystic fibrosis.
- 7 The progression of pulmonary disease is prevented by a two-pronged approach. Reducing or eradicating inflammation decreases cellular and tissue alterations associated with cystic fibrosis. Reducing the bacterial burden in the pulmonary tree may decrease acute exacerbations and alter the disease course.
- 8 Gene therapy may be the treatment of the future but current trial results have been disappointing.
- 9 The goal of cystic fibrosis therapy is to slow or stop the progression of the disease and allow young patients to normally grow and develop and to have as normal of a lifestyle as possible.

Cystic fibrosis is the most common lethal, genetic disease in the white population. The disease mainly involves the exocrine glands and thus affects a number of organ systems (Table 32-1). The more

common manifestations of this disease involve the gastrointestinal and pulmonary systems, with premature mortality associated with the latter. Most of the disease process results from a defect in electrolyte transport caused by a loss of functional chloride channels in epithelial cells. The protean nature of this disease dictates that care be multidisciplinary with a wide variety of therapeutic interventions.

EPIDEMIOLOGY

Cystic fibrosis is primarily inherited through an autosomal (mendelian) recessive mode. Within a couple, with each parent being a carrier (heterozygous for the trait), a child has a 1:4 chance of having the disease, a 1:2 chance of being a carrier, and a 1:4 chance of being normal (having neither the disease nor the trait). The incidence of cystic fibrosis is greatest in the white population; it occurs in about 1 of every 2,000 live births in the United States.¹ Thus, the incidence of the trait (carrier state) in this group is approximately 5%. The frequency of this disease is considerably less in other races, occurring in about 1 in 17,000 blacks and in 1 in 90,000 Asians.²

After years of intensive research, the cystic fibrosis gene was identified and cloned in 1989.³⁻⁵ The gene is located on the long arm of chromosome 7 and encodes for a protein called the cystic fibrosis transmembrane regulator (CFTR); this membrane protein functions as a chloride channel involved in the transport of electrolytes and water. In addition to the inherited recessive mutation affecting the CFTR protein, spontaneous mutation also occurs. More than 1,000 cystic fibrosis-associated mutations within the cystic fibrosis gene have been described, but the most common mutation involves a three-base pair deletion that results in the absence of a phenylalanine residue at position 508 of the CFTR protein.³⁻⁵ This common mutation, referred to as the ΔF_{508} allele, is present in approximately 70% of patients in the United States. The mutations have been divided into four classes: I—defective protein production; II—defective protein processing; III—defective channel regulation; and IV—defective channel conductance.⁶ Patients homozygous for the ΔF_{508} mutation, which falls primarily into class II, tend to be diagnosed at an earlier age, owing to a greater frequency of pancreatic insufficiency (99% vs. 72% in heterozygotes and 36% in patients with other genotypes).^{7,8}

PATHOPHYSIOLOGY

Cystic fibrosis is a disease of epithelia, especially those cells lining the intestinal tract, pancreatic ducts, hepatobiliary tree, vas deferens, sweat ducts, and airway lumen. In the normal state, these epithelial cells can transport chloride through CFTR chloride channels with sodium and water accompanying this ion flux. 1 Chloride transport through CFTR channels is activated by protein kinases in response to an increase in the intracellular second messenger, cyclic adenosine 3',5'-monophosphate.⁹ In cystic fibrosis, a loss of functional CFTR

TABLE 32-1 Organ Involvement in Cystic Fibrosis		
Organ System/ Organ	Abnormality	Consequence
Gastrointestinal Pancreas	Digestive enzyme deficiency	Maldigestion Malnutrition
	Insulin deficiency	Glucose intolerance
Intestines	Viscous secretions	Obstruction
Liver	Biliary cirrhosis/fatty infiltration	Portal hypertension/ esophageal varices
		Chronic obstruction
Pulmonary	Viscous secretions	Endobronchial infection
Sweat glands	Failure to reabsorb sodium	Hyponatremia
Reproductive	Obstruction of epididymis, vas deferens, and seminal vesicles	Aspermia
	Viscous cervical mucus	Decreased fertility
Hematologic	Chronic disease?	Anemia
Bone and joint	Unknown	Arthritis, osteopenia

chloride channels leads to defective cyclic adenosine 3',5'-monophosphate-stimulated chloride transport; in most epithelia, this defect results in decreased chloride secretion and increased sodium absorption (Fig. 32-1). ² Defective electrolyte transport is thought to alter the volume or composition of the fluid secreted by the pancreas, hepatobiliary tree, reproductive tract, sweat gland, and the airways.

GASTROINTESTINAL TRACT

The gastrointestinal tract may be involved in cystic fibrosis with either intestinal obstruction or deficient secretion of digestive enzymes by the pancreas. In 10% to 16% of cystic fibrosis patients, the first gastrointestinal manifestation of the disease is small bowel obstruction, which is evident shortly after birth and known as *meconium ileus*. In these patients, the basic electrolyte transport defect is thought to cause abnormally tenacious meconium that cannot be evacuated. A similar condition, known as *distal intestinal obstruction syndrome* or *meconium ileus equivalent*, occurs in older cystic fibrosis patients; it is also thought to result from abnormally tenacious gastrointestinal secretions and fecal impaction. Other intestinal complications include intussusception, volvulus, gastroesophageal reflux, atresia, perforation, giant cystic meconium peritonitis, and rectal prolapse.

A relative deficiency of pancreatic digestive enzymes (pancreatic achylia) is present with most genotypes and is clinically apparent in 85% of patients. Pancreatic lesions including fibrosis, fatty replacement, and cyst formation are secondary to obstruction of small pancreatic ducts by thickened secretions and cellular debris. Inspissated eosinophilic material may accumulate in the acini and ductules. As a result, the volume of pancreatic secretions and the concentration of pancreatic enzymes and bicarbonate are reduced. Affected enzyme concentrations include trypsin, chymotrypsin, carboxypeptidase, amylase, and lipase. This leads to a maldigestion of ingested nutrients,

FIGURE 32-1. Electrolyte transport in the airway epithelial cell. The cystic fibrosis transmembrane regulator is the cyclic-3',5'-AMP (cAMP)-dependent chloride channel.

including fats and protein. Increased fecal losses of bile acids (binding to undigested fecal fat decreases enterohepatic recycling) also may contribute to fat maldigestion. The maldigestion brings added food-stuffs into the colon, reducing transit time and contributing to additional malnutrition. ³

Because of the lipase deficiency, fat-soluble vitamin (A, D, E, and K) deficiencies may occur. ⁴ Whether lipase activity or bile acids (e.g., in micelle formation) are involved in fat-soluble vitamin absorption with steatorrhea is unclear. Vitamin B₁₂ and zinc deficiencies also may occur as a result of pancreatic enzyme deficiency. Although pancreatic involvement is predominantly and initially exocrine in nature, insulin deficiency with glucose intolerance also occurs in cystic fibrosis patients, especially as they advance in age. This probably occurs as a result of chronic inflammatory changes causing fibrotic changes to the entire pancreas including the endocrine function. Carbohydrate intolerance is characterized by low insulin concentrations and enhanced peripheral sensitivity to insulin, but not by the presence of islet cell or antiinsulin antibodies. Carbohydrate intolerance in cystic fibrosis is not usually associated with the ketosis as commonly occurs in type 1 diabetes. This complication involves an increase in the number of insulin receptors with decreased affinity for insulin. Despite a concomitant increase in tissue affinity for insulin, 8% of cystic fibrosis children older than 12 years of age require insulin therapy.

The liver can be involved in cystic fibrosis. Biliary cirrhosis secondary to bile duct obstruction occurs in as many as 18% of patients, whereas fatty infiltration occurs in approximately 30% of patients in a pattern unrelated to nutritional status. Bile ducts may be obstructed by inspissated mucus which may lead to focal or multilobar cirrhosis. ¹⁰ Such hepatic involvement can occur at any age, but is more common with advancing age and can lead to portal hypertension, esophageal varices and hypersplenism. The most common laboratory abnormality associated with hepatic involvement is elevated serum hepatic isoenzymes (γ -glutamyltranspeptidase, alanine aminotransferase, aspartate aminotransferase, and alkaline phosphatase).

PULMONARY SYSTEM

The pulmonary manifestations of cystic fibrosis result from an incompletely characterized defect in innate host defenses at the airway surface including an exaggerated inflammatory response, defective bactericidal activity, and altered mucus clearance. ¹¹⁻¹³ Chronic bacterial endobronchitis is the essential disease process that defines the pulmonary component of cystic fibrosis. ⁵ The three factors influencing the endobronchitis are airway infection, inflammation, and obstruction. Together, these culminate in long-term airway destruction. The ongoing controversy of which comes first— inflammation or infection—was studied in an effort to clarify this issue. Children diagnosed with cystic fibrosis detected by newborn screening but lacking signs and symptoms of infection were compared to controls with chronic stridor. In this group of children with cystic fibrosis, inflammation seems to be initiated and sustained by infection. ¹⁴ Other pathophysiology aspects of airways disease in cystic fibrosis are the defects found in natural pulmonary defenses and especially mucus clearance. ¹⁵ The mucus glands in cystic fibrosis appear to have defective anion-mediated fluid secretion resulting in hyposecretion rather than hyperabsorption of fluid. ¹⁶ Regulation of airway surface liquid also is an important part of the normal pulmonary defense system. Patients with cystic fibrosis are only partially able to adjust airway surface liquid volume related to the lack of CFTR. ¹⁷ The airway surface liquid in patients with cystic fibrosis also appears to be deficient in the antimicrobial factors that are present in normal airway surface liquid. The understanding of how defective CFTR influences the disease process has improved although a clear comprehension and its implications for disease treatment is still elusive.

The combination of persistent obstruction along with inflammation often leads to air trapping, atelectasis, and, eventually, bronchiectasis that progresses until respiratory insufficiency develops. The lung disease usually progresses from small airway obstruction to more generalized airway obstruction, and, finally, toward a component of restrictive lung disease as individual segments become completely obstructed and nonfunctional. Hyperinflation or dilation of the air spaces is a common finding. Furthermore, persistent obstruction of the small airways with mucus, an excellent culture medium for microorganisms, may facilitate the growth of bacteria within an extracellular matrix or biofilm, making the infection relatively resistant to antibiotics. Although bacterial infections are thought to be a major contributor to cystic fibrosis airway disease, viruses and other nonbacterial pathogens also play an important pathologic role.^{13,18,19} Environmental factors, such as exposure to tobacco smoke, may also contribute.²⁰

The three most common bacterial pathogens isolated from the respiratory secretions (sputum) of cystic fibrosis patients are *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and *Haemophilus influenzae*, with *P. aeruginosa* usually predominating throughout life. *Proteus*, *Klebsiella* species and *Stenotrophomonas maltophilia* are observed less frequently. Mucoid strains (alginate producers) of *P. aeruginosa* commonly observed in cystic fibrosis may be particularly resistant to antibiotics,²¹ as are nonmotile forms. The isolation of *Burkholderia cepacia* from the sputum of cystic fibrosis patients has become more common at some cystic fibrosis centers. The significance of this contagious organism varies from one patient to the next. Three fairly distinct syndromes associated with this *B. cepacia* have been described, these being asymptomatic colonization, chronic deterioration with intermittent fever and weight loss, and rapid, usually fatal, deterioration.²² The nature of the initially cultured oropharyngeal flora in patients younger than 2 years of age has prognostic significance. The finding of *P. aeruginosa* or *P. aeruginosa* plus *S. aureus* in initial cultures appears related to increased morbidity and mortality, respectively.²³

The presence of the above bacteria contributes to the destructive changes in the airways of cystic fibrosis patients by direct damage from bacterial toxins and the body's immune reaction to these bacteria. For example, *P. aeruginosa* elaborates a number of extracellular toxins, proteases, hemolysins, and exopolysaccharides, which may be responsible for direct airway damage, increased mucin production by the airway epithelium, and the production of immune complexes (immunoglobulins G and M) which may contribute to local damage. Elevated levels of such mediators as granulocyte elastase, tumor necrosis factor- α , interleukins 1 and 2, and related complexes with associated inhibitors are well documented in cystic fibrosis patients. One inflammatory mediator that clearly contributes to pulmonary pathophysiology is neutrophil elastase. Present in excess, it overwhelms and neutralizes native antiproteases (α_1 -antitrypsin and secretory leukocyte protease inhibitor), destroys structural fibers, and inhibits complement-mediated phagocytosis and antipseudomonal antibodies. Combined with other inflammatory mediators, a self-sustaining vicious cycle leading to progressive and often permanent tissue damage is established. The neutrophil influx that is part of this cycle results in release of neutrophil-derived DNA, which is thought to contribute to sputum viscosity. The occasional presence of *Aspergillus fumigatus* in the sputum of these patients may also contribute to the pulmonary pathology because it can induce a steroid-responsive allergic reaction.

The consequence of these pulmonary processes is a decrease in gas exchange by the lungs. The challenge of moving air through obstructed airways often requires the use of accessory muscles, resulting in an increased anterior-posterior chest diameter (also referred to as "barrel chest"), a flattened diaphragm, and pulmonary hypertension. The increased work of breathing in these patients produces a relative

exercise intolerance and increased resting energy expenditure. Hemoptysis secondary to bronchiectasis occurs but is seldom massive. Other respiratory complications include gastroesophageal reflux, pneumothorax, and right-sided heart failure (cor pulmonale), secondary to the pulmonary hypertension. Although seldom overt clinically, the findings of right ventricular hypertrophy, increased heart weight, and right atrial and right ventricular chamber dilation are usually present at autopsy. Digital clubbing, a common finding in cystic fibrosis as well as in other chronic pulmonary conditions, may be related to chronic hypoxia.

The upper respiratory tract is also commonly involved in cystic fibrosis. Sinusitis and nasal polyposis occur in 90% and 50% of patients, respectively.²⁴ Sinusitis is chronic in character and acute symptoms are unusual. Although its etiology is not entirely clear, sinusitis may result from obstruction of the sinus ducts, thus preventing drainage. The bacteria generally isolated in these cases include *P. aeruginosa*, *H. influenzae*, streptococci, and anaerobes. Usually, the same strain of *P. aeruginosa* found in the lungs is present in the upper airways (nasopharynx and sinuses), which may represent a reservoir for the pathogen.

SWEAT GLANDS

Abnormally high concentrations of sodium and chloride are found in the sweat of cystic fibrosis patients as a result of defective chloride absorption across the water-impermeable sweat duct epithelium. This forms the basis for measuring sweat chloride concentration as a diagnostic test for cystic fibrosis. This defect in salt absorption rarely causes clinical symptoms except in warmer environments or during hot weather, when excessive sweating may lead to salt depletion; this clinical problem can be prevented by supplementing the diet with salt. In the sweat coil where salt and water are excreted into the gland lumen, sodium and chloride are not excreted at abnormally high concentrations in cystic fibrosis because chloride is secreted through chloride channels other than the CFTR. However, as sweat progresses through the sweat duct toward the skin surface, chloride absorption across the water-impermeable epithelium is reduced because of a loss of CFTR chloride channels. Similar abnormalities can be seen in the excretions of the salivary glands.

REPRODUCTIVE SYSTEM

Approximately 95% of males with cystic fibrosis are sterile because of obstruction of the epididymis, vas deferens, and seminal vesicles resulting in aspermia. There is late maturation of the reproductive system with delayed onset of puberty in both sexes. Females also have reduced fertility owing to the production of abnormal cervical mucus. Menstrual irregularity and oligomenorrhea are also common. Nonetheless, owing to greater life expectancy in these patients, increasing numbers are becoming mothers. In these individuals, the course and tolerance of pregnancy are related to the pregravid nutritional and pulmonary status.

HEMATOLOGIC SYSTEM

Anemia is observed in some cystic fibrosis patients despite chronic hypoxia. The apparent deficient erythroid response occurs, at least in part, from disturbances in erythropoietin regulation and iron availability (impaired gastrointestinal absorption). Despite chronic hypoxia in some patients with cystic fibrosis, erythropoietin concentrations are normal or low. The condition is characterized by decreased hematocrit and serum ferritin, increased carboxyhemoglobin, and normal or low hemoglobin. Many patients may have iron deficiency as a consequence of decreased dietary intake, malabsorption, or blood loss.

BONES AND JOINTS

Arthritis may occur in cystic fibrosis and can take one of several forms.²⁵ The arthritis may be either mono- or polyarticular and is usually nondestructive. An episodic form is most common and may be a result of immune complexes formed in response to the chronic pulmonary infections. Hypertrophic osteoarthropathy occurs in cystic fibrosis as it does in association with other pulmonary diseases. The incidence of arthritis may be increasing as median survival age increases. Osteopenia and osteoporosis also occur more frequently in adults with cystic fibrosis. The causes of the resultant bone demineralization are multifactorial and include vitamin D malabsorption, decreased vitamin D conversion (via sunlight), delayed puberty and endocrine development, poor nutrition, limited physical activity, and chronic acidosis.

CLINICAL PRESENTATION

The clinical findings of cystic fibrosis develop as a direct consequence of the pathophysiologic processes described above. Thus, the clinical findings can be conveniently subdivided by organ system.

GASTROINTESTINAL SYSTEM

Intestinal symptoms are usually secondary to either intestinal obstruction or maldigestion of nutrients. Obstruction, manifested as meconium ileus, distal intestinal obstruction syndrome or intussusception, causes abdominal distension, pain, vomiting, or a change in stool output.

More commonly, the gastrointestinal symptoms of cystic fibrosis are caused by maldigestion of food causing steatorrhea and malnutrition. The stools are foul odorous, bulky, greasy, and more frequent in number; rectal prolapse may occur, especially in the presence of excessive weight loss. The stool's high fat content results from a relative lipase deficiency. Perhaps the most significant consequence of maldigestion is malnutrition; that is, cystic fibrosis children characteristically fall below their age-related norms for both weight and height.

PULMONARY SYSTEM

The respiratory symptoms of cystic fibrosis are usually those of obstructive airway disease such as coughing, sputum production, labored breathing, wheezing, retractions, pleurisy, and cyanosis. Digital clubbing is a common finding thought to be associated with bronchiectasis. Increased anterior-posterior chest diameter, a flattened diaphragm, and hyperaeration may be noted on chest roentgenogram.

The respiratory status usually follows a cyclical pattern, from a state of relative well-being to one of acute pulmonary deterioration theoretically paralleling the course of the airway infection. There may be significant declines in pulmonary function referred to as acute respiratory exacerbations and generally associated with symptoms of bacterial endobronchial infection. Common pathogens found in the lungs of a cystic fibrosis patient include *S. aureus*, *H. influenzae* and *P. aeruginosa*. Less-common pathogen include *S. maltophilia* and *B. cepacia*, which used to be referred to as *Pseudomonas cepacia*. Increased coughing, increased sputum production, changes in sputum character (e.g., thicker and darker in color), tachypnea, dyspnea, increasing oxygen requirement, and a decrease in exercise tolerance are common. Symptoms of chronic sinusitis and nasal polyposis may include nasal obstruction, pain over affected sinuses, and anosmia.

Concomitantly, laboratory testing of peripheral blood may reveal an increased white blood count with increased polymorphonuclear leukocytes and immature forms consistent with an acute infection. Tests of pulmonary function often demonstrate both intermittent

and persistent decreases in forced vital capacity, forced expiratory volume at 1 second (FEV₁), and increased residual volume. Tests of small airway function are more markedly affected as the pulmonary disease progresses. Arterial blood gases may reveal hypoxia or hypercapnia as the disease progresses.

OTHER SIGNS AND SYMPTOMS

The relative insulin deficiency observed in older cystic fibrosis patients is often asymptomatic and only detected on laboratory analysis of serum performed for other reasons. However, cystic fibrosis-related diabetes may present as a recent decline in weight without the typical gastrointestinal symptoms of malabsorption. They may also present as untreated cases of diabetes mellitus type 2. Cor pulmonale is not usually clinically evident unless signs of left-sided heart failure ensue, although enlargement in cardiac size may be noted on routine chest roentgenogram prior to that time. Signs and symptoms of anemia and arthritis with cystic fibrosis patients do not differ from those caused by other chronic diseases.

Excessive losses of sodium and chloride in the sweat of cystic fibrosis patients seldom result in symptoms of heat prostration, but this phenomenon may cause a "salty" taste on the skin.

DIAGNOSIS

The diagnosis of cystic fibrosis is usually made on the basis of elevated sweat chloride concentrations (sweat chloride testing)²⁶ and may be confirmed with CFTR mutational analysis. Another test, recording the potential difference across the nasal epithelium is usually reserved for cases in which the results of sweat testing and mutational analysis are nondiagnostic.²⁷ For sweat chloride determination, two samples of sweat are collected with the use of pilocarpine iontophoresis and the concentration of chloride in each sample is measured. Duplicate sweat chloride concentrations of 60 mEq/L or more are considered diagnostic of cystic fibrosis. However, a number of disorders, such as adrenal insufficiency, hypothyroidism, protein calorie malnutrition, anorexia nervosa, ectodermal dysplasia, mucopolysaccharidosis, nephrosis with edema, type 1 glycogen storage disease, familial hypoparathyroidism syndrome, fucosidosis, nephrogenic diabetes insipidus, and Mauriac syndrome may be associated with elevated sweat chloride concentrations, but generally these conditions do not present a problem in the differential diagnosis of cystic fibrosis. Ninety-eight percent of cystic fibrosis patients will have a sweat chloride concentration 60 mEq/L or greater. The remaining 2% usually have sweat chloride concentrations between 50 and 60 mEq/L and the test may have to be repeated one or more times to obtain definitive results. Nevertheless, the results of sweat testing alone may not be able to confirm the presence or absence of cystic fibrosis. The presence of chronic obstructive respiratory disease, exocrine pancreatic insufficiency, and/or a positive family history of the disease may also provide additional support for the diagnosis. Genetic (CFTR mutation) analysis and recording of nasal transepithelial potential difference may be helpful in making a diagnosis. Genetic (CFTR mutation) analysis may be used to confirm the diagnosis in utero or to detect heterozygotes (carriers) with obvious implications for genetic counseling. Newborn screening for the disease has been adopted in some states, though the benefits of making a presymptomatic diagnosis on long-term outcome are still being assessed.²⁸

COURSE

Cystic fibrosis is a heterogeneous disease in terms of initial presentation, organ involvement, and clinical course. Some children are diagnosed at birth because of meconium ileus, which occurs in approximately 16%

of people with cystic fibrosis. Neonatal screening programs are increasing, but the benefits of presymptomatic diagnosis are still being assessed; prenatal diagnosis is early in its implementation. Most patients are diagnosed by 1 year of age because of a history of steatorrhea and poor weight gain. The median age at diagnosis is 7 months and most patients are diagnosed by 12 years of age.²⁹

The course of the disease after diagnosis varies from one patient to another. A patient may have a rapid downhill course from early pulmonary involvement, while another may suffer only from gastrointestinal complaints for many years without significant pulmonary symptoms. Although the expected life span of cystic fibrosis patients has increased to longer than 30 years of age in the last two decades, some patients still die early in life, secondary to a fulminant pulmonary process. Still others, owing to minimal involvement and a mild course, may not be diagnosed until their second decade of life. The increased longevity now realized with early diagnosis and aggressive treatment may have led to an increase in formerly less-common complications such as diabetes and hepatic disease. Two-year mortality rates greater than 50% are associated with an FEV₁ less than 30% of predicted, PaO₂ less than 50 mm Hg, or PCO₂ greater than 50 mm Hg.³⁰

TREATMENT

Cystic Fibrosis

■ DESIRED OUTCOME

The desired pharmacotherapeutic outcomes for cystic fibrosis are both long- and short-term. ⁹ In the long-term, one obviously tries to halt or delay progression of the disease to allow for normal growth and development. In the short-term, acute problems must be dealt with. The ultimate goal of pharmacotherapy for the gastrointestinal involvement of cystic fibrosis is optimal nutrition. On a day-to-day basis, normal bowel habits, continued weight gain, and normal vitamin levels are desirable. The goal of therapy for the pulmonary component is to reduce the signs and symptoms of airway infection, inflammation, and obstruction. Thus, antibiotic, antiinflammatory, bronchodilator, and mucolytic therapy are geared toward treating the complications that compromise lung function. For an acute pulmonary exacerbation, a return of pulmonary function to the preexacerbation status is the central goal of therapy.

■ GENERAL APPROACH TO TREATMENT

The Cystic Fibrosis Foundation has published clinical guidelines for the diagnosis and care of cystic fibrosis patients, including applicable pharmacotherapy.³¹ The following information is generally in agreement

with those guidelines, although it may contain more current information. The interested reader is referred to that publication for more detail on the drug treatment of cystic fibrosis and its various complications.

Gastrointestinal System

The treatment of gastrointestinal involvement is ultimately aimed at correcting the nutritional deficit present in many patients.³² ⁴ In addition to the pancreatic enzyme replacement and other drug therapy described below, nutritional supplementation is frequently employed. Nutritional interventions range from behavioral modification to nocturnal feedings via gastrostomies.³³

Pancreatic Enzyme Supplementation The backbone of gastrointestinal therapy in cystic fibrosis is pancreatic enzyme replacement or supplementation.³⁴ The preferred products are microencapsulated pancreatic enzymes, although powders are marketed and are useful in patients unable to swallow capsules or to otherwise use the microencapsulated beads they contain. Microencapsulated products protect the contained enzymes from destruction by gastric acid and may be given in much lower doses than their predecessors, which were susceptible to acid breakdown. Most contemporary enzyme replacement products vary mainly in enzyme content per capsule, with lipase content being the chief variable. Table 32-2 lists representative products and their contents are presented. Infants are normally given 2,000 to 4,000 lipase units per 120 mL of formula or breast milk, which provides 450 to 900 lipase units per gram of ingested fat. In general, patients require 500 to 4,000 lipase units per gram of ingested fat, with the average pediatric or adult patient requiring 1,800 units per gram of fat. Enzymes may also be dosed based on weight, with an initial dose of 1,000 lipase units being administered per kilogram of body weight per meal. One-half that amount is administered with snacks.

Before the introduction of microencapsulated enzyme products, various maneuvers were used to circumvent or overcome the problem of acid breakdown. The most obvious of these was to administer large quantities of enzyme product. Enteric-coated (microencapsulated) pancreatic enzymes have largely solved this problem. The occasional patient may yet require large quantities of even the microencapsulated enzyme product. Whether such difficulties are caused by residual acid breakdown or perhaps low pH in the upper small intestine (secondary to deficient bicarbonate excretion by the pancreas) resulting in a failure to dissolve the coating of the microencapsulated beads is unknown. Defective enteric coating on some generic brands has also been described and led to FDA reclassification of these products, requiring bioequivalence data. Histamine H₂-receptor antagonists and proton pump inhibitors have been used to reduce the enzyme dose when residual acid breakdown of enzymes is suspected. Another possible maneuver is

TABLE 32-2 Pancreatic Enzyme Products

Trade Name	Manufacturer	Lipase	Protease	Amylase	Form ^a
Ku-Zyme	Schwarz Pharma	8,000	30,000	30,000	C
Pancrease	McNeil	4,000	25,000	20,000	ECM
Pancrease MT4		4,000	12,000	12,000	ECM
Pancrease MT10		10,000	30,000	30,000	ECM
Pancrease MT16		16,000	48,000	48,000	ECM
Pancrease MT20		20,000	65,000	65,000	C
Pancrelipase	Geneva	4,000	25,000	20,000	ECM
Ultrase		4,500	25,000	20,000	C

Ultrase MT18		24,000	78,000	78,000	ECM
Viokase 8	Robins	8,000	30,000	30,000	T
Viokase		16,800	20,000	70,000	P ^b

^aDosage form: C, capsule; ECM, enteric-coated microspheres or beads; T, tablet; P, powder.

^bViokase powder, units of enzymes per 700 mg.

to administer both microencapsulated and non-enteric-coated enzyme products (e.g., powder) concomitantly.

For patients who are unable to swallow capsules, the contents may be emptied into applesauce, jelly, or some other nonalkaline vehicle, provided the patient does not chew the microencapsulated beads. Side effects are uncommon with pancreatic enzyme products. Perianal irritation resembling diaper rash may occur in infants fed excess quantities of enzyme powders. Hyperuricosuria has also been reported to occur secondary to pancreatic enzyme use, apparently related to the high purine content of the products. Proximal colonic stricture (fibrosing colonopathy) is a dose-related side effect associated with lipase doses in excess of 24,000 units/kg/day.³⁵

Vitamin Supplementation Patients should receive multivitamin tablets daily to provide adequate water-soluble vitamins along with reasonable amounts of vitamins D and K. **4** Although clinically evident fat-soluble vitamin deficiencies are unusual in those patients who are taking adequate pancreatic enzymes and receiving a balanced diet, obvious vitamin K deficiency, manifested as bleeding diathesis, can occur. Demineralization of bone has also been described and vitamin E deficiency has been related to neurologic dysfunction. In addition, appropriate laboratory tests (serum carotene, vitamin E, and cholecalciferol concentrations) will often help document other deficiencies, leading to recommendations for additional supplementation of these vitamins. Water-miscible vitamin A, 4,000 international units/day, and vitamin E, 100 to 400 international units/day should also be administered either singly or in the form of a water-miscible combination product (containing vitamins A, D, E, and K). Vitamin K, in a dose of 5 mg twice weekly, should be given to those patients with prolonged international normalized ratio. It should also be noted that appropriately adjusted doses of fat-soluble preparations may be more cost-effective than their water-miscible counterparts (e.g., 800 international units fat-soluble vitamin E vs. 200 international units water-miscible vitamin E).³⁶

Treating Meconium Ileus and Distal Intestinal Obstruction Syndrome The treatment of meconium ileus or distal intestinal obstruction syndrome can sometimes be limited to the use of enemas with isoosmolar contrast. Unfortunately, surgery (bowel resection and primary anastomosis) is often necessary to treat meconium ileus and prevent its complications. Distal intestinal obstruction syndrome usually responds to management by oral or nasogastric administration of electrolyte lavage solutions. The adequacy of enzyme dosage should also be reassessed in the face of distal intestinal obstruction.

Prevention and Treatment of Cirrhosis Ursodeoxycholic acid, a bile acid with choleric properties, has been shown to produce morphologic and functional improvement in affected patients. The effects are dose related and 15 to 20 mg/kg/d has been used, sometimes in combination with taurine supplementation.³⁷ Administering this agent prophylactically to patients at risk for liver disease, if feasible, has been proposed.³⁸

Cardiovascular System

Various modalities have been used in attempts to treat pulmonary hypertension and secondary cor pulmonale of cystic fibrosis. These treatments, which include the use of vasodilators, inotropic agents, and diuretics, have all resulted in limited and transient effects. This is most likely due to the fact that none of these modes of therapy address the underlying cause of the cor pulmonale, hypoxia. Likewise, supplemental (often nocturnal) oxygen treatment has also failed to affect mortality rates or disease progression, although it does appear to prevent oxygen desaturation that occurs with exercise as well as that occurring during sleep. Thus, the most beneficial approach may be to attempt to improve oxygenation with aggressive pulmonary therapy.

Pulmonary System

Management of the pulmonary component of cystic fibrosis can be broken down into three general areas: antiobstructive, antiinflammatory, and antiinfective therapy.³⁹

Antiobstructive Therapy The cornerstone of pulmonary therapy is percussion and postural drainage, which aids in the clearance of pulmonary mucus and is performed once or twice daily in "healthy" patients and as often as six times daily during acute pulmonary exacerbations. **7** New flutter devices may also be useful adjuncts in this regard. A flutter device is a hand-held unit that produces vibrations in the airways when exhaled through. These vibrations loosen and facilitate the removal of mucus and secretions from the airways. Percussion is sometimes preceded by nebulizer therapy during which nebulized sterile water or 0.9% sodium chloride solution is breathed to liquefy pulmonary secretions. Bronchodilators may be added to the nebulizer solution to prevent bronchospasm and mucolytic agents (e.g., *N*-acetylcysteine; Mucomyst, Bristol-Myers Squibb Company, Princeton, NJ) may be added to liquefy pulmonary secretions or enhance mucus clearance. Although the effects of bronchodilators administered by inhalation can be demonstrated with pulmonary function testing, the efficacy of mucolytic agents are not readily demonstrated. Moreover, many patients prefer not to use *N*-acetylcysteine because of its unpleasant taste and odor and because it may induce bronchospasm. Normal saline and sodium bicarbonate solution may be administered by aerosol as aids to sputum expectoration, but documentation of efficacy is elusive.

Recombinant human DNase has been approved for use in cystic fibrosis. When given by inhalation (2.5 mg once or twice daily), Rh DNase reduces the viscosity of cystic fibrosis sputum and leads to statistically significant, though modest, improvement in pulmonary function.⁴⁰ More importantly, the regular use of Rh DNase may help decrease the incidence of (or lengthen the time between) respiratory exacerbations, thereby improving their quality of life and indirectly decreasing the overall costs of care in patients with mild to moderate disease. Should these outcomes be borne out in additional long-term studies, especially before the onset of clinical symptoms, this therapy may be justified as a way to prevent or delay the progression of pulmonary disease.

Hypertonic saline inhalation recently came to light as an additional therapy to slow the progression of lung damage associated with cystic fibrosis.^{41,42} A 7% solution has generally been used, although other concentrations have been used with similar results. Unfortunately, this product is not commercially available, so it must be extemporaneously compounded. Because of the hypertonic nature of the solution, this solution is associated with an increased incidence of local bothersome respiratory symptoms even though it is safe and effective. Preceding hypertonic saline therapy with a bronchodilator may reduce the incidence of these bothersome symptoms. This therapy may be used concurrently with other inhaled treatments, but should not be mixed with other nebulizer solutions, as it will change the osmolality of the resulting solution. As with other nebulized therapies, to assure appropriate delivery it should only be used with the recommended nebulizer.

Because some cystic fibrosis patients have a component of reactive airway disease that may contribute to their pulmonary disease, systemic bronchodilators such as theophylline and β -agonists may provide some benefit. Recurrent wheezing or dyspnea that improves with bronchodilators represents a legitimate indication for these agents; however, responsiveness to such agents (>15% improvement in FEV₁) should be documented, before a protracted course is begun. Standard antiasthmatic doses of most bronchodilators should be appropriate for cystic fibrosis patients, although theophylline clearance may differ in cystic fibrosis patients and bioavailability of some products may be decreased, sometimes necessitating the use of

higher-than-usual doses.⁴³ Because of the necessity of pharmacokinetic monitoring and its involvement in a number of common drug interactions, theophylline should be considered second-line bronchodilator therapy at most in these patients. Because cystic fibrosis patients are at high risk to develop complications from influenza, the influenza vaccine should be administered on a yearly basis, and amantadine prophylaxis or treatment may be indicated as well. Other interventions that would be appropriate include immunization for influenza, pneumococcal infections and *H. influenzae*.

Antiinflammatory Therapy In an attempt to block the consequences of the inflammatory component of this disease, corticosteroid therapy has been evaluated. **7** Although results of preliminary trials were encouraging, a large, multicenter, placebo-controlled trial found that alternate-day prednisone treatment at 2 mg/kg to have beneficial effects on pulmonary function, but undesirable effects on linear growth and glucose metabolism.⁴⁴ Further analysis of the data from this same study suggested that the benefits of a 1 mg/kg dose might outweigh the risks.⁴⁵ Data concerning the efficacy of inhaled corticosteroids are scant. A long-term trial of oral ibuprofen indicates a beneficial effect by slowing the rate of progression of pulmonary disease.⁴⁶ Unfortunately, therapeutic drug monitoring (periodic determination of ibuprofen serum concentrations) is required.

Antibiotic Therapy Young children with cystic fibrosis have an extended period of time, perhaps months or years, when they have no evidence of airway infection. Later, they develop a mild airway infection or early bacterial colonization often without associated symptoms. However, bronchoalveolar lavage fluid reveals evidence of infection and inflammation (high neutrophil count with a predominance of proinflammatory cytokines). **6** Eventually, they develop a chronic airway infection that cannot be fully eradicated, not even with prolonged use of systemic or topical antibiotics. This scenario is best explained by the ability of bacteria such as *P. aeruginosa* to achieve high-density growth within small airways whereby they become organized into a community that grows more slowly and secretes an extracellular matrix that protects the bacteria from local host defenses and/or most antibiotics. This complex growth pattern is referred to as a biofilm community. Acute exacerbations of cystic fibrosis are thought to involve satellite foci of bacterial proliferation that stimulate mucus production in response to bacterial exoproducts, worsening airway obstruction as a consequence of the host's proinflammatory response.

Because of the complexities of bacterial infections in cystic fibrosis, antibiotics are used with three different goals in mind. **6** First, before an infection develops the primary goal is to detect infections early in their course so that treatment is successful at preventing the bacteria from developing into a biofilm community (bacterial eradication). Second, once biofilm growth has become established, the primary goal is to use antibiotics to prevent rapid bacterial proliferation (bacterial suppression) to avoid excess sputum production, decreased lung function, and the concomitant loss of appetite and weight. Finally, once an acute exacerbation has developed, the primary goal is to eliminate bacterial proliferation, reduce the bacterial load and the degree of sputum production, return lung function to the preexacerbation (target) value, improve nutritional intake and to correct any weight losses (treatment of acute exacerbations).

However, the use of antibiotics in cystic fibrosis is somewhat controversial and certainly challenging. **6** Controversy exists because innate host defenses in cystic fibrosis may certainly be sufficient to eliminate most pathogens including *P. aeruginosa* from the airways. Without antibiotics, some patients with cystic fibrosis appear to go many years before they develop typical airway infections caused by *P. aeruginosa*. In addition, some cystic fibrosis patients have transiently positive throat and bronchoalveolar lavage cultures for *P. aeruginosa*

that resolve without exogenous antibiotics. Thus, it is unclear when antibiotics are actually needed to help eradicate these pathogens. Moreover, once bacterial eradication with antibiotics is accomplished, will some other organism soon initiate another airway infection? In other words, are the early stages of bacterial colonization merely a marker for a decrease in host defenses? Does this decrease in host defense persist suggesting that repeated courses of antibiotics will be required regardless of whether eradication therapy was successful? The answers to these questions remain unknown, thus the use of antibiotics in cystic fibrosis lung disease is controversial.

The chronic use of antibiotics to suppress bacteria in cystic fibrosis is controversial because antibiotic resistance may be induced or enhanced. Suppressive therapy is prescribed with the intention of prolonging the time between acute exacerbations and to slow the rate of progression of lung disease. Although intuitively attractive, this practice is not supported by well-designed clinical trials.⁴⁷ Moreover, the practice of routine, quarterly administration of intravenous courses of antibiotics used at some European centers still lacks proof of efficacy.⁴⁸

Antibiotic treatment for acute pulmonary exacerbations usually results in clinical improvement without eliminating bacteria from the sputum. In this case, the antibiotics are thought to lessen the bacterial burden within the airways, and thereby inhibit the quantity of exotoxins produced or the degree of host inflammation against the bacteria or their exoproducts.⁴⁹ The failure to eradicate the organism suggests that bacteria may be colonizing the airway surface, rather than penetrating the tissues as a pathogen. The bacteria may remain viable within an environment protected from the antibiotics, such as enclosed within a biofilm community. It also suggests the possibility that antibiotics may not be essential for the treatment of acute exacerbations. One study comparing antibiotic therapy to placebo indicated that antibiotics are not essential for recovery from an acute exacerbation.⁵⁰ However, because the study size was small and only included patients with mild to moderate disease, these results may not be applicable to all acute exacerbations. These results are also consistent with the notion that viral infections, air pollutants, irritants, allergens, or some other factors play a role in clinical exacerbations.

Finding known bacterial pathogens at high density in airway secretions, along with the clinical setting of increased cough, increased sputum production that is thicker and darker than baseline, and a significant decrease in lung function, loss of appetite and exercise tolerance, supports the addition of antibiotics to treat this clinical exacerbation. However, deciding to start antibiotic therapy leads to a number of other important, and sometimes perplexing, issues. These include the selection of the best antibiotic(s) for that individual patient, the optimal route of administration, the best dosage and dosage regimen to use, especially in light of altered pharmacokinetics in patients with cystic fibrosis, the potential emergence of antibiotic-resistant bacteria, and the identification of appropriate end points of therapy.

6 Selection of Antibiotic. Suppressive therapy may be accomplished with the use of common orally administered antibiotics such as trimethoprim-sulfamethoxazole, amoxicillin-clavulanic acid, or one of the many oral cephalosporins. Specific therapy for acute exacerbations is directed at proven or likely pathogens such as *P. aeruginosa* and *S. aureus* and usually includes an aminoglycoside and an extended-spectrum penicillin. As most *S. aureus* encountered are β -lactamase producers, use of an extended-spectrum penicillin- β -lactamase inhibitor combination (e.g., ticarcillin-clavulanate) will help avoid the necessity of triple-drug therapy. Single-agent therapy with newer antibiotics, especially on an outpatient basis, is frequently employed at some centers where significant resistance to these agents has not yet emerged. Such agents would include ceftazidime, aztreonam, and ciprofloxacin. However, the evidence supporting the

clinical superiority of two-drug combinations over single-agent therapy leads many clinicians to only treat with combinations.^{51–54} The fact that such combinations are sometimes synergistic in vitro and the possibility that they may act to suppress or delay the emergence of resistance provide attractive rationales for their use. Furthermore, in vitro synergism has been reported to persist even in the face of resistance to one of the single agents in a given combination.⁵⁵ Lastly, monodrug therapy has been met with rapid emergence of resistance.⁵⁶

Unlike other cases of lower respiratory tract infection, organism-specific drug treatment may be based on results from sputum cultures in cystic fibrosis patients because good agreement between sputum and thoracotomy cultures has been demonstrated.⁵⁷ Typically, such results will lead one to prescribe or recommend aminoglycoside-extended-spectrum penicillin combinations, although other antibiotics, such as ciprofloxacin, and older agents, such as colistin, also may play a role. While the complete eradication of *S. aureus* and *H. influenzae* are practical goals or end points of antibiotic therapy, the total eradication of *Pseudomonas* species is infrequent and transient. Thus, once a patient has been colonized/infected with *P. aeruginosa*, it is prudent to assume that it is always present regardless of culture results. Consistent with these infectious phenomena, the complete resolution of pulmonary signs and symptoms becomes less and less likely as the disease progresses. *B. cepacia* and *S. maltophilia* are generally resistant to most antibiotics. These bacteria may be susceptible to trimethoprim-sulfamethoxazole or chloramphenicol. *B. cepacia* from cystic fibrosis patients is frequently susceptible to ceftazidime, whereas some strains of *S. maltophilia* may be susceptible to other agents such as doxycycline and piperacillin.

Selection of Dose-Altered Pharmacokinetics. Although altered pharmacokinetics in cystic fibrosis are not limited to antibiotics (Table 32–3), this drug class has been the most extensively studied.⁵⁸ As is true for theophylline, many cystic fibrosis patients have increased total body clearance for many antibiotics, including the aminoglycosides, some of the β -lactams, and trimethoprim-sulfamethoxazole. Thus higher doses of these agents may be necessary to produce therapeutic concentrations (Table 32–4). Unfortunately, these alterations in pharmacokinetics are neither consistent nor predictable. Why the pharmacokinetics of these antibiotics are different in cystic fibrosis patients is unknown. It appears that for many β -

lactam antibiotics, increased total body clearance could be accounted for by increased renal clearance. However, it should be pointed out that renal function, as reflected by glomerular filtration rate and renal blood flow, is not different in cystic fibrosis patients as compared to noncystic fibrosis controls.⁵⁹ Moreover, a concomitant increase in renal clearance does not completely explain the increase in total-body clearance of aminoglycosides, leading some to speculate about extra-renal pathways for elimination. In any event, increased total body clearance dictates higher doses in many but not all patients. However, a range of dosage requirements should be expected, consistent with a range in the variation of pharmacokinetics in these patients. For example, experience with netilmicin revealed a dosage requirement range of 7 to 17 mg/kg/d to achieve peak concentrations (one-half hour after the end of a drug infusion) of 8 mcg/mL or greater.⁶⁰ The mean dosage requirement in this study was approximately 12 mg/kg/day. Peak concentrations of this magnitude are felt to be necessary to adequately treat pneumonia caused by gram-negative bacteria.^{61,62} Variations in hepatic metabolic activity or in phenotypic distribution of metabolic polymorphisms may explain some pharmacokinetic differences in cystic fibrosis.^{63,64}

Although alterations in pharmacokinetics of antibiotics may correlate with the severity of pulmonary disease,^{65,66} it is not possible to predict changes in antibiotic pharmacokinetics in cystic fibrosis patients based on markers of clinical status or disease progression. Attempts to correlate antibiotic pharmacokinetics with Shwachman score (a gross method for quantitation of disease status) have been unsuccessful.^{67,68} Attempts to guide aminoglycoside dosing are often based on measured serum concentrations during a course of therapy. However, this method may also meet with mixed success owing to changing pharmacokinetics of this family of antibiotics during an acute pulmonary exacerbation.⁶⁹ This observation should not, however, deter one from attempts to adjust doses to desirable concentrations based on serum concentration determinations and subsequent pharmacokinetic calculations.

TABLE 32-4 Antibiotic Doses in Cystic Fibrosis

Antibiotic	Dose (mg/kg/d)	Regimen	Adult Maximum Dose (g/d)
Parenteral antibiotics			
Tobramycin, ^a gentamicin, ^a or netilmicin ^a	6–9	q 8 h	NA
Amikacin ^a	20–30	q 8 h	NA
Azlocillin	400	q 4–6 h	24
Aztreonam	200	q 6 h	8
Ceftazidime	150	q 8 h	6
Colistin	2.5–6	q 6–8 h	NA
Imipenem	45–100	q 6 h	4
Nafcillin	100	q 4–6 h	6
Ticarcillin or ticarcillin/clavulanate	400	q 4–6 h	18
Piperacillin	400	q 4–6 h	18
Oral antibiotics			
Amoxicillin	20	q 8 h	
Amoxicillin/clavulanate	20	q 6 h	
Ciprofloxacin ^b	1,500 mg/d	q 12 h	1.5
Cephalexin	50–100	q 6–8 h	6
Dicloxacillin	80–100	q 6 h	6
Trimethoprim-sulfamethoxazole	10–15 ^c	q 12 h	0.64 ^c
Inhaled antibiotics			
Colistin	150 mg/d	q 6–12 h	NA
Gentamicin or tobramycin	600–1,800 mg/d	q 12 h	NA
Polymyxin B	250 mg/d	q 6–12 h	NA

^aStarting doses; adjust to desired serum concentrations based on dose-serum concentration relationship.

^bAdult dose.

^cBased on trimethoprim.

Alternate Routes of Administration. An additional route of antibiotic administration that is intuitively attractive in patients with cystic fibrosis is by inhalation of aerosolized solution. Theoretically, such a route of administration should deliver the drug to the actual site of infection and perhaps avoid systemic toxicity. Certainly, many classes of antibiotics including β -lactams, aminoglycosides, and polymyxins have been administered to cystic fibrosis patients in this fashion, often in conjunction with systemic antibiotics. However, until recently, no clear effect or advantage had been consistently demonstrated. Early studies suffered from lack of controls, small sample size, and a failure to ensure that the respiratory equipment used would, in fact, guarantee that drug is delivered to the small airways. In a subsequent, placebo-controlled, multicenter trial, 600 mg tobramycin administered by aerosol three times daily was found to produce a small but statistically significant improvement in FEV₁, forced vital capacity, forced expiratory flow 25% to 75%, *P. aeruginosa* density in sputum, and peripheral white blood cell count.⁷⁰ This being recognized, appropriate clinical circumstances for this form of therapy (type and condition of patient), length of therapy, and frequency of therapy remain to be clarified. One-half of this dose is apparently also effective and a 300-mg dose is the current norm. If such doses are to be used, preservative-free antibiotic preparations should be used. The efficacy of smaller doses of inhaled aminoglycosides remains unproven.

Bacterial Resistance. As already noted, emergence of antimicrobial resistance seems to follow the introduction and use of a new antibiotic.⁵⁶ *P. aeruginosa* can exhibit many resistance mechanisms revealed as resistance to quinolones (altered DNA gyrase target site), β -lactams (production of Bush group 1 β -lactamase), aminoglycosides (decreased permeability and modifying enzymes), and carbapenems (decreased permeability). *B. cepacia* is inherently resistant to most antibiotics. Methicillin-resistant staphylococci are increasingly common in institutional settings and will become a more pervasive problem in cystic fibrosis populations. These phenomena require close attention to susceptibility reports in selecting therapy and the avoidance of unnecessary or unnecessarily protracted courses of antibiotic therapy. Another area of increasing concern is the management of transmission of pathogens from one patient to another.⁷¹

Recommendations for Antibiotic Therapy. Despite these inherent difficulties, a number of recommendations regarding the use of systemic antibiotics in cystic fibrosis can be made. 6 The selection of antibiotics should be based on specific culture and susceptibility results. When instituting empiric therapy in the absence of culture results, the clinician can be guided by the most recent laboratory data or institute therapy based on likely pathogens in the patient's age group. Aminoglycosides should be initially dosed at the upper end of the normal dosage range (e.g., 6 to 7.5 mg/kg/d for tobramycin), and serum concentrations should be determined so that dosage can be appropriately adjusted to achieve peak concentrations of at least 8 mcg/mL. It should be kept in mind that aminoglycoside serum half-lives may lengthen during the course of treatment so that a constant relationship between dose and serum concentration may not exist. Consequently, upward adjustments in dosage should be made with some degree of caution and should be followed with further determination of serum concentrations. Once-daily administration of aminoglycosides is gaining popularity as in other settings. Obviously, such a dosing practice would result in much larger peak concentrations than those mentioned above. Comparative efficacy and safety of such dosing regimens in cystic fibrosis patients have not yet been fully elucidated, but this practice is likely to be increasingly employed as cystic fibrosis-specific data are generated.

β -Lactam antibiotics such as extended-spectrum penicillins should be prescribed with aminoglycosides to take advantage of their fre-

quent synergy and prevent the emergence of resistance. These agents should be prescribed in large doses to delay stepwise resistance. Ticarcillin, azlocillin, and piperacillin should be prescribed in a dose of at least 350 mg/kg/day divided into four to six doses. For patients with *P. aeruginosa* and *S. aureus*, the combination of an aminoglycoside and ticarcillin-clavulanate or piperacillin-tazobactam is appropriate. Selection among these agents should be based on local susceptibility patterns and cost considerations. The possible increased incidence of fever and exanthema with the newer penicillins should be kept in mind.⁷² Aztreonam would be a safe and effective β -lactam to use in patients experiencing these serum sickness-like reactions to the penicillins.⁷³ In older patients with *P. aeruginosa* isolates with broad resistance patterns, the clinician should work closely with the microbiology laboratory to identify effective agents or combinations. The potential use of older agents with unique mechanisms of action, such as colistin, should not be overlooked.

Oral antibiotics may be prescribed in symptomatic outpatients with susceptible pathogens in their sputum. Agents with activity against common pathogens such as *S. aureus* and *H. influenzae* are useful in this setting. These typically include such antibiotics as first-generation cephalosporins, trimethoprim-sulfamethoxazole, and amoxicillin-clavulanic acid. The use of such agents on a "prophylactic" basis is discouraged because the data available at present suggest that a beneficial effect does not outweigh the risk of development of resistance among the common bacterial pathogens of cystic fibrosis.⁷⁴ The 4-fluoroquinolone antibiotic ciprofloxacin possesses potent activity against most cystic fibrosis pathogens and has been evaluated in adult patients undergoing pulmonary exacerbations. Although not conclusive because of shortcomings in the studies, available data suggest that this oral agent is as effective as standard intravenous therapy.⁷⁵ The availability of a potent, oral antipseudomonal agent poses a number of potential uses in the cystic fibrosis population. However, it should be kept in mind that repeated or long-term use will likely lead to resistance and that antibiotics play only a supportive role in the treatment of these patients. Thus oral antibiotic therapy, regardless of efficacy, does not negate the need for other forms of therapy which are often best administered in the hospital setting. It should also be pointed out that although ciprofloxacin appears to be safe in patients younger than 18 years of age with little evidence of joint or cartilage toxicity,⁷⁶ this agent should be used with caution in the younger population.

Treatment of Other Pulmonary Complications The drug and nondrug treatments of the most serious of pulmonary complications, including pulmonary hypertension, right-sided heart failure, respiratory failure, pneumothorax, and hemoptysis, are beyond the scope of this chapter. In general, the therapeutic approach does not vary substantively from that caused by other respiratory diseases.

EVALUATION OF THERAPEUTIC OUTCOMES

GASTROINTESTINAL

Normal growth requires adequate nutrition and because of the increased energy needs and possible malabsorption, the nutritional needs of patients with cystic fibrosis cannot be overstated.⁷⁷ 4 The patient's nutritional status should be closely monitored on both short-term and long-term bases. Growth in children and adolescents along with height and weight in all patients should be followed with time; anthropometric measurements give more precise information. The adequacy of pancreatic enzyme replacement can be grossly assessed by following stool patterns with the goal of normal number per day and normal consistency. Any evidence of steatorrhea may indicate suboptimal enzyme therapy. A more precise method would involve assessment of fat quantities in the stool. If a

patient does not respond to normal doses of enzyme supplement, other factors that can cause similar symptoms (bloating, abdominal pain, symptomatic steatorrhea) should be considered. These would include lack of adherence with directions for taking the enzymes, outdated enzymes, dietary factors such as excessive fruit juice consumption, high-fat meals, and concomitant gastrointestinal disease (e.g., enteric bacterial or parasitic infection, celiac disease, inflammatory bowel disease). Vitamin status can be assessed through serum monitoring of fat-soluble vitamin concentrations.

PULMONARY

Pulmonary status can be monitored with a combination of clinical observation and examination and a variety of laboratory tests. Over the long run, pulmonary function is usually followed with spirometry, lung volumes and oxygenation. Physical examination should focus on signs and symptoms of upper and lower respiratory tract infection. In addition, exercise tolerance, recent character of sputum production, and oxygen requirements are key to long-term and short-term assessment. With antibiotic and bronchodilator treatment of acute respiratory exacerbations, a return to preexacerbation clinical status, based on physical examination or pulmonary function testing, becomes a practical end point for antimicrobial treatment. Although the goal of bacterial eradication is desirable, other attainable end points may be more reasonable, as discussed earlier. Bacterial density in sputum, sputum DNA and protein content, and C-reactive protein all have proven value as monitoring parameters but may not be available at many centers. Of the objective parameters, pulmonary function tests correlate best with clinical observations and scoring systems.⁷⁸ Response to intravenous antibiotics and aggressive chest physiotherapy, as measured by FEV₁ at the end of 1 week of treatment, has been used to predict total length of therapy necessary. In patients whose FEV₁ had recovered more than 40% at the end of 1 week, a total of 2 weeks of therapy was generally sufficient.⁷⁹ Little has been done by way of pharmacodynamic studies in treating cystic fibrosis. Therefore, symptomatic improvement is largely relied on to assess the relative success of antibiotic therapy. Oral antibiotic therapy should also be limited in length with specific end points, such as decreased cough and/or improved pulmonary function, identified as treatment commences.

GROWTH AND DEVELOPMENT IN CHILDREN

Realization that early detection and general growth early in life is important for development and general good clinical health status in children with cystic fibrosis, several new areas of investigation have arisen. Early diagnosis and treatment, where appropriate, is recognized as an important contributor to improved health for cystic fibrosis patients. Some states now require newborn screening so as to identify patients early and refer for further followup and education.⁸⁰ Another new area has been the use of growth hormone. Administration of growth hormone improves the growth of prepubertal children with cystic fibrosis.^{81,82} Furthermore, it improves the general clinical status of the patients.

NEW DIRECTIONS IN THERAPY

8 Now that the gene and gene product of cystic fibrosis are identified, gene therapy has obvious potential as treatment.⁸³ Research to date has centered on introduction of the correct gene into affected tissues. Viral vectors, chiefly adenovirus, have been studied in animal models, and human trials are under way. Liposomes may represent another useful delivery mode to introduce the correct gene.

Other novel approaches to therapy are currently being investigated and, for the most part, are directed at the inflammatory

component of the disease or the basic cellular defect. Protease inhibitors hold potential in this condition for reasons cited earlier. α_1 -Antitrypsin administered by aerosol shows promise, as does secretory leukocyte protease inhibitor and other antiproteases.^{84–86} Pentoxifylline, which is known to inhibit tumor necrosis factor- α transcription and its stimulatory effect on polymorphonuclear leukocytes, also shows promise.⁸⁷ In an attempt to directly approach the cellular defect in cystic fibrosis, the diuretic amiloride was shown to possess positive activity in improving respiratory secretion rheology and clearance,⁸⁸ presumably by blocking excessive sodium reabsorption, but was found to be no more effective than placebo in a large-scale controlled trial. At a similar level, the secretagogues adenosine and uridine triphosphate have been shown to increase chloride excretion in epithelial cells of cystic fibrosis patients.⁸⁹ The combination of amiloride and uridine triphosphate (thereby both blocking sodium absorption and stimulating chloride secretion) may also promote clearance of airway secretions.⁹⁰ Other experimental therapies interact with the defects in CFTR production or processing. Studies with phenylbutyrate (which increases the amount of functional protein that reaches the cell surface), 8-cyclopentyl-1,3-dipropylxanthine (CPX), milrinone (a phosphodiesterase inhibitor), and genistein (a tyrosine-kinase inhibitor), each of which activate mutant CFTR, and low concentration gentamicin, which suppresses certain premature stop mutations in CFTR, are all active.

It is hoped that some, if not all, of these approaches will provide viable additions to our pharmacologic armamentarium for this disease. For older, more severely affected patients who may not be able to benefit from such advances, organ transplantations (single lung, double lung, heart–lung) are more widely available and reasonably successful.⁹¹

CONCLUSIONS

Pharmacotherapeutic intervention plays an important role in the management of these patients but is complex. The clinician is, as yet, faced with many unresolved issues in attempting to apply sound therapeutic principles in this population. Although close attention should be paid to pharmacologic treatment, the approach to these patients should be multifaceted and multidisciplinary in character. In addition to the involvement of such pediatric subspecialties as pulmonology, gastroenterology, pharmacology, and infectious diseases, contributions from such areas as nutrition support and social work should be a regular and ongoing part of the management effort.

ABBREVIATIONS

CFTR: cystic fibrosis transmembrane regulator

FEV₁: forced expiratory volume at 1 second

PaO₂: partial pressure of arterial oxygen

PaCO₂: partial pressure of arterial carbon dioxide

SECTION 4

GASTROINTESTINAL DISORDERS

CHAPTER

33

Evaluation of the Gastrointestinal Tract

KEITH M. OLSEN, MARIE A. CHISHOLM-BURNS, AND MARK W. JACKSON

KEY CONCEPTS

- 1 The patient history is key to evaluating GI disorders and should include the problem onset, the setting in which it developed, and its presentation. Patient warning signs should be identified that require immediate referral for further evaluation.
- 2 A complete physical examination should be performed with severity and location of symptoms directing the focus of the examination.
- 3 Barium sulfate allows evaluation of the hollow organs of the digestive tract for mucosal lesions and stricture.
- 4 The upper GI series involves radiographic visualization of the esophagus, stomach, and small intestine; whereas the lower GI series involves visualization of the colon and rectum.
- 5 Enteroclysis is used to evaluate the small bowel by introducing contrast agents by tube through the nose or mouth.
- 6 GI ultrasonography, computed tomography, and magnetic resonance imaging provide images of the gallbladder, liver, pancreas, and abdominal wall.
- 7 Radionuclide imaging is useful to visualize the liver, spleen, bile ducts, gallbladder, and gut.
- 8 The endoscope, an illuminated optical instrument, remains an important tool for the diagnosis and management of GI disorders with common endoscopic studies, including esophagogastroduodenoscopy, colonoscopy, sigmoidoscopy, and endoscopic retrograde cholangiopancreatography.
- 9 Ambulatory pH-metry is an important diagnostic test for gastroesophageal reflux disease. The traditional method is gradually being replaced by wireless systems.
- 10 Multichannel intraluminal impedance and pH monitoring combines acid exposure with impedance changes in resistant flow to aide the diagnosis of reflux in patients receiving a proton pump inhibitor.
- 11 Capsule endoscopy takes pictures of the GI tract in the assessment of the small bowel.

The gastrointestinal (GI) tract is composed of organs and tissues that have diverse forms and functions. It includes the esophagus, stomach, small intestine, large intestine, colon, rectum, biliary tract, gallbladder, liver, and pancreas. Despite the rapid proliferation of technology for the diagnosis of digestive diseases, the patient history and physical examination remain important for initial assessment, triage, and direction of further diagnostic interventions. When combined with a thorough patient history and physical examination, diagnostic procedures are essential in the evaluation of GI disorders. This chapter describes the most commonly used tools available in clinical practice to evaluate patients with GI diseases.

SYMPTOMS OF GASTROINTESTINAL DYSFUNCTION

A variety of symptoms can arise from GI dysfunction. Common GI symptoms include heartburn, abdominal pain, dyspepsia, nausea, vomiting, diarrhea, constipation, and gastrointestinal bleeding. Signs and symptoms of malabsorption, hepatitis, and GI infection are also commonly seen. All clinicians must recognize warning symptoms that include weight loss, intractable vomiting, anemia, dysphagia, and bleeding, and a patient presenting with any of these symptoms should be immediately referred for further diagnostic interventions. The next sections describe methods that are commonly used to assess patients with GI complaints. For specific details concerning each GI disease state, please consult that particular chapter in this book.

PATIENT HISTORY

A comprehensive patient history is the cornerstone in the evaluation of a patient with digestive complaints. A clear, detailed, chronologic account of the patient's problems should be ascertained. This account

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

TABLE 33-1 General Questions in a Gastrointestinal History

- 1. Tell me about the problem that you are experiencing. When did it start?
- 2. Where is your pain located? Please point to the area where you feel pain. What were you doing when the pain occurred? How rapidly did the pain come on? Is your pain constant or intermittent? What factors exacerbate or alleviate your pain? Does the pain awaken you at night?
- 3. What medications are you taking to help the pain? How much do you take? Do these medications work?
- 4. What other medications are you currently taking? Why are you taking them?
- 5. Have you recently had a change in dietary intake? If so, please describe. Can you draw any correlation between the foods that you eat and your gastrointestinal (GI) complaint?
- 6. Have you recently had a change in bowel habits? Have you experienced any diarrhea or constipation lately? Do you experience painful bowel movements?
- 7. Have you experienced any nausea or vomiting lately? If so, please describe conditions centered around this event.
- 8. Have you experienced any recent change in weight? Was this intentional? How many pounds have you gained or lost and over what time period did this occur? How has your appetite been?
- 9. Have you passed any blood from your rectum or vomited blood? Have you noticed any dark, tarry stools?
- 10. Have you had any acid indigestion?
- 11. Do you have difficulty swallowing?
- 12. Has anyone in your family experienced similar GI complaints? If so, please describe. Does anyone in your family have a history of GI disorders, including cancer of the GI tract?
- 13. Describe your past medical history, including illnesses and surgeries.
- 14. Please describe any past injuries that you have experienced.
- 15. Have you recently traveled outside of the United States? If so, where? When? How long did you stay? What kind of living conditions did you experience? What foods and drinks did you ingest?

should include the onset of the problem, the setting in which it developed, and its manifestations. The symptoms onset often provides important information that helps to formulate a differential diagnosis. For example, biliary pain, such as that encountered with symptomatic gallstone disease, typically evolves over minutes and lasts for hours, but pain caused by pancreatitis evolves over hours and lasts for days. The setting is always relevant as it provides clues to the possible origin of the disorder. For example, in the patient with complaints of reflux or ulcer disease, when do the symptoms occur, are they alleviated or worsened by food and does the pain diminish when administered acid-suppressive therapy? Is the patient immunosuppressed (opportunistic infection)? Also aiding in the diagnosis is identification of factors that alleviate or exacerbate the principal symptom. For instance, ingesting a meal often relieves the pain of duodenal ulcer, but worsens that of gastric ulcer. The healthcare professional should ask questions that address the potential etiologic possibilities, including motility disorders, structural diseases, malignancies, infections, psychosocial factors, dietary factors, and travel-associated diseases.^{1,2} Questions concerning past medical and family history detailing illnesses, surgeries, injuries, foreign travel, living conditions, and habits are valuable (Table 33–1). Because some pharmacologic agents cause GI injury, a medication history is vital (Table 33–2).

PHYSICAL EXAMINATION

Because the organ systems of the body interact and may provide important data needed for diagnosis, it is necessary to perform a thorough physical examination.³ A comprehensive evaluation of the patient should be performed with notable attention to physical appearances and vital signs as they may suggest clues to the patient’s overall condition and stability. Depending on the acuteness and severity of the clinical presentation, careful examination of the abdomen is an essential part of the workup. Examination of the

abdomen classically includes inspection, auscultation, percussion, and palpation. Inspection of the abdomen may reveal scars, hernias, bulges, or peristalsis. Auscultation is mainly focused on analysis of bowel sounds and identification of bruits. Percussion of the abdomen allows for detection of tympany, measurement of visceral organs, and detection of ascites. Palpation may allow the clinician to identify tenderness, rigidity, masses, and hernias. A digital rectal examination is used to detect masses and tenderness, and to assess muscle tone. Stool on the examiner's glove obtained during rectal examination is often subjected to testing for detection of occult blood.^{2,3} Patients presenting with upper gastrointestinal symptoms need more careful questioning to distinguish symptoms of reflux disease versus peptic ulcer disease. Additionally, once cardiovascular disease is eliminated, patients with chest pain may have a gastrointestinal source to their symptoms and further diagnostic workup may be needed.

LABORATORY AND MICROBIOLOGIC TESTS

Laboratory and microbiologic tests may be used to (a) assess organ function, (b) screen for certain GI disorders, and (c) evaluate the effectiveness of therapy. To achieve an accurate diagnosis and provide the best care, it is important to assess the patient's fluid and electrolyte status, nutritional status, and abdominal organ function. A complete blood cell count should be completed early in the evaluation to provide information concerning infection, malignancy, bone marrow suppression, anemia, and blood loss.⁴ A serum chemistry panel provides clinicians with valuable information. For example, serum creatinine and blood urea nitrogen are often used as a measure of hydration status, as well as serving as indicators for renal function. Elevations in serum creatinine and blood urea nitrogen may be indicative of renal dysfunction or dehydration, and bleeding from the GI tract may lead to elevations in blood urea nitrogen. Albumin and prealbumin levels can be used to assess the patient's nutritional and hydration status and provide information concerning hepatic and renal function. Specifically, low albumin may be indicative of malnutrition, hepatic dysfunction, nephrotic syndromes, or protein-losing enteropathies such as Crohn's disease and ulcerative colitis. Serum measurements of sodium, chloride, and potassium are useful to determine electrolyte abnormalities associated with diarrheal illnesses.

Specific laboratory blood tests are used as screening tools for certain GI disorders. Measurements of serum aspartate transaminase and alanine transaminase are elevated in most diseases of the liver, and serum alkaline phosphatase and bilirubin are often elevated in hepatobiliary disorders. Prothrombin time and international normalized ratio are related to hepatocyte synthesis of vitamin K-dependent clotting factors and serve as indirect measurements of hepatic function. When evaluating patients with suspected pancreatitis, serum and urine measurements of amylase and lipase are important, because these will be elevated in most patients with acute pancreatitis (see Chap. 41).

Microbiologic and related studies are useful in evaluating patients with unexplained diarrhea, abdominal pain, and suspected GI infections. Examination studies of the stool may be used to detect the presence of bacteria, parasites, or toxins. Pathogens most often responsible for infectious diarrhea and enteritis include bacteria such as *Shigella*, *Salmonella*, *Escherichia coli*, *Yersinia*, and *Clostridium difficile*; viruses such as cytomegalovirus, especially in acquired immune deficiency syndrome (AIDS) patients; and parasites such as *Entamoeba histolytica* and *Giardia lamblia*.⁵ Patients presenting with watery, pseudomembranous diarrhea following antibiotic exposure within the previous 1–3 months should have their stool checked for *C. difficile* toxins A and B. Because *Helicobacter pylori* is a significant factor associated with peptic ulcer disease and MALT lymphomas,

identification of this organism is critical in patients experiencing upper gastrointestinal symptoms (see Chap. 35).⁵

DIAGNOSIS

The patient's history, physical examination, and routine laboratory tests are valuable in establishing a diagnosis, but frequently more specific studies are required to confirm or disprove a clinical suspicion. The most appropriate diagnostic test depends on the anatomic region involved, the suspected abnormality, reliability of the test (e.g., sensitivity vs. specificity), patient preference, the patient's overall condition, and clinical manifestations of the patient. The next sections outline the most frequently used diagnostic studies and procedures and their roles in evaluating the GI tract.

RADIOLOGY

Radiologic procedures rely on the differential absorption of radiation of adjacent tissues to highlight anatomy and pathology. Radiologic procedures important in evaluating the GI tract include plain radiography, upper GI series, lower GI series, and enteroclysis.^{6,7}

Plain Radiography of the GI System

Radiographic evaluation of the GI tract often starts with plain films of the abdomen, which are straightforward, noncontrast radiographs.⁷ Specific abdominal structures that may be identified include the kidneys, ureters, and bladder; esophagus; stomach; intestine; stones; and vessels. Plain films are often used to evaluate abdominal pain. Clinicians frequently employ plain radiographic fluoroscopy to guide and position other instruments that are used to evaluate and treat GI disorders; an example is the manipulation of dilation devices to treat esophageal strictures. Bowel obstruction and perforation are especially well identified by this technique.

Contrast Agents

Barium sulfate is the contrast agent of choice for studying the esophagus, stomach, and intestine; but it has largely been replaced to a great extent by direct visualization of the GI tract.⁷ Barium sulfate is a metallic material detected by radiography after swallowing the agent; it is termed the *barium swallow*. Barium sulfate is not generally absorbed, and constipation is the most frequent adverse effect reported with its use. Barium sulfate can reveal mucosal lesion defects and lumen size, and is helpful in diagnosing hiatal hernias, strictures along the GI tract, polyps, tumors, and ulcers. The barium esophagram should not serve as a primary diagnostic tool for patients with heartburn.

Upper GI Series

The upper GI series refers to the radiographic visualization of the esophagus, stomach, and small intestine. Patient preparation for an upper GI series usually consists of instructing patients to refrain from eating or drinking 8 to 12 hours prior to testing, which allows the upper GI tract to empty. A contrast agent such as barium sulfate is administered to the patient at the beginning of the study. The observed swallowing of the contrast agent permits visualization and monitoring of esophageal structural and motor functions. As the contrast medium flows into the stomach and small intestine, several regional radiographic films are taken in order to inspect these areas. This tracking of contrast agents through the small intestine is referred to as the *small bowel follow-through*. The upper GI series with small bowel follow-through commonly uncovers gastric cancer, peptic ulcer disease, esophagitis, gastric outlet obstruction, and Crohn's disease (Fig. 33–1). In general, the barium swallow is plagued by low sensitivity and specificity for many GI disorders.

FIGURE 33-1. Upper GI series with small bowel follow-through demonstrating narrowed distal terminal ileum and separation of small bowel loops (arrow). These findings are consistent with Crohn's disease.

Lower GI Series

The lower GI series is used to examine the colon and rectum. Patients complaining of lower abdominal pain, constipation, or diarrhea are often referred for a lower GI series. The colon is prepared for the procedure by instructing the patient to refrain from eating or drinking 8 to 12 hours before the procedure, and by administering bowel-cleansing agents such as bisacodyl, magnesium citrate, magnesium hydroxide, or polyethylene glycol-electrolyte solution. During a lower GI series, a barium sulfate enema is given to contrast the terminal large intestine and rectum. The lower GI series is useful to detect and evaluate enterocolitis, obstructions, volvulus, and mucosal and structural lesions.⁷ The lower GI series is commonly used to diagnose Crohn's disease, ulcerative colitis, colon cancers, and diverticulitis.

Small Bowel Enteroclysis

Enteroclysis, or small bowel enema, refers to the technique of direct small bowel introduction of a contrast agent through a tube inserted through the patient's mouth or nose. Intermittent radiographic films are taken of the small bowel as the contrast agent flows distally (Fig. 33-2). Because enteroclysis provides detailed imaging, it is an accurate method for evaluating the small bowel and for detecting small mucosal lesions that may be overlooked on the traditional small bowel follow-through.⁹ Methylcellulose is used to enhance the detail of the small intestine in enteroclysis, thereby improving visualization. Patient preparation for this procedure involves instructing patients to refrain from eating or drinking 8 to 12 hours before testing and administering bowel-cleansing agents. The most frequent disorder evaluated by enteroclysis is obscure GI bleeding.

IMAGING STUDIES

By using computer-assisted techniques, it is possible to generate cross-sectional radiographic images of the body. Ultrasonography,

FIGURE 33-2. Normal small bowel enteroclysis. Contrast agents are instilled into the small bowel to highlight tumors, strictures, or other lesions. In this image, one can identify the normal circular folds.

computed tomography, radionuclide scanning, and magnetic resonance imaging are frequently used imaging procedures for evaluating digestive disorders.^{6,7}

Ultrasonography

Ultrasonography provides images of deeper structures such as the gallbladder, liver, pancreas, and abdominal wall. The clinician is able to image slices of the GI tract by directing a narrow beam of high-energy sound waves into the body and recording the reflections from the various organs and structures. Because ultrasonography is non-invasive, relatively inexpensive, requires no ionizing radiation, and can be performed at bedside with a portable unit, it is a well-accepted and useful technology. It accurately depicts gallstones and gallbladder, and hepatobiliary and pancreatic diseases (Fig. 33-3). When combined with Doppler technologies, ultrasonography can image GI vascularity. Ultrasonography is limited by the presence of bowel gas and excessive amounts of body fat.^{6,7}

Computed Tomography

Computed tomography (CT) or computed axial tomography (CAT) scans provide detailed images of the GI system in which transverse planes of tissue are swept by a radiographic beam and a computer analysis of the variance in absorption produces a precise reconstructed image of that area.⁶ Contrast agents may be added in a CT procedure to illuminate specific hollow structures and vascularity of the GI tract. The abdominal CT displays organs from the diaphragm down to the pelvic brim, and is especially valuable for detecting GI diseases of the liver, pancreas, spleen, and colon. Patient preparation for CT includes refraining from eating or drinking for a minimum of 4 hours before the test. The remarkable detail that CT offers in imaging organs and tissues adds to its popularity for evaluation of the GI system. CT is useful in the identification of liver cancer, pancreatitis, pancreatic cancer, intra-abdominal abscesses, and cysts (Fig. 33-4).^{6,7} Unlike ultrasonography, patient body size or the presence of gas does not limit the quality of imaging with CT.

Radionuclide Imaging

Radionuclide imaging involves intravenous injections of a radiopharmaceutical imaging agent and the use of a computerized detection camera to gather images. Although the choice of a radiopharmaceutical agent depends on the specific organ or function being studied, the most commonly used agent is technetium (^{99m}Tc) tagged to a carrier molecule. Radiographic imaging is useful to visualize the liver and spleen (liver-spleen scan), bile ducts, gallbladder (HIDA [hepatoimin-

FIGURE 33-3. Abdominal ultrasonogram demonstrating a chronic pancreatic pseudocyst (arrows).

odiacetic acid] scan), and gut (bleeding scan).^{6,7} Cysts, abscesses, tumors, and obstructions are detected and displayed as areas of differential uptake of radioactivity (Fig. 33-5).⁶ Radionuclide bleeding scans may detect hemorrhages and may assist in localization. Contrast media nephrotoxicity in patients with preexisting renal impairment remains a clinically significant problem. Pretest treatment in high-risk patients with pharmacologic agents has demonstrated mixed results.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) places the patient in close proximity to a high-strength magnetic field through which pulses of radiofrequency radiation are projected, thereby exciting the nuclei of hydrogen, phosphorus, oxygen, and other elements. The radio-

frequency signals are manipulated and recorded by a computer, and a two-dimensional image representing a section of the patient is produced.^{6,7} MRI has greater sensitivity for identifying liver tumors than do ultrasonography, CT, and radionuclide imaging. Significant advances in MRI technology and imaging capabilities often makes this a preferred diagnostic test.^{6,7}

Arteriography

Arteriography of the gut depicts the configuration of visceral blood vessels after intravenous administration of a contrast medium. Arteriography may be employed for detecting tumors and bleeding lesions and therapeutic applications, including embolization of bleeding vessels, fistulas, and inoperable tumors.^{6,7}

FIGURE 33-4. CT scan of the abdomen showing pancreatitis with calcification (white arrow) and pancreatic pseudocyst (black arrows).

FIGURE 33-5. HIDA scan demonstrating normal gallbladder (arrow).

ENDOSCOPY

Refinement in optical engineering and fiber optics has made possible the development of the endoscope, which revolutionized the management of GI disorders. An endoscope is an illuminated white-light optical instrument designed to inspect the interior of the GI tract. Endoscopes enable the practitioner to inspect intraluminal mucosal lesions and to obtain biopsies and washings for cytology studies. Upper GI tract endoscopy (esophagogastroduodenoscopy [EGD]) is capable of inspecting the esophagus, stomach, and proximal small bowel. Lower GI tract endoscopy of the rectum and colon may be accomplished by colonoscopy or sigmoidoscopy. Endoscopy can also be used to perform many therapeutic procedures.⁸

Preparation for endoscopic examinations includes instructing patients to refrain from eating or drinking for at least 8 to 12 hours prior to the endoscopic procedure. Bowel cleansing is necessary for colonoscopy and sigmoidoscopy. Topical pharyngeal anesthetics, such as viscous lidocaine or benzocaine, usually improve patient acceptance of the upper endoscopic tube. Intravenous sedating agents, such as the benzodiazepines, lorazepam, midazolam, and, more recently, propofol, are among the most common agents used to induce “conscious sedation” prior to the endoscopy. These sedating agents tend to improve patient acceptance and ease of the procedure. The agents should not be used without appropriate monitoring and the availability of flumazenil, a benzodiazepine antagonist. Serious adverse events have occurred with these agents when used for conscious sedation. In addition, antimuscarinic agents such as atropine sulfate are occasionally used for their cardiovascular effects, such as increasing a patient’s heart rate, or for their antispasmodic effects, such as reducing duodenal and colonic motility. Because of its effectiveness at reducing bowel motility, glucagon may be used. Endoscopy should be used with caution in patients with severe respiratory or cardiac failure, and for patients with suspected perforated viscera. The most commonly used endoscopic studies are upper endoscopy, colonoscopy, sigmoidoscopy, and endoscopic retrograde cholangiopancreatography.⁸

Esophagogastroduodenoscopy

EGD is used to examine the esophagus, stomach, and duodenum. Patient preparation for EGD includes fasting for at least 6 to 8 hours prior to the procedure and the administration of sedatives and topical anesthetics. Common indications may be either diagnostic or therapeutic in nature, and include evaluating suspected upper GI bleeding, obstructions, upper abdominal pain, persistent vomiting, and radiographic abnormalities.¹² EGD can be used interventionally in upper gastrointestinal bleeding for ligation procedures, sclerosing or vasoconstrictive agent administration at the site of the bleed, or using a heat probe on a bleeding vessel. EGD commonly uncovers peptic ulcers and is the method of choice to diagnose Barrett esophagus and other esophageal erosions (Fig. 33–6). Once viewed as the method of choice to diagnosis gastroesophageal reflux disease, EGD has lost ground to the wide availability of proton pump inhibitors. Because of the favorable side-effect profile of proton pump inhibitors, they are frequently prescribed by primary care physicians for heartburn and other symptoms attributed to gastroesophageal reflux disease. Because primary care physicians usually refer patients only when they fail to respond to therapy, by the time an endoscopy is performed in patients on proton pump inhibitor therapy, the examination is likely to reveal normal-appearing mucosa.⁸

Colonoscopy

Colonoscopy permits direct examination of the large intestine and rectum. To prepare for colonoscopy, the patient should fast for at least 8 to 12 hours prior to the examination, and bowel cleansing should be completed. A benzodiazepine and a short-acting narcotic agent are given to produce conscious sedation. As with upper GI endoscopy, indications for lower GI endoscopy can be either diagnostic or therapeutic in nature, and include evaluation and detection of abnormalities visualized by radiography, as well as GI hemorrhage, colonic lesions, volvulus, ulcerative colitis, Crohn disease, diverticulitis, and excision of colonic polyps.⁹

Sigmoidoscopy

Sigmoidoscopy is used to evaluate the sigmoid colon and rectum (Fig. 33–7). Flexible sigmoidoscopy has virtually replaced rigid sigmoidoscopy because of increased patient comfort and superior performance. The major indication for this examination is to evaluate symptoms related to the colon or rectum, and to conduct screening of asymptomatic patients for colon polyps or cancer. Patient preparation involves instructing patients to abstain from eating or drinking for at least 8 hours prior to the procedure and the administering of bowel-cleansing agents. Anoscopy is especially useful in evaluating the anus.

FIGURE 33-6. EGD demonstrating linear red streaks with a central white streak extended up the esophagus in peptic regurgitant esophagitis. (From Kasper DL, Braunwald E, Hauser S, et al, eds. *Harrison’s Principles of Internal Medicine*, 16th ed. New York: McGraw-Hill, 2005:1731, with permission.)

FIGURE 33-7. Sigmoidoscopic photograph demonstrating severe ulcerative colitis with diffuse ulceration, bleeding, and exudation. (From Kasper DL, Braunwald E, Hauser S, et al., eds. *Harrison's Principles of Internal Medicine*, 16th ed. New York: McGraw-Hill, 2005:1732, with permission.)

The major indications for anoscopic examination include symptoms related to the anus and rectum, such as bleeding, protrusions or swelling, pain, and severe itching. Patients undergoing sigmoidoscopy or anoscopy generally do not require sedation.

Endoscopic Retrograde Cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) is an important procedure that is used to evaluate and treat diseases of the biliary tree and pancreas. By injecting contrast agents through a catheter placed in the pancreaticobiliary ducts during ERCP, abnormalities such as obstructions, calculi, and strictures can be examined. ERCP also allows for the use of therapeutic techniques such as the removal of ductal stones, stenting of strictures, and sphincterotomy. Preparation for ERCP consists of conscious sedation and glucagon to relax gut motility. Common reasons for ERCP include detection and evaluation of pancreatic malignancy, pancreatitis, biliary obstruction, bile duct stones, jaundice, and patients whose clinical presentation suggests biliary disease (Fig. 33-8).^{7,9}

Capsule Endoscopy

Capsule endoscopy allows the visualization of the small intestine, and consists of a vitamin-pill-sized video camera that is swallowed and acts as an endoscope. As the video capsule travels naturally through the digestive tract, images are transmitted to a recording device. Patients return the recording device to the practitioner so

that the images can be downloaded to a computer and evaluated. Eventually, the camera is naturally excreted and not retrieved.¹⁰

MISCELLANEOUS TESTS

Esophageal Manometry

Esophageal manometry is used to evaluate diseases of the esophagus by assessing esophageal motor functions. Common indications for this procedure include dysphagia and obscure chest pain. A special catheter equipped with pressure transducers is placed into the esophagus to measure esophageal pressures and peristalsis. Provocative testing with pharmacologic agents such as edrophonium chloride, a cholinergic muscle stimulant, may be used to precipitate esophageal pain during this procedure. Typical indications for esophageal manometry include evaluating esophageal dysmotility, nonobstructive dysphagia, obscure chest pain, scleroderma, intestinal pseudoobstruction, achalasia, and aiding in positioning instruments such as pH probes.

Ambulatory Esophageal pH Monitoring

Esophageal pH monitoring is considered by many clinicians as the gold standard for studying gastric fluid pH in patients who complain of gastroesophageal reflux. Ambulatory 24-hour pH monitoring is an elegant way to link esophageal acid exposure, as detected by a probe in the esophagus, with patient symptoms. The pH probe is placed approximately 5 cm above the distal esophagus. Because intraesophageal pH is normally higher (pH 6) than that of the stomach (pH approximately 1 to 3), the pH probe will record a decrease in pH if gastroesophageal reflux occurs. The most accepted method to identify gastroesophageal reflux during monitoring is the sudden decrease in pH below 4.0. The ambulatory 24-hour pH study links the patient's symptom to an acid event (Fig. 33-9). Wireless pH monitoring systems have gradually replacing the older methods that required a wire probe placement. A capsule is attached to the distal esophagus by a delivery system. The capsule then transmits measured pH data to a receiver by radiotelemetry technique. Wireless systems offer the advantage of better patient acceptance and extended monitoring of up to 96 hours versus 24 hours of the wire method. There are limitations to ambulatory pH monitoring in patients receiving proton pump inhibitor therapy or in the detection of nonacidic or weakly acidic refluxate.¹¹

Multichannel intraluminal impedance monitoring is an emerging technique to study acid and nonacid reflux. The method combines pH measurements with manometry that enables the measurement of

FIGURE 33-8. Endoscopic retrograde cholangiopancreatography (ERCP) demonstrating a dilated, irregular pancreatic duct with areas of stricturing (large arrow). A pancreatic pseudocyst is visible immediately adjacent to the spine (small arrows).

FIGURE 33-9. Ambulatory pH monitoring. The pH recordings from two esophageal probes are plotted over a 3-hour interval. Notice that the patient's symptom of regurgitation correlates with a low pH (<4) event (arrow).

and distinction between swallowing and reflux. In patients who have failed symptomatically to respond to empiric proton pump inhibitor therapy in GERD, the test can separate those in whom symptoms are associated with acid reflux from those in whom symptoms are associated with non-acid reflux. Outcomes studies are required to further evaluate the usefulness of this diagnostic method.^{12,13}

The Bernstein test, an older procedure that is used to measure gastric fluid pH, has largely been replaced by ambulatory pH monitoring. The procedure requires inserting a nasogastric tube and administering alternating dripped solutions of normal saline and 0.1 N hydrochloric acid (HCl) into the esophagus via the nasogastric tube. If patient symptoms are reproduced by the acid perfusion and not the saline, the study is considered abnormal and indicative of acid hypersensitivity.¹⁴

Endoscopic Ultrasonography

Endoscopic ultrasonography is useful in the diagnosis and staging of gastroenterologic disorders. The instrument itself functions very much like a typical upper endoscope but with the added feature of an ultrasound transducer. The examiner is then able to see the regional anatomy and pathology beneath the mucosa. The major advantage of this procedure is its capability to deliver the ultrasound transducer to close proximity of deep tissues for enhanced image resolution. In clinical practice, endoscopic ultrasonography is highly useful in detecting and defining gastrointestinal and pancreatic malignancies. It also plays a role in the diagnosis of submucosal lesions and small pancreatic malignancies. Endoscopic ultrasonographic guidance of fine-needle biopsy is increasingly performed.

Laparoscopy

Laparoscopy uses a tube-like device with an elaborate optical system that permits distinct visualization of the peritoneal cavity. General anesthesia is often required and a surgical incision is made in the abdomen to allow the passage of the laparoscope. The exterior of the liver, gallbladder, spleen, peritoneum, diaphragm, and pelvic organs may be examined during the laparoscopic examination. Similar to the other endoscopic techniques mentioned, biopsies and therapeutic interventions may be performed during the laparoscopy. Rea-

sons for doing laparoscopy include evaluating patients with ascites, abdominal masses, chronic abdominal pain, abnormalities indicated on liver-spleen scan, liver diseases, obstructive jaundice, and hepatic malignancy.

CONCLUSIONS

Evaluation of the GI tract begins with a careful history and comprehensive physical examination. It then proceeds in a deliberate and thoughtful manner to establish the correct diagnosis and appropriate management. Laboratory and microbiologic tests, radiography, ultrasonography, computed tomography, radionuclide scanning, magnetic resonance imaging, arteriography, endoscopy, esophageal manometry, pH monitoring, endoscopic ultrasonography, and laparoscopy have definite roles in diagnosing and evaluating GI disorders. Clinicians should be aware of warning signs that require immediate referral for further diagnostic studies.

DIANNE B. WILLIAMS AND ROBERT R. SCHADE

KEY CONCEPTS

- 1 Patients should be assessed for symptoms, such as heartburn, and for signs and symptoms of complications (e.g., dysphagia) that require immediate medical attention.
- 2 Endoscopy is used to evaluate mucosal damage from gastroesophageal reflux disease (GERD) and to assess for the presence of Barrett's esophagus or other complications; ambulatory reflux monitoring is useful for confirming GERD in patients with persistent symptoms without evidence of mucosal damage or in patients with atypical symptoms; manometry is useful in patients who are candidates for antireflux surgery and for ensuring proper placement of pH probes.
- 3 The goals of GERD treatment are to alleviate symptoms, decrease the frequency of recurrent disease, promote healing of mucosal injury, and prevent complications.
- 4 GERD treatment is determined by disease severity and includes lifestyle changes and patient-directed therapy, pharmacologic treatment, and interventional approaches (antireflux surgery or endoscopic therapies).
- 5 Patients with typical GERD symptoms should be treated with lifestyle modifications and a trial of empiric acid-suppression therapy. Those who do not respond to empiric therapy or who present with alarm symptoms should undergo endoscopy.
- 6 Interventional approaches offer an alternative treatment for selected patients when long-term pharmacologic management is undesirable.
- 7 Acid suppression is the mainstay of GERD treatment. H_2 -receptor antagonists are effective in less-severe GERD. Proton pump inhibitors provide the greatest symptom relief and the highest healing rates, especially in patients with erosive disease or moderate to severe symptoms.
- 8 Many patients with GERD will relapse if medication is withdrawn, so long-term maintenance treatment may be required. A proton pump inhibitor is the drug of choice for maintenance of patients with moderate to severe GERD.
- 9 Patient medication profiles should be reviewed for drugs that may aggravate GERD. Patients should be monitored for adverse drug reactions and potential drug–drug interactions.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

Gastroesophageal reflux disease (GERD) is a common medical disorder seen by clinicians from various specialties. GERD refers to symptoms or mucosal damage that results from abnormal reflux of the stomach contents into the esophagus.¹ When the esophagus is repeatedly exposed to refluxed material for prolonged periods of time, inflammation of the esophagus (reflux esophagitis) occurs, and in some cases, it can progress to erosion of the squamous epithelium of the esophagus (erosive esophagitis). Gastroesophageal reflux associated with disease processes in organs other than the esophagus, such as the lungs or larynx, is referred to as atypical (or extraesophageal) GERD. Severe reflux symptoms associated with normal endoscopic findings are referred to as “symptomatic GERD,” nonerosive reflux disease (NERD), or endoscopy-negative reflux disease (ENRD). Complications of long-term reflux may include the development of strictures, Barrett's esophagus, or adenocarcinoma of the esophagus.

Many patients suffering from mild GERD do not go on to develop erosive esophagitis and are often managed with lifestyle changes, antacids, and nonprescription histamine-2 (H_2)-receptor antagonists or nonprescription proton pump inhibitors. Those with more severe symptoms (with or without endoscopic findings) predictably follow a course of relapsing disease, requiring more intensive treatment with acid-suppression therapy followed by long-term maintenance therapy. Interventional approaches, including antireflux surgery and endoscopic therapies, offer an alternative for selected patients in whom prolonged medical management is undesirable.

EPIDEMIOLOGY

Gastroesophageal reflux disease occurs in people of all ages but is most common in those older than age 40 years. Although mortality associated with GERD is rare, GERD symptoms may have a significant impact on quality of life. The true prevalence and incidence of GERD is difficult to assess because many patients do not seek medical treatment, symptoms do not always correlate well with the severity of the disease, and there is no standardized definition or universal gold standard method for diagnosing the disease. However, an estimated 10% to 20% of people in Western countries suffer from GERD symptoms on a weekly basis.² Heartburn is the hallmark symptom of GERD and is generally described as a substernal sensation of warmth or burning rising up from the abdomen that may radiate to the neck. It may be waxing and waning in character.

The prevalence of GERD varies depending on the geographic region, but appears highest in Western countries.² Except during pregnancy and possibly NERD, there does not appear to be a major difference in incidence between men and women. NERD tends to be more common in women and in patients who are approximately a decade younger than patients who develop erosive disease. Although gender does not generally play a major role in the development of GERD, it is an important factor in the development of Barrett's

esophagus, a complication of GERD in which the normal squamous epithelium is replaced with specialized columnar epithelium. Barrett’s esophagus is most prevalent in white adult males in Western countries. The presence of Barrett’s esophagus increases the risk for adenocarcinoma of the esophagus. Other risk factors and comorbidities that may contribute to the development or worsening of GERD symptoms include family history, obesity, smoking, alcohol consumption, certain medications and foods, respiratory diseases, and chest pain.

PATHOPHYSIOLOGY

The key factor in the development of GERD is the abnormal reflux of gastric contents from the stomach into the esophagus.¹ In some cases, gastroesophageal reflux is associated with defective lower esophageal sphincter (LES) pressure or function. Patients may have decreased gastroesophageal sphincter pressures related to (a) spontaneous transient LES relaxations, (b) transient increases in intraabdominal pressure, or (c) an atonic LES, all of which may lead to the development of gastroesophageal reflux. Problems with other normal mucosal defense mechanisms, such as anatomic factors, esophageal clearance, mucosal resistance, gastric emptying, epidermal growth factor, and salivary buffering, may also contribute to the development of GERD. Aggressive factors that may promote esophageal damage upon reflux into the esophagus include gastric acid, pepsin, bile acids, and pancreatic enzymes. Thus the composition and volume of the refluxate, as well as duration of exposure, are important aggressive factors in determining the consequences of gastroesophageal reflux. Rational therapeutic regimens in the treatment of gastroesophageal reflux are designed to maximize normal mucosal defense mechanisms and attenuate the aggressive factors.

LOWER ESOPHAGEAL SPHINCTER PRESSURE

The lower esophageal sphincter is a manometrically defined zone at the distal esophagus with an elevated basal resting pressure. The sphincter is normally in a tonic, contracted state, preventing the reflux of gastric material from the stomach, but relaxes on swallowing to permit the free passage of food into the stomach.

Mechanisms by which defective LES pressure may cause gastroesophageal reflux are threefold. First, and probably most importantly, reflux may occur following spontaneous transient LES relaxations that are not associated with swallowing. Although the exact mechanism is unknown, esophageal distension, vomiting, belching, and retching have all been shown to cause relaxation of the LES. While not thought to contribute significantly to erosive esophagitis, these transient relaxations, which are normal postprandially, may play an important role in intermittent nonerosive reflux. Transient decreases in sphincter pressure are responsible for more than half of the reflux episodes in patients with GERD. The propensity to develop gastroesophageal reflux secondary to transient decreases in LES pressure is probably dependent on numerous factors, including the degree of sphincter relaxation, efficacy of esophageal clearance, patient position (more common in recumbent position), gastric volume, and intragastric pressure. Second, reflux may occur following transient increases in intraabdominal pressure (stress reflux). An increase in intraabdominal pressure such as that occurring during straining, bending over, coughing, eating, or a Valsalva maneuver may overcome a weak LES, and thus may lead to reflux. Third, the LES may be atonic, thus permitting free reflux as seen in patients with scleroderma. Although transient relaxations are more likely to occur when there is normal LES pressure, the latter two mechanisms are more likely to occur when the LES pressure is decreased by such factors as fatty foods, gastric distension, smoking, or certain medications. Table 34–1 lists medi-

TABLE 34-1 Foods and Medications That May Worsen GERD Symptoms

Decreased lower-esophageal sphincter pressure	
Foods	
Fatty meal	Garlic
Carminatives (peppermint, spearmint)	Onions
Chocolate	Chili peppers
Coffee, cola, tea	
Medications	
Anticholinergics	Ethanol
Barbiturates	Nicotine (smoking)
Caffeine	Nitrates
Dihydropyridine calcium channel blockers	Progesterone
Dopamine	Tetracycline
Estrogen	Theophylline
Direct irritants to the esophageal mucosa	
Foods	
Spicy foods	Tomato juice
Orange juice	Coffee
Medications	
Alendronate	Iron
Aspirin	Quinidine
Nonsteroidal antiinflammatory drugs	Potassium chloride

cations and foods that affect lower esophageal sphincter pressure.³ Various foods aggravate esophageal reflux by decreasing LES pressure or by precipitating symptomatic reflux by direct mucosal irritation (e.g., spicy foods, orange juice, tomato juice, and coffee).

Pregnancy is a condition in which reflux is common. There are many postulated reasons for the increased incidence of heartburn during pregnancy, including hormonal effects on esophageal muscle, LES tone, and physical factors (increased intraabdominal pressure) resulting from an enlarging uterus.

A decrease in LES pressure resulting from any of the previously mentioned causes is not always associated with gastroesophageal reflux. Likewise, individuals who experience decreases in sphincter pressures and subsequently reflux, do not always develop GERD. The other natural defense mechanisms (anatomic factors, esophageal clearance, mucosal resistance, and other gastric factors) must be evoked to explain this phenomenon.

ANATOMIC FACTORS

Disruption of the normal anatomic barriers by a hiatal hernia was once thought to be a primary etiology of gastroesophageal reflux and esophagitis. Now it appears that a more important factor related to the presence or absence of symptoms in patients with hiatal hernia is the LES pressure. The size of a hiatal hernia is proportional to the frequency of transient LES relaxations. Patients with hypotensive LES pressures and large hiatal hernias are more likely to experience gastroesophageal reflux following abrupt increases in intraabdominal pressure compared to patients with a hypotensive LES and no hiatal hernia. Although anatomic factors are still considered significant by some, the diagnosis of hiatal hernia is currently considered a separate entity with which gastroesophageal reflux may or may not simultaneously occur.

ESOPHAGEAL CLEARANCE

In many patients with GERD, the problem is not that they produce too much acid, but that the acid produced spends too much time in contact with the esophageal mucosa. This is not surprising, because the symptoms and/or severity of damage produced by gastroesophageal reflux are partially dependent on the duration of contact between the gastric contents and the esophageal mucosa. This contact time is, in turn, dependent on the rate at which the esopha-

gus clears the noxious material, as well as the frequency of reflux. The esophagus is cleared by primary peristalsis in response to swallowing, or by secondary peristalsis in response to esophageal distension and gravitational effects. Swallowing contributes to esophageal clearance by increasing salivary flow. Saliva contains bicarbonate that buffers the residual gastric material on the surface of the esophagus. The production of saliva decreases with increasing age, making it more difficult to maintain a neutral intraesophageal pH. Therefore esophageal damage caused by reflux occurs more often in the elderly, and similarly in patients with Sjögren's syndrome or xerostomia. Swallowing is also decreased during sleep, making nocturnal GERD a problem in many patients.

MUCOSAL RESISTANCE

Within the esophageal mucosa and submucosa there are mucus-secreting glands. The mucus secreted by these glands may contribute to the protection of the esophagus.⁴ Bicarbonate moving from the blood to the lumen can neutralize acidic refluxate in the esophagus. When the mucosa is repeatedly exposed to the refluxate in GERD, or if there is a defect in the normal mucosal defenses, hydrogen ions diffuse into the mucosa, leading to the cellular acidification and necrosis that ultimately cause esophagitis. In theory, mucosal resistance may be related not only to esophageal mucus, but also to tight epithelial junctions, epithelial cell turnover, nitrogen balance, mucosal blood flow, tissue prostaglandins, and the acid-base status of the tissue.⁴ Saliva is also rich in epidermal growth factor, stimulating cell renewal.

GASTRIC EMPTYING

Delayed gastric emptying can contribute to gastroesophageal reflux. An increase in gastric volume may increase both the frequency of reflux and the amount of gastric fluid available to be refluxed. Gastric volume is related to the volume of material ingested, rate of gastric secretion, rate of gastric emptying, and amount and frequency of duodenal reflux into the stomach. Factors that increase gastric volume and/or decrease gastric emptying, such as smoking and high-fat meals, are often associated with gastroesophageal reflux. This partially explains the prevalence of postprandial gastroesophageal reflux. Fatty foods may increase postprandial gastroesophageal reflux by increasing gastric volume, delaying the gastric emptying rate, and decreasing the LES pressure. Patients with gastroesophageal reflux, particularly infants, may have a defect in antral motility. The delay in emptying may promote regurgitation of feedings, which might, in turn, contribute to two common complications of GERD in infants (e.g., failure to thrive and pulmonary aspiration).⁵

COMPOSITION OF REFLUXATE

The composition, pH, and volume of the refluxate are important aggressive factors in determining the consequences of gastroesophageal reflux. In animals, acid has two primary effects when it refluxes into the esophagus. First, if the pH of the refluxate is less than 2, esophagitis may develop secondary to protein denaturation. In addition, pepsinogen is activated to pepsin at this pH and may also cause esophagitis. Duodenogastric reflux esophagitis, or "alkaline esophagitis," refers to esophagitis induced by the reflux of bilious and pancreatic fluid. The term *alkaline esophagitis* may be a misnomer in that the refluxate may be either weakly alkaline or acidic in nature. An increase in gastric bile concentrations may be caused by duodenogastric reflux as a result of a generalized motility disorder, slower clearance of the refluxate, or after surgery.⁶

Although bile acids have both a direct irritant effect on the esophageal mucosa and an indirect effect of increasing hydrogen ion

permeability of the mucosa, symptoms are more often related to acid reflux than to bile reflux. Specifically, the percentage of time that the esophageal pH is below 4 is greater for patients with severe disease as compared to those with mild disease. Esophageal pH monitoring in conjunction with 24-hour bile monitoring has shown a higher incidence of Barrett's esophagus in patients who have both acid and alkaline reflux.⁶ More study is needed to substantiate this finding. Nevertheless, the combination of acid, pepsin, and/or bile is a potent refluxate in producing esophageal damage.

COMPLICATIONS

Several complications may occur with gastroesophageal reflux, including esophageal strictures, Barrett's esophagus, and adenocarcinoma of the esophagus. Strictures are common in the distal esophagus and are generally 1 to 2 cm in length. The use of nonsteroidal antiinflammatory drugs or aspirin has been implicated as an additional risk factor that may contribute to the development or worsening of GERD complications.² Although GERD may lead to esophageal bleeding, the blood loss is usually chronic and low grade in nature, but anemia may occur. In some patients, the reparative process leads to the replacement of the squamous epithelial lining of the esophagus by specialized columnar-type epithelium. This condition, known as Barrett's esophagus, is more likely to occur in those patients with a long history (years) of symptomatic reflux.⁷ Patients with Barrett's esophagus have a greater than 30% incidence of esophageal stricture formation. The stricture is often the presenting finding, as once Barrett's esophagus is found, the patient gets treatment. Additionally, the risk of esophageal adenocarcinoma is 30 to 60 times higher in patients with Barrett's esophagus as compared to the general population.⁸

The pathophysiology of gastroesophageal reflux is a complex cyclic process. It is difficult, if not impossible, to determine which occurs first: gastroesophageal reflux leading to defective peristalsis with delayed clearing, or an incompetent LES pressure leading to gastroesophageal reflux. Understanding the factors associated with the development of GERD provides insight into the treatment modalities currently used to manage patients suffering from this disease.

CLINICAL PRESENTATION

1 Patients with GERD may display symptoms described as (a) typical, (b) atypical, or (c) alarm. Table 34–2 summarizes each of these clinical presentations of GERD. The severity of the symptoms of gastroesophageal reflux does not always correlate with the degree of esophagitis, but it does correlate with the duration of reflux. Patients with nonerosive disease may have symptoms as severe as those with endoscopic findings.

It is important to distinguish GERD symptoms from those of other diseases, especially when chest pain or pulmonary symptoms are present. Interestingly, close to half of patients presenting with chest pain who have a normal electrocardiogram have GERD.⁹ Similarly, approximately half of patients with asthma have GERD.⁹ Patients presenting with asthma (especially nocturnal asthma) that is poorly responsive to standard medical therapies should be evaluated to determine if GERD contributes to their symptoms. Pulmonary symptoms result from either direct irritation of the vagus nerve when refluxed acid comes in contact with the esophageal mucosa, causing bronchospasm (the reflex theory) or, less commonly, from aspiration of the refluxate into the lungs, causing chemical irritation that manifests as pneumonia or pulmonary fibrosis (the reflux theory).

As previously mentioned, patients who are inadequately treated for GERD may go on to develop complications from long-term acid exposure. Long-term, recurrent reflux symptoms that are not ade-

TABLE 34-2 Clinical Presentation of GERD
Typical symptoms: May be aggravated by activities that worsen gastroesophageal reflux such as recumbent position, bending over, or eating a meal high in fat. <ul style="list-style-type: none">• Heartburn• Water brash (hypersalivation)• Belching• Regurgitation
Atypical symptoms: In some cases, these extraesophageal symptoms may be the only symptoms present, making it more difficult to recognize GERD as the cause, especially when endoscopic studies are normal. <ul style="list-style-type: none">• Nonallergic asthma• Chronic cough• Hoarseness• Pharyngitis• Chest pain• Dental erosions
Alarm symptoms: These symptoms may be indicative of complications of GERD such as Barrett's esophagus, esophageal strictures, or esophageal cancer. <ul style="list-style-type: none">• Continual pain• Dysphagia• Odynophagia• Unexplained weight loss• Choking

quately treated may lead to the development of Barrett’s esophagus and may be an independent risk factor for the development of esophageal adenocarcinoma.⁸ Esophageal strictures may be present in patients presenting with dysphagia. However, these symptoms may occur in other esophageal disorders such as esophageal diverticulum, achalasia, obstruction, esophageal spasm, esophageal infections, scleroderma, and malignancy. The presence of alarm symptoms should be further investigated to differentiate other diseases as the cause.

The most useful tool in the diagnosis of gastroesophageal reflux is the clinical history, including both presenting symptoms and associated risk factors. Patients presenting with mild, typical symptoms of reflux (heartburn and regurgitation) do not usually require invasive esophageal evaluation. These patients generally benefit from an initial empiric trial of acid-suppression therapy. A clinical diagnosis of GERD can be assumed in patients who respond to appropriate therapy.¹ Further diagnostic evaluation should be performed in those patients do not respond to therapy, for those who present with alarm symptoms (e.g., dysphagia, weight loss), and in those with long-standing GERD symptoms. Alarm symptoms may indicate more complicated disease and long-standing GERD symptoms increase the risk for Barrett’s esophagus.

2 Useful tests in diagnosing GERD include endoscopy, ambulatory reflux monitoring, and manometry. Endoscopy is the preferred technique for assessing the mucosa for esophagitis, identifying Barrett’s esophagus and diagnosing complications.¹ It enables visualization and biopsy of the esophageal mucosa. Although endoscopy is a highly specific test, it is not extremely sensitive. In mild cases of GERD, the esophageal mucosa may appear relatively normal. In addition, noninflammatory GERD and major motor disorders may be missed by endoscopy. A camera-containing capsule swallowed by the patient offers the newest technology for visualizing the esophageal mucosa. The PillCam ESO is less invasive and takes less than 15 minutes to perform in the clinician’s office. Images of the esophagus are downloaded through sensors placed on the patient’s chest that are connected to a data collector. The camera-containing capsule is passed in the stool.

Although less expensive than endoscopy, barium radiography lacks the sensitivity and specificity needed to accurately determine the presence of mucosal injury or to distinguish between Barrett’s esophagus and esophagitis. For these reasons, barium radiography has limited use in the routine diagnosis of GERD. Unfortunately,

the presence or absence of mucosal damage does not prove the patient’s symptoms are reflux related; for that, ambulatory reflux monitoring is useful.

Ambulatory pH testing identifies patients with excessive esophageal acid exposure and helps determine if symptoms, both typical and atypical, are acid related. However, pH monitoring may be less reliable in confirming laryngopharyngeal reflux.¹⁰ Interestingly, patients may have severe symptoms, including esophagitis, even when total acid exposure is considered normal.¹ Ambulatory pH testing may also be useful in patients who are on what is considered adequate therapy, but whose symptoms are not improving. However, GERD that is truly refractory to medical therapy is uncommon. Ambulatory pH testing can be performed by passing a small pH probe transnasally and placing it approximately 5 cm above the LES.^{11,12} Patients are asked to keep a diary of symptoms that later are correlated with the pH measurement corresponding to the time the symptom was reported. In addition to correlating symptoms to abnormal esophageal acid exposure, ambulatory pH testing also documents the percentage of time the intraesophageal pH is below 4 and determines the frequency and severity of reflux. Two recent developments related to ambulatory reflux monitoring include (a) the use of combined impedance and acid testing and (b) the use of a tubeless method of acid monitoring.¹ Whereas ambulatory pH testing only measures acid reflux, combined impedance and acid testing measures both acid and nonacid reflux. This may be useful when evaluating patients on acid suppression therapy. The second method involves the attachment of a radiotelemetry capsule to the esophageal mucosa. The advantages of this method are that a longer period of monitoring is possible (48 hours) and it is more comfortable for the patient because a nasogastric tube is unnecessary.

The empiric use of standard- or even double-dose proton pump inhibitor (specifically omeprazole) as a therapeutic trial for diagnosing the presence of GERD may be useful in patients with atypical symptoms. This approach is less expensive, more convenient, and more readily available than ambulatory reflux monitoring. Problems with using a proton pump inhibitor as a diagnostic tool include lack of a standardized dosing regimen and duration of the diagnostic trial.

Esophageal manometry may be used to ensure the proper placement of esophageal pH probes and to evaluate esophageal peristalsis and motility prior to antireflux surgery. To perform manometry, a multilumen pressure sensing tube is passed into the stomach and the pressures are measured as the tube is pulled back across the lower esophageal sphincter, esophagus, and pharynx. The recent advancement of the tubeless pH monitoring system using endoscopic landmarks for placement may negate the need for manometry for ensuring proper placement of esophageal pH probes.¹

TREATMENT

DESIRED OUTCOMES

3 Therapeutic modalities used in the treatment of gastroesophageal reflux are targeted at reversing the various pathophysiologic abnormalities. The goals of treatment are to (a) alleviate or eliminate the patient’s symptoms; (b) decrease the frequency or recurrence and duration of gastroesophageal reflux; (c) promote healing of the injured mucosa; and (d) prevent the development of complications. Therapy is directed at augmenting defense mechanisms that prevent reflux and/or decrease the aggressive factors that worsen reflux or mucosal damage (Fig. 34–1). Specifically, therapy is directed at (a) decreasing the acidity of the refluxate; (b) decreasing the gastric volume available to be refluxed; (c) improving gastric emptying; (d) increasing LES pressure; (e) enhancing esophageal acid clearance; and (f) protecting the esophageal mucosa.

FIGURE 34-1. Therapeutic interventions in the management of gastroesophageal reflux disease. Pharmacologic interventions are targeted at improving defense mechanisms or decreasing aggressive factors. (LES, lower esophageal sphincter.)

■ GENERAL APPROACH TO TREATMENT

4 The treatment of GERD is categorized into one of the following modalities: (a) lifestyle modifications and patient-directed therapy with antacids, nonprescription H_2 -receptor antagonists, and/or nonprescription proton pump inhibitors; (b) pharmacologic intervention with prescription-strength acid suppression therapy; (c) and interventional therapies (antireflux surgery or endoscopic therapies; Table 34–3). The initial therapeutic modality used is in part dependent on the patient's condition (frequency of symptoms, degree of esophagitis, and presence of complications). Historically, a step-up approach was used, starting with noninvasive lifestyle modifications and patient-directed therapy, and progressing to pharmacologic management or interventional approaches (Table 34–4). A step-down approach, starting with a proton pump inhibitor given once or twice daily instead of an H_2 -receptor antagonist, and then stepping down to the lowest degree of acid suppression needed to control symptoms, is also effective. Neither the “step-up” nor the “step-down” approach has superior efficacy over the other. The clinician should determine the most appropriate approach for the individual patient. Every attempt should be made to aggressively control symptoms and to prevent relapses early in the course of the patient's disease in order to prevent the complications that are seen with long-standing symptomatic GERD.¹³ In patients with moderate to severe GERD, especially those with erosive disease, starting with a proton pump inhibitor as initial therapy is advocated because of its superior efficacy over H_2 -receptor antagonists.

Dietary and lifestyle modifications with education about factors that may worsen GERD symptoms is reasonable to discuss with the patient even though they are unlikely to control the patient's symptoms in most cases.¹ Table 34–5 lists many of the lifestyle modifications that can be recommended.¹ Although most patients do not respond to lifestyle changes alone, education about their potential benefits should be stressed on a routine basis. Patients with mild or infrequent symptoms may see improvement with the inexpensive nonprescription H_2 -receptor antagonists, proton pump inhibitors, antacids, or alginic acid.

5 Patients who do not respond to lifestyle modifications and patient-directed therapy after 2 weeks should seek medical attention and are generally started on empiric therapy consisting of an acid-suppression agent. Acid-suppression therapy with proton pump inhibitors or H_2 -

TABLE 34-3 Evidence-Based Treatment Recommendations for GERD

Recommendations	Level of Evidence ^a
Lifestyle modifications	
Patients may benefit from lifestyle modifications but most will require acid suppression therapy to control symptoms.	IV
Patient-directed therapy	
Over-the-counter antacids, H_2 -receptor antagonists, and proton pump inhibitors may be used in patients with mild, infrequent heartburn or regurgitation. Patients experiencing continuous symptoms for longer than 2 weeks should be seen by their clinician. Patients experiencing alarm symptoms should seek medical attention as soon as possible.	IV
Acid-suppression therapy	
Acid-suppression therapy is the preferred treatment for GERD. Proton pump inhibitors provide more rapid relief of symptoms and are more effective at healing the esophageal mucosa compared to H_2 -receptor antagonists in patients with moderate to severe GERD.	I
Promotility therapy	
Promotility therapy may be useful in some patients when combined with acid-suppression therapy. They are generally not recommended as monotherapy in patients with GERD.	II
Maintenance therapy	
Most patients with GERD will require continuous therapy to control symptoms and to prevent complications.	I
Surgery	
Antireflux surgery represents a viable maintenance option for patients with an established diagnosis of GERD.	II
Endoscopic therapy	
Symptom control may be achieved with the use of endoscopic therapies in some patients with an established diagnosis of GERD.	III
Refractory GERD	
GERD that is refractory to adequate acid suppression is uncommon. In these cases, the diagnosis should be confirmed through further diagnostic tests, preferably ambulatory pH testing, before antireflux surgery is considered.	IV

^aLevel of evidence:

I = Strong evidence from at least one published systematic review of multiple, well-designed, randomized, controlled trials.

II = Strong evidence from at least one published, properly designed, randomized, controlled trial of appropriate size and in an appropriate clinical setting.

III = Strong evidence from published, well-designed trials without randomization, single group, pre-post, cohort, time series, or matched case-controlled studies.

IV = Evidence from well-designed nonexperimental studies from more than one center or research group or opinion of respected authorities, based on clinical evidence, descriptive studies, or reports of expert consensus committees.

Data from DeVault KR, Castell DO. Updated guidelines for the diagnosis and treatment of gastroesophageal reflux disease. *Am J Gastroenterol* 2005;100:190–200.

receptor antagonists is the mainstay of GERD treatment. Patients presenting with moderate to severe symptoms (with or without esophageal erosions) should be started on a proton pump inhibitor as initial therapy because it provides the most rapid symptomatic relief and healing in the highest percentage of patients.¹ H_2 -receptor antagonists in divided doses are effective in patients with mild GERD. Standard H_2 -receptor antagonist doses may be increased to 2 to 4 times the normal dose in patients who do not respond to standard doses. However, if this is necessary, it is more cost-effective to switch to a proton pump inhibitor.

Promotility agents are not as effective as acid-suppression agents. Combining promotility agents with acid-suppression drugs offers only modest improvements in symptoms over standard doses of H_2 -receptor antagonists and should not be routinely recommended. In addition, the availability of a promotility agent that has an acceptable adverse effect profile is lacking. Mucosal protectants, such as sucralfate, have a very limited role in the treatment of GERD.

TABLE 34-4 Therapeutic Approach to GERD in Adults

Patient Presentation	Recommended Treatment Regimen	Comments
Intermittent, mild heartburn	Lifestyle modifications plus patient-directed therapy Antacids <ul style="list-style-type: none"> • Maalox or Mylanta 30 mL as needed or after meals and at bedtime • Gaviscon 2 tabs after meals and at bedtime • Calcium carbonate 500 mg, 2–4 tablets as needed and/or Nonprescription H ₂ -receptor antagonists (taken up to twice daily) <ul style="list-style-type: none"> • Cimetidine 200 mg • Famotidine 10 mg • Nizatidine 75 mg • Ranitidine 75 mg or Nonprescription proton pump inhibitor (taken once daily) <ul style="list-style-type: none"> • Omeprazole 20 mg 	Lifestyle modifications should be started initially and continued throughout the course of treatment. If symptoms are unrelieved with lifestyle modifications and nonprescription medications after 2 weeks, patient should seek medical attention.
Symptomatic relief of GERD	Lifestyle modifications plus prescription-strength acid suppression therapy H ₂ -receptor antagonists (for 6–12 weeks) <ul style="list-style-type: none"> • Cimetidine 400 mg twice daily • Famotidine 20 mg twice daily • Nizatidine 150 mg twice daily • Ranitidine 150 mg twice daily or Proton pump inhibitors (for 4–8 weeks); all are given once daily <ul style="list-style-type: none"> • Esomeprazole 20 mg • Lansoprazole 15 mg • Omeprazole 20 mg • Pantoprazole 40 mg • Rabeprazole 20 mg 	For typical symptoms, treat empirically with prescription-strength acid-suppression therapy. If symptoms recur, consider maintenance therapy (MT). Note: Most patients will require standard doses for MT. Mild GERD can usually be treated effectively with H ₂ -receptor antagonists. Patients with moderate to severe symptoms should receive a proton pump inhibitor as initial therapy.
Healing of erosive esophagitis or treatment of patients presenting with moderate to severe symptoms or complications	Lifestyle modifications plus Proton pump inhibitors for 4–16 weeks (up to twice daily) <ul style="list-style-type: none"> • Esomeprazole 20–40 mg daily • Lansoprazole 30 mg daily • Omeprazole 20 mg daily • Rabeprazole 20 mg daily • Pantoprazole 40 mg daily or High-dose H ₂ -receptor antagonist (for 8–12 weeks) <ul style="list-style-type: none"> • Cimetidine 400 mg four times daily or 800 mg twice daily • Famotidine 40 mg twice daily • Nizatidine 150 mg four times daily • Ranitidine 150 mg four times daily 	For atypical or alarm symptoms, obtain endoscopy (if possible) to evaluate mucosa. Give a trial of a proton pump inhibitor. If symptoms are relieved, consider MT. Proton pump inhibitors are the most effective maintenance therapy in patients with atypical symptoms, complications, and erosive disease. Patients not responding to pharmacologic therapy, including those with persistent atypical symptoms, should be evaluated via ambulatory reflux monitoring to confirm the diagnosis of GERD (if possible).
Interventional therapies	Antireflux surgery or endoscopic therapies	

Maintenance therapy is generally necessary to control symptoms and to prevent complications. In patients with more severe symptoms (with or without esophageal erosions), or in patients with other complications, maintenance therapy with a proton pump inhibitor is most effective. Routine use of combination therapy has no role in maintenance therapy of GERD. GERD that is refractory to adequate acid suppression is rare. In these cases, the diagnosis should be confirmed through further diagnostic tests before long-term, high-dose therapy or interventional approaches (antireflux surgery or endoscopic therapies) are considered.¹

■ NONPHARMACOLOGIC THERAPY

Nonpharmacologic treatment of GERD includes (a) lifestyle modifications, which should be started initially and continued throughout the treatment course for GERD, and (b) interventional approaches (antireflux surgery or endoscopic therapies), which may be viable maintenance modalities in selected patients.

Lifestyle Modifications

The most common lifestyle modifications that a patient should be educated about include (a) weight loss; (b) elevation of the head of the bed; (c) consumption of smaller meals and not eating 3 hours prior to sleeping; (d) avoidance of foods or medications that exacerbate GERD; (e) smoking cessation; and (f) avoidance of alcohol (see Table 34–5).

Obesity increases the risk of GERD, most likely through increased intraabdominal pressure. Disruption of the esophagogastric junction has also been seen in obese patients.¹⁴ A high-fat meal will decrease LES pressure for 2 hours or more postprandially. In contrast, a high-protein, low-fat meal will elevate LES pressure. Consequently, weight loss and a low-fat diet may help to improve GERD symptoms. Elevating the head of the bed approximately 6 to 8 inches with a foam wedge under the mattress (not just elevating the head with pillows) decreases nocturnal esophageal acid contact time and should be recommended. Many foods may worsen the

TABLE 34-5 Nonpharmacologic Treatment of GERD with Lifestyle Modifications

- Elevate the head of the bed (increases esophageal clearance). Use 6- to 8-inch blocks under the head of the bed. Sleep on a foam wedge.
- Dietary changes
 - Avoid foods that may decrease lower esophageal sphincter pressure (fats, chocolate, alcohol, peppermint, and spearmint)
 - Avoid foods that have a direct irritant effect on the esophageal mucosa. (spicy foods, orange juice, tomato juice, and coffee)
 - Include protein-rich meals in diet (augments lower esophageal sphincter pressure)
 - Eat small meals and avoid eating immediately prior to sleeping (within 3 hours if possible; decreases gastric volume)
 - Weight reduction (reduces symptoms)
- Stop smoking (decreases spontaneous esophageal sphincter relaxation)
- Avoid alcohol (increases amplitude of the lower esophageal sphincter, peristaltic waves, and frequency of contraction)
- Avoid tight-fitting clothes
- Discontinue, if possible, drugs that may promote reflux (calcium channel blockers, β -blockers, nitrates, theophylline)
- Take drugs that have a direct irritant effect on the esophageal mucosa with plenty of liquid if they cannot be avoided (bisphosphonates, tetracyclines, quinidine, and potassium chloride, iron salts, aspirin, nonsteroidal antiinflammatory drugs)

Data from DeVault KR, Castell DO. Updated guidelines for the diagnosis and treatment of gastroesophageal reflux disease. *Am J Gastroenterol* 2005;100:190-200.

symptoms of GERD. Fats and chocolate can decrease LES pressure, whereas citrus juice, tomato juice, coffee, and pepper may irritate damaged endothelium.

It is important to evaluate patient profiles and to identify potential medications that may exacerbate GERD symptoms. Medications, such as anticholinergics, barbiturates, calcium channel blockers, and theophylline decrease LES pressure. Other medications, including aspirin, iron, nonsteroidal antiinflammatory drugs, quinidine, potassium chloride, and bisphosphonates can act as direct contact irritants to the esophageal mucosa. Patients taking bisphosphonates (e.g., alendronate) should be instructed to drink 6 to 8 ounces of plain tap water and remain upright for at least 30 minutes following administration. Proper patient education can help prevent dysphagia or esophageal ulceration. Patients should be closely monitored for worsening symptoms when any of these medications are started. If symptoms worsen, alternative therapies may be warranted. The clinician must weigh the risks and benefits of continuing a drug known to worsen GERD and esophagitis.

Smoking can cause aerophagia, which leads to increased belching and regurgitation. However, data are lacking to show that symptoms improve in patients who quit smoking. Nevertheless, patients with GERD should be encouraged to quit smoking. Alcohol, although not thought to play a role in severe disease, decreases LES pressure and may exacerbate symptoms such as heartburn.

Many patients are noncompliant with lifestyle modifications, and even those who do comply generally continue to have symptoms that require acid-suppression therapy. Nonetheless, it is important to regularly stress the potential benefits of lifestyle modifications.

Interventional Approaches

Interventional approaches include antireflux surgery and endoscopic therapies.

Antireflux Surgery 6 Surgical intervention is a viable maintenance alternative for selected patients with well-documented GERD.¹ The goal of antireflux surgery is to reestablish the antireflux barrier, to position the lower esophageal sphincter within the abdomen where it is under positive (intraabdominal) pressure, and to close any associated hiatal defect.¹⁵ Antireflux surgery should be considered in patients (a) who fail to respond to pharmacologic

treatment; (b) who opt for surgery despite successful treatment because of lifestyle considerations, including age, time, or expense of medications; (c) who have complications of GERD (e.g., Barrett's esophagus, strictures); or (d) who have atypical symptoms and reflux documented with ambulatory reflux monitoring.¹⁵

The antireflux surgical procedure chosen depends on the surgeon's expertise and preference, as well as on anatomic considerations.¹⁵ In general, 90% of patients have symptom resolution following successful open Nissen's fundoplication. Because of the diminished surgical complications with the newer laparoscopic surgical procedures (Nissen's fundoplication being one of the most commonly performed procedures), the role of surgery in the long-term management of GERD has become more appealing. The major complications with antireflux surgery include gas bloat syndrome (inability to belch or vomit), dysphagia, vagal denervation, splenic trauma, and, very rarely, death. In contrast, death has not occurred as a consequence of pharmacologic treatment with a proton pump inhibitor.

Antireflux surgery is superior to medical management with an H_2 -receptor antagonist or a promotility agent. However, omeprazole doses of 40 to 60 mg were equally efficacious to antireflux surgery. Long-term effectiveness of antireflux surgery is uncertain. Patients younger than 50 years old and those with typical symptoms that are responsive to medical therapy have the best outcomes with surgery.¹

Endoscopic Therapies Several new endoscopic approaches for the management of GERD include endoscopic sewing devices and endoluminal application of radiofrequency heat energy resulting in tissue injury or nerve ablation (the Stretta procedure).¹⁶ These techniques are FDA-approved, but their exact role in the management of GERD has yet to be determined.

An endoscopic sewing device (EndoCinch) and full-thickness plication devices (NDO Surgical) significantly reduce symptoms of heartburn and regurgitation, and improve the quality-of-life scores. Use of acid suppression therapy may be reduced by as much as 70% at 12-month followup.¹⁷

The Stretta device delivers radiofrequency energy through specialized needles placed into the submucosal tissue of the esophagus while monitoring esophageal mucosal surface temperatures, resulting in an increase in the LES reflux barrier. The primary outcome has been reduction in symptomatic heartburn and improvement in quality of life. Because of the paucity of sufficient data, it is unclear what the role of this device will be in the management of GERD.

CLINICAL CONTROVERSY

Some clinicians believe that patients should be offered the newer endoscopic therapies instead of proton pump inhibitors for long-term maintenance of GERD. Although the newer endoscopic therapies provide good results and less recovery time than surgery, the long-term effects are still unknown. Conversely, many patients prefer not to have to take medication indefinitely, and in some cases still complain of symptoms despite drug therapy.

PHARMACOLOGIC THERAPY

Pharmacologic treatment consists of (a) patient-directed therapy with nonprescription antacids, H_2 -receptor antagonists, or proton pump inhibitors and (b) prescription-strength acid suppression therapy or promotility medications.

Patient-Directed Therapy

Patient-directed therapy is appropriate for mild, intermittent symptoms. Patients with continuous symptoms lasting longer than 2 weeks should seek medical attention.

Antacids and Antacid-Alginate Acid Products

Patients should be educated that antacids are an appropriate component of treating mild GERD, even though documentation of their efficacy in placebo-controlled clinical trials is lacking.¹ Although the literature is somewhat controversial on the superiority of antacids to placebo, clinicians and patients clearly consider antacids to be effective for immediate symptomatic relief, and antacids are often used concurrently with other acid-suppression therapies. Maintaining the intragastric pH >4 decreases the activation of pepsinogen to pepsin, a proteolytic enzyme. Also, neutralization of gastric fluid leads to increased LES pressure. Patients who require frequent use of antacids for chronic symptoms should be treated with prescription-strength acid suppression therapy because their illness is considered more significant.

An antacid product combined with alginate acid is not a potent neutralizing agent and does not enhance LES pressure; however, it does form a highly viscous solution that floats on the surface of the gastric contents. This viscous solution is thought to serve as a protective barrier for the esophagus against reflux of gastric contents. It also reduces the frequency of the reflux episodes. The combination product may be superior to antacids alone in relieving the symptoms of GERD.¹ Efficacy data indicating endoscopic healing are lacking.

Antacid or antacid combination products may cause gastrointestinal adverse effects (diarrhea or constipation, depending on the product), alterations in mineral metabolism, and acid-base disturbances. Aluminum-containing antacids may bind to phosphate in the gut and lead to bone demineralization. In addition, antacids interact with a variety of medications by altering gastric pH, increasing urinary pH, adsorbing medications to their surfaces, providing a physical barrier to absorption, or forming insoluble complexes with other medications. Antacids have clinically significant drug interactions with tetracycline, ferrous sulfate, isoniazid, quinidine, sulfonylureas, and quinolone antibiotics. Antacid-drug interactions are influenced by composition, dose, dosage schedule, and formulation of the antacid.

Dosage recommendations for antacids in the management of GERD are somewhat difficult to derive from the literature. Doses range from hourly to an as-needed basis (see Table 34-4). In general, antacids have a short duration of action, which necessitates frequent administration throughout the day to provide continuous neutralization of acid. Taking antacids after meals can increase the duration of action from about 1 hour to 3 hours; however, nighttime acid suppression cannot be maintained with bedtime doses.

Nonprescription H₂-Receptor Antagonists and Proton Pump Inhibitors

Nonprescription H₂-receptor antagonists (cimetidine, famotidine, nizatidine, and ranitidine) are effective in lowering gastric acid when taken prior to meals and decrease GERD symptoms associated with exercise. Antacids may have a slightly faster onset of action, while the H₂-receptor antagonists have a much longer duration of action compared with antacids.

The proton-pump inhibitor omeprazole is available over-the-counter. A dose of 20 mg per day is indicated for short-term (14 days) treatment of heartburn. Patients who do not respond to lifestyle modifications and patient-directed therapy after 2 weeks should be seen by their clinician.

Acid-Suppression Therapy

⑦ Acid-suppression therapy with prescription-strength H₂-receptor antagonists and proton pump inhibitors are the mainstay of GERD treatment.

H₂-Receptor Antagonists (Cimetidine, Famotidine, Nizatidine, and Ranitidine) H₂-receptor antagonists in divided doses are effective in treating patients with mild to moderate GERD.¹ The majority of the trials assessing the efficacy of standard doses of H₂-receptor antagonists indicate that symptomatic improvement is achieved in an average of 60% of patients after 12 weeks of therapy.¹ However, endoscopic healing rates tend to be lower, an average of 50%.¹

The efficacy of H₂-receptor antagonists in the management of GERD is extremely variable and is frequently lower than desired. Response to the H₂-receptor antagonists is dependent on the (a) severity of disease, (b) dosage regimen used, and (c) duration of therapy. These factors are important to keep in mind when comparing various clinical trials and/or assessing a patient's response to therapy. The severity of esophagitis at baseline has a profound impact on the patient's response to H₂-receptor antagonists. For symptomatic relief of mild GERD, low-dose, nonprescription H₂-receptor antagonists or standard doses given twice daily may be beneficial. Patients who do not respond to standard doses may be hypersecretors of gastric acid and will require higher doses. Although higher doses of H₂-receptor antagonists may provide higher symptomatic and endoscopic healing rates, limited information exists regarding the safety of these regimens, and they can be less effective and more costly than once-daily proton pump inhibitors. Unlike duodenal ulcer disease, in which the duration of therapy is relatively short (e.g., 4 to 6 weeks), prolonged courses of H₂-receptor antagonists are frequently required in the treatment of GERD.

Because all of the H₂-receptor antagonists have similar efficacy, selection of the specific agent to use in the management of GERD should be based on factors such as differences in pharmacokinetics, safety profile, and cost. In general, the H₂-receptor antagonists are well tolerated. The most common adverse effects are headache, somnolence, fatigue, dizziness, and either constipation or diarrhea. Patients should be monitored for the presence of adverse effects as well as potential drug interactions, especially when on cimetidine. Cimetidine may inhibit the metabolism of theophylline, warfarin, phenytoin, nifedipine, and propranolol, among others. An alternate H₂-receptor antagonist should be selected if the patient is on any of these medications.

Proton Pump Inhibitors (Esomeprazole, Lansoprazole, Omeprazole, Pantoprazole, and Rabeprazole) Proton pump inhibitors are superior to H₂-receptor antagonists in treating patients with moderate to severe GERD. This includes not only those patients with erosive esophagitis or complications (e.g., Barrett's esophagus, strictures), but also those patients with nonerosive GERD who have moderate to severe symptoms. FDA-approved doses (per day) of proton pump inhibitors are omeprazole 20 mg, esomeprazole 20 mg, lansoprazole 30 mg, rabeprazole 20 mg, and pantoprazole 40 mg. Symptomatic relief is seen in approximately 83% of patients after 8 weeks treated with a proton pump inhibitor, whereas the endoscopic healing rate at 8 weeks is 78%.¹

Proton pump inhibitors block gastric acid secretion by inhibiting gastric H⁺/K⁺-adenosine triphosphatase in gastric parietal cells.¹⁸ This produces a profound, long-lasting antisecretory effect capable of maintaining the gastric pH above 4, even during postprandial acid surges. A correlation appears to exist between the percentage of time the gastric pH remains above 4 during the 24-hour period and healing erosive esophagitis.

A few trials have compared proton pump inhibitors to each other. In general, healing rates at 4 weeks and 8 weeks are similar; lansoprazole and rabeprazole, however, may relieve symptoms faster after the first dose when compared to omeprazole. Healing rates at 4 weeks and 8 weeks were similar. Whether proton pump inhibitors have a role in the management of Barrett's esophagus remains a topic for debate. The use of high-dose omeprazole (40 mg twice daily) caused

partial regression of Barrett's esophagus, but no change was noted in patients receiving ranitidine 150 mg twice daily.¹⁹ Others propose that these islands of normal squamous cells that appear in patients with Barrett's esophagus after high-dose proton pump inhibitors may be covering Barrett's esophagus epithelium and may mask the development of cancerous changes in the mucosa.²⁰ It is unknown whether regression of Barrett's esophagus reduces the risk of adenocarcinoma in someone who already has Barrett's esophagus, but aggressive therapy aimed at adequate suppression of acid reflux early in the course of a patient's disease may help to prevent the development of this GERD complication. No drug has FDA approval for treating Barrett's esophagus. However, drugs can be used to manage reflux in patients with Barrett's esophagus as it is known that reflux is very common in this patient population.

The proton pump inhibitors are usually well tolerated; however, potential adverse effects include headache, dizziness, somnolence, diarrhea, constipation, nausea, and vitamin B₁₂ deficiency. The frequency of adverse events appears to be similar to that seen with the H₂-receptor antagonists.

Drug interactions with the proton pump inhibitors vary with each agent. All proton pump inhibitors can decrease the absorption of drugs such as ketoconazole or itraconazole, which require an acidic environment to be absorbed. All proton pump inhibitors are metabolized by the cytochrome P450 system to some extent, specifically by the CYP2C19 and CYP3A4 enzymes. However, no interactions with lansoprazole, pantoprazole, or rabeprazole have been seen with CYP2C19 substrates such as diazepam, warfarin, and phenytoin.¹³ Esomeprazole does not appear to interact with warfarin or phenytoin, and an interaction with diazepam is generally not considered clinically relevant. Pantoprazole is also metabolized by a cytosolic sulfotransferase and is therefore less likely to have significant drug interactions compared with the other proton pump inhibitors. Although generally not causing major concern, omeprazole has the potential to inhibit the metabolism of warfarin, diazepam, and phenytoin, and lansoprazole may decrease theophylline concentrations. Patients taking warfarin should be monitored for potential bleeding.

Drug interactions with omeprazole are of particular concern in patients who are considered "slow metabolizers," which is more common in the Asian population, but also found in approximately 3% of the caucasian population. Unfortunately, it is unclear which patients have the polymorphic gene variation that makes them slow metabolizers. Like omeprazole, the metabolism of esomeprazole may also be altered in patients with this polymorphic gene variation. Patients on potentially interacting drugs, such as warfarin, should be monitored closely for potential problems. In general, all of these agents are safe and effective and the choice of a particular agent will most likely be based on cost.

The proton pump inhibitors degrade in acidic environments and are therefore formulated in a delayed-release capsule or tablet formulation. Lansoprazole, esomeprazole, and omeprazole contain enteric-coated (pH-sensitive) granules in a capsule form. For patients who are unable to swallow the capsule, or for pediatric patients, the contents of the delayed-release capsule can be mixed in applesauce or placed in orange juice. If a patient has a nasogastric tube, the contents of an omeprazole capsule can be mixed in 8.4% sodium bicarbonate solution. Esomeprazole granules can be dispersed in water. Lansoprazole comes in a packet for oral suspension and a delayed-release, orally disintegrating tablet. Although these dosage forms are beneficial for those who cannot swallow the capsule, such as elderly or pediatric patients, the packet for oral suspension should not be placed through a nasogastric tube. Patients taking pantoprazole or rabeprazole should be instructed not to crush, chew, or split the delayed-release tablets. Lansoprazole, esomeprazole, and pantoprazole are available in an intravenous formulation, which offers an alternative route of administration for

patients who are unable to take an oral proton pump inhibitor. Importantly, the intravenous product is not more efficacious than oral proton pump inhibitors and is significantly more expensive. Careful patient selection is necessary to avoid the increased cost from the use of the intravenous product.

The newest dosage form is omeprazole in a nonprescription delayed-release tablet and a combination product with sodium bicarbonate in an immediate-release capsule and oral suspension (Zegerid). It is the first immediate-release proton pump inhibitor and should be taken on an empty stomach at least 1 hour before a meal. Zegerid offers an alternative to the delayed-release capsules or the intravenous formulation in adult patients with a nasogastric tube.

Patients should be instructed to take their proton pump inhibitor in the morning, 15 to 30 minutes before breakfast, to maximize efficacy, because these agents inhibit only actively secreting proton pumps. Patients with nocturnal symptoms may benefit from taking their proton pump inhibitor prior to the evening meal. If dosed twice daily, the second dose should be administered approximately 10 to 12 hours after the morning dose and prior to a meal or snack.¹³ Twice daily dosing may also be appropriate during a diagnostic trial for noncardiac chest pain, in patients with atypical or complicated symptoms, and in those with breakthrough symptoms.¹

Promotility Agents

Promotility agents may be useful as an adjunct to acid suppression therapy in patients with a known motility defect (e.g., LES incompetence, decreased esophageal clearance, delayed gastric emptying). Unfortunately, all available promotility agents are fraught with undesirable side effects and are not generally as effective as acid-suppression therapy. Extrapyramidal effects, sedation, and irritability are common with bethanechol and metoclopramide.

Cisapride Cisapride has comparable efficacy to H₂-receptor antagonists in treating patients with mild esophagitis. Unfortunately, cisapride is no longer available for routine use because of life-threatening cardiac arrhythmias when it is combined with certain medications and other disease states. It is currently available only through a limited access program from the manufacturer.

Metoclopramide Metoclopramide, a dopamine antagonist, increases LES pressure in a dose-related manner, and accelerates gastric emptying in gastroesophageal reflux patients. Unlike cisapride, however, metoclopramide does not improve esophageal clearance. Metoclopramide provides symptomatic improvement for some patients with gastroesophageal reflux disease; however, substantial data indicating that metoclopramide provides endoscopic healing are lacking. In addition, metoclopramide's side effect profile and the incidence of tachyphylaxis with continued use limits its usefulness in treating many patients with GERD. The risk of adverse effects is much greater in elderly patients and in patients with renal dysfunction because the drug is primarily eliminated by the kidneys. Contraindications include Parkinson's disease, mechanical obstruction, concomitant use of other dopamine antagonists or anticholinergic agents, and pheochromocytoma.

Bethanechol Bethanechol, a promotility drug, has very limited value in the treatment of GERD because of unwanted side effects. Bethanechol is not routinely recommended for the treatment of GERD.

Other Promotility Drugs Under Investigation Other promotility drugs under investigation include domperidone, a dopamine antagonist, itopride, and baclofen. Because domperidone does not cross the blood-brain barrier, it does not cause the central nervous system effects seen with metoclopramide. However, it is not currently available in the United States. Baclofen, an aminobutyric acid (GABA) receptor type B agonist, may decrease esophageal acid exposure and

the number of reflux episodes by decreasing the number of transient relaxations of the LES. However, this agent has many side effects, limiting its usefulness in GERD.

Mucosal Protectants

Sucralfate, a nonabsorbable aluminum salt of sucrose octasulfate, has very limited value in the treatment of GERD. Sucralfate is not routinely recommended for use in the treatment of GERD.

Combination Therapy

Combination therapy with an acid suppression agent and a pro-motility agent or a mucosal protectant agent would seem logical given the multifactorial nature of the disease, particularly in light of the disappointing results seen with many monotherapy regimens. However, sufficient data to support combination therapy are limited, and this approach should not be routinely recommended unless a patient has GERD plus motor dysfunction occurring. The addition of an H₂-receptor antagonist at bedtime to proton pump inhibitor therapy for the treatment of nocturnal symptoms has been evaluated. The effectiveness of this strategy may decrease over time.²¹

Maintenance Therapy

8 Although healing and/or symptomatic improvement may be achieved via many different therapeutic modalities, a large percentage of patients with gastroesophageal reflux will relapse following discontinuation of therapy, especially those with more severe disease. Patients who have symptomatic relapse following discontinuation of therapy or lowering of dose, including patients with complications such as Barrett's esophagus, strictures, or hemorrhage, should be considered for long-term maintenance therapy to prevent complications or worsening of esophageal function.¹ The goal of maintenance therapy is to improve quality of life by controlling the patient's symptoms and preventing complications. These goals cannot generally be achieved by decreasing the dose of the therapeutic modality used for initial healing or switching to a less potent acid suppression agent. Most patients will require standard doses to prevent relapses. Patients should be counseled on the importance of complying with lifestyle changes and long-term maintenance therapy in order to prevent recurrence or worsening of disease.¹

H₂-receptor antagonists may be effective maintenance therapy for patients with mild disease.¹ The proton pump inhibitors are the drugs of choice for maintenance treatment of moderate to severe esophagitis or symptoms. Lower doses of a proton pump inhibitor or alternate-day dosing may be effective in some patients with less-severe disease, thereby allowing titration in some cases. "On-demand" maintenance therapy, by which patients take their proton pump inhibitor only when they have symptoms, may be effective for patients with endoscopy-negative GERD.¹ Although not well studied, many patients with only mild to moderate symptoms may decide on their own to take their medication this way for the financial benefit. However, patients with more-severe disease and/or complications should be maintained on standard doses of proton pump inhibitors.

Long-term chronic use of higher doses of proton pump inhibitors is not indicated unless the patient has complicated symptoms, has erosive esophagitis per endoscopy, or has had further diagnostic evaluation to determine the level of acid exposure. Metoclopramide is not approved for maintenance therapy and use is limited by adverse effect profile. Antireflux surgery and endoscopic therapies may also be considered a viable alternative to long-term drug therapy for maintenance of healing in patients who are candidates.

Maintenance Therapy with Proton Pump Inhibitors Long-term use of the proton pump inhibitors are safe, with no evidence of carcinoid tumors directly linked to their use. Prolonged hypergastrine-

mia leading to the development of colonic polyps, and potentially adenocarcinoma, was also a concern that has proven unfounded with long-term use.²² However, the role of *Helicobacter pylori* status in patients with GERD has been questioned. As a consequence of the controversy surrounding *H. pylori* and GERD, specific guidelines on how to handle these patients are lacking. Most clinicians would probably opt to eradicate *H. pylori* infections once detected. Further studies are needed to determine the role of *H. pylori* in patients with GERD.

CLINICAL CONTROVERSY

The role of *Helicobacter pylori* infection in GERD patients remains unclear. One study suggested that long-term proton pump inhibitor use in the presence of *H. pylori* may increase the risk of atrophic gastritis with subsequent increase in risk for gastric cancer.²³ Conversely, the presence of *H. pylori* infection may actually have a protective effect on GERD and clearing the symptoms may worsen GERD symptoms.²⁴

Maintenance Therapy with H₂-Receptor Antagonists The studies evaluating the efficacy of the H₂-receptor antagonists in maintaining GERD patients in remission have been disappointing. Currently, ranitidine 150 mg twice daily is the only H₂-receptor antagonist regimen that is FDA approved for maintenance of healing of erosive esophagitis.

SPECIAL POPULATIONS

There are several special populations that should be considered when discussing GERD, such as patients with atypical symptoms, patients with nonerosive symptoms, pediatric patients, elderly patients, and patients with refractory symptoms.

PATIENTS WITH ATYPICAL GERD SYMPTOMS

Patients presenting with atypical symptoms may require higher doses and longer treatment courses as compared with patients with typical symptoms. These patients are best diagnosed with ambulatory reflux monitoring.²⁵ In patients who present with noncardiac chest pain, a short course (1 to 8 weeks) of omeprazole 20 mg twice daily has been advocated.²⁵ In patients with asthma, antireflux medications improve asthma symptoms and even decrease antiasthma medication use, but have little or no effect on lung function.²⁶ A trial of 3 months has been advocated using twice-daily proton pump inhibitor therapy for both asthma and laryngeal symptoms thought to be associated with GERD. Omeprazole doses as high as 60 mg daily have been used.²⁵ In patients with chronic cough, ambulatory reflux monitoring, when available, is the preferred approach for evaluation of GERD.²⁷ Maintenance therapy is generally indicated in patients who respond to the therapeutic trial or have endoscopic evidence of reflux. Antireflux surgery or endoscopic therapies may be an option in selected patients.

PATIENTS WITH ENDOSCOPY-NEGATIVE REFLUX DISEASE

Although the integrity of the esophageal mucosa is best evaluated with endoscopy, endoscopy does not confirm whether or not the patient's symptoms are related to GERD.¹ In some cases, patients with typical symptoms and increased acid exposure have no evidence of esophageal damage. Many patients with persistent severe symptoms but normal endoscopy will require therapy similar to those with positive endoscopic findings. Patients who present with normal esophageal mucosa on endoscopy should undergo ambulatory reflux monitoring to further confirm the diagnosis of GERD.

PEDIATRIC PATIENTS WITH GERD

Gastroesophageal reflux occurs in approximately 18% of the infant population. Most have physiologic reflux with no clinical consequence.²⁸ Complications, although rare, include distal esophagitis, failure to thrive, esophageal peptic strictures, Barrett's esophagus, and pulmonary disease.²⁹ Chronic vomiting associated with gastroesophageal reflux must be distinguished from other causes, such as neurologic, metabolic, eating, and rumination disorders. Developmental immaturity of the LES is one suspected cause of gastroesophageal reflux in infants.²⁹ Like adults, transient LES relaxations seem to be the most common cause of gastroesophageal reflux in children. Other causes include impaired luminal clearance of gastric acid, neurologic impairment, and type of infant formula. Uncomplicated gastroesophageal reflux usually resolves without incident by 12 to 18 months of life, and usually responds to supportive therapy, including dietary adjustments, postural management, and reassurance for the parents.²⁹ Thickened feedings may be useful in milder cases. Smaller, more frequent feedings may also be beneficial. If there is no improvement, medical therapy might be indicated. Combined use of a promotility agent and an acid suppression agent seems to work the fastest.²⁹ Unfortunately, with the removal of cisapride, there is no longer a readily available promotility agent without major side effects. Metoclopramide is used as a promotility agent in pediatric patients. Ranitidine is commonly used at a dose of 2 mg/kg twice daily.²⁹

The use of proton pump inhibitors is becoming more common in pediatrics. Lansoprazole is indicated for treating symptomatic and erosive GERD in pediatric patients older than age 1 year. A dose of 5 mg once daily is recommended for children who weigh 30 kg or less, and a dose of 30 mg once daily is recommended for those who weigh more than 30 kg. Although not FDA approved for use in children, there is evidence supporting the effectiveness of omeprazole in treating children with GERD. A common dose for treating esophagitis is 1 mg/kg per day (divided once or twice daily).³⁰ Even though no major adverse events have been noted in children receiving proton pump inhibitors for up to 7 years, the relative safety of prolonged proton pump inhibitor use in children remains unknown.³⁰ There are no data involving the other proton pump inhibitors in the treatment of GERD in pediatric patients.

ELDERLY PATIENTS WITH GERD

Many elderly patients have decreased host defense mechanisms, such as saliva production. More aggressive therapy with a proton pump inhibitor may be warranted in patients older than 60 years of age with symptomatic GERD. Often these patients do not seek medical attention because they feel their symptoms are part of the normal aging process. They may present with atypical symptoms such as chest pain, asthma, hoarseness, coughing, wheezing, poor dentition, or jaw pain. Decreased GI motility is a common problem in elderly patients. Unfortunately, there are no good promotility agents available to these patients. Cisapride is not available for general use and elderly patients are especially sensitive to the central nervous system effects of metoclopramide. They may also be sensitive to the central nervous system effects of H₂-receptor antagonists. Proton pump inhibitors appear to be the most useful treatment modality because they have superior efficacy and are dosed once daily, which is beneficial in all patients, but is especially beneficial in the elderly.

PATIENTS WITH REFRACTORY GERD

GERD refractory to medical management is rare. Other causes for the patient's symptoms should be evaluated. The majority of patients with refractory symptoms experience nocturnal acid break-

through. Other reasons for refractory symptoms may be related to timing of proton pump inhibitor and drug metabolism differences in certain patients. Because of this, switching to another proton pump inhibitor may be effective for refractory symptoms in some patients. Ambulatory reflux monitoring is useful in patients who are not responding to therapy. Adding an H₂-receptor antagonist at bedtime for nocturnal symptoms has been suggested; however, the effect may be short-lived.²¹ Antireflux surgery and endoscopic therapies may also be considered in this patient population.

PHARMACOECONOMIC CONSIDERATIONS

In addition to the traditional clinical end points that demonstrate that a certain therapy is effective, the cost-effectiveness of the therapy in relation to predicted outcomes and its effects on quality of life must be evaluated. For GERD, one must consider the primary goals of treatment: to relieve symptoms, to heal injury, to prevent recurrence, and to prevent complications. These factors must be evaluated separately, because different costs are associated with achieving each end point. For example, patients with complications associated with GERD, such as strictures, would be more likely to use medical resources as a consequence of revisits and diagnostic tests. Although effects on quality of life may be difficult to evaluate when your goal is preventing recurrence, untreated GERD has a more negative impact on psychological well being than untreated hypertension, mild heart failure, angina pectoris, or menopause. Improving a patient's quality of life is a measure of treatment success and may help decide which therapy a patient receives.

The proton pump inhibitors are generally more expensive than the H₂-receptor antagonists or promotility agents. Omeprazole's generic and over-the-counter availability makes this less of an issue. However, the most expensive therapy is the one that is ineffective. If the H₂-receptor antagonist does not accomplish the treatment goals, then it costs more because the patient must be retreated.

Patient compliance is another factor that affects the outcome of drug therapy. Drug regimens that are easily managed improve compliance, and thus improve outcome for the patient. This especially can be a problem in patients who require high-dose therapy with H₂-receptor antagonists. Not only is the patient required to take the drug more often in higher doses, but there is also increased expense associated with such regimens. The patient may be unable to afford the drug. Choosing a drug that is least expensive and provides the greatest benefit related to dosing interval and number of tablets taken is the optimal regimen. Studies comparing various treatment strategies for GERD show that proton pump inhibitors are more cost-effective than H₂-receptor antagonists, especially in patients with moderate to severe disease.

Decision analysis has been used to evaluate the cost-effectiveness of lifestyle modifications and/or patient-directed therapy alone or combined with omeprazole 20 mg daily or ranitidine 150 mg twice daily for patients with persistent symptomatic GERD. A complex model that evaluated the influence of empiric versus definitive therapy, compliance, and efficacy of the three treatment regimens was employed. Although the retail cost of omeprazole was highest among the treatments evaluated, it was the most cost-effective strategy and was associated with the lowest overall cost. Studies also show that proton pump inhibitors improve quality-of-life measures in symptomatic patients with erosive esophagitis.³¹ Additional studies are needed to evaluate the impact of various treatment regimens on quality-of-life issues and cost, and to compare long-term medical management with antireflux surgery and endoscopic therapies. At least one study showed that proton pump inhibitors were as effective as antireflux surgery and slightly more cost effective at 5 years. However, the costs were similar after 10 years.³²

EVALUATION OF THERAPEUTIC OUTCOMES

9 The long-term benefits of treatment are difficult to assess because of the limited information known about the epidemiology and natural history of GERD. Consequently, successful outcomes are generally measured in terms of three separate end points: (a) relieving symptoms, (b) healing the injured mucosa, and (c) preventing complications.

The short-term goal of therapy is to relieve symptoms such as heartburn and regurgitation to the point at which they do not impair the patient’s quality of life. Patients should be educated regarding lifestyle modifications that should be adhered to throughout the course of therapy, including smoking cessation, weight loss, raising the head of the bed, eating smaller meals, and avoiding eating prior to bedtime. Patients should also be instructed to avoid or limit foods that aggravate GERD symptoms, such as fat and chocolate. In addition, the patient’s drug profile should be reviewed to identify medications that may contribute to GERD symptoms. These agents should be avoided if possible. Table 34–6 has recommendations for providing pharmaceutical care to patients with GERD.

The clinician should take an active role in educating the patient about potential adverse effects and drug interactions that may occur with drug therapy. The frequency and severity of symptoms should be monitored and patients should be counseled on symptoms that suggest the presence of complications requiring immediate medical attention, such as dysphagia or odynophagia. Patients with persistent symptoms should be evaluated for the presence of strictures or other complications. Patients should also be monitored for the presence of atypical symptoms such as cough, nonallergic asthma, or chest pain. These symptoms require further diagnostic evaluation. Long-term maintenance treatment is indicated in patients who have strictures because the strictures commonly recur if reflux esophagitis is not treated.

The second goal is to heal the injured mucosa. Again, lifestyle modifications and the importance of complying with the therapeutic regimen chosen to heal the mucosa should be stressed. Patients should be educated about the risk of relapse and the need for long-term maintenance therapy to prevent recurrence or complications.

TABLE 34-6 Recommendations for Providing Pharmaceutical Care to Patients with GERD

1. Assess the patient’s symptoms to determine if patient-directed therapy is appropriate or whether patient should be evaluated by a clinician. Determine the type of symptoms, frequency, and exacerbating factors. Refer any patient with alarm or atypical symptoms to a clinician for further diagnostic workup.
2. Obtain a thorough history of prescription, nonprescription, and natural drug product use.
3. Counsel the patient on lifestyle modifications that will improve symptoms.
4. Recommend appropriate drug therapy based on patient presentation.
5. Develop a plan to assess effectiveness of acid suppression therapy after an appropriate amount of time (8 to 16 weeks). Recommend alternative therapy if necessary.
6. Assess improvement in quality-of-life measures such as physical, psychological, and social functioning and well-being.
7. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.
8. Stress the importance of compliance with the therapeutic regimen, including lifestyle modifications. Recommend a therapeutic regimen that is easy for the patient to accomplish.
9. Provide patient education with regard to disease state, lifestyle modifications, and drug therapy. Patients should be counseled on:
• What causes GERD and what things to avoid
• When to take their medications
• What potential adverse effects may occur
• Which drugs may interact with their therapy
• What alarm signs they should report to their clinician

The final, more long-term goal of therapy is to decrease the risk of complications (esophagitis, strictures, and Barrett’s esophagus). A small subset of patients may continue to fail treatment despite therapy with high doses of H₂-receptor antagonists or a proton pump inhibitor. Patients should be monitored for the presence of continual pain, dysphagia, or odynophagia.

CONCLUSIONS

Gastroesophageal reflux disease is a common disease that classically presents as heartburn. The pathophysiology of reflux is complex, involving both aggressive factors (acid, pepsin, bile acids, pancreatic enzymes, and prostaglandins) and defense mechanisms (anatomic factors, LES pressure, esophageal clearance, and gastric emptying). Therapeutic modalities are designed to minimize the aggressive factors and/or augment the defense mechanisms.

ABBREVIATIONS

- ENRD: endoscopy-negative reflux disease
- GERD: gastroesophageal reflux disease
- GI: gastrointestinal
- H₂: histamine type-2
- LES: lower esophageal sphincter
- NERD: nonerosive reflux disease

ROSEMARY R. BERARDI AND LYNDIA S. WELAGE

KEY CONCEPTS

- 1 Patients with peptic ulcer disease should reduce psychological stress, cigarette smoking, and nonsteroidal antiinflammatory drug (NSAID) use, and should avoid foods and beverages that exacerbate ulcer symptoms.
- 2 Eradication is recommended for all *Helicobacter pylori*-positive patients with an active ulcer, a documented history of a prior ulcer, or a history of ulcer-related complications.
- 3 Treatment with a conventional antiulcer drug (H_2 -receptor antagonist, proton pump inhibitor, or sucralfate) may be an alternative to *H. pylori* eradication, but is discouraged because of the high rate of ulcer recurrence and ulcer-related complications. Combining conventional antiulcer drugs adds to treatment costs without enhancing efficacy.
- 4 Maintenance therapy with a low-dose H_2 -receptor antagonist or proton pump inhibitor may be indicated for high-risk patients who fail *H. pylori* eradication, patients with severe complications, heavy smokers, or those with *H. pylori*-negative ulcers.
- 5 The selection of an *H. pylori* eradication regimen should be based on efficacy, safety, antibiotic resistance, cost, and the likelihood of medication adherence. Treatment should be initiated with a proton pump inhibitor-based three-drug regimen. If a second course of *H. pylori* therapy is required, the regimen should contain different antibiotics.
- 6 Proton pump inhibitor cotherapy reduces the risk of NSAID-related gastric and duodenal ulcers and is at least as effective as recommended dosages of misoprostol and superior to the H_2 -receptor antagonists.
- 7 Standard dosages of a proton pump inhibitor and a nonselective NSAID are as effective as a selective cyclooxygenase-2 (COX-2) inhibitor in reducing the risk of NSAID-induced ulcers and upper GI complications.
- 8 The eradication of *H. pylori* improves clinical outcomes and decreases the use of healthcare resources when compared to conventional antisecretory therapy. Misoprostol or proton pump inhibitor cotherapy, or switching to a selective COX-2 inhibitor is cost-effective in patients with the highest risk for NSAID-related ulcers and upper GI complications.

- 9 Patients with peptic ulcer disease, especially those receiving *H. pylori* eradication or misoprostol cotherapy, require patient education regarding their disease and drug treatment to successfully achieve a positive therapeutic outcome.

Acid-related diseases (gastritis, erosions, and peptic ulcer) of the upper gastrointestinal (GI) tract require gastric acid for their formation.¹⁻⁴ Peptic ulcer disease (PUD) differs from gastritis and erosions in that ulcers typically extend deeper into the muscularis mucosa.¹ There are three common forms of peptic ulcers: *Helicobacter pylori* (*H. pylori*)-associated, nonsteroidal antiinflammatory drug (NSAID)-induced, and stress ulcers (Table 35-1). The term “stress-related mucosal damage” (SRMD) is preferred to stress ulcer or stress gastritis, because the mucosal lesions range from superficial gastritis and erosions to deep ulcers.

Chronic peptic ulcers vary in etiology, clinical presentation, and tendency to recur (see Table 35-1). *H. pylori*-associated and NSAID-induced ulcers develop most often in the stomach and duodenum of ambulatory patients (Fig. 35-1). Occasionally, ulcers develop in the esophagus, jejunum, ileum, or colon. Peptic ulcers are also associated with Zollinger-Ellison’s syndrome (ZES), radiation, chemotherapy, and vascular insufficiency (Table 35-2).^{1,4} In contrast, acute ulcers (stress-related mucosal damage [SRMD]) occur primarily in the stomach in critically ill hospitalized patients (see Table 35-1). This chapter focuses on chronic PUD associated with *H. pylori* and NSAIDs. A brief discussion of ZES and upper GI bleeding related to PUD and SRMD is included.

The natural course of chronic PUD is characterized by frequent ulcer recurrence. Approximately 60% to 100% of ulcers recur within 1 year of initial ulcer healing with conventional antiulcer regimens.¹ The most important factors that influence ulcer recurrence are *H. pylori* infection and NSAID use. Other factors include gastric acid hypersecretion, cigarette smoking, alcohol use, a long duration of PUD, ulcer-related complications, and patient noncompliance. The cause of ulcer recurrence is most likely multifactorial.

EPIDEMIOLOGY

Approximately 10% of Americans develop chronic PUD during their lifetime.¹ The incidence varies with ulcer type, age, gender, and geographic location. Race, occupation, genetic predisposition, and societal factors may play a minor role in ulcer pathogenesis, but are attenuated by the importance of *H. pylori* infection and NSAID use. The prevalence of PUD in the United States has shifted from predominance in men to nearly comparable prevalence in men and women. Recent trends suggest a declining rate for younger men and an increasing rate for older women.¹ Factors influencing these trends include the declining smoking rates in younger men and the increased use of NSAIDs in older adults.

TABLE 35-1 Comparison of Common Forms of Peptic Ulcer			
Characteristic	<i>H. pylori</i> Induced	NSAID Induced	SRMD
Condition	Chronic	Chronic	Acute
Site of damage	Duodenum > stomach	Stomach > duodenum	Stomach > duodenum
Intragastric pH	More dependent	Less dependent	Less dependent
Symptoms	Usually epigastric pain	Often asymptomatic	Asymptomatic
Ulcer depth	Superficial	Deep	Most superficial
GI bleeding	Less severe, single vessel	More severe, single vessel	More severe, superficial mucosal capillaries

H. pylori, *Helicobacter pylori*; NSAID, nonsteroidal antiinflammatory drug; SRMD, stress-related mucosal damage.

Since 1960, ulcer-related physician visits, hospitalizations, operations, and deaths have declined in the United States by more than 50%, primarily because of decreased rates of PUD among men.¹ The decline in hospitalizations has resulted from a reduction in hospital admissions for uncomplicated duodenal ulcer. However, hospitalizations of older adults for ulcer-related complications (bleeding and perforation) have increased.¹ Although the overall mortality from PUD has decreased, death rates have increased in patients older than 75 years of age, most likely a result of increased consumption of NSAIDs and an aging population. Patients with gastric ulcer have a higher mortality rate than do patients with duodenal ulcer because gastric ulcer is more prevalent in older individuals. Despite these trends, PUD remains one of the most common GI diseases, resulting in impaired quality of life, work loss, and high-cost medical care.

ETIOLOGY AND RISK FACTORS

Most peptic ulcers occur in the presence of acid and pepsin when *H. pylori*, NSAIDs, or other factors (see Table 35–2) disrupt normal mucosal defense and healing mechanisms.¹ Hypersecretion of acid is the primary pathogenic mechanism in hypersecretory states such as ZES.⁴ Ulcer location is related to a number of etiologic factors. Benign gastric ulcers can occur anywhere in the stomach, although most are located on the lesser curvature, just distal to the junction of the antral and acid-secreting mucosa (see Fig. 35–1). Most duodenal ulcers occur in the first part of the duodenum (duodenal bulb).

HELICOBACTER PYLORI

H. pylori infection causes chronic gastritis in all infected individuals and is causally linked to PUD, gastric cancer, and mucosa-associated lymphoid tissue (MALT) lymphoma (Fig. 35–2).^{1,5–7} However, only a small number of infected individuals will develop symptomatic PUD (approximately 20%) or gastric cancer (less than 1%).^{1,7} Serologic studies confirm an association between *H. pylori* and gastric cancer.¹ Evidence for PUD is based on the fact that most non-NSAID ulcers

are infected with *H. pylori*, and that *H. pylori* eradication markedly decreases ulcer recurrence.^{1,5} Host-specific cofactors and *H. pylori* strain variability play an important role in the pathogenesis of PUD and gastric cancer.^{5–7} Although an association between *H. pylori* and PUD bleeding is less clear, eradication of *H. pylori* decreases recurrent bleeding.⁸ No specific link has been established between *H. pylori* and dyspepsia, nonulcer dyspepsia (NUD), or gastroesophageal reflux disease (GERD).^{9,10} There is insufficient data to support a link between *H. pylori* and extragastric manifestations, for example, cardiovascular disease.¹¹

The prevalence of *H. pylori* varies by geographic location, socioeconomic conditions, ethnicity, and age. In developing countries, *H. pylori* prevalence exceeds 80% in adults and correlates with lower socioeconomic conditions.⁵ In industrialized countries, the prevalence of *H. pylori* in adults is between 20% and 50%.⁵ The prevalence of *H. pylori* in the United States is 30% to 40%, but remains higher in ethnic groups such as African and Latin Americans. During the last few years, the incidence of *H. pylori* has declined dramatically in developed countries, most likely as a consequence of improved living standards and socioeconomic conditions.⁶ There is an increased *H. pylori* prevalence with age, but this mainly reflects acquisition during infancy and early childhood.¹ Infection rates do not differ with gender or smoking status.

H. pylori is transmitted person-to-person by three possible pathways; fecal–oral, oral–oral, and gastro–oral.^{1,6} Transmission of the organism most likely is by the fecal–oral route, either directly from an infected person, or indirectly from fecal-contaminated water or food.¹ Members of the same household are likely to become infected when someone in the same household is infected.^{1,6} Risk factors include crowded living conditions, a large number of children, unclean water, and consumption of raw vegetables. Transmission by the oral–oral route has been postulated, but this is an unlikely route of transmission. *H. pylori* could be transmitted by the gastro–oral route by vomiting or iatrogenically with the use of inadequately sterilized endoscopes.¹

NONSTEROIDAL ANTIINFLAMMATORY DRUGS

NSAIDs are one of the most widely prescribed classes of medications in the United States, particularly in individuals 60 years of age and older.¹ There is overwhelming evidence linking chronic nonselective

NSAID (including aspirin) use to a variety of GI tract injuries (Table 35–3).^{1,12–14} Subepithelial gastric hemorrhages occur within 15 to 30 minutes of ingestion, and progress to gastric erosions with continued ingestion.^{1,12} These lesions heal within a few days with continued NSAID use and do not lead to GI complications. Gastroduodenal ulcers occur in 15% to 30% of regular NSAID users and may develop within a week or with continued treatment (6 months or longer).¹² Gastric ulcers are most common, occur primarily in the antrum (see Fig. 35–1), and are of greater concern than erosions because of their potential to bleed or perforate (see Table 35–1). NSAID-induced ulcers occur less frequently in the esophagus and colon.^{1,15} Each year, nonselective NSAIDs account for at least 16,500 deaths and 107,000 hospitalizations in the United States.¹ Clinically important upper GI events occur in 3% to 4.5% of arthritis patients who are taking NSAIDs, and about 1.5% of patients taking NSAIDs have a serious upper GI complication.¹²

Table 35–4 lists the risk factors for NSAID-induced ulcers and GI-related complications. Combinations of factors confer an additive risk. The risk of NSAID complications is increased as much as 14-fold in patients with a previous history of an ulcer or ulcer-related complication.¹ Advanced age is an independent risk factor and increases linearly with the age of the patient.¹ The high incidence of ulcer complications in older individuals may be explained by age-related changes in gastric mucosal defense. The risk for NSAID-induced ulcers and complications is dose related, but can occur with low dosages of nonprescription NSAIDs or low cardioprotective dosages of aspirin (81 to 325 mg/day).^{1,12–16} Adverse GI events may

TABLE 35-3 Selected Nonsteroidal Antiinflammatory Drugs (NSAIDs) and Cyclooxygenase-2(COX-2) Inhibitors

Nonacetylates ^a	
Nonselective (traditional) NSAIDs:	indomethacin, piroxicam, ibuprofen, naproxen, sulindac, ketoprofen, ketorolac, flurbiprofen
Partially selective NSAIDs:	etodolac, nabumetone, meloxicam, celecoxib, diclofenac
Selective COX-2 inhibitors:	rofecoxib, ^b valdecoxib ^b
Salicylates	
Acetylated:	aspirin
Nonacetylated:	salsalate, trisaliclate

TABLE 35-4 Risk Factors for Nonsteroidal Antiinflammatory Drug (NSAID)-Induced Ulcers and Upper Gastrointestinal Complications^a

Established risk factors

Older than 60 years of age
Previous peptic ulcer
Previous ulcer-related upper GI complication
Concomitant use of corticosteroid
High-dose NSAIDs
Multiple NSAID use or NSAID plus aspirin use
Choice of NSAID
Aspirin (including cardioprotective dosages)
Concomitant use of anticoagulant or coagulopathy
Concomitant use of antiplatelet drug such as clopidogrel
Concomitant use of oral bisphosphonates
Concomitant use of selective serotonin reuptake inhibitor
Chronic illness (e.g., cardiovascular disease)

Possible risk factors

NSAID-related dyspepsia
Helicobacter pylori infection
Rheumatoid arthritis (extent of disability)
Alcohol consumption

Questionable risk factors

Cigarette smoking

^aCombinations of risk factors are additive.

From Del Valle et al.,¹ Suerbaum and Michetti,⁵ Laine,¹² Naesdal and Brown,¹³ Lanus et al.,¹⁵ and Tata et al.¹⁷

occur at any time, during treatment. The use of low-dose aspirin in combination with another NSAID increases the risk of upper GI complications to a greater extent than the use of either drug alone.¹ NSAID-related dyspepsia that is not relieved by antiulcer medications may suggest an ulcer or ulcer complication, but dyspepsia does not correlate directly with mucosal injury or clinical events.

Corticosteroids, when used alone, do not increase the risk of ulcer or complications, but ulcer risk is increased twofold in corticosteroid users who are also taking concurrent NSAIDs.¹ The risk of GI bleeding markedly increases when NSAIDs are taken concurrently with anticoagulants,¹ and may increase with concurrent use of serotonin reuptake inhibitors.¹⁷ Whether *H. pylori* infection is a risk factor for NSAID-induced ulcers remains controversial.^{13,18} However, *H. pylori* and NSAIDs act independently to increase ulcer risk and ulcer-related bleeding and appear to have additive effects.¹⁴ The incidence of peptic ulcer is reported to be higher in *H. pylori*-positive NSAID users when the two factors are combined.^{19,20}

There is little evidence to support clinically important differences in ulcer frequency and upper GI complications among most available nonaspirin, nonselective NSAIDs (see Table 35–3) when used in equipotent antiinflammatory dosages.¹ However, the nonacetylated salicylates (e.g., salsalate) and the partially selective NSAIDs (e.g., etodolac, nabumetone, meloxicam, diclofenac, and celecoxib) may be associated with a decreased incidence of GI toxicity.^{1,13,21,22} NSAIDs that selectively inhibit cyclooxygenase-2 (COX-2) decrease the incidence of gastroduodenal ulcers and related GI complications when compared to the nonselective NSAIDs.^{13,21} The use of buffered or enteric-coated aspirin confers no added protection from ulcer or GI complications.^{13,22}

CIGARETTE SMOKING

Epidemiologic evidence links cigarette smoking to PUD, but it is uncertain whether smoking causes peptic ulcers.¹ The risk is proportional to the number of cigarettes smoked and is modest when fewer than 10 cigarettes are smoked per day. Death rates are higher among patients who smoke than among nonsmoking patients, although it is not known whether the increase in mortality reflects PUD or the cardiac and pulmonary sequelae of smoking. The exact mechanism

by which cigarette smoking contributes to PUD remains unclear. Possible mechanisms include delayed gastric emptying of solids and liquids, inhibition of pancreatic bicarbonate secretion, promotion of duodenogastric reflux, and reduction in mucosal prostaglandin (PG) production. Smoking increases gastric acid secretion, but this effect is inconsistent. Whether nicotine or other components of smoke are responsible for these physiologic alterations is unknown. Cigarette smoking may provide a favorable milieu for *H. pylori* infection.

PSYCHOLOGICAL STRESS

The importance of psychological factors in the pathogenesis of PUD remains controversial.¹ Clinical observation suggests that ulcer patients are adversely affected by stressful life events. However, results from controlled trials are conflicting and have failed to document a cause-and-effect relationship.¹ Emotional stress may induce behavioral risks such as smoking and the use of NSAIDs, or alter the inflammatory response or resistance to *H. pylori* infection. The role of stress and how it affects PUD is complex and probably multifactorial.

DIETARY FACTORS

The role of diet and nutrition in PUD is uncertain, but may explain regional variations.¹ Coffee, tea, cola beverages, beer, milk, and spices may cause dyspepsia, but do not increase the risk for PUD. Beverage restrictions and bland diets do not alter the frequency of ulcer recurrence. Although caffeine is a gastric acid stimulant, constituents in decaffeinated coffee or tea, caffeine-free carbonated beverages, beer, and wine may also increase gastric acid secretion. In high concentrations, alcohol ingestion is associated with acute gastric mucosal damage and upper GI bleeding; however, there is insufficient evidence to confirm that alcohol causes ulcers.¹

DISEASE ASSOCIATED WITH PEPTIC ULCERS

There is epidemiologic evidence linking duodenal ulcers with certain chronic diseases, but the pathophysiologic mechanisms of these associations are unclear.¹ A strong association exists with systemic mastocytosis, multiple endocrine neoplasia type 1, chronic pulmonary diseases, chronic renal failure, kidney stones, hepatic cirrhosis, and α_1 -antitrypsin deficiency. An association may exist with cystic fibrosis, chronic pancreatitis, Crohn's disease, coronary artery disease, polycythemia vera, and hyperparathyroidism.

PATHOPHYSIOLOGY

A physiologic imbalance between aggressive factors (gastric acid and pepsin) and protective factors (mucosal defense and repair) remain important issues in the pathophysiology of gastric and duodenal ulcers. Gastric acid is secreted by the parietal cells, which contain receptors for histamine, gastrin, and acetylcholine. Acid (as well as *H. pylori* infection and NSAID use) is an independent factor that contributes to the disruption of mucosal integrity. Increased acid secretion has been observed in patients with duodenal ulcers and may be a consequence of *H. pylori* infection.^{23,24} Patients with ZES (described later in the chapter; see Zollinger-Ellison's Syndrome) have profound gastric acid hypersecretion resulting from a gastrin-producing tumor.⁴ Patients with gastric ulcer usually have normal or reduced rates of acid secretion (hypochlorhydria).

Acid secretion is expressed as the amount of acid secreted under basal or fasting conditions, basal acid output (BAO); after maximal stimulation, maximal acid output (MAO); or in response to a meal.²³ Basal, maximal, and meal-stimulated acid secretion varies according to time of day and the individual's psychological state, age, gender, and health status. The BAO follows a circadian rhythm,

with the highest acid secretion occurring at night and the lowest in the morning. An increase in the BAO:MAO ratio suggests a basal hypersecretory state such as ZES. A review of gastric acid secretion and its regulation can be found elsewhere.²³

Pepsin is an important cofactor that plays a role in the proteolytic activity involved in ulcer formation.²³ Pepsinogen, the inactive precursor of pepsin, is secreted by the chief cells located in the gastric fundus (see Fig. 35–1). Pepsin is activated by acid pH (optimal pH of 1.8 to 3.5), inactivated reversibly at pH 4, and irreversibly destroyed at pH 7.

Mucosal defense and repair mechanisms (mucus and bicarbonate secretion, intrinsic epithelial cell defense, and mucosal blood flow) protect the gastroduodenal mucosa from noxious endogenous and exogenous substances.^{1,24} The viscous nature and near-neutral pH of the mucus-bicarbonate barrier protect the stomach from the acidic contents in the gastric lumen. Mucosal repair after injury is related to epithelial cell restitution, growth, and regeneration. The maintenance of mucosal integrity and repair is mediated by the production of endogenous prostaglandins. The term *cytoprotection* is often used to describe this process, but *mucosal defense* and *mucosal protection* are more accurate terms, as prostaglandins prevent deep mucosal injury and not superficial damage to individual cells. Gastric hyperemia and increased prostaglandin synthesis characterize adaptive cytoprotection, the short-term adaptation of mucosal cells to mild topical irritants. This phenomenon enables the stomach to initially withstand the damaging effects of irritants. Alterations in mucosal defense that are induced by *H. pylori* or NSAIDs are the most important cofactors in the formation of peptic ulcers.

HELICOBACTER PYLORI

H. pylori is a spiral-shaped, pH-sensitive, gram-negative, microaerophilic bacterium that resides between the mucus layer and surface epithelial cells in the stomach, or any location where gastric-type epithelium is found.^{1,5} The combination of its spiral shape and flagellum permits it to move from the lumen of the stomach, where the pH is low, to the mucus layer, where the local pH is neutral. The acute infection is accompanied by transient hypochlorhydria, which permits the organism to survive in the acidic gastric juice.²⁴ The exact method by which *H. pylori* initially induces hypochlorhydria is unclear. One theory is that *H. pylori* produces large amounts of urease, which hydrolyzes urea in the gastric juice and converts it to ammonia and carbon dioxide.⁵ The local buffering effect of ammonia creates a neutral microenvironment within and surrounding the bacterium, which protects it from the lethal effect of acid. *H. pylori* also produces acid-inhibitory proteins, which allows it to adapt to the low-pH environment of the stomach.²⁴ *H. pylori* attaches to gastric-type epithelium by adherence pedestals, which prevent the organism from being shed during cell turnover and mucus secretion. Antral organisms colonize gastric metaplastic tissue (which is thought to arise secondary to changes in acid or bicarbonate secretion, products of *H. pylori*, or host inflammatory responses) in the duodenal bulb, leading to duodenal ulcer (see Fig. 35–2).¹ Colonization of the corpus (body) of the stomach is associated with gastric ulcer.

Bacterial and host factors contribute to the ability of *H. pylori* to cause gastroduodenal mucosal injury. Pathogenic mechanisms include (a) direct mucosal damage, (b) alterations in the host immune/inflammatory response, and (c) hypergastrinemia leading to increased acid secretion.^{1,5} In addition, *H. pylori* enhances the carcinogenic conversion of susceptible gastric epithelial cells.^{7,25,26}

Direct mucosal damage is produced by virulence factors (vacuolating cytotoxin, cytotoxin-associated gene protein, and growth-inhibitory factor), elaborating bacterial enzymes (lipases, proteases, and urease), and adherence.^{1,5,26} Approximately 50% of *H. pylori* strains produce vacuolating cytotoxin (Vac A) that leads to cell death and is

important in the development of gastric cancer.^{1,26} Strains with cytotoxin-associated gene (cagA) protein are associated with duodenal ulcer, atrophic gastritis, and gastric cancer.^{1,5,7,25} Lipases and proteases degrade gastric mucus, ammonia produced by urease may be toxic to gastric epithelial cells, and bacterial adherence enhances the uptake of toxins into gastric epithelial cells. *H. pylori* infection alters the host inflammatory response and damages epithelial cells directly by cell-mediated immune mechanisms, or indirectly by activated neutrophils or macrophages attempting to phagocytose bacteria or bacterial products.^{1,5} Host polymorphisms are important markers of disease susceptibility and may identify high-risk patients.²⁶ Polymorphisms of interleukin-1 and its receptor antagonist may be associated with either increased gastric acid secretion and duodenal ulcer or decreased acid output, atrophic gastritis, and gastric cancer.^{1,7}

NONSTEROIDAL ANTIINFLAMMATORY DRUGS

Nonselective NSAIDs, including aspirin (see Table 35–3), cause gastric mucosal damage by two important mechanisms: (a) direct or topical irritation of the gastric epithelium and (b) systemic inhibition of endogenous mucosal prostaglandin synthesis.^{1,13,14} Although the initial injury is initiated topically by the acidic properties of many of the NSAIDs, systemic inhibition of the protective prostaglandins plays the predominant role in the development of gastric ulcer.^{1,13,14} Cyclooxygenase (COX) is the rate-limiting enzyme in the conversion of arachidonic acid to prostaglandins and is inhibited by NSAIDs (Fig. 35–3).

Two similar COX isoforms have been identified: cyclooxygenase-1 (COX-1) is found in most body tissue, including the stomach, kidney, intestine, and platelets; cyclooxygenase-2 (COX-2) is undetectable in most tissues under normal physiologic conditions, but its expression can be induced during acute inflammation and arthritis (Fig. 35–4).^{1,13} COX-1 produces protective prostaglandins that regulate physiologic processes such as GI mucosal integrity, platelet homeostasis, and renal function. COX-2 is induced (unregulated) by inflammatory stimuli such as cytokines, and produces prostaglandins involved with inflammation, fever, and pain. COX-2 is also constitutionally expressed in organs such as the brain, kidney, and reproductive tract. Adverse effects (e.g., GI or renal toxicity) of NSAIDs are primarily associated with the inhibition of COX-1, whereas antiinflammatory actions result primarily from NSAID inhibition of COX-2.^{1,13} Nonselective NSAIDs, including aspirin (see Table 35–3), inhibit both COX-1 and COX-2 to varying degrees.^{1,13} The COX-1-to-COX-2 inhibitory ratio determines the relative GI toxicity of a specific NSAID. In addition, aspirin and nonaspirin NSAIDs irreversibly inhibit platelet COX-1, resulting in decreased platelet aggregation and prolonged bleeding times, thereby increasing the potential for upper and lower GI bleeding.¹

FIGURE 35-3. Metabolism of arachidonic acid after its release from membrane phospholipids. Broken arrow indicates inhibitory effects. (ASA, aspirin; HPETE, hydroperoxyeicosatetraenoic acid; NSAIDs, nonsteroidal antiinflammatory drugs; PG, prostaglandin.)

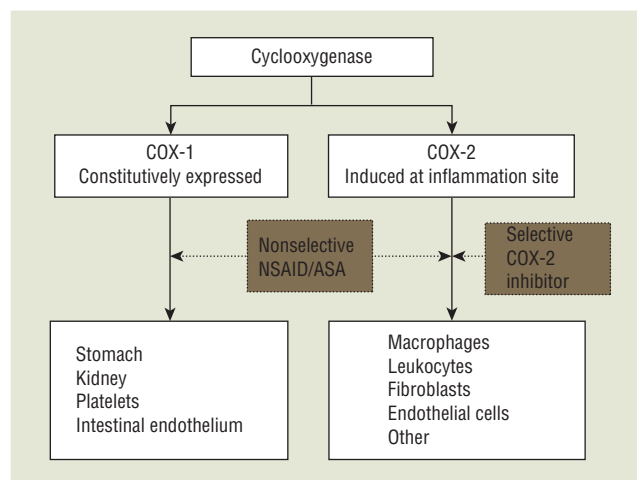

FIGURE 35-4. Tissue distribution and actions of cyclooxygenase (COX) isoenzymes. Nonselective nonsteroidal antiinflammatory drugs (NSAIDs) including aspirin (ASA) inhibit COX-1 and COX-2 to varying degrees; COX-2 inhibitors inhibit only COX-2. Broken arrow indicates inhibitory effects.

Other mechanisms may also contribute to the development of NSAID-related mucosal injury.¹

Topical irritant properties are predominantly associated with acidic NSAIDs (e.g., aspirin) and their ability to decrease the hydrophobicity of the mucous gel layer in the gastric mucosa.¹ Most nonaspirin NSAIDs have topical irritant effects, but aspirin is the most damaging. Although NSAID prodrugs, enteric-coated aspirin tablets, salicylate derivatives, and parenteral or rectal preparations are associated with less-acute topical gastric mucosal injury, they can cause ulcers and related GI complications as a result of their systemic inhibition of endogenous PGs.

COMPLICATIONS

Upper GI bleeding, perforation, and obstruction occur with *H. pylori*-associated and NSAID-induced ulcers and constitute the most serious, life-threatening complications of chronic PUD.^{1,2} Bleeding is caused by the erosion of an ulcer into an artery and occurs in approximately 10% to 15% of patients.^{1,2} The bleeding may be occult (hidden) and insidious, or may present as melena (black-colored stools) or hematemesis (vomiting of blood). The use of NSAIDs (especially in older adults) is the most important risk factor for upper GI bleeding. Deaths occur primarily in patients who continue to bleed, or in those patients who rebleed after the initial bleeding has stopped (see Upper Gastrointestinal Bleeding).

Ulcer-related perforation into the peritoneal cavity occurs in approximately 7% of patients with PUD.¹ The incidence of perforation is increasing with the increased use of NSAIDs. Mortality is usually higher for perforated gastric ulcer than duodenal ulcer. The pain of perforation is usually sudden, sharp, and severe, beginning first in the epigastrium, but quickly spreading over the entire abdomen. Most patients experience ulcer symptoms prior to perforation. However, older patients who experience perforation in association with NSAID use may be asymptomatic. Penetration occurs when an ulcer burrows into an adjacent structure (pancreas, biliary tract, or liver) rather than opening freely into a cavity.

Gastric outlet obstruction occurs in approximately 2% of patients with peptic ulcers.¹ Mechanical obstruction is caused by scarring or edema of the duodenal bulb or pyloric channel and can lead to gastric retention. Symptoms usually occur over several months and include early satiety, bloating, anorexia, nausea, vomiting, and weight loss. Perforation, penetration, and gastric outlet obstruction occur most often in patients with long-standing PUD.

Treatment of PUD has improved so dramatically that even the most virulent ulcers can be managed with medication. Intractability to drug therapy is now an infrequent manifestation of PUD and an infrequent indication for surgery.

CLINICAL PRESENTATION

SIGNS AND SYMPTOMS

The clinical presentation of PUD varies depending on the severity of epigastric pain and the presence of complications (Table 35–5).¹ Ulcer-related pain in duodenal ulcer often occurs 1 to 3 hours after meals and is usually relieved by food, but this is variable. In gastric ulcer, food may precipitate or accentuate ulcer pain. Antacids usually provide immediate pain relief in most ulcer patients. Pain usually diminishes or disappears during treatment; however, recurrence of epigastric pain after healing often suggests an unhealed or recurrent ulcer.

Epigastric pain does not define an ulcer.^{1,14} The absence of pain does not preclude the diagnosis especially in the elderly who may present with “silent” ulcer complications. The reasons for this are unclear, but may relate to differences in the way the elderly perceive pain or the analgesic effect of NSAIDs. Dyspepsia in itself is of little clinical value when assessing subsets of patients who are most likely to have an ulcer. Patients taking NSAIDs often report dyspepsia, but dyspeptic symptoms do not directly correlate with an ulcer. Patients with dyspeptic symptoms may have either uninvestigated (no upper endoscopy) or investigated (underwent upper endoscopy) dyspepsia. If an ulcer is not confirmed in a patient with ulcer-like symptoms at the time of endoscopy, the disorder is referred to as *nonulcer dyspepsia*.³ Ulcer-like symptoms may occur in the absence of peptic ulceration in association with *H. pylori* gastritis or duodenitis. There is no one sign or symptom that differentiates between *H. pylori*-associated and NSAID-induced ulcer.

DIAGNOSIS

Routine laboratory tests are not helpful in establishing the diagnosis of uncomplicated PUD (see Table 35–5).¹

TESTS FOR HELICOBACTER PYLORI

The diagnosis of *H. pylori* infection can be made using endoscopic or nonendoscopic tests (Table 35–6).^{1,5,27} The tests that require upper endoscopy are invasive, more expensive, and usually require a mucosal biopsy for histology, culture, or detection of urease activity. At least three tissue samples are taken from specific areas of the stomach, as patchy distribution of *H. pylori* infection can lead to false-negative results. Because certain medications may decrease the sensitivity of these tests, antibiotics and bismuth salts should be withheld for 4 weeks and proton pump inhibitors (PPIs) for 1 to 2 weeks prior to endoscopic testing. A new method permits the *in vivo* observation of *H. pylori* in their natural niche during endoscopy.²⁸

Two types of nonendoscopic tests are available: tests that identify active infection and tests that detect antibodies (see Table 35–6). Antibody tests do not differentiate between active infection and previously eradicated *H. pylori*. The nonendoscopic tests are noninvasive, more convenient, and less expensive than the endoscopic tests and include the urea breath test (UBT), serologic antibody detection tests, and the stool antigen test.^{1,5,27} The UBT is the most accurate noninvasive test and is based on *H. pylori* urease activity.²⁷ The ¹³carbon (nonradioactive isotope) and ¹⁴carbon (radioactive isotope) tests require that the patient ingest radiolabeled urea, which is then hydrolyzed by *H. pylori* (if present in the stomach) to ammonia and radiolabeled bicarbonate. The

TABLE 35-5 Presentation of Peptic Ulcer Disease

General
• Mild epigastric pain or acute life-threatening upper gastrointestinal complications
Symptoms
• Abdominal pain that is often epigastric and described as burning, but may present as vague discomfort, abdominal fullness, or cramping
• A typical nocturnal pain that awakens the patient from sleep (especially between 12 AM and 3 AM)
• The severity of ulcer pain varies from patient to patient, and may be seasonal, occurring more frequently in the spring or fall; episodes of discomfort usually occur in clusters, lasting up to a few weeks and followed by a pain-free period or remission lasting from weeks to years
• Changes in the character of the pain may suggest the presence of complications
• Heartburn, belching, and bloating often accompany the pain
• Nausea, vomiting, and anorexia, are more common in patients with gastric ulcer than with duodenal ulcer, but may also be signs of an ulcer-related complication
Signs
• Weight loss associated with nausea, vomiting, and anorexia
• Complications, including ulcer bleeding, perforation, penetration, or obstruction
Laboratory tests
• Gastric acid secretory studies
• Fasting serum gastrin concentrations are only recommended for patients who are unresponsive to therapy, or for those in whom hypersecretory diseases are suspected
• The hematocrit and hemoglobin are low with bleeding, and stool hemoccult tests are positive
• Tests for <i>Helicobacter pylori</i> (see Table 35–6)
Other diagnostic tests
• Fiberoptic upper endoscopy (esophagogastroduodenoscopy) detects more than 90% of peptic ulcers and permits direct inspection, biopsy, visualization of superficial erosions, and sites of active bleeding
• Routine single-barium contrast techniques detect 30% of peptic ulcers; optimal double-contrast radiography detects 60% to 80% of ulcers

From Del Valle et al.¹ and Yuan et al.¹⁴

radiolabeled bicarbonate is absorbed in the blood and excreted in the breath. A mass spectrometer is used to detect ¹³carbon, whereas ¹⁴carbon is measured using a scintillation counter. Serologic tests are a cost-effective alternative for the initial diagnosis of *H. pylori* infection in the untreated patient. However, serology should not be used to confirm *H. pylori* eradication and is unreliable in young children.^{1,5,27} Office-based tests provide rapid results but are less accurate than laboratory-based enzyme-linked immunosorbent assay (ELISA) tests. The stool antigen test is less expensive and easier to perform than the UBT, and may be useful in children. Although comparable to the UBT in the initial detection of *H. pylori*, the stool antigen test is less accurate when used to confirm *H. pylori* eradication posttreatment. Salivary and urine antibody tests are under investigation.^{1,27}

Testing for *H. pylori* is only recommended if eradication therapy is considered. If endoscopy is not planned, serologic antibody testing is a reasonable choice to determine *H. pylori* status. The diagnostic accuracy of tests used to detect *H. pylori* in patients with a bleeding ulcer has not been evaluated as extensively. However, endoscopic biopsy-based tests such as the rapid urease test have the highest degree of specificity in patients with a bleeding peptic ulcer (see Peptic Ulcer-Related Bleeding below).²⁹ Posttreatment evaluation to confirm eradication is unnecessary in most patients with PUD unless they have recurrent symptoms, complicated ulcer, MALT lymphoma, or gastric cancer.¹ The UBT is the preferred nonendoscopic method to verify *H. pylori* eradication after treatment. To avoid confusing bacterial suppression with eradication, the UBT must be delayed at least 4 weeks after the completion of treatment. The term *eradication* or *cure* is used when posttreatment tests conducted 4 weeks after the end of treatment do not detect the organism. Quantitative antibody tests are considered impractical

TABLE 35-6 Tests for Detection of *Helicobacter pylori*

Test	Description	Comments
Endoscopic tests		
Histology	Microbiologic examination using various stains	Gold standard; >95% sensitive and specific; permits classification of gastritis; results are not immediate; not recommended for initial diagnosis; tests for active <i>H. pylori</i> infection
Culture	Culture of biopsy	Enables sensitivity testing to determine appropriate treatment or antibiotic resistance; 100% specific; results are not immediate; not recommended for initial diagnosis; used after failure of second-line treatment; tests for active <i>H. pylori</i> infection
Biopsy (rapid) urease	<i>H. pylori</i> urease generates ammonia, which causes a color change	Test of choice at endoscopy; >90% sensitive and specific; easily performed; rapid results (usually within 24 hours); tests for active <i>H. pylori</i> infection
Nonendoscopic tests		
Antibody detection (laboratory based)	Detects antibodies to <i>H. pylori</i> in serum; in the U.S., only FDA-approved anti- <i>H. pylori</i> IgG antibody should be used	Quantitative; less sensitive and specific than endoscopic tests; more accurate than in-office; unable to determine if antibody is related to active or cured infection; antibody titers vary markedly between individuals and take 6 months to 1 year to return to the uninfected range; not affected by PPIs or bismuth; antibiotics given for unrelated indications may cure the infection but antibody test will remain positive
Antibody detection (can be performed in office or near patient)	Detects IgG antibodies to <i>H. pylori</i> in whole blood or fingerstick	Qualitative; quick (within 15 minutes); unable to determine if antibody is related to active or cured infection; most patients remain seropositive for at least 6 months to 1 year after <i>H. pylori</i> eradication; not affected by PPIs, bismuth, or antibiotics
Urea breath test	<i>H. pylori</i> urease breaks down ingested labeled C-urea, patient exhales labeled CO ₂	Tests for active <i>H. pylori</i> infection; 95% sensitive and specific; results take about 2 days; antibiotics, bismuth, PPIs, and H ₂ RAs may cause false-negative results; withhold PPIs or H ₂ RAs (1–2 weeks) and bismuth or antibiotics (4 weeks) prior to testing; may be used posttreatment to confirm eradication
Stool antigen	Identifies <i>H. pylori</i> antigen in stool, leading to color change that can be detected visually or by spectrophotometer	Tests for active <i>H. pylori</i> infection; sensitivity and specificity comparable to urea breath test when used for initial diagnosis; antibiotics, bismuth, and PPIs may cause false-negative results, but to a lesser extent than with the urea breath test; may be used posttreatment to confirm eradication

H₂RA, H₂-receptor antagonist; PPI, proton pump inhibitor.

for posttreatment eradication as antibody titers remain elevated for long periods of time.

IMAGING AND ENDOSCOPY

The diagnosis of PUD depends on visualizing the ulcer crater either by upper GI radiography or upper endoscopy (see Table 35-5).¹ Because of its lower cost, greater availability, and greater safety, radiography is often the initial diagnostic procedure in patients with suspected uncomplicated PUD. If complications are thought to exist, or if an accurate diagnosis is warranted, upper endoscopy is the diagnostic procedure of choice. If a gastric ulcer is found on radiography, malignancy should be excluded by direct endoscopic visualization and histology.

CLINICAL COURSE AND PROGNOSIS

The natural history of PUD is characterized by periods of exacerbations and remissions.¹ Ulcer pain is usually recognizable and episodic, but symptoms are variable, especially in older adults and in patients taking NSAIDs. Antiulcer medications, including the histamine-2 receptor antagonists (H₂RAs), PPIs, and sucralfate, relieve symptoms, accelerate ulcer healing, and reduce the risk of ulcer recurrence, but they do not cure the disease. Both duodenal ulcers and gastric ulcers recur unless the underlying cause (*H. pylori* or NSAID) is removed. Successful *H. pylori* eradication markedly decreases ulcer recurrence and complications. Prophylactic cotherapy or a COX-2 inhibitor dramatically decreases the risk for ulcers and related complications in high-risk patients who are taking NSAIDs. Approximately 20% of patients with chronic PUD experience upper GI bleeding, perforation, or obstruction. Mortality in patients with gastric ulcer is slightly higher than in duodenal ulcer and the general population. The development of adenocarcinoma in *H. pylori*-infected patients is a slow process that occurs over 20 to 40 years and is associated with a lifetime risk of less than 1%.^{1,7}

TREATMENT

DESIRED OUTCOME

The treatment of chronic PUD varies depending on the etiology of the ulcer (*H. pylori* or NSAID), whether the ulcer is initial or recurrent, and whether complications have occurred (Fig. 35-5). Overall treatment is aimed at relieving ulcer pain, healing the ulcer, preventing ulcer recurrence, and reducing ulcer-related complications. The goal of therapy in *H. pylori*-positive patients with an active ulcer, a previously documented ulcer, or a history of an ulcer-related complication, is to eradicate *H. pylori*, heal the ulcer, and cure the disease. Successful eradication heals ulcers and reduces the risk of recurrence to less than 10% at 1 year.¹ The goal of therapy in a patient with a NSAID-induced ulcer is to heal the ulcer as rapidly as possible. Patients who are at high risk of developing NSAID ulcers should receive prophylactic cotherapy or be switched to a COX-2 inhibitor (if available) to reduce ulcer risk and related complications. When possible, the most cost-effective drug regimen should be used.

GENERAL APPROACH TO TREATMENT

The treatment of PUD centers on healing the ulcer and reducing the risk of ulcer recurrence and related complications. Drug regimens containing antimicrobials such as clarithromycin, metronidazole, amoxicillin, and bismuth salts and antisecretory drugs (PPIs or H₂RAs) relieve ulcer symptoms, heal the ulcer, and eradicate *H. pylori* infection. Successful eradication will alter the natural history of PUD and cure the disease. PPIs are preferred to H₂RAs or sucralfate for healing *H. pylori*-negative NSAID ulcers because they accelerate ulcer healing and provide more effective relief of symptoms. Treatment with a PPI should be extended to 8 to 12 weeks if the NSAID must be continued. A PPI-based *H. pylori* eradication regimen is recommended in *H. pylori*-positive patients with an active ulcer who are also taking an NSAID. Prophylactic cotherapy with either a PPI or miso-

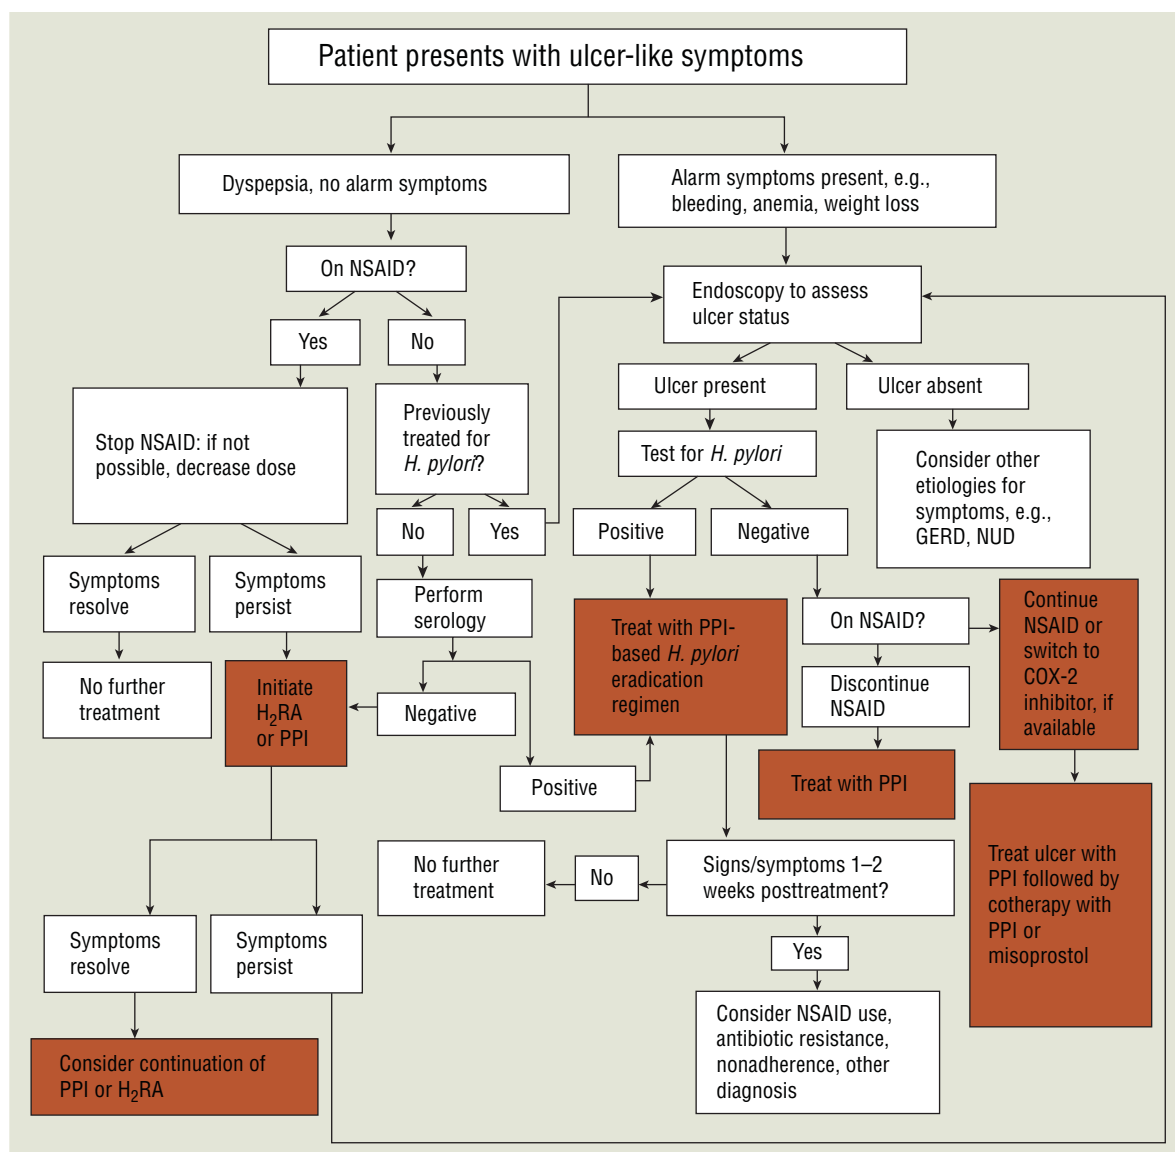

FIGURE 35-5. Algorithm. Guidelines for the evaluation and management of a patient who presents with dyspeptic or ulcer-like symptoms. (COX-2, cyclooxygenase-2; GERD, gastroesophageal reflux disease; *H. pylori*, *Helicobacter pylori*; H₂RA, H₂-receptor antagonist; PPI, proton pump inhibitor; NSAID, nonsteroidal antiinflammatory drug; NUD, nonulcer dyspepsia.)

prostaglandin decreases ulcer risk and upper GI complications in patients taking nonselective NSAIDs. A COX-2 inhibitor may be used as an alternative to a nonselective NSAID, but the risk of adverse cardiovascular effects must be weighted against the gastroprotective benefits in each patient. The optimal therapeutic strategy for patients at very high risk of NSAID-related GI events is not known, but selected patients may benefit from the use of a COX-2 inhibitor and a PPI.

Dietary modifications are important for patients who are unable to tolerate certain foods and beverages. Lifestyle modifications such as reducing stress and decreasing or stopping cigarette smoking is encouraged. Some patients may require radiographic or endoscopic procedures for a definitive diagnosis or for complications such as bleeding. Surgery may be necessary in patients with ulcer-related complications.

■ NONPHARMACOLOGIC THERAPY

1 Patients with PUD should eliminate or reduce psychological stress, cigarette smoking, and the use of nonselective NSAIDs (including aspirin). Although there is no “antiulcer diet,” the patient should

avoid foods and beverages (e.g., spicy foods, caffeine, and alcohol) that cause dyspepsia or that exacerbate ulcer symptoms. If possible, alternative agents such as acetaminophen, nonacetylated salicylate (e.g., salsalate), or COX-2 inhibitors should be used for relief of pain.

Elective surgery for PUD is rarely performed today because of highly effective medical management such as the eradication of *H. pylori* and the use of potent acid inhibitors.³⁰ A subset of patients, however, may require emergency surgery for bleeding, perforation, or obstruction. In the past, surgical procedures were performed for medical treatment failures and included vagotomy with pyloroplasty or vagotomy with antrectomy.³⁰ Vagotomy (truncal, selective, or parietal cell) inhibits vagal stimulation of gastric acid. A truncal or selective vagotomy frequently results in postoperative gastric dysfunction and requires a pyloroplasty or antrectomy to facilitate gastric drainage. When an antrectomy is performed, the remaining stomach is anastomosed with the duodenum (Billroth I) or with the jejunum (Billroth II). A vagotomy is unnecessary when an antrectomy is performed for gastric ulcer. The postoperative consequences associated with these procedures include postvagotomy diarrhea, dumping syndrome, anemia, and recurrent ulceration.

TABLE 35-7 Guidelines for the Eradication of *Helicobacter pylori* Infection**Strongly recommended**

- Gastric and duodenal ulcer (active or inactive), including complicated ulcers, and following gastric surgery for peptic ulcer
- Mucosa-associated lymphoid tissue (MALT) lymphoma
- Atrophic changes in the gastric mucosa (atrophic gastritis)
- Following resection of gastric cancer
- Infected patients who are first-degree relatives of patients with gastric cancer
- Infected patients who are aware and concerned about the risks of infection

Controversial

- Use of nonsteroidal antiinflammatory drugs (*H. pylori* infection and the use of nonsteroidal antiinflammatory drugs or aspirin are independent risk factors for peptic ulcer disease)
- Nonulcer dyspepsia
- Patients with gastroesophageal reflux disease receiving long-term proton pump inhibitor therapy

From Malfertheiner et al.³⁵ and Chex and Wong.³⁶

■ PHARMACOLOGIC THERAPY

Recommendations

2 Table 35–7 presents guidelines for the eradication of infection in *H. pylori*-positive individuals. Table 35–8 lists the recommended *H. pylori* eradication regimens. First-line therapy should be initiated with a PPI-based three-drug regimen for a minimum of 7 days, but preferably for 10 to 14 days. If a second course of treatment is required, the PPI-based three-drug regimen should contain different antibiotics or a four-drug regimen with bismuth subsalicylate, metronidazole, tetracycline, and a PPI should be used.

3 Treatment with a conventional antiulcer drug, such as a PPI, an H₂RA, or sucralfate alone (Table 35–9), is an alternative to *H. pylori* eradication, but is discouraged because of the high rate of ulcer recurrence and ulcer-related complications associated with these regimens. Concomitant therapy (e.g., an H₂RA and sucralfate or an H₂RA and a PPI) is not recommended because it adds to drug costs without enhancing efficacy. Maintenance therapy with a PPI or H₂RA is recommended for high-risk patients with ulcer complications, patients who fail eradication, and those with *H. pylori*-negative ulcers.

4 Patients with NSAID-induced ulcers should be tested to determine their *H. pylori* status. If *H. pylori*-positive, treatment should be initiated with a PPI-based three-drug eradication regi-

men. If *H. pylori*-negative, the NSAID should be discontinued and the patient treated with either a PPI, H₂RA, or sucralfate. If the NSAID must be continued, treatment should be initiated with a PPI (if *H. pylori*-negative) or with a PPI-based three-drug eradication regimen (if *H. pylori*-positive). Prophylactic cotherapy with a PPI or misoprostol or switching to a selective COX-2 inhibitor (if available) is recommended for patients at risk of developing ulcer-related upper GI complications (Table 35–10).

Treatment of *Helicobacter pylori*-Associated Ulcers

The following discussion focuses on the eradication of *H. pylori* in adults. Guidelines for the treatment of *H. pylori* infection in the elderly,^{31,32} children,³³ and patients with chronic renal insufficiency³⁴ are found elsewhere.

5 The goal of *H. pylori* drug therapy is eradication of the organism. Treatment should be effective, well-tolerated, easy to comply with, and cost-effective. *H. pylori* regimens should have eradication (cure) rates of at least 80% based on intention-to-treat analysis, or at least 90% based on per-protocol analysis, and should minimize the potential for antimicrobial resistance.^{1,5,36–37} The use of a single antibiotic, bismuth salt, or antiulcer drug does not achieve this goal.^{1,5} However, clarithromycin is the single most effective antibiotic.¹ Two-drug regimens that combine a PPI and either amoxicillin or clarithromycin have yielded marginal and variable eradication rates in the United States and are not recommended.^{1,5} In addition, the use of only one antibiotic is associated with a higher rate of antimicrobial resistance.¹

Eradication regimens (see Table 35–8) that combine two antibiotics and one antisecretory drug (triple therapy) or a bismuth salt, two antibiotics, and an antisecretory drug (quadruple therapy) increase eradication rates to an acceptable level and reduce the risk of antimicrobial resistance.^{35–38} When selecting a first-line eradication regimen, an antibiotic combination should be used that permits second-line treatment (if necessary) with different antibiotics. The antibiotics that have been most extensively studied and found to be effective in various combinations include clarithromycin, amoxicillin, metronidazole, and tetracycline.^{1,5} Although other antibiotics may be effective, they should not be used as part of the initial *H. pylori* regimen. Because of insufficient data, ampicillin should not be substituted for amoxicillin, doxycycline should not be substituted for tetracycline, and azithromycin or erythromycin should not be substi-

TABLE 35-8 Drug Regimens to Eradicate *Helicobacter pylori*^a

Drug #1	Drug #2	Drug #3	Drug #4
Proton pump inhibitor-based 3-drug regimens			
Omeprazole 20 mg twice daily or lansoprazole 30 mg twice daily or pantoprazole 40 mg twice daily or esomeprazole 40 mg daily or rabeprazole 20 mg daily	Clarithromycin 500 mg twice daily	Amoxicillin 1 g twice daily or metronidazole 500 mg twice daily	
Bismuth-based 4-drug regimens^b			
Omeprazole 40 mg twice daily or lansoprazole 30 mg twice daily or pantoprazole 40 mg twice daily or esomeprazole 40 mg daily or rabeprazole 20 mg daily or standard ulcer-healing dosages of an H ₂ -receptor antagonist taken for 4–6 weeks (see Table 35–9)	Bismuth subsalicylate 525 mg four times daily	Metronidazole 250–500 mg four times daily	Tetracycline 500 mg four times daily or amoxicillin 500 mg four times daily, or, clarithromycin 250–500 mg four times daily

^aAlthough treatment is minimally effective if used for 7 days, 10–14 days of treatment is recommended. The antisecretory drug may be continued beyond antimicrobial treatment in patients with a history of a complicated ulcer, e.g., bleeding or in heavy smokers.

^bIn the setting of an active ulcer, acid suppression is added to hasten pain relief.

TABLE 35-9 Oral Drug Regimens Used to Heal Peptic Ulcers or Maintain Ulcer Healing

Drug	Duodenal or Gastric Ulcer Healing (mg/dose)	Maintenance of Duodenal or Gastric Ulcer Healing (mg/dose)
<i>Proton pump inhibitors</i>

Pantoprazole	40 daily	40 daily
Esomeprazole	20–40 daily	20–40 daily
<i>H₂-receptor antagonists</i>		
Cimetidine	300 four times daily 400 twice daily 800 at bedtime	400–800 at bedtime
Famotidine	20 twice daily 40 at bedtime	20–40 at bedtime
Nizatidine	150 twice daily 300 at bedtime	150–300 at bedtime
Ranitidine	150 twice daily 300 at bedtime	150–300 at bedtime
<i>Promote mucosal defense</i>		
Sucralfate	1 g four times daily 2 g twice daily	1–2 g twice daily 1 g four times daily

tuted for clarithromycin. Amoxicillin should not be used in penicillin-allergic patients and metronidazole should be avoided if alcohol is consumed.³⁶ Bismuth salts have a topical antimicrobial effect.¹ Explanations as to why antisecretory drugs enhance the efficacy of antibiotics include increased activity or stability of the antibiotic at a higher intragastric pH and enhanced topical antibiotic concentration resulting from decreased intragastric volume.

Proton Pump Inhibitor-Based Three-Drug Regimens

Proton pump inhibitor-based three-drug regimens with two antibiotics (see Table 35–8) constitute first-line therapy for eradication of *H. pylori*.^{1,5,35,36} There is now consensus that PPI-based regimens that combine either clarithromycin and amoxicillin or clarithromycin and metronidazole provide successful efficacy^{1,35,36} and that the amoxicillin–metronidazole combination may be less effective.¹ In most cases, increasing the antibiotic dosage dose not improve eradication rates. Amoxicillin is preferred over clarithromycin for initial eradication because bacterial resistance is almost absent and it has fewer adverse effects.¹⁴ It also leaves metronidazole as a backup agent for second-line therapy. The PPI–clarithromycin–metronidazole reg-

imen should be used as first-line treatment in penicillin-allergic patients (see Table 35–8).³⁶

An initial 7-day course of therapy provides minimally acceptable eradication rates and has been approved by the FDA and is recommended in Europe.^{1,5,35,36} The duration of therapy, however, remains controversial in the United States, as longer treatment periods (10- and 14-day) favor higher eradication rates and are less likely to be associated with antimicrobial resistance.^{1,5,36} A number of other antibiotics and antibiotic combinations have been evaluated as part of the PPI-based three-drug regimen with varying degrees of success.^{1,5,36,39}

The PPI is an integral part of the three-drug regimen and should be taken 30 to 60 minutes before a meal along with the two antibiotics (see Table 35–8). Prolonged PPI treatment beyond 2 weeks after eradication is not necessary for ulcer healing.⁴⁰ A single daily dose of a PPI may be less effective than a double dose when used as part of a triple-therapy *H. pylori* eradication regimen.⁴¹ Substitution of one PPI for another is acceptable and does not appear to enhance or diminish *H. pylori* eradication.⁴² An H₂RA should not be substituted for a PPI, because more effective eradication rates have been demonstrated with a PPI.⁴³ Pretreatment with a PPI does not influence *H. pylori* eradication.⁴⁴

Sequential therapy with a PPI and amoxicillin for 5 days followed by a PPI, clarithromycin, and metronidazole for an additional 5 days has achieved eradication rates which are superior to the traditional PPI-based three-drug regimens.^{36,45} The rationale for sequential eradication therapy is to initially treat the patient with antibiotics that rarely promote resistance (e.g., amoxicillin) to reduce the bacterial load and preexisting resistant organisms and then to follow with different antibiotics (e.g., clarithromycin and metronidazole) to kill the remaining organisms. Sequential drug regimens must be validated in the United States before they can be recommended as first-line eradication therapy.

CLINICAL CONTROVERSY

Some clinicians favor an initial 7-day *H. pylori* regimen, whereas others favor a 10- or 14-day treatment course. The optimal duration of therapy is uncertain, as shorter periods may enhance compliance, but longer treatment periods in compliant patients favor higher eradication rates and are less likely to be associated with antimicrobial resistance. Patients receiving a second course of therapy after an unsuccessful eradication should receive treatment for 14 days.

Bismuth-Based Four-Drug Regimens

The bismuth-based four-drug regimens presented in Table 35–8 are used as first-line therapy to eradicate *H. pylori*. Eradication rates for a 14-day regimen containing bismuth, metronidazole, tetracycline,

TABLE 35-10 Risk Assessment and Suggested Guidelines for Reducing Gastrointestinal Risk in Patients Receiving Chronic NSAID Therapy

Risk Assessment (see Table 35–4)	Definition	Suggested Guidelines
Low	No risk factors or age <65 years and no aspirin, no prior ulcer, no history of ulcer-related GI complication	Nonselective NSAID or partially selective NSAID (see Table 35–3)
Moderate	1–2 risk factors (e.g., age >65 years, low-dose aspirin, high-dose NSAID)	Nonselective NSAID or partially selective NSAID plus PPI or misoprostol cotherapy; selective COX-2 inhibitor (if available)
High	≥3 risk factors or concomitant use of low-dose aspirin and either corticosteroids, warfarin, or clopidogrel	Nonselective or partially selective NSAID plus PPI or misoprostol cotherapy; COX-2 inhibitor if available plus PPI or misoprostol cotherapy
Very high	Prior ulcer or ulcer-related complication plus additional risk factors (e.g., age >65 years, concomitant use of low-dose aspirin, corticosteroids, warfarin, or clopidogrel)	Nonselective or partially selective NSAID plus PPI or misoprostol cotherapy; COX-2 inhibitor if available plus PPI or misoprostol cotherapy; consider NSAID or COX-2 inhibitor if available plus PPI and misoprostol cotherapy

COX-2, cyclooxygenase-2 inhibitor; NSAID, nonsteroidal antiinflammatory drug; PPI, proton pump inhibitor. From Del Valle et al.,¹ Elta,² Naesdal and Brown,¹³ Dubois et al.,⁵¹ and Chan and Graham.⁵²

and an H_2 -receptor antagonist are similar to those achieved with PPI-based triple therapy.^{1,5,36,46} Increasing the duration of treatment to 1 month does not substantially increase eradication. Substitution of amoxicillin for tetracycline lowers the eradication rate and is usually not recommended.^{1,46} Substitution of clarithromycin 250 to 500 mg four times a day for tetracycline yields similar results, but increases adverse effects. The antisecretory drug is used to hasten pain relief in patients with an active ulcer. Although the original bismuth-based four-drug regimen is effective and inexpensive, it is associated with frequent adverse effects and poor compliance. Comparable eradication rates occur when bismuth subcitrate potassium (bismuth subcitrate) is used in place of bismuth subsalicylate.

First-line treatment with quadruple therapy using a PPI (with bismuth, metronidazole, and tetracycline) in place of the H_2 RA achieves similar eradication rates as those of PPI-based triple therapy and permits a shorter treatment duration (7 days).^{1,46} Although evidence supports the efficacy of bismuth-based quadruple therapy as first-line treatment, it is often recommended as second-line treatment when a clarithromycin-amoxicillin regimen is used initially (see section on eradication regimens after initial treatment failure). All medications except the PPI should be taken with meals and at bedtime.

Eradication Regimens after Initial Treatment Failure

H. pylori eradication is often more difficult after initial treatment fails and successful eradication is extremely variable.^{5,36,37} Because there are limited data on second attempts to eradicate *H. pylori*, treatment failures should be handled on a case-by-case basis. Patients who fail first-line regimens should be referred to a gastroenterologist for further diagnostic evaluation.

Second-line treatment should (a) use antibiotics that were not previously used during initial therapy; (b) use antibiotics that do not have resistance problems; (c) use a drug that has a topical effect such as bismuth; and the duration of treatment should be extended to 14 days.⁴⁷ Thus after unsuccessful initial treatment with a PPI-amoxicillin-clarithromycin regimen, second-line therapy should be instituted with bismuth subsalicylate, metronidazole, tetracycline, and a PPI for 14 days (see Table 35–8).^{5,47} Other second-line regimens are discussed elsewhere.^{36,47,48}

Factors That Contribute to Unsuccessful Eradication

Factors that contribute to unsuccessful eradication include poor medication adherence, resistant organisms, low intragastric pH, and a high bacterial load.^{37,47,49} Medication adherence decreases with multiple medications, increased frequency of administration, increased length of treatment, intolerable adverse effects, and costly drug regimens. Although longer treatment duration may contribute to nonadherence, missed doses in a 7-day regimen may also lead to failed eradication.⁴⁷ Tolerability varies with different regimens. Metronidazole-containing regimens increase the frequency of adverse effects (especially when the dose is >1 g/day). Other common adverse effects include taste disturbances (metronidazole and clarithromycin), nausea, vomiting, abdominal pain, and diarrhea. Antibiotic-associated colitis, a serious complication, occurs occasionally. Oral thrush and vaginal candidiasis may also occur.

An important determinant of successful *H. pylori* eradication is the presence of preexisting antimicrobial resistance.^{1,26,37,47} Metronidazole resistance is most common (10% to 60%), but varies depending on prior antibiotic exposure and geographic region.^{1,26,37} The clinical importance of metronidazole resistance in eradicating *H. pylori* remains uncertain, as the synergistic effect of combining metronidazole with other antibiotics appears to render resistance to metronidazole less important. Primary resistance to clarithromycin

is lower (10% to 15%) than with metronidazole, but it is more likely to affect the clinical outcome.^{1,47} Secondary resistance occurs in up to two-thirds of treatment failures. Resistance to tetracycline and amoxicillin is uncommon.¹ Resistance to bismuth has not been reported. The role of antibiotic sensitivity testing before initiating *H. pylori* treatment has not been established.

Probiotics

Probiotics (e.g., strains of *Lactobacillus* and *Bifidobacterium*) and foodstuffs (e.g., cranberry juice and some milk proteins) with bioactive components have been used to proactively control *H. pylori* colonization in at-risk individuals and may have a possible role in decreasing mucosal inflammation and healing gastric ulcer in the *H. pylori*-infected patient.⁵⁰ Thus, regular intake of probiotics may eventually constitute a low-cost alternative for individuals who are at-risk for *H. pylori* colonization and, in combination with antibiotics, may increase eradication rates. A review of this subject is found elsewhere.⁵⁰

Treatment of NSAID-Induced Ulcers

Nonselective NSAIDs should be discontinued (when possible) if an active ulcer is confirmed. If the NSAID is stopped, most uncomplicated ulcers will heal with standard regimens of an H_2 -receptor antagonist, PPI, or sucralfate (see Table 35–9).^{1,12,14} PPIs are usually preferred because they provide more rapid relief of symptoms and ulcer healing than H_2 RAs or sucralfate. If the NSAID must be continued despite ulceration, consideration should be given to reducing the NSAID dose, or switching to acetaminophen, a nonacetylated salicylate, a partially selective COX-2 inhibitor, or a selective COX-2 inhibitor (see Table 35–3). The PPIs are the drugs of choice when the NSAID must be continued, as potent acid suppression is required to accelerate ulcer healing.^{1,12,14} H_2 RAs and sucralfate are less effective in the presence of continued NSAID use. If *H. pylori* is present, eradication should be initiated with a regimen that contains a PPI.^{1,12–14}

Strategies to Reduce the Risk of NSAID-Induced Ulcers and Upper GI Complications

There are three therapeutic approaches to reducing the risk of nonselective NSAID-related ulcers and serious upper GI complications (see Table 35–10). Medical cotherapy with either a PPI or misoprostol decreases ulcer risk and GI complications in high-risk patients.^{1,12–14,21,51,52} The use of a selective COX-2 inhibitor instead of a nonselective NSAID also decreases risk of ulcers and serious GI events.^{1,12–14,21,51,52} Unfortunately, these strategies, when used alone, do not completely eliminate ulcer recurrence and complications in patients at the “highest risk.” Strategies aimed at reducing the topical irritant effects of nonselective NSAIDs—prodrugs, slow-release formulations, and enteric-coated products—do not prevent ulcers or GI complications.

Misoprostol Cotherapy Misoprostol, 200 mcg orally four times per day, reduces the risk of NSAID-induced gastric and duodenal ulcer, and ulcer-related GI complications, but diarrhea and abdominal cramping limit its use.^{12–14,21} Because a dosage of 200 mcg three times per day is comparable in efficacy to 800 mcg/day, the lower dosage should be considered in patients unable to tolerate the higher dose.^{1,12–14} Reducing the misoprostol dosage to 400 mcg per day or less to minimize diarrhea compromises its beneficial effects. A fixed combination of misoprostol 200 mcg and diclofenac (50 mg or 75 mg) is available and may enhance compliance, but the flexibility to individualize drug dosage is lost. A large clinical trial in rheumatoid arthritis patients provides the most compelling evidence that misoprostol reduces the risk of serious upper GI complications in high-risk patients.⁵³

Proton Pump Inhibitor Cotherapy 6 Proton pump inhibitor cotherapy reduces the risk of nonselective NSAID-related gastric and duodenal ulcer^{1,12–14,21} and is superior to the H_2 RAs.^{1,13,52} All

PPIs, when used in standard PPI dosages (see Table 35–9) are effective. When lansoprazole (15 or 30 mg/day) was compared to misoprostol 800 mcg/day or placebo, both dosages of lansoprazole and misoprostol effectively reduced the risk of ulcer recurrence, although the PPI was better tolerated.⁵⁴ A greater proportion of those in the misoprostol group reported treatment-related adverse events and withdrew early from the study. Two small studies report a reduction in serious upper GI complications in patients with a history of upper GI bleeding receiving PPI cotherapy.^{55,56}

H₂-Receptor Antagonist Cotherapy Standard H₂-receptor antagonist dosages (e.g., famotidine 40 mg/day) are effective in reducing the risk of NSAID-induced duodenal ulcer, but not gastric ulcer (the most frequent type of ulcer associated with NSAIDs).^{1,12–14,21} Higher dosages (e.g., famotidine 40 mg twice daily, ranitidine 300 mg twice daily) may reduce the risk of gastric and duodenal ulcer, but results from clinical trials are variable.^{1,13,21} It is unknown whether H₂RAs reduce the risk of ulcer-related upper GI complications. Therefore, the H₂RAs are not recommended as prophylactic cotherapy. However, the H₂RAs may be used when necessary to relieve NSAID-related dyspepsia.

Selective COX-2 Inhibitors Two large, multicenter, clinical trials with selective COX-2 inhibitors have reported a reduction in the risk of symptomatic ulcers and upper GI complications by 50% to 60% when compared to nonselective NSAIDs.^{57,58} Patients in the Celecoxib Long-term Arthritis Safety Study (CLASS) trial who were taking celecoxib and required cardioprotection (antiplatelet effects of aspirin), were permitted to also take low-dose aspirin.⁵⁷ The initial 6-month analysis of the CLASS trial found a higher rate of ulcer complications in those treated with nonselective NSAIDs compared to celecoxib, but longer-term data presented at the FDA Advisory Meeting found the rate of ulcer complications to be nearly identical in both groups.⁵⁹ The most likely explanation for these results is that celecoxib is not a highly selective COX-2 inhibitor as was originally anticipated. Today, celecoxib is no longer considered a selective COX-2 inhibitor (Table 35–3) because its improved GI safety when compared to nonselective NSAIDs has not been established. A post hoc analysis confirmed that patients who were taking aspirin had a nearly identical event incidence rate with those who were taking nonselective NSAIDs, and that the only benefit of celecoxib was in patients who were not taking aspirin. Thus the gastroprotective benefits of celecoxib were negated in aspirin users. Similar effects have been observed with rofecoxib.

The Vioxx Gastrointestinal Outcomes Research (VIGOR) trial excluded aspirin users and found that ulcers and ulcer-related complications were lower with rofecoxib than with naproxen.⁵⁸ However, there was an increased number of nonfatal myocardial infarctions observed in the rofecoxib group compared to those taking naproxen. It was initially suggested that the lack of antiplatelet effects from rofecoxib, in contrast to the platelet inhibition associated with naproxen, was responsible for the increased thrombotic events observed in the rofecoxib group. Rofecoxib was later withdrawn from the market following an interim analysis of a study to prevent colorectal adenomas that revealed an increased risk of myocardial infarction and thrombotic stroke with rofecoxib when compared to placebo.⁶⁰ Subsequently, valdecoxib was withdrawn from the market amid concerns about cardiovascular risk.

Cardiovascular safety was also evaluated in the CLASS trial, but serious cardiovascular thromboembolic events were no different between celecoxib and the comparative nonselective NSAIDs. Increased risk appears to be dependent on a number of factors including increased COX-2 selectivity, higher dosages, and a longer duration of treatment.⁶¹ Although celecoxib remains on the market in the United States (at the time of writing), individual patient risk factors for cardiovascular disease must be considered when determining treat-

ment and the lowest effective dose should be used for the shortest duration of time. Patients should be counseled about the signs and symptoms of cardiovascular disease and what they should do if they occur. It remains unclear as to whether cardiovascular effects are limited to the selective COX-2 inhibitors or also apply to other NSAIDs, for example, ibuprofen, diclofenac, meloxicam. Although retrospective trials suggest an association, causality has not been prospectively demonstrated.⁶² Dyspepsia and abdominal pain, fluid retention, hypertension, and renal toxicity are associated with both nonselective NSAIDs and the COX-2 inhibitors.²¹ New classes of COX-2 inhibitors (e.g., nitric oxide donors, 5-lipoxygenase inhibitors) are under investigation.

⑦ Two small, non-placebo-controlled trials in *H. pylori*-negative patients at high risk for NSAID-related complications, found that the use of a PPI and a nonselective NSAID was equivalent to the use of a selective COX-2 inhibitor with regard to incidence of ulcer complications.^{63,64} In one trial,⁶³ patients were randomized to receive celecoxib or naproxen plus lansoprazole, and in the other,⁶⁴ celecoxib was compared to diclofenac plus omeprazole. A substantial number of patients in both trials had recurrent bleeding after 6 months of treatment. Cotherapy using a PPI and a COX-2 inhibitor in high-risk patients should be considered, but this regimen is likely to have a very modest benefit when compared to a PPI plus a nonselective NSAID.⁶⁵

CLINICAL CONTROVERSY

Some clinicians favor the concomitant use of an NSAID and low-dose aspirin in a high-risk patient, whereas others favor the use of a selective COX-2 inhibitor and low-dose aspirin. Ulcer risk is increased when a nonselective NSAID and aspirin are used concomitantly, but the benefit of the COX-2 inhibitor may be reduced in a patient taking low-dose aspirin. The comparative risks and benefits of these two methods to reduce ulcer complications has not been studied and remains controversial.

Conventional Treatment of Active Ulcers and Long-Term Maintenance of Ulcer Healing

Conventional treatment with standard dosages of H₂-receptor antagonist or sucralfate relieves ulcer symptoms and heals the majority of gastric and duodenal ulcers in 6 to 8 weeks (see Table 35–9).¹ Proton pump inhibitors provide comparable ulcer healing rates over a shorter treatment period (4 weeks).¹ A higher daily dose or a longer treatment duration is sometimes needed to heal larger gastric ulcers. Antacids are not used as single agents to heal ulcers because of the high volume and frequent doses required.¹ When conventional antiulcer therapy is discontinued after ulcer healing, most patients develop a recurrent ulcer within 1 year.^{1,5}

Continuous antiulcer therapy (see Table 35–9) is aimed at the long-term maintenance of ulcer healing and at preventing ulcer-related complications. Because *H. pylori* eradication dramatically decreases ulcer recurrence (<10% at 1 year), continuous maintenance therapy has become largely obsolete.¹ However, maintenance therapy may be indicated for patients who have previous ulcer-related complications, failed *H. pylori* eradication therapy, or who are heavy smokers or NSAID users.

Treatment of Refractory Ulcers

Ulcers are considered refractory to therapy when symptoms, ulcers, or both persist beyond 8 weeks (duodenal ulcer) or 12 weeks (gastric ulcer) despite conventional treatment, or when several courses of *H. pylori* eradication fail.¹ Poor patient compliance, antimicrobial resistance, cigarette smoking, NSAID use, gastric acid hypersecretion, or tolerance to the antisecretory effects of an H₂RA (see Antiulcer

Agents below) may contribute to refractory PUD. Patients with refractory ulcers should undergo upper endoscopy to confirm a nonhealing ulcer, exclude malignancy, and assess *H. pylori* status. *H. pylori*-positive patients should receive eradication therapy (see Treatment of *Helicobacter pylori*-Associated Ulcers). In *H. pylori*-negative patients, higher PPI dosages (e.g., omeprazole 40 mg/day) heal the majority of ulcers.¹ Continuous treatment with a PPI is often necessary to maintain healing, as refractory ulcers typically recur when therapy is discontinued or the dose is reduced. Switching from one PPI to another is not beneficial. Patients with refractory gastric ulcer may require surgery because of the fear of malignancy.

Antiulcer Agents

A comprehensive review of the pharmacology, pharmacokinetics, pharmacodynamics, efficacy, drug interactions, and tolerability of the antiulcer agents is found elsewhere.^{1,66–69}

Proton Pump Inhibitors The PPIs (omeprazole, esomeprazole, lansoprazole, rabeprazole, and pantoprazole) dose-dependently inhibit basal and stimulated gastric acid secretion.^{1,66,68} When PPI therapy is initiated, the degree of acid suppression increases over the first 3 to 4 days of therapy, as more and more proton pumps are inhibited.^{66,68} Because PPIs inhibit only those proton pumps that are actively secreting acid, they are most effective when taken 30 to 60 minutes before meals.^{66,68} The duration of acid suppression is a function of binding to the H^+/K^+ -adenosine triphosphatase (ATPase) enzyme and is substantially longer than that predicted based on the short half-lives of the agents.⁶⁶

The PPIs are formulated in delayed-release enteric-coated dosage forms, including pH-sensitive granules contained in gelatin capsules (omeprazole, esomeprazole, and lansoprazole), rapidly disintegrating tablets (lansoprazole), and delayed release enteric-coated tablets (rabeprazole, pantoprazole, and nonprescription omeprazole). The pH-sensitive enteric coating prevents degradation and premature protonation of the drug in stomach acid. The enteric coating dissolves in the duodenum at pH values above approximately 6 and then the drug is systemically absorbed.^{66,68} Omeprazole is also available in immediate release formulations that contain sodium bicarbonate (oral suspension, oral capsule) or sodium bicarbonate and magnesium hydroxide (oral tablet).^{69–71} In this case, sodium bicarbonate

and magnesium hydroxide serve as antacids to raise gastric pH and protect the immediate release omeprazole from premature protonation.⁶⁹ Intravenous products available in the U.S. include pantoprazole, lansoprazole, and esomeprazole.⁶⁶ The various formulations provide numerous options for administering proton pump inhibitors (Table 35–11).

All five PPIs provide similar ulcer-healing rates, maintenance of ulcer-healing rates, and relief of ulcer symptoms when used in recommended dosages (see Tables 35–8 and 35–9).^{1,67,72} When higher dosages are indicated, the daily dose should be divided in order to obtain better 24-hour pH control.^{66,68} A dosage reduction is unnecessary in patients with renal impairment or in older adults, but should be considered in severe hepatic disease.^{1,73}

The short-term adverse effects of the PPIs are similar to those observed with the H_2 RAs and include headache, nausea, and abdominal pain.^{1,67} Because the immediate-release formulations contain sodium bicarbonate, these formulations are contraindicated in patients with metabolic alkalosis and hypocalcemia.^{69,70} In addition, the sodium content in the immediate-release formulations should be taken into consideration in patients who are on sodium-restricted diets.⁶⁷ Because all PPIs increase intragastric pH, they may alter the bioavailability of some orally administered drugs, such as ketoconazole (weak bases) and digoxin, or in pH-dependent dosage forms.^{1,67,68} Omeprazole and esomeprazole selectively inhibit hepatic cytochrome P450 (CYP450) isoenzyme 2C19 and decrease the elimination of phenytoin, and diazepam.^{1,67,68} Lansoprazole produces a slight increase in the metabolism of theophylline, presumably by inducing CYP1A.^{1,67,68} A review of the FDA database for the years 1997 to 2001 revealed that drug interactions with PPIs are rare and usually do not constitute a major clinical risk.⁷⁴

Consequences of Prolonged Hypochlorhydria. All PPIs dose-dependently increase serum gastrin concentrations approximately two- to fourfold as a function of their potent acid-inhibitory effect.^{1,75} Fasting gastrin elevations are usually within the normal range and return to baseline within 1 month of discontinuing the drug. In humans, use of PPIs may lead to enterochromaffin-like (ECL) hyperplasia as a result of the hypergastrinemia; however, there has been no evidence that these changes result in dysplasia, carcinoid tumors, or gastric adenocarcinoma.^{1,75} Long-term PPI

TABLE 35-11 Proton Pump Inhibitor Formulations and Options for Administration

<i>Parenteral formulations</i>					
Intravenous	Not available in U.S.	X		X	

X, product is available.

^aOmeprazole available as delayed-release enteric-coated pellets in a capsule or as immediate-release formulation that contains 20 or 40 mg of omeprazole with 1100 mg sodium bicarbonate. Because 20- and 40-mg dosages contain the same amount of bicarbonate, two 20- mg tablets should not be substituted for the 40-mg immediate-release omeprazole-bicarbonate capsule.

^bOmeprazole oral tablets are available as 20-mg delayed-release tablets over-the-counter, as well as in an immediate-release formulation containing 20 or 40 mg of omeprazole, 600 mg sodium bicarbonate, and 700 mg magnesium hydroxide. Because 20- and 40-mg dosages contain the same amount of bicarbonate, two 20-mg tablets should not be substituted for the 40-mg immediate-release omeprazole-bicarbonate-magnesium hydroxide tablet.

^cOmeprazole oral suspension is available as 20 or 40 mg omeprazole with 1680 mg sodium bicarbonate. Because 20- and 40-mg dosages contain the same amount of bicarbonate, two 20-mg tablets should not be substituted for the 40-mg immediate-release omeprazole-bicarbonate packet.

^dNo published data; information extrapolated from omeprazole.

From Devlin et al.,⁶⁶ Welage,⁶⁸ Castell,⁶⁹ reference 70, and Waknine.⁷¹

therapy in *H. pylori*-positive patients is associated with progressive atrophic gastritis of the gastric body.⁷⁵ At this time there is inadequate evidence to link the long-term use of PPIs with gastric cancer in *H. pylori*-positive patients or to support an association between PPIs, colonic polyps, and colorectal cancer.¹ Although bacterial overgrowth occurs in the stomach as a consequence of hypochlorhydria which may lead to carcinogenic *N*-nitroso compounds in animals, it is unlikely to result in significant gastric nitrosation in humans.^{1,75,76} PPI therapy is associated with an increased risk of enteric infections (*Salmonella*, *Campylobacter*, *Clostridium difficile*); however, data suggesting that PPI therapy predisposes patients to infections outside of the gastrointestinal tract remains controversial.⁷⁶ A decrease in vitamin B₁₂ has been reported in some patients received long-term PPI therapy, but it is not a major concern.⁷⁵

H₂-Receptor Antagonists Ulcer healing is comparable among H₂RAs (cimetidine, famotidine, nizatidine, and ranitidine) with equipotent multiple daily doses or a single full dose given after dinner or at bedtime (see Table 35–9), but tolerance to their antisecretory effect occurs.¹ Twice-daily administration suppresses daytime acid and benefits patients with daytime ulcer pain. Cigarette smokers may require higher doses or a longer duration of treatment. H₂-receptor antagonists are eliminated renally and therefore a dosage reduction is recommended in patients with moderate to severe renal failure.¹

The short- and long-term safety of all four H₂RAs is similar.¹ Thrombocytopenia, the most common hematologic effect, is reversible and occurs with all four H₂RAs. However, the propensity for H₂RAs to cause thrombocytopenia is likely overestimated.^{1,77} Cimetidine inhibits several CYP450 isoenzymes, resulting in numerous drug interactions (e.g., theophylline, lidocaine, phenytoin, and warfarin).^{1,78} Ranitidine binds less avidly to hepatic CYP450 isoenzymes than does cimetidine, and has less potential for drug interactions. Famotidine and nizatidine do not interact with drugs metabolized by hepatic CYP450 isoenzymes. Because the H₂RAs decrease acid secretion they may alter the bioavailability of some orally administered drugs, similar to that seen with the PPIs.⁷⁸

Sucralfate Sucralfate should be taken on an empty stomach to prevent binding to dietary protein and phosphate. Deterrents to its use include multiple doses per day, large tablet size, and the need to separate the drug from meals and potentially interacting medications. Constipation is most common and develops in approximately 3% of patients.¹ Seizures may occur in dialysis patients who are also receiving aluminum-containing antacids. Hypophosphatemia may develop with long-term treatment. Gastric bezoar formation has been reported. The concomitant use of sucralfate with oral fluoroquinolones, phenytoin, digoxin, theophylline, quinidine, amitriptyline, warfarin, and ketoconazole may reduce their bioavailability.^{1,78} The interaction is often minimized by giving the interacting drug at least 2 hours before sucralfate. Alternative antiulcer therapy may be warranted in patients taking oral fluoroquinolones.

Prostaglandins Misoprostol, a synthetic prostaglandin E₁ analog, moderately inhibits acid secretion and enhances mucosal defense.^{1,79} Antisecretory effects are dose-dependent over the range of 50 to 200 mcg; cytoprotective effects occur in humans at doses of greater than 200 mcg. Because protective effects occur at higher doses, it is difficult to establish the protective effect independent of the antisecretory action. Although not recommended in the United States, a dose of 200 mcg four times daily or 400 mcg twice daily heals duodenal ulcers and gastric ulcers comparable to standard H₂RA or sucralfate regimens.¹

Diarrhea, the most troublesome adverse effect, is dose dependent and develops in 10% to 30% of patients.^{1,79} Abdominal cramping, nausea, flatulence, and headache typically accompany the diarrhea. Taking the drug with or after meals and at bedtime may minimize the diarrhea. Because misoprostol is uterotonic and produces uterine contractions that may endanger pregnancy, it is contraindi-

cated for use by pregnant women to reduce the risk of NSAID-induced ulcers.⁷⁹ If misoprostol is prescribed to women in their childbearing years, use of adequate contraceptive measures must be confirmed and a negative serum pregnancy test should be documented within 2 weeks of initiating treatment. Patients should be counseled about the GI effects and the need to avoid magnesium antacids, as they may increase the propensity for GI adverse effects.

Bismuth Preparations Bismuth subsalicylate and bismuth subcitrate potassium (bismuth citrate) are currently the only available bismuth salt in the United States.¹ Possible ulcer-healing mechanisms include an antibacterial effect, a local gastroprotective effect, and stimulation of endogenous prostaglandins. Bismuth salts do not inhibit or neutralize acid. Bismuth subsalicylate is regarded as safe and has few adverse effects when taken in recommended dosages. Because renal insufficiency may decrease bismuth elimination, bismuth salts should be used with caution in older patients and in renal failure. Bismuth subsalicylate may cause salicylate sensitivity or bleeding disorders, and should be used with caution in patients receiving concurrent salicylate therapy. Patients should be advised that bismuth salts may impart a black color to the stool and possibly the tongue (liquid preparations).

Antacids Antacids neutralize gastric acid, inactivate pepsin, and bind bile salts. Aluminum-containing antacids also suppress *H. pylori* and enhance mucosal defense.^{1,80,81} GI adverse effects are most common with antacids and are dose dependent.^{1,81} Magnesium salts cause an osmotic diarrhea, whereas aluminum salts cause constipation. Diarrhea usually predominates with magnesium/aluminum preparations. Aluminum-containing antacids (except aluminum phosphate) form insoluble salts with dietary phosphorus and interfere with phosphorus absorption.¹ Hypophosphatemia occurs most often in patients with low dietary phosphate intake (e.g., malnutrition or alcoholism). Combined treatment with sucralfate may amplify the hypophosphatemia and the potential for aluminum toxicity.

Magnesium-containing antacids should not be used in patients with a creatinine clearance of less than 30 mL/min because magnesium excretion is impaired which may lead to toxicity.⁸¹ Hypercalcemia may occur in patients with normal renal function taking more than 20 g/day of calcium carbonate, and in patients with renal failure who are taking more than 4 g/day. The milk-alkali syndrome (hypercalcemia, alkalosis, renal stones, increased blood urea nitrogen, and increased serum creatinine concentration) occurs with high calcium intake in patients with systemic alkalosis produced by either ingestion of absorbable antacids (sodium bicarbonate) or prolonged vomiting. Antacids may alter the absorption and excretion of drugs when administered concomitantly.^{1,78,81} Important interactions may occur when antacids are administered with iron supplements, tetracycline, warfarin, digoxin, quinidine, isoniazid, ketoconazole, or the fluoroquinolones. Most interactions can be avoided by separating the antacid from the oral drug by at least 2 hours.

Pharmacoeconomic Considerations

8 The eradication of *H. pylori* improves clinical outcomes and decreases the use of healthcare resources when compared to conventional antisecretory therapy.⁸² Thus the costs of continued treatment and recurrence far outweigh the cost of *H. pylori* drug regimens. The cost-effectiveness of misoprostol cotherapy is greatest in patients with the highest risk for NSAID-related GI complications.⁸³ The use of a PPI with a nonselective NSAID or switching to a selective COX-2 inhibitor (if available) is also cost-effective in high-risk patients.⁸⁴

EVALUATION OF THERAPEUTIC OUTCOMES

9 Table 35–12 lists the recommendations for treating and monitoring patients with PUD. Relief of epigastric pain should be monitored

TABLE 35-12 Recommendations for Treating and Monitoring Patients with *Helicobacter pylori*-Associated and Nonsteroidal Antiinflammatory Drug (NSAID)-Induced Ulcers

Helicobacter pylori-associated ulcer

1. Recommend drug treatment as presented in the chapter text.
2. Assess patient allergies to determine if allergic to penicillin (or other antibiotics) so that drug regimens that contain penicillin (or other antibiotics) can be avoided. Avoid regimens that contain tetracycline in children.
3. Assess patient use of alcohol or alcohol-containing products with metronidazole and oral birth control medications with antibiotics and counsel appropriately.
4. Assess likelihood of nonadherence to the drug regimen as a cause of treatment failure.
5. Recommend a different antibiotic combination if *H. pylori* eradication fails and a second treatment is planned.
6. Inform the patient of change in stool color when bismuth salicylate is included in an *H. pylori* eradication regimen.
7. Assess and monitor patients for potential adverse effects, especially those associated with metronidazole, clarithromycin, and amoxicillin.
8. Assess and monitor patients for potential drug interactions, especially those receiving metronidazole, clarithromycin, or cimetidine.
9. Monitor patients for salicylate toxicity, especially patients receiving cotherapy with other salicylates, anticoagulants, and patients with renal failure.
10. Monitor patients for persistent or recurrent symptoms within 14 days after completion of a course of *H. pylori* eradication therapy.
11. Provide patient education to patients who are receiving *H. pylori* eradication therapy, including why antibiotic and antiulcer combinations are used; when and how to take medications; adverse effects; alarm symptoms; the importance of adherence to the entire course of drug treatment; and to contact their healthcare provider if alarm symptoms develop (e.g., blood in the stools, black tarry stools, vomiting, severe abdominal pain), or if symptoms persist or return after *H. pylori* eradication.

NSAID-induced ulcer

1. Recommend drug treatment as presented in the chapter text.
2. Assess risk factors for NSAID-induced ulcers and ulcer-related complications, and when indicated recommend appropriate strategies for reducing ulcer risk (see Table 35-10).
3. Recommend eradication treatment for *H. pylori*-positive patients taking NSAIDs.
4. Monitor patients for signs and symptoms of NSAID-related upper GI complications.
5. Assess and monitor patients for potential drug interactions and adverse effects (especially misoprostol).
6. Provide patient education to patients who are at risk of NSAID-induced ulcers or GI-related complications, including why cotherapy is used with nonselective NSAIDs; when and how to take medications; adverse effects; alarm symptoms; when to contact their healthcare provider; and the importance of adherence to drug treatment.

throughout the course of treatment in patients with either *H. pylori*- or NSAID-related ulcers. Ulcer pain typically resolves in a few days when NSAIDs are discontinued, and within 7 days upon initiation of antiulcer therapy. Most patients with uncomplicated PUD will be symptom free after treatment with any one of the recommended antiulcer regimens. The persistence, or recurrence, of symptoms within 14 days after the end of treatment suggests failure of ulcer healing or *H. pylori* eradication, or an alternative diagnosis such as GERD. The majority of patients with uncomplicated *H. pylori*-positive ulcers do not require confirmation of ulcer healing or *H. pylori* eradication. However, eradication should be confirmed after treatment in individuals who are at high-risk for complications, for example, individuals who had a prior bleeding ulcer. When endoscopy is not indicated, the UBT is the preferred test to confirm *H. pylori* eradication. Medication adherence should be assessed in patients who fail therapy.

High-risk patients on NSAIDs should be closely monitored for signs or symptoms of bleeding, obstruction, penetration, or perforation. Patients who remain symptomatic, have recurrent attacks, or who have ulcer-related complications should be referred to a gastroenterologist. Follow-up endoscopy can be justified in patients with frequent

symptomatic recurrence, refractory disease, complications, or suspected hypersecretory states.

ZOLLINGER-ELLISON'S SYNDROME (ZES)

ZES is characterized by gastric acid hypersecretion and recurrent peptic ulcers that result from a gastrin-producing tumor (gastrinoma).^{4,67,85,86} In the United States, ZES accounts for 0.1% to 1% of patients with duodenal ulcer; however, this may be an underestimation of the true incidence because of the heterogeneity of clinical manifestations.⁸⁶ Gastrinomas are classified as those associated with multiple endocrine neoplasia type 1 (MEN 1) or sporadic tumors, which have a greater tendency to behave as malignant tumors. In more than 80% of cases, gastrinomas are localized in an area referred to as the “triangle of gastrinomas,” which includes the convergence of the cystic duct and the common bile duct, the junction of the second and third portion of the duodenum, and the junction of the head and body of the pancreas.⁸⁵ Malignant gastrinomas occur in up to 65% of patients, with metastases to regional lymph nodes, liver, and bone.⁸⁵

A diagnosis of ZES should be considered in patients with multiple ulcers and recurrent or refractory PUD, often accompanied by esophagitis or ulcer complications.^{4,85,86} Ulcers occur most often in the duodenum, but may involve the stomach or jejunum. Diarrhea occurs in approximately 50% of patients and results from high concentrations of acid that overwhelm the duodenum's buffering capacity and damage the mucosa.^{4,85} Intraluminal acid also causes steatorrhea by inactivating pancreatic lipase and precipitating bile acids. Vitamin B₁₂ malabsorption may result from reduced intrinsic factor activity. The diagnosis is established when the serum gastrin is higher than 1,000 pg/mL and the BAO is greater than 15 mEq/h in patients with an intact stomach (BAO >5 mEq/h in patients with previous gastric surgery) or when the hypergastrinemia is associated with a gastric pH value of <2.^{4,86} In situations in which the serum gastrin is between 100 and 1,000 pg/mL and gastric pH is <2, a secretin or calcium provocative test is used to aid the diagnosis.⁸⁶ Identification of the location of the tumor with imaging techniques is essential, as early surgical resection prior to liver metastases is often curative.^{4,85} Unfortunately, effective medical therapy may delay the recognition of the disease and adversely influence outcome. The widespread use of PPIs, although effective in reducing symptoms, may mask the clinical presentation and complicate the diagnosis.^{4,85} In addition, PPIs can cause hypergastrinemia, which may further complicate the diagnosis of ZES.^{75,85,87}

Treatment is based on the presence or absence of peptic ulcers, esophagitis, diarrhea, and a gastrinoma, which may be malignant. The PPIs are the oral drugs of choice for managing gastric acid hypersecretion. Treatment should be instituted with omeprazole 60 mg/day (or an equivalent dose of esomeprazole, lansoprazole, rabeprazole, or pantoprazole) and should be adjusted based on individual patient response.^{4,85,86} Dividing the daily dose and giving the PPI every 8 to 12 hours is most effective in controlling acid output and relieving symptoms. Although doses as high as 360 mg/day of omeprazole have been administered, an average dose of 60 to 100 mg/day reduces basal acid output to target levels.^{85,86} The goal of therapy for uncomplicated patients is to maintain BAO between 1 and 10 mEq/h, in the hour preceding the next dose of the PPI.⁸⁶ In complicated cases, such as patients with MEN 1, GERD, or those who are undergoing partial gastrectomy, the BAO should be maintained below 5 mEq/h. A gradual reduction in PPI dose is recommended after the initial dose required for adequate control of gastric acid hypersecretion is achieved.^{4,86} Intravenous PPIs are used to suppress gastric acid secretion in patients who are unable to take oral PPIs.^{67,85}

Octreotide directly inhibits gastric acid secretion and the release of gastrin.⁴ Although a subcutaneous dose of 100 to 250 mcg three times a day substantially reduces gastric acid secretion, octreotide is not considered first-line therapy. The long-acting repeatable octre-

otide formulation is efficacious in patients with gastrointestinal neuroendocrine tumors and has been shown to stabilize tumor growth in between 37% and 80% of patients.⁸⁵ However, it is important to demonstrate that the patient tolerates octreotide prior to converting to the long-acting product. Usually an initial dose of octreotide long-acting repeatable depot 20 mg is given intragluteally once every 4 weeks and is subsequently titrated based on response. The most common side effects of somatostatin analogs like octreotide include abdominal pain, diarrhea, gallstones, and pain at the injection site.^{4,85} Patients with metastatic gastrinoma require tumor resection or treatment with chemotherapeutic agents.

UPPER GASTROINTESTINAL BLEEDING

There are approximately 170 cases of upper GI bleeding per 100,000 adults annually.⁸⁸ Despite a decreased incidence of PUD and improvements in the management of upper GI bleeding, the mortality rate associated with acute hemorrhage remains approximately 7%.^{2,88} Upper GI bleeding can be broadly categorized as variceal or nonvariceal bleeding. Two common types of nonvariceal bleeding are bleeding from chronic peptic ulcers and bleeding from SRMD (stress gastritis, stress ulcer, or stress erosions), both of which are acid-peptic complications.^{2,67,88,89} The presentation and pathophysiology of these two conditions are different, as bleeding associated with chronic PUD usually precedes hospital admission, whereas bleeding associated with SRMD develops in severely ill patients during hospitalization.^{1,2,89}

The underlying pathophysiology of bleeding from a peptic ulcer or from SRMD is similar in that impaired mucosal defense in the presence of gastric acid and pepsin leads to mucosal damage. In chronic PUD, *H. pylori* infection and NSAID use are the most important etiologic factors, whereas the primary pathogenic factor in SRMD is thought to be mucosal ischemia resulting from reduced gastric blood flow.^{1,89,90} In contrast to chronic PUD, stress-related mucosal lesions are characteristically asymptomatic, multiple, located in the proximal stomach, and are unlikely to perforate.⁹⁰ Bleeding from SRMD occurs from superficial mucosal capillaries, whereas bleeding associated with chronic PUD usually results from a single vessel. The mortality rate associated with clinical significant stress-related mucosal bleeding (SRMB) approximates 50% and is related to the underlying severity in the patient population.^{67,89,90} In contrast, the mortality associated with chronic PUD-related bleeding is approximately 12%, but can increase dramatically in selected patient populations.^{88,91–93} Although the initial management of acute upper GI bleeding focuses on aggressive resuscitative measures and ensuring hemodynamic stability, and is the same for both PUD-related bleeding and SRMB, the medical management of each condition is distinctly different.^{88,90}

PEPTIC ULCER-RELATED BLEEDING

The degree of risk must be assessed to determine how aggressively to treat the patient with chronic PUD-related bleeding.^{88,91} Patients older than 60 years of age who have comorbid conditions, high transfusion requirements, ongoing blood loss, presence of shock, prolonged prothrombin time (or increased international normalized ratio [INR]), and erratic mental status generally have poorer prognoses and usually require more aggressive intervention including admission to an intensive care unit (ICU).^{88,92} Diagnostic endoscopy is usually performed to identify the source of the bleeding, assess the potential risk for rebleeding, and if appropriate, therapeutic interventions are employed to promote hemostasis.^{2,92} Several endoscopic treatment approaches (e.g., thermocoagulation, laser therapy, injection sclerotherapy, hemoclipping, and ligation) can be used; however, to maximize the likelihood of positive outcomes, patients are usually treated with a combination of thermocoagulation and injection with epinephrine.⁹² The appearance

of the ulcer at the time of endoscopy is a prognostic indicator for the risk of rebleeding.^{88,92} Clean-based ulcers are most commonly seen and are associated with a low risk of rebleeding.⁹² In most cases, these patients can be immediately discharged after endoscopy on antiulcer therapy. Patients with an adherent clot overlying the ulcer base are at intermediate risk of rebleeding, and controversy exists as to the appropriate management of these patients.^{92,93} It has been recommended that adherent clots be removed and then the lesion be reclassified based on what is observed following clot removal.⁹³ Patients with a visible vessel or active bleeding are at high risk of rebleeding, and must be carefully managed, as rebleeding increases the mortality rate 10-fold.^{92,93}

Antisecretory therapy is often used as adjuvant therapy to prevent PUD rebleeding in high-risk patients because acid impairs clot stability.^{67,92,93} H_2 -receptor antagonists are ineffective in preventing PUD rebleeding because they do not achieve an intragastric pH of 6 (which is needed to promote clot stability), and tolerance to their antisecretory effect develops rapidly.^{67,88,91–93} In contrast, PPI therapy significantly reduces the incidence of rebleeding, and need for surgery, but has no significant impact on mortality.^{67,88,91–95} A post hoc analysis, however, of the Cochrane Collaboration review assessing PPI therapy for ulcer bleeding, revealed a significant decrease in all-cause mortality when data from Asian randomized, controlled trials were pooled and compared to other trials.⁹⁶ The greater reduction in rebleeding rates, need for surgery, and significant reduction in mortality rate in Asian studies may be a result of several factors, including lower parietal cell mass, increased prevalence of *H. pylori* infection, and a higher prevalence of the CYP2C19 slow metabolizer phenotype leading to higher plasma PPI concentrations in Asian patients.

Both the precise route (oral or intravenous) and the dose of PPI remain controversial with no significant differences emerging in a recent meta-analysis.⁹¹ Based on the theoretical goal of maintaining gastric pH values >6, and data from randomized, controlled trials, practice guidelines recommend that high-dose continuous infusion PPI (equivalent to omeprazole 80 mg given intravenously as a loading dose, followed by 8 mg/h continuous infusion for 3 days) be used to reduce the risk of rebleeding in high-risk patients who have undergone endoscopy hemostasis.^{67,88,91–95} Administration of high-dose continuous-infusion PPI therapy given prior to endoscopy hastened resolution of bleeding stigmata.⁹⁴ However, PPI therapy is not a replacement for interventional endoscopy in patients who are at high risk of rebleeding, as data demonstrate that the combination of a high-dose PPI continuous intravenous infusion with therapeutic endoscopy is superior to either strategy alone.⁹⁵ High-dose oral PPI therapy (omeprazole 80 mg/day for 5 days) is also effective; however, concerns exist whether critically ill patients will absorb the medication.^{67,91,92} The risk of rebleeding is greatest within the first 72 hours (especially the first 24 hours) and it is during this time that antisecretory therapy to prevent rebleeding in high-risk patients should be employed.^{88,92} Subsequently, the patient's underlying PUD should be evaluated and treated.

Patients with upper GI bleeding should be tested for *H. pylori* at the time of endoscopy (see Tests for *Helicobacter pylori* above). However, tests are associated with an increased rate of false-negatives when obtained during acute bleeding episodes.²⁹ If the initial results of the rapid urease test and/or histology are negative, a confirmatory test (¹⁴C-urea breath test or serology) should be performed following the acute bleeding episode. There is no rationale for using intravenous therapy to eradicate *H. pylori*. Ulcer treatment, including *H. pylori* eradication, if appropriate, should be initiated after the acute bleeding episode (see Treatment of *Helicobacter pylori*-Associated Ulcers and Treatment of NSAID-Induced Ulcers above).

STRESS-RELATED MUCOSAL BLEEDING

More than 75% of critically ill patients develop SRMD within 24 hours of admission to an ICU, but the incidence of clinically

significant SRMB is considered to be in the range of 1.2% to 6%.^{89,90} Clinically significant bleeding increases the length of ICU stay by approximately 4 to 8 days, results in excessive healthcare costs, and is associated with an increased mortality rate.^{67,90} Thus attempts to prevent SRMB are warranted in high-risk patients. Prophylactic therapy to prevent bleeding is most effective if initiated early in the patient's course.

Patients who are at risk for SRMB include those with respiratory failure (need for mechanical ventilation for longer than 48 hours), coagulopathy, hypotension, sepsis, hepatic failure, acute renal failure, multiple trauma, severe burns (>35% of body surface area), head injury, traumatic spinal cord injury, major surgery, or history of GI bleeding.^{67,89,90,97} Although the relative importance of the various risk factors remains controversial, most clinicians concur that patients with respiratory failure (mechanical ventilation for longer than 48 hours) or coagulopathy should receive prophylaxis, as these two factors have been shown to be independent risk factors.⁶⁷ In the absence of these two risk factors, some clinicians only administer prophylaxis to patients who have two of the aforementioned risk factors.⁸⁹ Although exactly who should receive prophylaxis remains controversial, not all patients in a hospital or ICU are at increased risk of SRMB. A cost-effective approach is to target prophylactic therapy at high-risk patients.

Prevention of SRMB includes resuscitative measures that restore mucosal blood.^{89,90} Although the benefits of enteral nutrition to patient outcome (e.g., improved nutritional status enhances mucosal integrity) are of overall clinical importance, its precise role as a sole modality to prevent SRMB remains controversial.⁹⁰ Therapeutic options for the prevention of SRMB include antacids (which are of historical interest, as they are no longer used because of cumbersome dosage schedules and side effects), antisecretory drugs (H₂RAs and PPIs), and sucralfate, a mucosal protectant.^{67,89,90,97–100} Cimetidine, given as a continuous intravenous infusion, is FDA-labeled for the prevention of SRMB; however, intermittent intravenous H₂RAs are more commonly used in clinical practice.^{67,90}

Immediate-release omeprazole sodium bicarbonate suspension (40 mg × 2 doses, then 40 mg/day) was more effective than continuous infusion cimetidine in maintaining intragastric pH >4 in critically ill patients; however, there was no difference in the incidence of clinically important SRMD between the two groups.⁹⁸ Based on meeting the prespecified criteria for noninferiority criteria, immediate-release omeprazole gained FDA labeling for the prevention of SRMB.^{69,98}

Antisecretory therapy is generally preferred for SRMB prophylaxis for several reasons. First, a large landmark study demonstrated that intravenous ranitidine was superior to oral sucralfate in preventing SRMB.⁹⁹ Second, ranitidine did not increase the risk for nosocomial pneumonia, as the incidence of pneumonia was not different between the two treatment groups.⁹⁹ Finally, sucralfate therapy is cumbersome, requiring multiple daily dosage administration which may clog nasogastric tubes, cause constipation, and/or interact with several medications.⁹⁰ Although controversy exists as to which antisecretory agent should be used to prevent SRMB, data published in 2004 indicated that H₂RAs were the most commonly prescribed agents.¹⁰⁰ Extensive studies and years of experience support the use of H₂RAs.^{89,90,100} However, PPIs are more potent than H₂RAs in inhibiting acid secretion and unlike H₂RAs tolerance does not develop to PPIs.^{67,90,97} Although limited data exists assessing the efficacy of PPIs for the prevention of SRMB, based on data from Conrad and others, one would conclude oral PPI suspensions may be used as alternatives to H₂RAs or sucralfate for preventing SRMB.^{97,98} However numerous questions remain unanswered regarding the use of PPIs for the prevention of SRMB. What is the efficacy and optimal dosage of intravenous PPIs for the prevention of SRMB? What is the role of the various enteral PPI formulations

(see Table 35–11)? What is the preferred route of administration for this indication?⁶⁷

Improvement in the patient's overall medical condition (discharge from the ICU, extubation, and oral intake) suggests that prophylactic therapy can be discontinued. If a patient develops clinically important bleeding, endoscopic evaluation of the GI tract is indicated along with aggressive antisecretory therapy.

CONCLUSIONS

H. pylori eradication and antisecretory drugs are the mainstay of today's treatment strategies for PUD. Although *H. pylori* can be successfully treated with available regimens, there is a need for new therapies that will simplify treatment while improving eradication rates. In the future, new classes of COX-2 inhibitors may reduce cardiovascular concerns by maintaining antiplatelet effects while decreasing GI damage. Identification of genetic markers linked to PUD may eventually help identify patients who are at high risk of developing gastric and duodenal ulcers. In the interim, this common disease will continue to impact quality of life and the cost of healthcare.

ABBREVIATIONS

- BAO: basal acid output
- COX-1: cyclooxygenase-1
- COX-2: cyclooxygenase-2
- CYP450: cytochrome P450
- ECL: enterochromaffin-like
- ELISA: enzyme-linked immunosorbent assay
- GERD: gastroesophageal reflux disease
- H. pylori*: *Helicobacter pylori*
- H₂RA: histamine-2 receptor antagonist
- ICU: intensive care unit
- MALT: mucosa-associated lymphoid tissue
- MAO: maximal acid output
- MEN: multiple endocrine neoplasia
- NSAID: nonsteroidal antiinflammatory drug
- NUD: nonulcer dyspepsia
- PG: prostaglandin
- PPI: proton pump inhibitor
- PUD: peptic ulcer disease
- SRMB: stress-related mucosal bleeding
- SRMD: stress-related mucosal damage
- UBT: urea breath test
- ZES: Zollinger-Ellison's syndrome

BRIAN A. HEMSTREET AND JOSEPH T. DIPIRO

KEY CONCEPTS

- 1 The exact cause of inflammatory bowel disease (IBD) is unknown, although there are components that appear to be infectious and other components that suggest immune dysregulation. Genetic variations explain some of the increased risk of disease occurrence.
- 2 Ulcerative colitis is confined to the rectum and colon, causes continuous lesions, and affects primarily the mucosa and the submucosa. Crohn's disease can involve any part of the GI tract, often causes discontinuous (skip) lesions, and is a transmural process that can result in fistulas, perforations, or strictures.
- 3 Common gastrointestinal complications of IBD include rectal fissures, fistulas (Crohn's disease), perirectal abscess (ulcerative colitis), and colon cancer; possible extraintestinal manifestations include hepatobiliary complications, arthritis, uveitis, skin lesions (including erythema nodosum and pyoderma gangrenosum), and aphthous ulcerations of the mouth.
- 4 The severity of ulcerative colitis may be assessed by factors such as stool frequency, presence of blood in stool, fever, pulse, hemoglobin, erythrocyte sedimentation rate, C-reactive protein, abdominal tenderness, and radiologic or endoscopic findings. The severity of Crohn's disease can be assessed using similar parameters, in addition to the Crohn's disease activity index, which includes stool frequency, presence of blood in stool, endoscopic appearance, and physician's global assessment.
- 5 The goals of treatment of IBD are resolution of acute inflammation and complications, alleviation of systemic manifestations, maintenance of remission, and in some patients, surgical palliation or cure.
- 6 The first-line treatment for mild to moderate ulcerative colitis or Crohn's colitis consists of oral aminosalicylates, such as sulfasalazine or mesalamine; mesalamine or steroid enemas or suppositories may be used for rectosigmoid disease. Delayed-release oral formulations of mesalamine may be used for Crohn's ileitis.
- 7 Corticosteroids are often required for acute ulcerative colitis or Crohn's disease. The duration of steroid use should be minimized and the dose tapered gradually over 3 to 4 weeks. Infliximab is an option for patients with moderate to severe active ulcerative colitis, and for those patients with ulcerative colitis who are dependent on corticosteroids.

- 8 Intravenous continuous infusion of cyclosporine is effective in treating severe colitis that is refractory to steroids.
- 9 Sulfasalazine and mesalamine derivatives can prevent recurrence of acute disease in many patients, while steroids are ineffective for this purpose.
- 10 Other drugs that are useful for treatment of Crohn's disease include metronidazole (for perineal disease), azathioprine or mercaptopurine (for inadequate response or to reduce steroid dosage), cyclosporine (for refractory disease), and infliximab for refractory or fistulizing disease.

There are two forms of idiopathic inflammatory bowel disease (IBD): (a) ulcerative colitis, a mucosal inflammatory condition confined to the rectum and colon; and (b) Crohn's disease, a transmural inflammation of the gastrointestinal tract that can affect any part, from the mouth to the anus. The etiologies of both conditions are unknown, but they may have some common pathogenic mechanisms.

EPIDEMIOLOGY

Inflammatory bowel disease is most prevalent in western countries and in areas of northern latitude.¹ The reported rates of IBD are highest in Scandinavia, Great Britain, and North America.² Crohn's disease has a reported incidence of 3.6 to 8.8 per 100,000 persons in the United States and a prevalence of 20 to 40 per 100,000 people.³ The incidence of Crohn's disease varies considerably among studies, but has clearly increased dramatically over the last three or four decades.³ Ulcerative colitis incidence ranges from 3 to 15 cases per 100,000 persons per year among the white population, with a prevalence of 80 to 120 per 100,000 persons.³ The incidence of ulcerative colitis has remained relatively constant over many years.² Although most epidemiologic studies combine ulcerative proctitis with ulcerative colitis, from 17% to 49% of cases are proctitis.

Both sexes are affected equally with inflammatory bowel disease, although some studies show slightly greater numbers of women with Crohn's disease and males with ulcerative colitis.² Ulcerative colitis and Crohn's disease have bimodal distributions in age of initial presentation. The peak incidence occurs in the second or third decades of life, with a second peak occurring between 60 and 80 years of age.^{1,2} A significantly increased incidence of ulcerative colitis (four to five times normal) has been observed in Ashkenazi Jews, whereas blacks and Asians have a relatively low incidence of occurrence.^{2,4,5}

ETIOLOGY

- 1 Although the exact etiology of ulcerative colitis and Crohn's disease is unknown, similar factors are believed responsible for both

Occupation

conditions (Table 36–1). The major theories of the cause of IBD involve a combination of infectious, genetic, and immunologic factors.⁶ The inflammatory response with IBD may indicate abnormal regulation of the normal immune response or an autoimmune reaction to self-antigens. The microflora of the gastrointestinal tract may provide an environmental trigger to activate inflammation.⁷ Crohn's disease has been described as a disorder mediated by T lymphocytes that arises in genetically susceptible individuals as a result of a breakdown in the regulatory constraints on mucosal immune responses to enteric bacteria.⁷⁸

INFECTIOUS FACTORS

Microorganisms are a likely factor in the initiation of inflammation in IBD.⁷ However, no definitive infectious cause of IBD has been found, even though the presentation is similar to that caused by some invasive microbial pathogens. Patients with IBDs have increased numbers of surface-adherent and intracellular bacteria.⁹ IBD may involve a loss of tolerance toward normal bacterial flora.¹⁰ Other supporting evidence for an infectious etiology is that colitis does not appear to occur in genetically altered germ-free animals, intestinal lesions in IBD typically predominate in areas of highest bacterial exposure, and observed differences in the existing makeup of the resident luminal and mucosal bacterial flora in healthy subjects versus those with IBD.⁷

Suspect infectious agents include the measles virus, protozoans, mycobacteria, such as *Mycobacterium paratuberculosis*, and other bacteria such as *Listeria monocytogenes*, *Chlamydia trachomatis*, and *Escherichia coli*.¹¹ Also, certain strains of bacteria produce toxins (necrotoxins, hemolysins, and enterotoxins) that cause mucosal damage. Bacteria elaborate peptides (e.g., formyl-methionyl-leucyl-phenylalanine) that have chemotactic properties and that cause an influx of inflammatory cells with subsequent release of inflammatory mediators and tissue destruction. Microbes may elaborate superantigens, which are capable of global T-lymphocyte stimulation and subsequent inflammatory response.¹² As many as 60% of patients with Crohn's disease have circulating antibody to *Saccharomyces cerevisiae*, but this may not represent a disease mechanism.⁸

GENETIC FACTORS

Genetic factors predispose patients to IBDs, particularly Crohn's disease. In studies of monozygotic twins, there has been a high concordance rate, with both individuals of the pair having an IBD

(particularly Crohn's disease).⁸ Also, first-degree relatives of patients with IBD may have up to a 20-fold increase in the risk of disease.⁹ Several genetic markers have been identified that occur more frequently in patients with IBD. The CARD15 gene on chromosome 16, formerly referred to as NOD2, is thought to account for 20% of the genetic predisposition to Crohn's disease. Human leukocyte antigen (HLA) DR2 has been associated with ulcerative colitis in Japanese subjects, while HLA-DR3 has been associated with ulcerative colitis in European subjects.^{11,13} Additionally the multidrug-resistance gene 1 (ABCB/MDR 1) on chromosome 7 is a potential susceptibility gene for ulcerative colitis.¹⁴ Multiple other genes have been associated with IBD, including DLG5, OCTN1, and CARD4; however, the nature of these gene products has not been established.^{11,13}

IMMUNOLOGIC MECHANISMS

The immune system is known to play a critical role in the underlying pathogenesis of IBD. In Crohn's disease, the bowel wall is infiltrated with lymphocytes, plasma cells, mast cells, macrophages, and neutrophils. Similar infiltration has been observed in the mucosal layer of the colon in patients with ulcerative colitis. Inflammation in IBD is maintained by an influx of leukocytes from the vascular system into sites of active disease. This influx is promoted by expression of adhesion molecules (such as α_4 -integrins) on the surface of endothelial cells in the microvasculature in the area of inflammation.^{10,15} Many of the systemic manifestations of IBD have an immunologic etiology (e.g., arthritis or uveitis). Finally, IBD is typically responsive to immunosuppressive drugs (e.g., corticosteroids and azathioprine).

The immune theory of IBD assumes that IBD is caused by an inappropriate reaction of the immune system. Potential immunologic mechanisms include both autoimmune and nonautoimmune phenomena.⁹ Autoimmunity may be directed against mucosal epithelial cells or against neutrophil cytoplasmic elements. Some patients with IBD have abnormal structural features for colonic epithelial cells even in the absence of active disease. Autoantibodies to these structures have been reported. Also, antineutrophil cytoplasmic antibodies are found in a high percentage of patients with ulcerative colitis (70%) and much less frequently with Crohn's disease.⁹ Presence of antineutrophil cytoplasmic antibodies in left-sided ulcerative colitis is associated with resistance to medical therapy.¹⁶ Dysregulation of cytokines is a component of IBD. Specifically, T-helper type 1 (TH₁) cytokine activity (which enhances cell-mediated immunity and suppresses humoral immunity) is excessive with Crohn's disease, whereas T-helper type 2 (TH₂) cytokine activity (which inhibits cell-mediated immunity and enhances humoral immunity) is excessive with ulcerative colitis.¹⁷ The result is that patients have inappropriate T-cell responses to antigens from their own intestinal microflora.¹⁷ Expression of interferon γ (a TH₁ cytokine) in intestinal mucosa of diseased patients is increased, whereas interleukin-4 (a TH₂ cytokine) is reduced.^{6,18}

Tumor necrosis factor- α (TNF- α) is a pivotal proinflammatory cytokine in Crohn's disease. TNF- α can recruit inflammatory cells to inflamed tissues, activate coagulation, and promote the formation of granulomas. Production of TNF- α is increased in the mucosa and intestinal lumen of patients with Crohn's disease.^{6,9,18} Eicosanoids such as leukotriene B₄ are increased in rectal dialysates and tissues of IBD patients and are related to disease activity. Leukotriene B₄ enhances neutrophil adherence to vascular endothelium and acts as a neutrophil chemoattractant. These findings have led to the consideration of leukotriene inhibitor strategies for therapy.

PSYCHOLOGICAL FACTORS

Mental health changes appear to correlate with remissions and exacerbations, especially of ulcerative colitis, but psychological

factors overall are not thought to be an etiologic factor. There is a weak association between the number of stressful events experienced and the time to relapse of ulcerative colitis.¹⁹

DIET, SMOKING, AND NONSTEROIDAL ANTIINFLAMMATORY DRUG USE

Changes in diet by people in industrialized countries where Crohn's disease is more common have not been consistently associated with the disease. Studies of increased intake of refined sugars or chemical food additives and reduced fiber intake have provided conflicting results regarding risk for Crohn's disease. Smoking plays an important but contrasting role in ulcerative colitis and Crohn's disease.

Smoking is protective for ulcerative colitis.⁹ The risk of developing ulcerative colitis in smokers is approximately 40% of that in non-smokers.² Clinical relapses are associated with smoking cessation, and nicotine transdermal administration has been effective in improving symptoms in patients with ulcerative colitis.^{20,21} In contrast, smoking is associated with a twofold increased frequency of Crohn's disease.² Crohn's disease patients who stop smoking have a more benign course than patients who continue smoking.²² The mechanisms of these differing effects have not been identified.

Use of nonsteroidal antiinflammatory drugs (NSAIDs) can trigger disease occurrence or lead to disease flares.^{9,23} The effect of NSAIDs to inhibit prostaglandin production through cyclooxygenase inhibition may impair mucosal barrier protective mechanisms. The increased risk seems to be present for cyclooxygenase-2 inhibitors as well as cyclooxygenase-1 inhibitors, however it is unclear whether cyclooxygenase-2 inhibitors may be somewhat safer in select patients with IBD.^{24,25}

PATHOPHYSIOLOGY

Ulcerative colitis and Crohn's disease differ in two general respects: anatomic sites and depth of involvement within the bowel wall. There is, however, overlap between the two conditions, with a small fraction of patients showing features of both diseases. Confusion can occur, particularly when the inflammatory process is limited to the colon. Table 36-2 compares pathologic and clinical findings of the two diseases.

TABLE 36-2 Comparison of the Clinical and Pathologic Features of Crohn's Disease and Ulcerative Colitis

Feature	Crohn's Disease	Ulcerative Colitis
Clinical		
Malaise, fever	Common	Uncommon
Rectal bleeding	Common	Common
Abdominal tenderness	Common	May be present
Abdominal mass	Common	Absent
Abdominal pain	Common	Unusual
Abdominal wall and internal fistulas	Common	Absent
Distribution	Discontinuous	Continuous
Aphthous or linear ulcers	Common	Rare
Pathologic		
Rectal involvement	Rare	Common
Ileal involvement	Very common	Rare
Strictures	Common	Rare
Fistulas	Common	Rare
Transmural involvement	Common	Rare
Crypt abscesses	Rare	Very common
Granulomas	Common	Rare
Linear clefts	Common	Rare
Cobblestone appearance	Common	Absent

ULCERATIVE COLITIS

2 Ulcerative colitis is confined to the rectum and colon, and affects the mucosa and the submucosa. In some instances, a short segment of terminal ileum may be inflamed; this is referred to as *backwash ileitis*. Unlike Crohn's disease, the deeper longitudinal muscular layers, serosa, and regional lymph nodes are not usually involved.^{1,9,10} Fistulas, perforation, or obstruction are uncommon because inflammation is usually confined to the mucosa and submucosa.

The primary lesion of ulcerative colitis occurs in the crypts of the mucosa (crypts of Lieberkühn) in the form of a crypt abscess. Here, frank necrosis of the epithelium occurs; it is usually visible only with microscopy, but may be seen grossly when coalescence of ulcers occurs. Extension and coalescence ulcers may surround areas of uninvolved mucosa. These islands of mucosa are called *pseudopolyps*. Other typical ulceration patterns include a "collar-button ulcer," which results from extensive submucosal undermining at the ulcer edge.^{9,26,27} The extensive mucosal damage seen in ulcerative colitis can result in significant diarrhea and bleeding, although a small percentage of patients experience constipation.

3 Ulcerative colitis can be accompanied by complications that may be local (involving the colon or rectum) or systemic (not directly associated with the colon). With either type the complications may be mild, serious, or even life-threatening. Local complications occur in the majority of ulcerative colitis patients. Relatively minor complications include hemorrhoids, anal fissures, or perirectal abscesses, and are more likely to be present during active colitis. Enterointestinal fistulas are rare.

A major complication is toxic megacolon, which is a segmental or total colonic distension of >6 cm with acute colitis and signs of systemic toxicity.²⁸ It is a severe condition that occurs in up to 7.9% of ulcerative colitis patients admitted to hospitals and results in death rates up to 50%. With toxic megacolon, ulceration extends below the submucosa, sometimes even reaching the serosa. Vasculitis, swelling of the vascular endothelium, and thrombosis of small arteries occurs; involvement of the muscularis propria causes loss of colonic tone, which leads to dilation and potential perforation. The patient with toxic megacolon usually has a high fever, tachycardia, distended abdomen, and elevated white blood cell count, and a dilated colon is observed on radiography.^{6,28} Colonic perforation, however, may occur with or without toxic megacolon and is a greater risk with the first attack. Another infrequent major local complication is massive colonic hemorrhage. Colonic stricture, sometimes with clinical obstruction, may also complicate long-standing ulcerative colitis.

The risk of colonic carcinoma is much greater in patients with ulcerative colitis as compared to the general population. The risk of colon cancer begins to increase 10 to 15 years after the diagnosis of ulcerative colitis. The absolute risk may be as high as 30% 35 years after diagnosis, and as high as 49% for patients who have a long history of disease and who were younger than 15 years of age at the time of diagnosis.

The inflammatory response seen in IBD has also been blamed for the systemic complications seen in both Crohn's disease and ulcerative colitis. The next section summarizes the systemic extraintestinal complications of ulcerative colitis.

Hepatobiliary Complications

Approximately 11% of patients with ulcerative colitis are reported to have hepatobiliary complications, with frequencies ranging from 5% to 95% in IBD patients overall.²⁹⁻³² Hepatic complications include fatty liver, pericholangitis, chronic active hepatitis, and cirrhosis. Biliary complications include sclerosing cholangitis, cholangiocarcinoma, and gallstones.

Fatty infiltration of the liver may be a result of malabsorption, protein-losing enteropathy, or concomitant steroid use. The most

common hepatic complication is pericholangitis (acute inflammation surrounding the intrahepatic portal venules, bile ducts, and lymphatics), which occurs in up to one-third of ulcerative colitis patients. This is associated with progressive fibrosis of intrahepatic and extrahepatic bile ducts in a small percentage of ulcerative colitis patients, and is referred to as primary sclerosing cholangitis. Cirrhosis may be a sequela of cholangitis or of chronic active hepatitis. Often the severity of hepatic disease does not correlate with gastrointestinal disease activity.

Gallstones occur commonly in patients with Crohn's disease (particularly with terminal ileal disease) and may be related to bile salt malabsorption. Also, cholangiocarcinoma occurs 10 to 20 times more frequently in IBD patients as compared to the general population.²⁹

Joint Complications

Arthritis commonly occurs in IBD patients and is typically asymmetric (unlike rheumatoid arthritis) and migratory, involving one or a few, usually large, joints.^{29,31,32} The joints most often affected, in decreasing frequency, are the knees, hips, ankles, wrists, and elbows. Sacroiliitis also occurs commonly. Arthritis associated with ulcerative colitis is generally related to the severity of colonic disease, and resolution without recurrence is seen with proctocolectomy. Also, arthritis in this setting is different from rheumatoid arthritis in that rheumatoid factors are generally not detected. It is nondeforming and nondestructive, even after multiple episodes.

Another potential joint complication is ankylosing spondylitis, which is often unresponsive to treatment. The incidence of ankylosing spondylitis in patients with ulcerative colitis is 30 times that of the general population and occurs most commonly in patients with the HLA-B27 phenotype.

Ocular Complications

Ocular complications, including iritis, uveitis, episcleritis, and conjunctivitis, occur in up to 10% of patients with IBD.^{29,31,32} The most commonly reported symptoms with iritis and uveitis include blurred vision, eye pain, and photophobia. Episcleritis is associated with scleral injection, burning, and increased secretions. These complications may parallel the severity of intestinal disease, and recurrence after colectomy with ulcerative colitis is uncommon.

Dermatologic and Mucosal Complications

Skin and mucosal lesions associated with IBD include erythema nodosum, pyoderma gangrenosum, and aphthous ulceration. Five to 10% of IBD patients experience dermatologic or mucosal complications.^{1,31,32}

Raised, red, tender nodules, which vary in size from 1 cm to several centimeters, are manifestations of erythema nodosum. They are typically found on the tibial surfaces of the legs and arms. These lesions are more commonly observed in Crohn's disease patients and are noted to correlate with disease severity.

Pyoderma gangrenosum occurs more commonly in patients with ulcerative colitis (1% to 5% incidence) and is characterized by discrete skin ulcerations that have a necrotic center and a violaceous color of the surrounding skin.³¹ They can be seen on any part of the body but are more commonly found on the lower extremities.

Oral lesions are found in 6% to 20% of patients with Crohn's disease and 8% of patients with ulcerative colitis.³¹ The most common lesion is aphthous stomatitis, seen with Crohn's disease. The severity of these lesions tends to parallel GI disease.

CROHN'S DISEASE

2 Crohn's disease is best characterized as a transmural inflammatory process. The terminal ileum is the most common site of the disorder, but it may occur in any part of the GI tract from mouth to

anus. About two-thirds of patients have some colonic involvement, and 15% to 25% of patients have only colonic disease.^{9,12} Patients often have normal bowel separating segments of diseased bowel; that is, the disease is discontinuous.

Regardless of the site, bowel wall injury is extensive and the intestinal lumen is often narrowed. The mesentery first becomes thickened and edematous and then fibrotic. Ulcers tend to be deep and elongated and extend along the longitudinal axis of the bowel, at least into the submucosa. The "cobblestone" appearance of the bowel wall results from deep mucosal ulceration intermingled with nodular submucosal thickening.

3 Complications of Crohn's disease may involve the intestinal tract or organs unrelated to it. Small-bowel stricture and subsequent obstruction is a complication that may require surgery. Fistula formation is common and occurs much more frequently than with ulcerative colitis.¹² Fistulae often occur in the areas of worst inflammation, where loops of bowel have become matted together by fibrous adhesions. Fistulae may connect a segment of the GI tract to skin (enterocutaneous fistula), two segments of the GI tract (enteroenteric fistula), or the intestinal tract with the bladder (enterovesicular fistula) or vagina. Crohn's disease fistulae or abscesses associated with them frequently require surgical treatment.

Bleeding with Crohn's disease is usually not as severe as with ulcerative colitis, although patients with Crohn's disease may have hypochromic anemia. Also, as with ulcerative colitis, the risk of carcinoma is increased but not as greatly as with ulcerative colitis.

Systemic complications of Crohn's disease are common, and similar to those found with ulcerative colitis. Arthritis, iritis, skin lesions, and liver disease often accompany Crohn's disease. Renal stones occur in up to 10% of patients with Crohn's disease (less frequently with ulcerative colitis) and are caused by fat malabsorption, which allows for greater oxalate absorption and formation of calcium oxalate stones. Gallstones also occur with greater frequency in patients with ileitis, possibly because of bile acid malabsorption at the terminal ileum.

Nutritional deficiencies are common with Crohn's disease.^{33,34} Reported frequencies of various nutritional parameters are weight loss, 40% to 80%; growth failure in children, 15% to 88%; iron-deficiency anemia, 25% to 50%; vitamin B₁₂ deficiency, 20% to 37%; folate deficiency, 13% to 37%; hypoalbuminemia, 25% to 76%; hypokalemia, 33%; and osteomalacia, 36%. There are usually decreased fat stores and lean tissue. Growth failure in children may be associated with hypozincemia.

CLINICAL PRESENTATION

The patterns of clinical presentation of IBD can vary widely. Patients may have a single acute episode that resolves and does not recur, but most patients experience acute exacerbations after periods of remission. With more severe disease, prolonged illness may occur.

ULCERATIVE COLITIS

Although a typical clinical picture of ulcerative colitis can be described, there is a wide range of presentation, from mild abdominal cramping with frequent small-volume bowel movements to profuse diarrhea (Table 36-3). Most patients with ulcerative colitis experience intermittent bouts of illness after varying intervals with no symptoms. Only a small percentage of patients have continuous unremitting symptoms or have a single acute attack with no subsequent symptoms.

4 Complex disease classifications are generally not used in clinical practice for ulcerative colitis. The arbitrarily determined distinctions of mild, moderate, and severe disease activity are generally used, and these are determined largely by clinical signs and symptoms.^{35,36}

TABLE 36-3 Clinical Presentation of Ulcerative Colitis

Signs and symptoms
• Abdominal cramping
• Frequent bowel movements, often with blood in the stool
• Weight loss
• Fever and tachycardia in severe disease
• Blurred vision, eye pain, and photophobia with ocular involvement
• Arthritis
• Raised, red, tender nodules that vary in size from 1 cm to several centimeters
Physical examination
• Hemorrhoids, anal fissures, or perirectal abscesses may be present
• Iritis, uveitis, episcleritis, and conjunctivitis with ocular involvement
• Dermatologic findings with erythema nodosum, pyoderma gangrenosum
Laboratory tests
• Decreased hematocrit/hemoglobin
• Increased erythrocyte sedimentation rate
• Leukocytosis and hypoalbuminemia with severe disease

Mild—Fewer than 4 stools daily, with or without blood, with no systemic disturbance and a normal erythrocyte sedimentation rate.

Moderate—More than 4 stools per day but with minimal systemic disturbance.

Severe—More than 6 stools per day with blood, with evidence of systemic disturbance as shown by fever, tachycardia, anemia, or erythrocyte sedimentation rate of >30 .

It is also important to determine disease extent; that is, which part of the colon is involved—rectum, descending colon only, or the entire colon. Patients with “distal” disease have inflammation limited to areas below the splenic flexure (also referred to as *left-sided* disease), whereas those with “extensive disease” have inflammation extending proximal to the splenic flexure.^{35,36} Likewise, inflammation confined to the rectal area is referred to as *proctitis*, whereas disease involving the rectum and sigmoid colon is referred to as *proctosigmoiditis*.²⁶ Inflammation of the majority of the colon is deemed *pancolitis*.

Two-thirds of patients with ulcerative colitis have mild disease, which almost always starts in the rectum. Occasionally, the mild form may progress to severe disease, which may be called “fulminant” if it occurs acutely. Systemic signs and symptoms of the disease (e.g., arthritis, uveitis, or pyoderma gangrenosum) may be present in these patients, and in fact may be the reason the patient seeks medical attention. Patients with mild disease are believed to be at lower risk of colon cancer. Moderate disease is observed in one-fourth of patients.

With severe disease, the patient is usually found to be in acute distress, has profuse bloody diarrhea, and often has a high fever with leukocytosis and hypoalbuminemia. Often, the patient is dehydrated, and therefore may be tachycardic and hypotensive. This presentation may have a sudden onset with rapid progression.

The diagnosis of ulcerative colitis is made on clinical suspicion and confirmed by biopsy, stool examinations, sigmoidoscopy or colonoscopy, or barium radiographic contrast studies. The presence of extracolonic manifestations such as arthritis, uveitis, and pyoderma gangrenosum may also aid in establishing the diagnosis.³⁵

CROHN'S DISEASE

As with ulcerative colitis, the presentation of Crohn's disease is highly variable. A single episode may not be followed by further episodes, or the patient may experience continuous, unremitting disease. The time between the onset of complaints and the initial diagnosis may be as long as 3 years. The patient typically presents with diarrhea and abdominal pain. Hematochezia occurs in about one-half of the patients with colonic involvement and much less frequently when there is no colonic involvement. Commonly, a patient first presents with a perirectal or perianal lesion (Table 36-4). The diagnosis should

TABLE 36-4 Clinical Presentation of Crohn's Disease

Signs and symptoms
• Malaise and fever
• Abdominal pain
• Frequent bowel movements
• Hematochezia
• Fistula
• Weight loss
• Arthritis
Physical examination
• Abdominal mass and tenderness
• Perianal fissure or fistula
Laboratory tests
• Increased white blood cell count and erythrocyte sedimentation rate

also be suspected in children with growth retardation, especially with abdominal complaints.

Much like ulcerative colitis, guidelines classify the severity of active Crohn's disease by the presence of several signs and symptoms.³⁷ Patients with mild to moderate Crohn's disease are typically ambulatory and have no evidence of dehydration, systemic toxicity, loss of body weight, or abdominal tenderness, mass, or obstruction. Crohn's disease is considered moderate to severe in patients who fail to respond to treatment for mild to moderate disease, and in those with fever, weight loss, abdominal pain or tenderness, vomiting, intestinal obstruction, or significant anemia. Severe to fulminant Crohn's disease is classified as the presence of persistent symptoms or evidence of systemic toxicity despite outpatient corticosteroid treatment, or presence of cachexia, rebound tenderness, intestinal obstruction, or abscess.

The course of Crohn's disease is characterized by periods of remission and exacerbation. Some patients may be free of symptoms for years, whereas others experience chronic problems in spite of medical therapy. As with ulcerative colitis, the diagnosis of Crohn's disease involves a thorough evaluation using laboratory, endoscopic, and radiologic testing to detect the extent and characteristic features of the disease. Because of similarities that may exist between ulcerative colitis and Crohn's disease confined to the colon, a definitive diagnosis cannot be made in up to 15% of cases, even with pathologic specimens in hand. Small-bowel involvement and strictures detected on radiographs are characteristic of Crohn's disease.

TREATMENT

Inflammatory Bowel Disease

■ DESIRED OUTCOME

5 To treat IBD properly, the clinician must have a clear concept of realistic therapeutic goals for each patient. These goals may relate to resolution of acute inflammatory processes, resolution of attendant complications (e.g., fistulas and abscesses), alleviation of systemic manifestations (e.g., arthritis), maintenance of remission from acute inflammation, or surgical palliation or cure. The approach to the therapeutic regimen differs considerably with varying goals, as well as with the two diseases, ulcerative colitis and Crohn's disease.

When determining goals of therapy and selecting therapeutic regimens it is important to understand the natural history of IBD.³⁸ Some cases of acute ulcerative colitis are self-limited. With mild to moderate acute colitis without systemic symptoms, 20% of patients may experience spontaneous improvement in their disease within a few weeks; however, a small percentage of patients may go on to experience more serious disease. With severe colitis, improvement without treatment cannot be expected. For instance, the response to medical management of toxic megacolon is variable and emergent

colectomy may be required. When remission of ulcerative colitis is achieved, it is likely to last at least 1 year with medical therapy. In the absence of medical therapy, one-half to two-thirds of patients are likely to relapse within 9 months.³⁷ In some reports, remission rates with placebo have approached those found with active treatment.

A considerable number of patients with active Crohn's disease may achieve at least temporary remission without drug therapy. In two large trials, 26% and 42% of ambulatory patients on placebo achieved remission.^{39,40} Once remission is achieved, two-thirds to three-fourths of patients remain in remission up to 2 years without drug therapy.⁴⁰ The implication of these data is that up to 40% of patients with active Crohn's disease improve in 3 to 4 months with observation alone, and that most patients remain in remission for prolonged periods without medical intervention. These observations apply more to mild or moderate disease than to severe disease.

■ GENERAL APPROACH TO TREATMENT

6 Treatment of IBD centers on agents used to relieve the inflammatory process. Salicylates, corticosteroids, antimicrobials, and immunosuppressive agents such as azathioprine, mercaptopurine, and methotrexate are commonly used to treat active disease and, for some agents, to lengthen the time of disease remission. Information regarding the extent and distribution of the disease should be taken into account, as this often dictates the route and formulation of drug therapy that are most effective.

In addition to the use of drugs, surgical procedures are sometimes performed when active disease is inadequately controlled or when the required drug dosages pose an unacceptable risk of adverse effects. For most patients with IBD, nutritional considerations are also important, because these patients are often malnourished. Finally, a variety of therapies may be used to address complications or symptoms of IBD. For example, antidiarrheals may be used in some patients, although these are generally to be avoided in severe ulcerative colitis because they may contribute to the development of toxic colonic dilation. Antimicrobial agents may be used in conjunction with surgical drainage when abscesses are present. Iron may be required, particularly with ulcerative colitis, where blood loss from the colon can be significant.

■ NONPHARMACOLOGIC THERAPY

Nutritional Support

Proper nutritional support is an important aspect of the treatment of patients with IBD, not because specific types of diets are useful in alleviating the inflammatory conditions, but because patients with moderate to severe disease are often malnourished either because the inflammatory process results in significant malabsorption or maldigestion, or because of the catabolic effects of the disease process. Elevated levels of interleukin-6 and TNF- α are known to increase protein turnover, resulting in protein loss and muscle wasting.³⁴ Malabsorption may occur in the patient with Crohn's disease with inflammatory involvement of the small bowel, where many nutrients are absorbed, as well as in patients who have undergone multiple small-bowel resections with subsequent reduction in absorptive surface ("short gut"). Maldigestion with accompanying diarrhea can occur if there is a bile salt deficiency in the gut.

Many specific diets have been tried to improve the condition of patients with IBD, but none has gained widespread acceptance. With each individual it is helpful to eliminate specific foods that exacerbate symptoms. This elimination process must be conducted cautiously, as patients have been known to exclude a wide range of nutritious products without adequate justification. Some patients with IBD, although not the majority, have lactase deficiency; consequently, diarrhea may be associated with milk intake. In these patients,

avoidance of milk or supplementation with lactase generally improves the patient's symptoms. Patients with small-bowel strictures as a consequence of Crohn's disease should avoid excessive high-residue foods, such as citrus fruits and nuts.¹

The nutritional needs of the majority of patients can be adequately addressed with enteral supplementation.⁴¹ In severe acute ulcerative colitis, enteral nutrition resulted in a significantly greater increase in serum albumin, fewer adverse effects related to the nutritional regimen, and fewer postoperative infections, as compared to isocaloric, isonitrogenous parenteral nutrition.⁴² The regimens were similar with regard to remission rate and the need for colectomy. Consideration should be given to lipid administration for its caloric value, as well as in recognition of depleted peripheral fat stores in many IBD patients and the greater potential for fatty acid deficiency. The use of enteral nutrition in patients with Crohn's disease is preferable, as favorable effects on modulation of proinflammatory cytokine production may lead to enhanced maintenance of nutritional stores and increased growth rates in children.^{43,44} Likewise, use of enteral nutrition may facilitate induction of remission in up to 60% of patients with active Crohn's disease.^{43,45}

Parenteral nutrition is an important component of the treatment of severe Crohn's disease or ulcerative colitis. The use of parenteral nutrition allows complete bowel rest in patients with severe ulcerative colitis, which may alter the need for proctocolectomy. Parenteral nutrition has also been valuable in Crohn's disease, because remission may be achieved with parenteral nutrition in about 50% of patients.⁴⁶ In some patients, the disease may worsen when parenteral nutrition is stopped. Patients who have severe Crohn's disease may require a course of parenteral nutrition to attain a reasonable nutritional status or in preparation for surgery, as poor perioperative nutritional status is associated with an increased incidence of postoperative complications.³⁴ Patients with enterocutaneous fistulas of various etiologies benefit from parenteral nutrition.⁴⁶ Parenteral nutrition may also be valuable in children or adolescents with growth retardation associated with Crohn's disease, but surgery is often necessary with severe disease. Finally, when possible, home parenteral nutrition should be used for patients requiring long-term therapy, particularly those with "short gut" as a consequence of surgical resection.

There is a growing interest in using probiotic approaches for IBD. Probiotics involves the reestablishment of normal bacterial flora within the gut by oral administration of live bacteria such as nonpathogenic *E. coli*, bifidobacteria, lactobacilli, or *Streptococcus thermophilus*. Probiotic formulations have been effective in maintaining remission in ulcerative colitis.^{47,48}

Surgery

Even with medical therapy 30% to 40% of patients with ulcerative colitis and 70% to 80% of patients with Crohn's disease require surgical intervention at some point in their life.⁴⁹ Although surgery (proctocolectomy) is curative for ulcerative colitis, this is not the case for Crohn's disease. Surgical procedures involve resection of segments of intestine that are affected, as well as correction of complications (e.g., fistulas) or drainage of abscesses.

For ulcerative colitis, colectomy may be necessary when the patient has disease uncontrolled by maximum medical therapy or when there are complications of the disease such as colonic perforation, toxic dilation (megacolon), uncontrolled colonic hemorrhage, or colonic strictures. Colectomy may be indicated in patients with long-standing disease (longer than 8 years), as a prophylactic measure against the development of cancer, and in patients with premalignant changes (severe dysplasia) on surveillance mucosal biopsies. The most common surgical procedures include proctocolectomy, after which the patient is left with a permanent ileostomy, and abdominal colectomy, with removal of the mucosa of the rectum and anastomosis of an ileal pouch to the anus (ileal pouch–anal anastomosis).⁴⁹ The risk from

TABLE 36-5 Mesalamine Derivatives for Treatment of Inflammatory Bowel Disease

Product	Trade Name(s)	Formulation	Dose/Day	Site of Action
Sulfasalazine	Azulfidine	Immediate-release or enteric-coated tablets	4–6 g	Colon
	Azulfidine EN-tabs			
Mesalamine	Rowasa, Salofalk	Enema	1–4 g	Rectum, distal colon
	Asacol	Mesalamine tablet coated with Eudragit-S (delayed-release acrylic resin)	2.4–4.8 g	Distal ileum and colon
	Pentasa	Mesalamine capsules encapsulated in ethylcellulose microgranules	2–4 g	Small bowel and colon
	Lialda	Mesalamine tablet formulated with MMX delayed release technology (pH-dependent outer coat with polymeric matrix core); allows for once-daily dosing	2.4–4.8g	Colon
	Canasa	Mesalamine suppository	500–1,000 mg	Rectum
Olsalazine	Dipentum	Dimer of 5-aminosalicylic acid oral capsule	1.5–3 g	Colon
Balsalazide	Colazal	Capsule	6.75 g	Colon

surgery in these patients is relatively low if the operations are performed on a nonemergent basis.

The indications for surgery with Crohn's disease are not as well established as for ulcerative colitis, and surgery is usually reserved for the complications of the disease. A recognized problem with intestinal resection for Crohn's disease is the high recurrence rate. Surgery may be appropriate in well-selected patients who have severe or incapacitating disease or obstruction in spite of aggressive medical management. The surgical procedures performed include resections of the major intestinal areas of involvement. In some patients with severe rectal or perianal disease, particularly abscesses, diversion of the fecal stream is performed with a colostomy. Other indications for surgery include strictures, resection of colon cancer or an inflammatory mass, or management of intestinal perforations or fistulae.

■ PHARMACOLOGIC THERAPY

Drug therapy plays an integral part in the overall treatment of IBD. None of the drugs used for IBD are curative; at best they serve to control the disease process. Therefore a reasonable goal of drug therapy is resolution of disease symptoms such that the patient can carry on normal daily functions. The major types of drug therapy used in IBD include aminosalicylates, corticosteroids, immunosuppressive agents (azathioprine, mercaptopurine, cyclosporine, and methotrexate), antimicrobials (metronidazole and ciprofloxacin), and agents to inhibit TNF- α (anti-TNF- α antibodies) (Table 36–5).

Sulfasalazine, an agent that combines a sulfonamide (sulfapyridine) antibiotic and mesalamine (5-aminosalicylic acid) in the same molecule, has been used for many years to treat IBD but was originally intended to treat arthritis. Sulfasalazine is cleaved by gut bacteria in the colon to sulfapyridine (which is mostly absorbed and excreted in the urine) and mesalamine (which mostly remains in the colon and is excreted in stool).^{45,50,51}

The active component of sulfasalazine is mesalamine.^{45,50,51} The mechanism of action of mesalamine is not well understood. Cyclooxygenase or lipoxygenase inhibition alone does not entirely account for the agent's effects. Aminosalicylates may block production of prostaglandins and leukotrienes, inhibit bacterial peptide-induced neutrophil chemotaxis and adenosine-induced secretion, scavenge reactive oxygen metabolites, and inhibit activation of the nuclear regulatory factor nuclear factor kappa B.⁹

Because the mechanism of action of sulfasalazine is not related to the sulfapyridine component, and because sulfapyridine is believed to be responsible for many of the adverse reactions to sulfasalazine, mesalamine alone can be used. Mesalamine can be used topically as an enema or suppository for the treatment of proctitis, or given orally in slow-release formulations that deliver mesalamine to the small intestine and colon (Table 36–6 and Fig. 36–1). Slow-release oral formulations of mesalamine, such as Pentasa®, release mesalamine from the duodenum to the ileum, with up to 59% of the drug passing into the colon.⁵⁰ Lialda® is a newly available tablet formulation of

mesalamine that uses a pH-dependent coating in combination with a polymeric matrix core, which releases the drug evenly throughout the colon and allows for once-daily dosing.⁵¹ Olsalazine is a dimer of two 5-aminosalicylate molecules linked by an azo bond. Mesalamine is released in the colon after colonic bacteria cleave olsalazine. Balsalazide is a mesalamine prodrug that is enzymatically cleaved in the colon to produce mesalamine. The recommended daily doses of the oral mesalamine derivatives are intended to approximate the molar equivalent of mesalamine present in 4 g of sulfasalazine. At present, sulfasalazine is often used versus oral mesalamine derivatives, mainly because it costs much less. However, it is not tolerated as well as the mesalamine alternatives. Because the oral mesalamine formulations are coated tablets or granules, they should not be crushed or chewed. Unlike sulfasalazine, all of these agents are safe to use in patients with sulfonamide allergies.

Corticosteroids and adrenocorticotrophic hormone have been widely used for the treatment of ulcerative colitis and Crohn's disease, given parenterally, orally, or rectally.⁵² Corticosteroids are believed to modulate the immune system and inhibit production of cytokines and mediators. It is not clear whether the most important steroid effects are systemic or local (mucosal). Budesonide is a corticosteroid that is administered orally in a controlled-release formulation designed to release in the terminal ileum. The drug undergoes extensive first-pass metabolism, so systemic exposure is thought to be minimized.⁵³ Immunosuppressive agents such as azathioprine, mercaptopurine (a metabolite of azathioprine), methotrexate, or cyclosporine are sometimes used for the treatment of IBD.

Azathioprine and mercaptopurine are effective for long-term treatment of Crohn's disease and ulcerative colitis.^{45,54} These agents are generally reserved for patients who are refractory to steroids, and they may be associated with serious adverse effects such as lymphomas, pancreatitis, or nephrotoxicity. They are usually used in conjunction with mesalamine derivatives and/or steroids, and must be used for long periods of time (from a few weeks up to 6 months) before benefits may be observed.⁵⁴ Remission can be prolonged by azathioprine in steroid-dependent patients with ulcerative colitis. Cyclosporine has also been of short-term benefit in treatment of acute, severe ulcerative colitis when used in a continuous intravenous infusion. Lower-dose continuous infusions (2 mg/kg vs. 4 mg/kg daily), or oral daily doses of 5 to 6 mg/kg may in conjunction with steroids may be an effective option for those with fulminant disease.⁵⁵ The agent poses a risk of nephrotoxicity and neurotoxicity. Some studies evaluating tacrolimus for the treatment of IBD suggest a potential role for its use in patients with fistulizing Crohn's disease, in patients unresponsive to steroids or infliximab, and in management of some extraintestinal manifestations.⁵⁶ Methotrexate given 15 to 25 mg intramuscularly once weekly is useful for treatment and maintenance of Crohn's disease but not ulcerative colitis.^{57,58}

Antimicrobial agents, particularly metronidazole, are frequently used in attempts to control Crohn's disease but are not useful in ulcerative colitis.^{37,59} Metronidazole is of value in some patients with

TABLE 36-6 Levels of Evidence for Therapeutic Interventions in Inflammatory Bowel Disease	
Interventions	Evidence Grades
Ulcerative colitis	
Mild-moderate active distal disease may be treated with oral aminosalicylates, topical mesalamine, or topical steroids	A
Combined oral and topical aminosalicylates are more effective than either alone for mild-moderate active distal disease	A
Oral prednisone in doses of 40–60 mg/day or 1 mg/kg/day may be used in patients with mild-moderate distal disease unresponsive to oral or topical aminosalicylates	B
Sulfasalazine in doses of 4–6 g/day or an alternate aminosalicylate in doses of up to 4.8 g/g of the active 5-aminosalicylate moiety are effective for induction of mild-moderate extensive colitis	A
Infliximab is effective for moderate to severe disease in those patients not responding to corticosteroids or an immunosuppressive agent	A
Systemic corticosteroids are effective in moderate to severe active disease	A
Hospitalization for parenteral steroids is indicated for patients with severe disease or those failing to respond to oral steroids	A
Failure to demonstrate improvement following 7–10 days of parenteral steroids in patients with severe disease is an indication for cyclosporine or colectomy	B
Mesalamine suppositories (proctitis) and enemas (distal colitis) are effective in maintenance of remission when dosed as infrequently as every third night	A
Sulfasalazine, mesalamine, or balsalazide are effective in maintenance of remission of distal disease; combining oral and topical mesalamine is more effective than either alone	A
Sulfasalazine, olsalazine, mesalamine, and balsalazide are effective in preventing relapses in patients with mild to moderate extensive disease	A
Corticosteroids are ineffective as maintenance treatment	A
Azathioprine, mercaptopurine, or infliximab are effective in lowering or eliminating corticosteroid use in corticosteroid-dependent patients	A
Azathioprine, mercaptopurine, or infliximab may be effective in patients with severe disease flares or those requiring retreatment with corticosteroids within 1 year	C
Oral cyclosporine is effective in patients with corticosteroid refractory disease but requires concomitant administration of azathioprine or mercaptopurine	C
Infliximab therapy is effective for maintenance if there is an initial response	A
Crohn's disease	
Oral aminosalicylates are effective for mild-moderate ileal, ilealocolonic, or colonic active disease	D
Metronidazole may be effective in patients not responding to sulfasalazine	D
Ileal-release budesonide is effective for mild-moderate ileal or right-sided colonic disease	A
Topical hydrocortisone is effective for distal colonic inflammation	A
Systemic corticosteroids are effective in moderate to severe active disease	A
Systemic corticosteroids are not effective in patients with perianal fistulas	C
Hospitalization for parenteral steroids is indicated for patients with severe disease or those failing to respond to oral steroids	A
Parental methotrexate is effective for induction of remission in patients with active disease, and to reduce corticosteroid dependency	B
Infliximab is effective for moderate to severe disease in those patients not responding to corticosteroids or an immunosuppressive agent	A
Infliximab is effective for those patients with fistulas who have not responded to antibiotics, immunosuppressive agents, or surgical drainage	A
High-dose oral cyclosporine (7.6 mg/kg) has short-term efficacy in patients with active disease	B
Intravenous cyclosporine is effective for the treatment of fistulizing disease	B
Corticosteroids are ineffective as maintenance treatment	A
Budesonide is effective as short-term maintenance therapy (3 months) but not as long-term therapy	A
Azathioprine, 6-mercaptopurine, or infliximab is effective in lowering or eliminating corticosteroid use in corticosteroid-dependent patients.	A
Azathioprine, 6-mercaptopurine, or infliximab may be effective in patients with severe disease flares or those requiring retreatment with corticosteroids within 1 year	A
Azathioprine or 6-mercaptopurine are effective for maintenance of remission regardless of disease distribution	A
Azathioprine or 6-mercaptopurine may be effective for treating perianal or enteric fistulae	C
Methotrexate maintenance therapy (15–25 mg IM weekly) is effective for patients whose active disease has responded to IM methotrexate	A
Methotrexate IM 25 mg IM weekly for up to 16 weeks followed by 15 mg IM weekly is effective for patients with chronic active disease	A
Infliximab therapy is effective for maintenance if there is an initial response	A

Grade A: Homogenous evidence from multiple well-designed, randomized (therapeutic) or cohort (descriptive) controlled trials, each involving a number of participants so as to be of sufficient statistical power.
Grade B: Evidence from at least one large, well-designed clinical trial with or without randomization from cohort or case control analytic studies or well-designed meta-analysis.
Grade C: Evidence based on clinical experience, descriptive studies, or reports of expert committees.
Grade D: Not rated.
Compiled from Kornbluth and Sachar,³⁶ Hanauer et al.,⁶⁹ and Simms and Steinhardt.⁹⁷

active Crohn's disease, particularly involving the perineal area or fistulas.⁵⁹ The mechanism of metronidazole's effect on Crohn's disease has not been determined but is theorized to relate to interruption of a bacterial role in the inflammatory process. Ciprofloxacin has also been used for treatment of IBD. Rifaximin, a new nonabsorbable antibiotic, has also shown some efficacy in treatment of both ulcerative colitis and Crohn's disease.⁵⁹

Infliximab is an immunoglobulin G₁ chimeric monoclonal antibody that binds TNF- α and inhibits its inflammatory effect in the gut. The agent is useful for moderate to severe active disease and steroid-dependent or fistulizing disease, but the cost far exceeds that of other regimens.⁶⁰

Adalimumab is also an IgG1 antibody to TNF- α , however this agent, unlike infliximab is fully humanized and contains no murine sequences. Theoretically, the lack of a murine component in adalimumab avoids the problem of antibody development seen with use of infliximab. This agent can be given subcutaneously, unlike infliximab,

FIGURE 36-1. Site of activity of various agents used to treat inflammatory bowel disease.

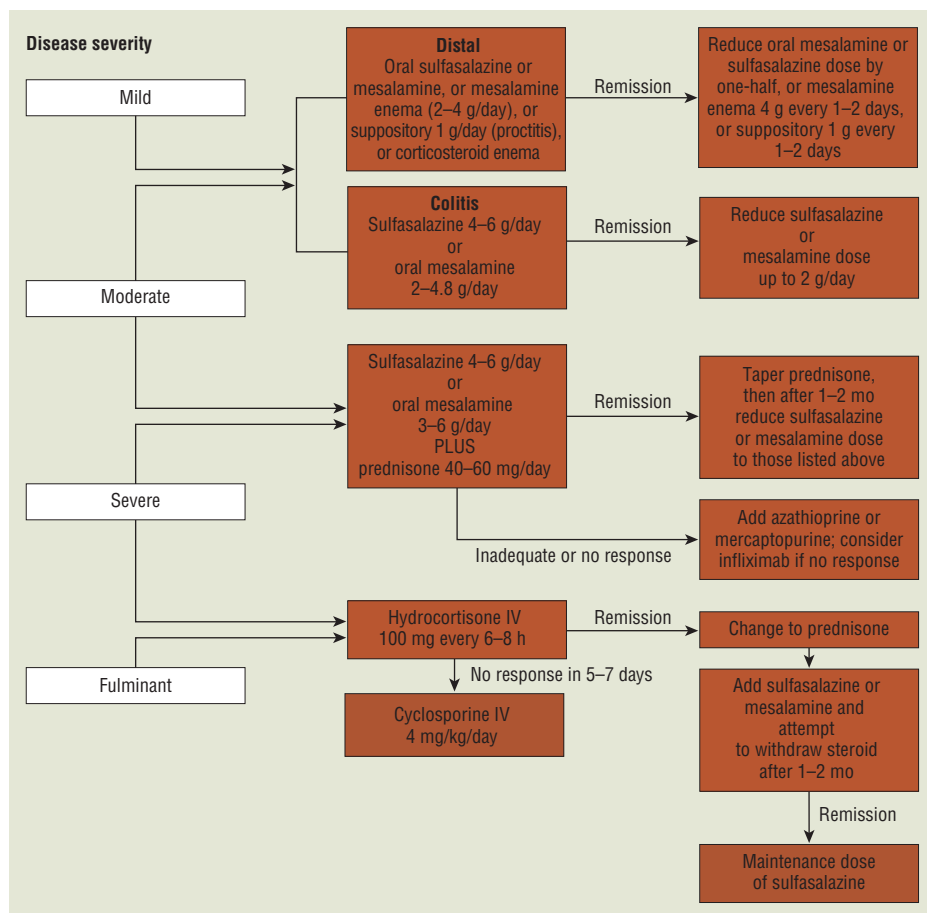

FIGURE 36-2. Treatment approaches for ulcerative colitis.

which is given intravenously. Adalimumab is a treatment option for patients with moderate to severe active Crohn's disease previously treated with infliximab who have lost response.^{61,62,63}

Ulcerative Colitis

Mild to Moderate Disease Most patients with active ulcerative colitis have mild to moderate disease and do not require parenteral medications (Fig. 36–2). The first line of drug therapy for patients with extensive disease is oral sulfasalazine or an oral mesalamine derivative.³⁶ Topical mesalamine is more effective than oral mesalamine or topical steroids for distal disease.³⁶ The combination of oral and topical mesalamine is more effective than either alone for active distal disease.^{26,36,64,65} When given orally, usually 4 to 6 g/day, and possibly up to 8 g/day, of sulfasalazine is required to attain control of active inflammation. There does not appear to be an increased rate of response with increased dosage over 6 g/day, although side effects increase. Even with the use of adequate doses, patient improvement usually takes 4 weeks, and sometimes longer.³⁶ The dosage of sulfasalazine that can be given is usually limited by the patient's tolerance of the agent; most adverse effects of sulfasalazine are dose related (GI disturbances, headache, and arthralgia).³⁵ Sulfasalazine therapy should be instituted at 500 mg/day and increased every few days up to 4 g/day or the maximum tolerated. It should not be used in patients with allergy to sulfonamide containing drugs.

Oral mesalamine derivatives (such as those listed in Table 36–5) are reasonable alternatives to sulfasalazine for treatment of ulcerative colitis. Oral mesalamine products are used for patients with extensive disease, while topical agents, such as enemas and suppositories, are used for distal disease. Mesalamine is clearly more effective than placebo but no more effective than sulfasalazine for extensive disease.^{66,67} Mesalamine preparations are typically better tolerated, and

the majority of patients intolerant to sulfasalazine or topical steroids should tolerate one of the other oral mesalamine derivatives.^{35,36} Dose-related effects do exist and when used orally for active extensive disease, the equivalent of 4.8 g of the active 5-aminosalicylic acid moiety should be administered when possible.^{36,66,67} Studies comparing daily doses of 2.4 g versus 4.8 g of mesalamine (Asacol formulation) in patients with moderate active ulcerative colitis demonstrated greater efficacy at 6 weeks of therapy (58% vs. 72%, $P < 0.05$).^{64,68,69} Although the dosage range for Pentasa is 2 to 4 g/day, 4 g/day appears to be more effective.⁶⁶ Olsalazine (a dimer of 5-aminosalicylic acid that is given orally) is effective for treatment of mild to moderate ulcerative colitis. However, of patients taking olsalazine, 15% to 25% experience severe diarrhea, often necessitating discontinuation of the drug. This results from a direct osmotic effect of the drug to induce small-bowel fluid secretion. For this reason it is not the drug of first choice.³⁶ Balsalazide is another viable agent that couples mesalamine with the inert carrier molecule 4-aminobenzoyl-L-alanine, and is effective for treatment of mild to moderate ulcerative colitis.^{70,71} When used topically, mesalamine suppositories will only reach to approximately 10 to 20 cm and thus should be reserved for patients with proctitis. Because enema formulations reach to the splenic flexure, they can be used for distal disease.^{26,36}

⑦ Steroids have a place in the treatment of moderate to severe active ulcerative colitis regardless of disease location, or in those patients who are unresponsive to maximal doses of oral and/or topical mesalamine derivatives.^{36,71} Oral steroids (usually up to 1 mg/kg per day of prednisone equivalent or 40 to 60 mg daily) may be used for patients who do not have an adequate response to sulfasalazine or mesalamine.³⁶ Overall, steroids and sulfasalazine appear to be equally efficacious; however, the response to steroids may be evident sooner. Oral steroids should not be used as initial therapy for mild to moderate ulcerative colitis, mainly because of the known risks of

steroid use. If steroids are used to attain remission, tapered drug withdrawal should be accomplished to minimize long-term steroid exposure.

Rectally administered steroids given as suppositories, enemas, or foams can be used as initial therapy for patients with ulcerative proctitis or distal colitis. Rectal agents are also beneficial for treatment of tenesmus. With these agents, local actions are believed to be responsible for drug effects. Rectal steroids are effective in the treatment of active, distal ulcerative colitis. However, rectal mesalamine is more effective than rectal steroids for inducing remission.^{26,36,64,65,72}

Infliximab is another viable option for patients with moderate to severe active ulcerative colitis who are unresponsive to steroids or other immunosuppressive agents.^{60,64,72,73} Outpatients with moderately active ulcerative colitis have response rates of up to 69% at 8 weeks following initial doses of 5 mg/kg.⁷⁴ Hospitalized patients have mixed results, with some demonstrating reduced rates of colectomy for patients receiving infliximab.^{73,75,76}

Nicotine has been proposed as a treatment for ulcerative colitis (but not as a treatment for Crohn's disease) based on the observation of the onset of a flare of ulcerative colitis after smoking cessation in some individuals. While less effective than aminosalicylates, transdermal nicotine in daily doses of 15 to 25 mg may improve symptoms in patients with mild to moderate active ulcerative colitis and can be considered as an adjunctive therapy.^{36,77}

Severe or Intractable Disease

Patients with uncontrolled severe colitis or who have incapacitating symptoms require hospitalization for effective management. Under these conditions, patients generally receive nothing by mouth to put the bowel at rest. Most medication is given by the parenteral route. Sulfasalazine or mesalamine derivatives are not beneficial for treatment of severe colitis because of rapid elimination of these agents from the colon with diarrhea, thereby not allowing sufficient time for gut bacteria to cleave the molecules. Overall it is difficult to evaluate drugs in this setting, because patients with severe disease almost always receive additional medications including steroids.

Steroids have been valuable in the treatment of severe disease because the use of these agents may allow some patients to avoid colectomy. Intravenous hydrocortisone 300 to 400 mg daily in three divided doses or methylprednisolone 48 to 60 mg once daily are considered first-line agents.^{36,72} Methylprednisolone is typically preferred because of its lesser mineralocorticoid effects. A trial of steroids is warranted in most patients before proceeding to colectomy, unless the condition is grave or rapidly deteriorating. The length of the medical trial before consideration of surgery is open to debate. Steroids increase surgical risk, particularly infectious risk, if an operation is required later. After a colectomy is performed, steroids should no longer be required for the disease; however, they must be withdrawn gradually (usually over 3 to 4 weeks) to avoid hypoadrenal crisis because of adrenal suppression.

8 Patients who are unresponsive to parenteral corticosteroids after 7 to 10 days should receive cyclosporine by intravenous infusion. Seventy to 80% of hospitalized patients who are unresponsive to corticosteroids will respond to cyclosporine.⁵⁵ Continuous intravenous infusion of cyclosporine (4 mg/kg per day) is typically effective in steroid-resistant acute severe ulcerative colitis and may reduce the need for emergent colectomy.^{55,78} Intravenous cyclosporine has also been recommended as an alternative to steroids in patients with severe attacks of ulcerative colitis (fulminant colitis).⁷⁹ Patients who are controlled on intravenous cyclosporine can then be switched to an oral cyclosporine taper regimen with subsequent transition to azathioprine or 6-mercaptopurine.⁷² As mentioned earlier, infliximab is also an alternative to cyclosporine, and may also deter the need for colectomy in patients with severe disease not responsive to steroids.^{72,73-75}

Maintenance of Remission

9 After remission from active disease is achieved, the goal of therapy is to then maintain remission. The major agents used for maintenance of remission are sulfasalazine and the mesalamine derivatives.^{66,80} The value of sulfasalazine in preventing recurrences has been documented in several placebo-controlled trials.⁸⁰ Sulfasalazine, most commonly given 2 g/day, was superior to mesalamine when using the main end point of failure to maintain endoscopic or clinical remission (odds ratio 1.29 [95% confidence interval 1.05 to 1.57]).⁸⁰ Sulfasalazine also appears to be more effective in maintaining remission compared to the newer agents, such as olsalazine.

For patients with distal disease or proctitis, mesalamine enemas or suppositories are considered first-line agents.^{26,36,65} The frequency of administration of topical agents may possibly lessen to every third night over time. Oral agents, including sulfasalazine, mesalamine, and balsalazide, are also effective options if patients do not wish to use a topical preparations.^{26,36,65} The combination of topical and oral mesalamine is superior to either regimen alone for maintenance therapy.

CLINICAL CONTROVERSY

A major question about the use of aminosalicylates for maintenance of remission of ulcerative colitis is whether or not they reduce the patient's risk of developing colorectal cancer. It has been suggested that mesalamine, in doses greater than 1.2 g/day, is protective against the development of colorectal cancer; however, this is not supported by controlled trials. Given the often slow development of colorectal cancer and the relapsing nature of ulcerative colitis, these significantly limit the ability to conduct long-term surveillance studies in patients in remission.

Steroids do not have a role in the maintenance of remission with ulcerative colitis because they are ineffective.³⁶ Steroids should be gradually withdrawn after remission is induced (over 3 to 4 weeks). If they are continued, the patient will be at risk for steroid induced adverse effects without likelihood of benefits. For patients who require chronic steroid use (steroid dependency), there is a strong justification for alternative therapies or colectomy. Azathioprine is effective in preventing relapse of ulcerative colitis for periods exceeding 4 years.^{54,69,72,81} However, 3 to 6 months may be required before beneficial effects are noted. For patients who initially respond to infliximab, continued dosing of 5 mg/kg as maintenance therapy every 8 weeks is another alternative for corticosteroid dependent patients, or those failing immunosuppressive therapy.^{60,72,73}

■ CROHN'S DISEASE

Management of Crohn's disease often proves more difficult than management of ulcerative colitis, partly because of the greater complexity of presentation with Crohn's disease (Fig. 36-3). The disease may involve any segment of the GI tract, from mouth to anus, and may involve other visceral structures and soft tissues through fistulization. There is a greater reliance on drug therapy with Crohn's disease, because resection of all involved intestine may not be possible. Unfortunately, recurrence of Crohn's disease is common following surgery with reported rates of up to 64% recurrence following surgical resection of affected areas of bowel.⁴⁹

Active Crohn's Disease

The goal of treatment for active Crohn's disease is to achieve remission; however, in many patients, reduction of symptoms so the patient may carry out normal activities, or reduction of the steroid dose

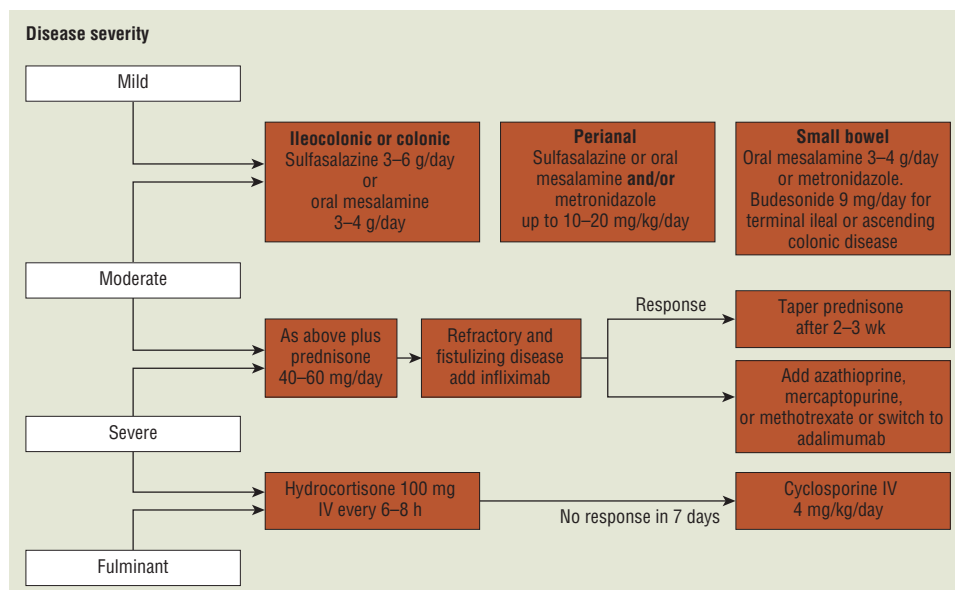

FIGURE 36-3. Treatment approaches for Crohn's disease.

required for control, is a significant accomplishment. In the majority of patients, active Crohn's disease is treated with sulfasalazine, mesalamine derivatives, or steroids, although azathioprine, mercaptopurine, methotrexate, infliximab, and metronidazole are frequently used.

The role of sulfasalazine in the treatment of active Crohn's disease is not as well established as its role in the treatment of ulcerative colitis. Sulfasalazine is superior to placebo, but is more effective when Crohn's disease involves the colon.³⁷ In these circumstances, sulfasalazine is as effective as prednisone.^{36,82,83} Mesalamine formulations such as Pentasa or Asacol have the ability to release mesalamine in the small bowel, thus targeting ileal disease, yet have demonstrated variable results in patients with active Crohn's disease.^{82,83} Only a few small trials using Asacol at 3.8 g/day or Pentasa at 4 g/day have demonstrated superiority to placebo for treatment of active Crohn's disease.^{82,83} Despite variable effectiveness, the mesalamine derivatives may be better tolerated than sulfasalazine, particularly at higher doses. Thus, a trial of sulfasalazine or an oral mesalamine derivative is reasonable as initial therapy in patients with mild to moderate active Crohn's disease with ileal, ileocolonic, or colonic involvement.³⁶

7 Steroids are frequently used for the treatment of active Crohn's disease, particularly with more moderate to severe presentations, or in those patients unresponsive to aminosalicylates. Budesonide (Entocort) is a viable first-line option for patients with mild to moderate ileal or right-sided (ascending colonic) disease.^{53,72,84} This agent is superior to placebo and has demonstrated superiority to mesalamine in some trials.⁸¹ Budesonide is inferior to traditional systemic steroids for severe disease, although it carries a lower risk of adverse effects, and does not reach areas distal to the ascending colon. Oral systemic steroids are effective in inducing remission in up to 70% of patients and should be reserved for patients with moderate to severe disease who have failed aminosalicylates or budesonide.^{72,82} Hospitalized patients with severe or fulminant disease, or those who are unable to tolerate oral therapy, are candidates for administration of parenteral steroids.^{53,72} Systemic steroids do not appear to be effective for treatment of perianal fistulas.⁷²

10 Metronidazole (given orally up to 20 mg/kg per day in divided doses) has demonstrated variable efficacy, but may possibly be useful in some patients with Crohn's disease, particularly in patients with colonic or ileocolonic involvement, or in those patients with perineal disease.^{59,82,83,85} For most patients with colonic or perineal disease, metronidazole is added to a mesalamine product or steroids as adjunctive therapy, where satisfactory control of Crohn's disease is not gained with first-line agents, or in attempts to reduce steroid

dosage.⁷³ Ciprofloxacin has gained attention as an alternative to metronidazole, and has demonstrated some efficacy in small trials only.^{82,83} The combination of metronidazole and ciprofloxacin appears to be efficacious in some patients with perianal disease.^{59,85}

The immunosuppressive agents (azathioprine and its metabolite mercaptopurine) are effective, but are generally limited to use in patients who are not achieving adequate response to standard medical therapy, or to reduce steroid doses when high steroid doses are required.^{54,72,82,86} Azathioprine and mercaptopurine have both demonstrated long-term benefits in patients with Crohn's disease.^{54,81} The usual dose of azathioprine is 2 to 3 mg/kg per day; the usual dose of mercaptopurine is 1 to 1.5 mg/kg per day.⁷² Starting doses are typically 50 mg/day and increased at 2-week intervals; complete blood counts with differential should be monitored every 2 weeks while doses are being titrated.⁷² The onset of therapeutic effects is delayed with both azathioprine and mercaptopurine, and a minimum of 3 to 4 months is often required to see clinical benefits.^{72,82}

Clinical response to mercaptopurine is related to whole-blood concentrations of the metabolite 6-thioguanine (6-TGN), while toxicity is correlated with concentrations of another metabolite, 6-methylmercaptopurine (6-MMPR).^{13,54,87} Metabolic inactivation of azathioprine and mercaptopurine occurs mainly by the enzyme thiopurine S-methyltransferase (TPMT), which exhibits genetic polymorphism. Enzyme-deficient patients are at greater risk of bone marrow suppression from these agents.^{14,54} Determination of TPMT activity is possible, and may be necessary to determine which patients require lower doses of these agents.^{14,54} Alternatively, a newer strategy for evaluating a patient's risk for toxicity is to perform a TPMT genotype or phenotype.^{54,72} This is recommended prior to therapy with subsequent dose adjustments based on the patient's genotypic profile.⁷²

CLINICAL CONTROVERSY

Although thiopurines, such as azathioprine and mercaptopurine, are effective for maintenance of remission of Crohn's disease, it is debated how long treatment should be continued once remission is achieved. Evidence has demonstrated efficacy of these agents in maintaining remission for longer than 4 years; however, some authors argue that long-term exposure to these potentially toxic agents outweighs the benefit.

Although mostly used in the setting of maintenance therapy, methotrexate is another option for use as induction therapy.⁸² Use of

a weekly intramuscular injection of 25 mg has demonstrated efficacy for induction of remission in Crohn's disease, and has also demonstrated corticosteroid-sparing effects.^{72,82,88} Although there are risks of bone marrow suppression, hepatotoxicity, and pulmonary toxicity, use of low-dose methotrexate appears relatively safe when continued as maintenance therapy if proper monitoring is implemented.

Infliximab is used for treating moderate to severe active Crohn's disease in patients failing immunosuppressive therapy, in those who are corticosteroid dependent, and for treatment of fistulizing disease.^{60,72,89} In large trials, a 5-mg/kg single intravenous infusion of infliximab resulted in clinical improvement in 58% of patients at 2 weeks and in 65% of patients at 8 weeks.^{60,89} Continued dosing of 5 mg/kg at 2 and 6 weeks following the initial dose leads to higher response rates, and is recommended as the regimen of choice for induction therapy in active disease.⁷² Response rates of up to 62% in the reduction of number of draining fistulae have been reported following induction therapy and continued maintenance dosing with infliximab.^{60,89,90} Patients who receive infliximab often develop antibodies to infliximab, which can result in increases in the occurrence of serious infusion reactions and loss of response to the drug. Strategies to reduce formation of antibodies to infliximab include administration of a second dose within 8 weeks of the first dose, concurrent administration of steroids (hydrocortisone 200 mg intravenously on the day of the infusion or oral prednisone the day prior), and use of concomitant immunosuppressive agents.^{60,72,89} Induction of tolerance using a dose escalation technique was also effective in administering infliximab to patients with previous severe infusion reactions.⁹¹

Cyclosporine is typically not recommended for treatment of Crohn's disease except for acute management of patients with severe fistulizing disease.^{72,90,92} Up to 83% of patients with refractory fistulas responded to intravenous cyclosporine (4 mg/kg per day) within a mean of 7.9 days.⁸² The dose of cyclosporine is important in determining efficacy. An oral dose of 5 mg/kg per day is ineffective, whereas 7.6 mg/kg per day has demonstrated effectiveness in some trials.^{72,92} However, toxic effects limit the routine use of this higher dosage. At present, the therapeutic blood or plasma concentration range for cyclosporine has not been established for Crohn's disease, but whole-blood trough concentrations of 300 to 500 ng/mL for intravenous therapy or 200 to 400 ng/mL for oral therapy are reasonable goals.^{72,82} When using cyclosporine clinicians should recognize the accompanying long-term risk of renal toxicity and infection, as well as the potential for drug interactions.

Trials evaluating treatment with adalimumab in patients with moderately to severe active Crohn's disease who have lost response to infliximab have demonstrated up to a 54% complete response in some instances.^{61,62,63} Doses used are typically 160 mg subcutaneously initially, followed by 80 mg subcutaneously at week two, with subsequent doses of 40 mg subcutaneously every over week thereafter.

Maintenance of Remission

9 Prevention of recurrence of disease is clearly more difficult with Crohn's disease than with ulcerative colitis. There is minimal evidence to support sulfasalazine and oral mesalamine derivatives' effectiveness for maintenance of Crohn's disease following medically induced remission.^{82,93,94} Despite these findings, an attempt to maintain remission with sulfasalazine and oral mesalamine following a medically induced remission is reasonable given the favorable side-effect profile of these drugs compared to that of the immunosuppressive agents and infliximab.⁷⁹ Mesalamine does appear to have some efficacy in preventing postsurgical relapse following resection, with absolute risk reductions of 10% to 15% for relapse reported in some studies.^{94,95}

Systemic steroids have no place in the prevention of recurrence of Crohn's disease. These agents do not appear to alter the long-term

course of the disease and predispose patients to serious adverse effects with long-term use.^{37,72,96} Although budesonide at maintenance doses of 6 mg/day demonstrated efficacy in maintaining remission at 3 months, use longer than this is not recommended as a loss of efficacy is seen after this timeframe.^{72,97}

Azathioprine, mercaptopurine, and methotrexate are useful in some patients to maintain remission. Although the published data are somewhat inconsistent, there is evidence to suggest that azathioprine and mercaptopurine are effective in maintaining remission in Crohn's disease; consequently, these drugs are generally considered first-line agents. Patients who may benefit from these agents include those with quiescent disease who are steroid dependent or refractory, postsurgical patients so as to prevent recurrence, those with frequent flares requiring steroids, and those patients with perianal or enteric fistulae.^{54,72,82} For patients who initially respond to methotrexate, continued dosing at 15 mg intramuscularly once weekly is also effective in maintaining remission.^{72,82} This agent has steroid-sparing effects, and thus represents an alternative therapy to azathioprine and mercaptopurine.

Infliximab infusion given at a dose of 5 mg/kg every 8 weeks is more effective than placebo in maintaining remission in patients who initially respond to infliximab for active Crohn's disease.^{60,64,72,74,89} An increase in the dose to 10 mg/kg is acceptable if loss of efficacy over time is evident. Additionally, infliximab is the most effective maintenance therapy for fistulizing disease; however, given the high cost of this agent, some have questioned whether this approach is the most cost-effective.⁹⁰

Adalimumab is also a treatment option for maintenance therapy of Crohn's disease. Following induction therapy, dose of 40 mg subcutaneously every other week have resulted in clinical remission rates of 36–46% after 56 weeks of therapy.^{98,99} Again this agent should be reserved for those patients unresponsive to conventional therapies, including infliximab.

CLINICAL CONTROVERSY

Given the delayed onset of azathioprine some have advocated using infliximab as a "bridge" therapy, using three induction doses to treat active Crohn's disease in steroid-dependent patients while waiting for the therapeutic effects of azathioprine to become evident. Although one recent study has demonstrated this to be effective, some argue that this regimen only delays relapse and does not prevent it, while adding significant expense.^{100,101}

SELECTED COMPLICATIONS

TOXIC MEGACOLON

The treatment required for toxic megacolon includes general supportive measures to maintain vital functions, consideration for early surgical intervention, and use of various drugs (steroids, cyclosporine, and antimicrobials).^{28,36} Aggressive fluid and electrolyte management is required for dehydration. Fluids and electrolytes may be lost through vomiting, diarrhea, and nasogastric intubation, as well as through fluid accumulation in the bowel. When the patient has lost significant amounts of blood (through the rectum), blood replacement may be necessary. Opiates and medications with anticholinergic properties should be discontinued because these agents enhance colonic dilatation, thereby increasing the risk of bowel perforation. Broad-spectrum antimicrobials that include coverage for gram-negative bacilli and intestinal anaerobes should be used as preemptive therapy in the event that perforation occurs.²⁸ Fortunately perforation occurs in only 2% to 3% of cases.³⁶ The duration of the antimicrobial regimen (often 2 to 3 weeks) should be determined

with consideration that there may be significant intraabdominal contamination with signs and symptoms hidden by steroid effects.

If the patient is not on steroids, then high-dose intravenous therapy should be administered to reduce acute inflammation. Recommended regimens include hydrocortisone 100 mg every 8 hours, methylprednisolone 15 mg every 6 hours, or corticotropin 40 units every 8 hours.²⁸ Although the duration of steroid administration is uncertain, most clinicians continue the high-dose steroids for up to 2 weeks after improvement is observed, and then reduce the dosage (approximately 0.5 to 1 mg/kg per day) for a few additional weeks.

Emergent surgical intervention, mainly an abdominal colectomy with formation of an ileostomy, is an important consideration in patients with toxic megacolon and prevents death in some patients.^{28,36,49} Surgical resection is usually reserved for patients failing maximal medical therapy, however the timing of surgery following initiation of medical therapy is somewhat controversial. Some authors advocate 24 to 72 hours of observation following initiation of medical treatment before performing a colectomy,^{36,49} whereas others advocate waiting up to 7 days as long as the patient is stable.²⁸

SYSTEMIC MANIFESTATIONS

The common systemic manifestations of IBD include arthritis, anemia, skin manifestations such as erythema nodosum and pyoderma gangrenosum, uveitis, and liver disease. These problems may be related to the inflammatory process. For some of these manifestations specific therapies can be instituted, whereas for others the treatment that is used for the GI inflammatory process also addresses the systemic manifestations.

Anemia occurs when there is significant blood loss from the GI tract. If the patient can consume oral medication, ferrous sulfate should be administered. If the patient is unable to take oral medication and the patient's hematocrit is sufficiently low, blood transfusions or intravenous iron infusions may be required.^{31,32} Anemia may also be related to malabsorption of vitamin B₁₂ or folic acid, particularly in patients who have had ileal resection, so these may also be required. Patients with IBD are also at high risk for bone loss, osteoporosis, and fractures.^{32,102} Screening for osteoporosis via digital X-ray absorptiometry is recommended for patients using steroids for longer than 3 months, in postmenopausal females, males older than age 50 years, and those who have sustained a low-stress fracture.^{32,102} If the patient is deemed at high risk for osteoporosis, vitamin D and calcium should be instituted. If osteoporosis is present, then calcium, vitamin D, and a bisphosphonate are recommended.^{32,102} Corticosteroid use should be limited and weight-bearing exercise initiated.

There are no consistently recommended therapies for aphthous ulcers, liver disease, episcleritis, or uveitis associated with IBD. Some reports suggest that these manifestations are worse during exacerbations of the intestinal disease and that measures improving intestinal disease will improve these systemic manifestations. Unfortunately, this association has not been demonstrated consistently. For arthritis associated with IBD, aspirin or another NSAID may be beneficial, as might be steroids. However NSAID use may exacerbate the underlying IBD. Liver transplantation is being used more frequently for definitive treatment of primary sclerosing cholangitis. Infliximab has demonstrated efficacy in treatment of some arthritic and skin manifestations such as ankylosing spondylitis, erythema nodosum, and pyoderma gangrenosum.^{32,103}

SPECIAL CONSIDERATIONS

PREGNANCY

Either the occurrence or consideration of pregnancy may cause significant concerns in the patient with IBD. Patients with IBD have

similar infertility rates as the general female population, thus the rate of normal childbirth is similar to that for healthy populations.¹⁰⁴ Some studies have noted a greater risk of spontaneous abortions in patients with IBD. Also, there is a greater incidence of low birth weight infants in mothers with chronic idiopathic ulcerative colitis.¹⁰⁴ Pregnancy has minimal effects on the course of IBD.^{104,105} Likewise, IBD appears to have little effect on the course of pregnancy, particularly if the IBD is quiescent at the time of conception.^{104,105} Patients who are pregnant experience IBD recurrence rates similar to those of nonpregnant females. Also, there is no justification for therapeutic abortion with IBD because termination of the pregnancy has not been observed to improve the disease. There is also unfounded concern that the drugs required to treat IBD may be teratogenic.

Steroids and sulfasalazine may be administered during pregnancy with the same guidelines that would be applied to the nonpregnant patient.^{104,105} Steroids given systemically do not appear to be detrimental to the fetus. Sulfasalazine is generally well tolerated; however it does interfere with folate absorption, so supplementation with folic acid 1 mg twice daily should be used during the pregnancy.¹⁰⁴ Interestingly, sulfasalazine has also been reported to cause decreased sperm counts and reduced fertility in males.¹⁰⁴ This effect is reversible on discontinuation of the drug, and it is not reported with mesalamine. Immunosuppressive drugs (azathioprine and mercaptopurine) may be associated with fetal deformities in humans; however, they have been used without detriment in some patients.^{104,105} Infliximab also appears to be safe for use in pregnant patients.¹⁰⁴ Metronidazole may be used for short courses for treatment of trichomoniasis, but prolonged use should be avoided due to potential mutagenic effects.¹⁰⁴ Methotrexate should not be used during pregnancy, as it is a known abortifacient (category X).^{72,104}

Overall, drug therapy for IBD is not a contraindication for pregnancy, and most pregnancies are well managed in patients with these diseases. The indications for medical and surgical treatment are similar to those in the nonpregnant patient. If a patient has an initial bout of IBD during pregnancy, a standard approach to treatment should be initiated. Recommendations for the use of drugs in nursing mothers vary. Although prednisone and prednisolone can be detected in breast milk, breast-feeding is believed to be safe for the infant when low doses of prednisone are used.¹⁰⁵ Sulfasalazine does not pose a risk of kernicterus, as levels of sulfapyridine in breast milk are low or undetectable. Metronidazole should not be given to nursing mothers because it is excreted into breast milk.¹⁰⁵

ADVERSE DRUG EFFECTS

Drug intolerance often limits the usefulness of agents used to treat IBD. Many patients receiving sulfasalazine, mesalamine, corticosteroids, metronidazole, azathioprine, mercaptopurine, methotrexate, or infliximab experience undesired effects. In some cases, these adverse effects can be significant and require discontinuation of the therapy. Knowledge of the common or important adverse reactions will assist in avoiding or minimizing their effects.

Sulfasalazine is often associated with adverse drug effects and these effects may be classified as either dose related or idiosyncratic.^{106,107} The sulfapyridine portion of the sulfasalazine molecule is believed to be responsible for much of the sulfasalazine toxicity.¹⁰⁶ Dose-related side effects usually include GI disturbances such as nausea, vomiting, diarrhea, or anorexia, but may also include headache and arthralgia. These adverse reactions tend to occur more commonly on initiation of therapy and decrease in frequency as therapy is continued. Approaches to the management of these adverse effects include discontinuing the agent for a short period and then reinstituting therapy at a reduced dosage with subsequent slower dose escalation, administration with food, or substitution of another enteric-coated mesalamine product.^{106,107} Folic acid absorption is impaired by sul-

fasalazine, which may lead to anemia. Patients receiving sulfasalazine should receive oral folic acid supplementation.

Adverse effects that are idiosyncratic are not dose related and most commonly include rash, fever, or hepatotoxicity, as well as relatively uncommon but serious reactions such as bone marrow suppression, thrombocytopenia, pancreatitis, pneumonitis, interstitial nephritis, and hepatitis. For most patients with idiosyncratic reactions, sulfasalazine must be discontinued. In some patients who have experienced allergic reactions to sulfasalazine, a desensitization procedure can be instituted. By gradually increasing sulfasalazine dosage over weeks to months, patient tolerance has been improved.¹⁰⁷

Oral mesalamine derivatives may impose a lower frequency of adverse effects as compared to sulfasalazine.⁵² Up to 90% of patients who are intolerant to sulfasalazine will tolerate oral mesalamine derivatives.¹⁰⁶ However, olsalazine, may cause watery diarrhea in up to 25% of patients, often requiring drug discontinuation.¹⁰⁶

Adverse reactions to corticosteroids are well recognized and may occur when corticosteroids are used for any indication. However, there is a greater potential for adverse effects when corticosteroids are used for the treatment of IBD because high doses must often be used for extended periods. In the National Cooperative Crohn's Disease Study, half of patients receiving high-dose steroid therapy experienced side effects, as did one-third of the patients on the lower-dose regimens for maintenance.³⁹ The well-appreciated adverse effects of corticosteroids include hyperglycemia, hypertension, osteoporosis, acne, fluid retention, electrolyte disturbances, myopathies, muscle wasting, increased appetite, psychosis, and reduced resistance to infection. In addition, corticosteroid use may cause adrenocortical suppression. To minimize corticosteroid effects, clinicians have used alternate-day steroid therapy; however, some patients do not do well clinically on the days when no steroid is given. For most patients a single daily corticosteroid dose suffices, and divided daily doses are unnecessary. Another problem with corticosteroids is adrenal insufficiency after abrupt steroid withdrawal. This necessitates gradual tapering of steroid therapy for patients using these agents daily for more than 2 to 3 weeks.¹⁰⁶

Immunosuppressants such as azathioprine and mercaptopurine have a significant potential for adverse reactions and have resulted in withdrawal rates in clinical trials of up to 20%.⁵⁴ Adverse events to thiopurines are typically divided into two groups, type A and type B.⁵⁴ Type A are dose related and include malaise, nausea, infectious complications, hepatitis, and myelosuppression. As mentioned earlier, the myelosuppression from azathioprine and mercaptopurine is related to a deficiency of TPMT with subsequent accumulation of toxic metabolites. Type B reactions are considered idiosyncratic and include fever, rash, arthralgia, and pancreatitis (3% to 15% of patients).^{54,106} Mercaptopurine causes adverse reactions similarly to azathioprine; however, there are fewer reports of lymphomas with this agent. In one cohort of IBD patients, adverse effects from mercaptopurine were as follows: pancreatitis, 1.2%; allergic reactions, 3.9%, significant leukopenia, 11.5%; and infectious complications, 14%.¹⁰⁸ Allopurinol inhibits the metabolism of mercaptopurine, and a dosage reduction of the latter is required when the two are used in combination.

Most patients receiving metronidazole for Crohn's disease tolerate the agent fairly well; however, mild adverse effects occur frequently. They commonly include nausea, metallic taste, urticaria, and glossitis.^{59,106} More serious effects that occur with long-term use include development of paresthesia and reversible peripheral neuropathy.^{59,106} Other effects include a disulfiram-like reaction if alcohol is ingested in conjunction.

Infliximab has been related to adverse effects such as infusion reactions, serum sickness, and increases in serious infections such as sepsis and reactivation of latent tuberculosis.^{60,89} Infusion reactions and serum sickness relate to the immune response to foreign protein.

Patients often develop anti-infliximab antibodies with multiple infusions. Serum sickness has occurred in patients who received infliximab doses separated by a long period of time.⁶⁰ Sepsis and tuberculosis may occur because of the inhibition of TNF-protective mechanisms. Patients should receive a tuberculin skin test (purified protein derivative) and a chest radiograph prior to initiating therapy to rule out undiagnosed tuberculosis.⁶⁰ Patients with clinically significant active infections should not receive infliximab. Lastly, infliximab may worsen existing heart failure and should be avoided in patients with severe or decompensated disease. Despite the potential for adverse effects, the reported rate of nonadherence to infliximab is low.¹⁰⁹

Adalimumab carries similar risks to infliximab, and therefore the same screening and monitoring that is used for infliximab should also be implemented for adalimumab.

EVALUATION OF THERAPEUTIC OUTCOMES

The success of therapeutic regimens to treat IBD can be measured by patient-reported complaints, signs, and symptoms; by direct clinician examination (including endoscopy); by history and physical examination; by selected laboratory tests; and by quality-of-life measures. Evaluation of IBD severity is difficult because much of the assessment is subjective.¹¹⁰ To create more objective measures, disease rating scales or indices have been created. The Crohn's Disease Activity Index is a commonly used scale, particularly for evaluation of patients during clinical trials.¹¹¹ The scale incorporates eight elements: (a) number of stools in the past 7 days; (b) sum of abdominal pain ratings from the past 7 days; (c) rating of general well-being in the past 7 days; (d) use of antidiarrheals; (e) body weight; (f) hematocrit; (g) finding of abdominal mass; and (h) a sum of extraintestinal symptoms present in the past week. Elements of this index provide a guide for those measures that may be useful in assessing the effectiveness of treatment regimens. A subsequent scale was developed specifically for perianal Crohn's disease, known as the Perianal Crohn's Disease Activity Index.¹¹⁰ The Perianal Crohn's Disease Activity Index includes five items: (a) presence of discharge; (b) pain; (c) restriction of sexual activity; (d) type of perianal disease; and (e) degree of induration.

Standardized assessment tools have also been constructed for ulcerative colitis.¹¹² Elements in these scales include (a) stool frequency; (b) presence of blood in the stool; (c) mucosal appearance (from endoscopy); and (d) physician's global assessment based on physical examination, endoscopy, and laboratory data.

Additional studies that are often useful include direct endoscopic examination of affected areas and radiocontrast studies. For patients with acute disease, assessment of fluid and electrolyte status is important, because these may be lost during diarrheal episodes. Other laboratory tests, such as serum albumin, transferrin, or other markers of visceral protein status, as well as markers of inflammation (erythrocyte sedimentation rate), may be used.

Assessment of the IBD patient must include consideration of adverse drug effects. Because many of the agents used have a relatively high probability of causing adverse effects, particularly corticosteroids and other immunosuppressive agents, patient assessment should include collection of history and physical and laboratory data that are necessary to prevent or recognize adverse drug effects.

Finally, a patient quality-of-life assessment should be performed regularly.¹¹⁰ Agents that appear clinically equivalent may differ substantially in resulting quality of life. Inquiry should be made regarding general well-being, emotional function, and social function. Social function may include assessment of the ability to perform routine daily functions, maintain occupational activities, sexual function, and recreation. The most common tool used to

assess quality of life is the Inflammatory Bowel Disease Questionnaire, a 32-item questionnaire that covers four disease dimensions: bowel function, emotional status, systemic symptoms, and social function.¹¹⁰ The Inflammatory Bowel Disease Questionnaire has shown good correlation with the Crohn's Disease Activity Index.¹¹⁰ A shortened version has also been developed for use in the community practice setting.¹¹³ A less-frequently used tool is the Rating Form of Inflammatory Bowel Disease Patient Concerns.¹¹⁰

Quality-of-life studies have been conducted with infliximab. To balance the exceptionally high cost of this therapy, Crohn's disease patients who receive infliximab have improved quality of life, fewer emergency room visits, a reduced requirement for surgery, and are more likely to be employed.^{114,115}

ABBREVIATIONS

HLA: human leukocyte antigen

IBD: inflammatory bowel disease

NSAIDs: nonsteroidal antiinflammatory drugs

TPMT: thiopurine S-methyltransferase

TNF- α : tumor necrosis factor- α

CECILY V. DIPIRO

KEY CONCEPTS

- 1 Nausea and/or vomiting may be a part of the symptom complex for a variety of gastrointestinal, cardiovascular, infectious, neurologic, metabolic, or psychogenic processes.
- 2 Nausea or vomiting may be caused by a variety of medications or other noxious agents.
- 3 The overall goal of treatment should be to prevent or eliminate nausea and vomiting regardless of etiology.
- 4 Treatment options for nausea and vomiting include drug and nondrug modalities such as relaxation, biofeedback, and self-hypnosis.
- 5 The primary goal with chemotherapy-induced nausea and vomiting (CINV) is to *prevent* nausea and/or vomiting. Optimal control of acute nausea and vomiting positively impacts the incidence and control of delayed and anticipatory nausea and vomiting.
- 6 The emetic risk of the chemotherapeutic regimen is the primary factor to consider when selecting prophylactic antiemetics for CINV.
- 7 Patients at high risk of vomiting should receive prophylactic antiemetics for postoperative nausea and vomiting (PONV).
- 8 Patients receiving single-exposure, high-dose radiation therapy to the upper abdomen or receiving total or hemibody irradiation, should receive prophylactic antiemetics for radiation-induced nausea and vomiting (RINV).

Nausea and vomiting are common complaints among many individuals with gastrointestinal (GI) disorders. However, because of the variable etiologies of these problems, management can be quite simple or detailed and complex, essentially innocuous or associated with therapy-induced adverse reactions. This chapter provides an overview of nausea and vomiting, two multifaceted problems.

Nausea is usually defined as the inclination to vomit or as a feeling in the throat or epigastric region alerting an individual that vomiting is imminent. Vomiting is defined as the ejection or expulsion of gastric contents through the mouth and is often a forceful event. Either condition may occur transiently with no other

associated signs or symptoms; however, these conditions also may be only part of a more complex clinical presentation.

ETIOLOGY

1 Nausea and vomiting may be associated with a variety of clinical presentations. In addition to GI diseases, either or both may accompany cardiovascular, infectious, neurologic, or metabolic disease processes. Nausea and vomiting may be a feature of such conditions as pregnancy, or may follow operative procedures or administration of certain medications, such as those used in cancer chemotherapy. Psychogenic etiologies of these symptoms may be present, especially in young women with an underlying emotional disturbance. Anticipatory etiologies may be involved, such as in patients who have previously received cytotoxic chemotherapy. Table 37–1 lists specific etiologies associated with nausea and vomiting.¹

In addition to identifying conditions associated with nausea and vomiting, it is important to address the specific causative medical problems. For example, nausea and vomiting may occur in as many as 70% of patients with inferior myocardial infarction or diabetic ketoacidosis. Eighty percent to 90% of patients with an Addisonian crisis, acute pancreatitis, or acute appendicitis may present with nausea and vomiting.

The etiology of nausea and vomiting may vary with the age of the patient. For example, vomiting in the newborn during the first day of life suggests upper digestive tract obstruction or an increase in intracranial pressure. Other illnesses associated with vomiting in children include pyloric stenosis, duodenal ulcer, stress ulcer, adrenal insufficiency, septicemia, and diseases of the pancreas, liver, or biliary tree. Also, the hepatocellular failure seen in Reye syndrome may lead to profound cerebral edema followed by persistent emesis. A common etiology of vomiting in children is viral gastroenteritis caused by rotavirus. Vomiting in infants may be associated with something as simple as overfeeding, rapid feeding, inadequate burping, or lying down too soon after feeding. These types of vomiting are usually indicative of minor problems and may be altered by changing the approach to feeding.

2 Drug-induced nausea and vomiting are of particular concern, especially with the increasing number of patients receiving cytotoxic treatment. A four-level classification system defines the risk for emesis with specific cytotoxic agents (Table 37–2).² Although some agents may have greater emetic risk than others, combinations of agents, high doses, clinical settings, psychological conditions, prior treatment experiences, and unusual stimulus of sight, smell, or taste may alter a patient's response to drug treatment. In this setting, nausea and vomiting may be unavoidable and some patients experience these problems so intensely that chemotherapy is postponed or discontinued. In addition to the emetic risk of various cytotoxic regimens, a variety of other common etiologies have been proposed for the development of nausea and vomiting in cancer patients (Table 37–3).^{3,4}

PATHOPHYSIOLOGY

The three consecutive phases of emesis include nausea, retching, and vomiting. Nausea, the imminent need to vomit, is associated with gastric stasis and may be considered a separate and singular symptom. Retching is the labored movement of abdominal and thoracic muscles before vomiting. The final phase of emesis is vomiting, the forceful expulsion of gastric contents caused by GI retroperistalsis. The act of vomiting requires the coordinated contractions of the abdominal muscles, pylorus, and antrum, a raised gastric cardia, diminished lower esophageal sphincter pressure, and esophageal dilatation.⁵ Vomiting should not be confused with regurgitation, an act in which the gastric or esophageal contents rise to the pharynx because of pressure differences caused by, for example, an incompetent lower esophageal sphincter. Accompanying autonomic symptoms of pallor, tachycardia, and

TABLE 37-2 Emetic Risk of Intravenous Cytotoxic Agents

Emetic Risk (If No Prophylactic Medication is Administered)	Cytotoxic Agent (in Alphabetical Order)
High (>90%)	Carmustine
	Cisplatin
	Cyclophosphamide $\geq 1,500$ mg/m ²
	Dacarbazine
	Dactinomycin
	Mechlorethamine
	Streptozotocin
Moderate (30% to 90%)	Carboplatin
	Cytarabine >1 g/m ²
	Cyclophosphamide $<1,500$ mg/m ²
	Daunorubicin
	Doxorubicin
	Epirubicin
	Idarubicin
	Ifosfamide
	Irinotecan
	Oxaliplatin
Low (10% to 30%)	Bortezomib
	Cetuximab
	Cytarabine ≤ 1 g/m ²
	Docetaxel
	Etoposide
	Fluorouracil
	Gemcitabine
	Methotrexate
	Mitomycin
	Mitoxantrone
	Paclitaxel
	Pemetrexed
	Topotecan
	Trastuzumab
Minimal (<10%)	Bevacizumab
	Bleomycin
	Busulfan
	2-Chlorodeoxyadenosine

diaphoresis account for many of the distressing feelings associated with emesis.

Vomiting is triggered by afferent impulses to the vomiting center, a nucleus of cells in the medulla. Impulses are received from sensory centers, such as the chemoreceptor trigger zone (CTZ), cerebral cortex, and visceral afferents from the pharynx and GI tract. When excited, afferent impulses are integrated by the vomiting center, resulting in efferent impulses to the salivation center, respiratory center, and the pharyngeal, GI, and abdominal muscles, leading to vomiting.

The CTZ, located in the area postrema of the fourth ventricle of the brain, is a major chemosensory organ for emesis and is usually associated with chemically induced vomiting. Because of its location, bloodborne and cerebrospinal fluid toxins have easy access to the CTZ. Therefore, cytotoxic agents primarily stimulate this area rather than the cerebral cortex and visceral afferents. Similarly, pregnancy-associated vomiting probably occurs through stimulation of the CTZ.

Numerous neurotransmitter receptors are located in the vomiting center, CTZ, and GI tract, including cholinergic, histaminic, dopaminergic, opiate, serotonergic, neurokinin, and benzodiazepine receptors. Chemotherapeutic agents, their metabolites, or other emetic compounds theoretically trigger the process of emesis through stimulation of one or more of these receptors. Effective antiemetics are able to antagonize or block the emetogenic receptors.

CLINICAL PRESENTATION

Because it is impossible to discuss all clinical settings in which the presence of nausea and vomiting might be a pertinent finding, these processes are presented in Table 37–4 as they might occur together, and also as *simple* or *complex* in presentation.

TREATMENT

Nausea and Vomiting

■ DESIRED OUTCOME

③ The overall goal of antiemetic therapy is to prevent or eliminate nausea and vomiting. This should be accomplished without adverse effects or with clinically acceptable adverse effects. Although this goal may be accomplished easily in patients with simple nausea and vomiting, patients with more complex problems require greater assistance. In addition to these clinical goals, appropriate cost issues should be considered, particularly in the management of chemotherapy-induced and postoperative nausea and vomiting.

TABLE 37-4 Presentation of Nausea and Vomiting

General
Depending on severity of symptoms, patients may present in mild to severe distress
Symptoms
<i>Simple:</i> Self-limiting, resolves spontaneously and requires only symptomatic therapy
<i>Complex:</i> Not relieved after administration of antiemetics; progressive deterioration of patient secondary to fluid–electrolyte imbalances; usually associated with noxious agents or psychogenic events
Signs
<i>Simple:</i> Patient complaint of queasiness or discomfort
<i>Complex:</i> Weight loss; fever; abdominal pain
Laboratory tests
<i>Simple:</i> None
<i>Complex:</i> Serum electrolyte concentrations; upper/lower GI evaluation
Other information
Fluid input and output
Medication history
Recent history of behavioral or visual changes, headache, pain, or stress
Family history positive for psychogenic vomiting

■ GENERAL APPROACH TO TREATMENT

④ Treatment options for nausea and vomiting include drug and nondrug modalities. The treatment of nausea and vomiting is quite varied depending on the associated medical situation. Even though a number of potentially effective measures are available, most patients receive a medication at some point in their care. For simple nausea and vomiting, patients may choose to do nothing or to select from a variety of nonprescription drugs. As symptoms become worse or are associated with more serious medical problems, patients are more likely to benefit from prescription antiemetic drugs. When prescribed according to reliable clinical information, these agents often provide acceptable relief; however, some patients will never be totally free of symptoms. This lack of relief is most disabling when it is associated with an unresolved medical problem or when the necessary therapy for this condition is the cause of the nausea or vomiting, as in the case of patients who are receiving chemotherapy of moderate or high emetic risk.

■ NONPHARMACOLOGIC MANAGEMENT

Nonpharmacologic management of nausea and vomiting may include a variety of dietary, physical, or psychological changes consistent with the etiology of symptoms. For patients with simple complaints, perhaps resulting from excessive or disagreeable food or beverage consumption, avoidance or moderation in dietary intake may be preferable. Patients suffering symptoms of systemic illness may improve dramatically as their underlying condition resolves. Finally, patients in whom these symptoms result from labyrinthine changes produced by motion may benefit quickly by assuming a stable physical position.

Cancer patients who are undergoing chemotherapy may experience nausea and/or vomiting despite receiving prophylactic antiemetics. Anticipatory nausea or vomiting rarely occurs unless the patient has previously experienced posttreatment nausea or vomiting, suggesting that the mechanism for anticipatory nausea and vomiting is a learned process involving elements of classic conditioning.⁶ This conditioning model may also be important in understanding the development of pregnancy-related nausea. Nonpharmacologic interventions are classified as behavioral interventions and include relaxation, biofeedback, self-hypnosis, cognitive distraction, guided imagery, and systematic desensitization.^{7,8}

The management of psychogenic vomiting is greatly dependent on psychological intervention. However, because the underlying problems are so complex and intertwined in personal relationships, psychological therapy may require lengthy, in-depth treatment. Pharmacologic therapy offers only minimal benefit in these patients. Surgery, such as gastroenterostomy, is of no value.

■ PHARMACOLOGIC THERAPY

④ Although many approaches to the treatment of nausea and vomiting have been suggested, antiemetic drugs (nonprescription and prescription) are most often recommended. These agents represent a variety of pharmacologic and chemical classes, as well as dosage regimens and routes of administration. With so many treatment possibilities available, factors that enable the clinician to discriminate among various choices include (a) the suspected etiology of the symptoms; (b) the frequency, duration, and severity of the episodes; (c) the ability of the patient to use oral, rectal, injectable, or transdermal medications; and (d) the success of previous antiemetic medications. Table 37–5 gives information concerning commonly available antiemetic preparations.

The treatment of simple nausea and vomiting usually requires minimal therapy. For these symptoms, patients may choose from a lengthy list of nonprescription products. Both nonprescription and

TABLE 37-5 Common Antiemetic Preparations and Adult Dosage Regimens

Drug	Adult Dosage Regimen	Dosage Form/Route	Availability
Antacids			
Antacids (various)	15–30 mL every 2–4 h prn	Liquid	OTC
Histamine (H₂) antagonists			
Cimetidine (Tagamet HB)	200 mg twice daily prn	Tab	OTC
Famotidine (Pepcid AC)	10 mg twice daily prn	Tab	OTC
Nizatidine (Axid AR)	75 mg twice daily prn	Tab	OTC
Ranitidine (Zantac 75)	75 mg twice daily prn	Tab	OTC
Antihistaminic–anticholinergic agents			
Cyclizine (Marezine)	50 mg before departure; may repeat in 4–6 h prn	Tab	OTC
Dimenhydrinate (Dramamine)	50–100 mg every 4–6 h prn	Tab, chew tab, cap	OTC
Diphenhydramine (Benadryl)	25–50 mg every 4–6 h prn	Tab, cap, liquid	Rx/OTC
	10–50 mg every 2 to 4 h prn	IM, IV	
Hydroxyzine (Vistaril, Atarax)	25–100 mg every 4–6 h prn	IM (unlabeled use)	Rx
Meclizine (Bonine, Antivert)	12.5–25 mg 1 h before travel; repeat every 12–24 h prn	Tab, chew tab	Rx/OTC
Scopolamine (Transderm Scop)	1.5 mg every 72 h	Transdermal patch	Rx
Trimethobenzamide (Tigan)	300 mg three to four times daily	Cap	Rx
	200 mg three to four times daily	IM, supp	
Phenothiazines			
Chlorpromazine (Thorazine)	10–25 mg every 4–6 h prn	Tab, liquid	Rx
	25–50 mg every 4–6 h prn	IM, IV	
Prochlorperazine (Compazine)	5–10 mg three to four times daily prn	Tab, liquid	
	5–10 mg every 3 to 4 h prn	IM	Rx
	2.5–10 mg every 3 to 4 h prn	IV	Rx
	25 mg twice daily prn	Supp	Rx
Promethazine (Phenergan)	12.5–25 mg every 4–6 h prn	Tab, liquid, IM, IV, supp	Rx
Thiethylperazine (Torecan)	10 mg one to six times daily prn	Tab, IM, IV	Rx
Cannabinoids			
Dronabinol (Marinol)	5–15 mg/m ² every 2–4 h prn	Cap	Rx (C-III)
Nabilone (Cesamet)	1–2 mg twice daily	Cap	Rx (C-II)
Butyrophenones			
Haloperidol (Haldol)	1–5 mg every 12 h prn	Tab, liquid, IM, IV	Rx
Droperidol (Inapsine) ^a	2.5 mg; additional 1.25 mg may be given	IM, IV	Rx
Benzodiazepines			
Alprazolam (Xanax)	0.5–2 mg three times per day prior to chemotherapy	Tab	Rx (C-IV)
Lorazepam (Ativan)	0.5–2 mg on night before and morning of chemotherapy	Tab	Rx (C-IV)
Miscellaneous agents			
Metoclopramide (Reglan), for delayed CINV	20–40 mg three to four times daily	Tab	Rx

C-II, C-III, C-IV, controlled substance schedule 2, 3, and 4, respectively; cap, capsule; chew tab, chewable tablet; CINV, chemotherapy-induced nausea and vomiting; liquid, oral syrup, concentrate, or suspension; OTC, nonprescription; Rx, prescription; supp, rectal suppository; tab, tablet.

^aSee text for current warnings.

prescription drugs useful in the treatment of simple nausea and vomiting are usually effective in small, infrequently administered doses. Side effects and toxic effects in these settings are also usually minimal. Although suitable for occasional simple nausea and vomiting, nonprescription agents are often abandoned by the patient as symptoms continue or become progressively worse. As the patient's condition warrants, prescription medications may be chosen, either as single-agent therapy or in combination.

The management of complex nausea and vomiting, for example, in patients who are receiving cytotoxic chemotherapy, may require combination therapy. In combination regimens, the goal is to achieve symptomatic control through administration of agents with different pharmacologic mechanisms of action.

■ ANTACIDS

Patients who are experiencing simple nausea and vomiting may use various antacids. In this setting, single or combination nonprescription antacid products, especially those containing magnesium hydroxide, aluminum hydroxide, and/or calcium carbonate, may provide sufficient relief, primarily through gastric acid neutralization.

Common antacid regimens for the relief of acute or intermittent nausea and vomiting include one or more 15 to 30 mL doses of single- or multiple-agent products. Potential adverse effects from antacids are usually related to the presence of magnesium, alumi-

num, or calcium salts. Specifically, osmotic diarrhea from magnesium and constipation from aluminum or calcium salts may be of concern to patients, particularly those self-medicating with high or frequently administered antacid doses. Generally, however, when used occasionally for acute episodic relief of nausea and vomiting, antacids do not produce serious toxicities.

■ H₂-RECEPTOR ANTAGONISTS

Patients may use histamine₂-receptor antagonists in low doses to manage simple nausea and vomiting associated with heartburn or gastroesophageal reflux. Individual dosages of cimetidine 200 mg, famotidine 10 mg, nizatidine 75 mg, or ranitidine 75 mg may be used for brief periods. Except for potential drug interactions with cimetidine, these agents cause few side effects when used for episodic relief.

■ ANTIHISTAMINE–ANTICHOLINERGIC DRUGS

Antiemetic drugs from the antihistaminic–anticholinergic category appear to interrupt various visceral afferent pathways that stimulate nausea and vomiting and may be appropriate in the treatment of simple nausea and vomiting. Adverse reactions associated with the use of the antihistaminic–anticholinergic agents primarily include drowsiness, confusion, blurred vision, dry mouth, and urinary reten-

tion, and possibly tachycardia, particularly in elderly patients. Also, as doses are increased or are more frequently administered, patients with narrow-angle glaucoma, prostatic hyperplasia, or asthma are at greater risk of complications from the anticholinergic effects of these drugs.

■ PHENOTHIAZINES

Phenothiazines have been the most widely prescribed antiemetic agents and appear to block dopamine receptors, most likely in the CTZ. Phenothiazines are marketed in an array of dosage forms, none of which appears to be more efficacious than another. These agents may be most practical for long-term treatment and are inexpensive in comparison with newer drugs. Rectal administration is a reasonable alternative in patients in whom oral or parenteral administration is not feasible.

Phenothiazines are most useful in adult patients with simple nausea and vomiting. Intravenous prochlorperazine provides quicker and more complete relief with less drowsiness than intravenous promethazine in adult patients treated in an emergency department for nausea and vomiting associated with uncomplicated gastritis or gastroenteritis.⁹ There are numerous potential side effects with these medications, including extrapyramidal reactions, hypersensitivity reactions with possible liver dysfunction, bone marrow aplasia, and excessive sedation.

■ BUTYROPHENONES

Two butyrophenone compounds that have antiemetic activity are haloperidol and its congener droperidol; both block dopaminergic stimulation of the CTZ. Although each agent is effective in relieving nausea and vomiting, haloperidol is not considered first-line therapy for uncomplicated nausea and vomiting but has been used in palliative care situations.¹⁰ The current labeling of droperidol recommends that all patients should undergo a 12-lead electrocardiogram prior to administration, followed by cardiac monitoring for 2 to 3 hours after administration because of the possibility of the development of potentially fatal QT prolongation and/or torsade de pointes.¹¹ The clinical use of droperidol has effectively ceased outside of clinical trials in anesthesia.

■ CORTICOSTEROIDS

Corticosteroids have demonstrated antiemetic efficacy since the initial recognition that patients who received prednisone as part of their Hodgkin disease protocol appeared to develop less nausea and vomiting than did those patients who were treated with protocols that excluded this agent. Methylprednisolone has also been used as a component of an antiemetic regimen, but the majority of trials have included dexamethasone.

Dexamethasone has been used successfully in the management of chemotherapy-induced and postoperative nausea and vomiting, either as a single agent or in combination with selective serotonin reuptake inhibitors (SSRIs). For chemotherapy-induced nausea and vomiting (CINV), dexamethasone is effective in the prevention of both cisplatin-induced acute emesis and when used alone or in combination for the prevention of delayed nausea and vomiting associated with CINV.^{12–15} For patients with simple nausea and vomiting, steroids are not indicated and may be associated with unacceptable risks.

■ METOCLOPRAMIDE

Metoclopramide, procainamide's congener, provides significant antiemetic effects by blocking the dopaminergic receptors centrally in the CTZ. Metoclopramide increases lower esophageal sphincter tone, aids gastric emptying, and accelerates transit through the small bowel, possibly through the release of acetylcholine. Metoclopra-

midate is used for its antiemetic properties in patients with diabetic gastroparesis and with dexamethasone for prophylaxis of delayed nausea and vomiting associated with chemotherapy administration. Its use as prophylaxis for acute chemotherapy-induced nausea and vomiting was supplanted by the introduction of the SSRIs in the early 1990s. These agents have greater efficacy and decreased toxicity compared with metoclopramide in patients who are receiving cisplatin-based regimens.^{16,17}

■ CANNABINOIDS

Thirty randomized, controlled trials from 1975 to 1996 were analyzed to quantify the antiemetic efficacy and adverse effects of cannabis when given to 1,366 patients who received chemotherapy.¹⁸ Oral nabilone, oral dronabinol, and intramuscular levonantradol were compared with conventional antiemetics (prochlorperazine, metoclopramide, chlorpromazine, thiethylperazine, haloperidol, domperidone, and alizapride) or placebo. Across all trials, cannabinoids were slightly more effective than active comparators and placebo when the chemotherapy regimen was of moderate emetogenic potential, and patients preferred them. No dose-response relationships were evident to the authors. The cannabinoids were also more toxic; side effects included euphoria, drowsiness, sedation, somnolence, dysphoria, depression, hallucinations, and paranoia. The efficacy of cannabinoids as compared to SSRIs has not been studied. Use of these agents should be considered when other regimens do not provide desired efficacy.

■ SUBSTANCE P/NEUROKININ 1 RECEPTOR ANTAGONISTS

Substance P is a peptide neurotransmitter in the neurokinin (NK) family whose preferred receptor is the NK₁ receptor.¹⁹ The acute phase of CINV is believed to be mediated by both serotonin and substance P, whereas substance P is believed to be the primary mediator of the delayed phase. Aprepitant is the first substance P/NK₁ receptor antagonist in clinical use; others are in development. The efficacy of aprepitant was demonstrated in patients receiving high-dose cisplatin-based chemotherapy^{14,15} and in patients receiving doxorubicin and cyclophosphamide,²⁰ a regimen of moderate emetic risk. The three-drug regimen of aprepitant, dexamethasone, and ondansetron provided improved protection from vomiting for the 5 days after chemotherapy administration as compared with the combination of dexamethasone and ondansetron.

Aprepitant has the potential for numerous drug interactions because it is a substrate, moderate inhibitor, and an inducer of cytochrome isoenzyme CYP3A4 and an inducer of CYP2C9. Aprepitant can increase serum concentrations of many drugs metabolized by CYP3A4, including docetaxel, paclitaxel, etoposide, irinotecan, ifosfamide, imatinib, vinorelbine, vincristine, and vinblastine. In clinical studies, aprepitant was concomitantly administered with etoposide, vinorelbine, or paclitaxel, with no adjustment in the doses of these agents to account for potential drug interactions. The efficacy of oral contraceptives may be reduced when given with aprepitant. Concomitant administration with warfarin may result in a clinically significant decrease in the international normalized ratio.²¹ The dose of oral dexamethasone should be reduced 50% when coadministered with aprepitant, because of the 2.2-fold increase in observed area under the plasma-concentration-versus-time curve.²² Aprepitant is not approved for use in children.

■ SELECTIVE SEROTONIN REUPTAKE INHIBITORS

SSRIs block presynaptic serotonin receptors on sensory vagal fibers in the gut wall, effectively blocking the acute phase of CINV. These

agents do not completely block the acute phase of CINV and are less efficacious in preventing the delayed phase, but they are the standard of care in the management of chemotherapy-induced, radiation-induced, and postoperative nausea and vomiting. Issues involved in the use of dolasetron, granisetron, ondansetron, and palonosetron are reviewed in detail in the sections that follow. The most common side effects associated with these agents are constipation, headache, and asthenia. Safety and efficacy in children younger than 2 years old have not been established.

■ CHEMOTHERAPY-INDUCED NAUSEA AND VOMITING

5 Nausea and vomiting that occurs within 24 hours of chemotherapy administration is defined as acute, whereas when it starts more than 24 hours after chemotherapy administration, it is defined as delayed. The primary goal with CINV is to *prevent* nausea and/or vomiting. Optimal control of acute nausea and vomiting positively impacts the incidence and control of delayed and anticipatory nausea and vomiting. Clinical practice guidelines for the use of antiemetics in CINV have been published.^{2,23,24} Despite the availability of these practice guidelines, product availability and recommended doses are institution-specific and may vary considerably from the doses listed in Table 37–6.

Factors to consider when selecting an antiemetic for CINV include the following:

- The emetic risk of the chemotherapy agent or regimen (see Table 37–2).
- Patient-specific factors.
- Patterns of emesis after administration of specific chemotherapy agents or regimens.

Prophylaxis of CINV

6 The emetic risk of the chemotherapeutic agent (see Table 37–2) is the primary factor to consider when deciding whether to administer prophylactic agents and which antiemetic(s) to select. Tables 37–6 and 37–7 summarize recommendations from the updated American Society of Clinical Oncology (ASCO) antiemetic guidelines.²³ Antiemetic guidelines published by other groups are in overall agreement with the ASCO guidelines. Minor differences reflect the volume of literature published and the varying doses studied.

Patients receiving chemotherapy that is classified as being of high emetic risk should receive a combination antiemetic regimen containing three drugs on the day of chemotherapy administration (day

TABLE 37-7 Dosage Recommendations for CINV

Emetic Risk	Prophylaxis of Acute Phase of CINV (one dose administered prior to chemotherapy)	Prophylaxis of Delayed Phase of CINV
High	SSRI: Dolasetron 100 mg PO or 100 mg IV or 1.8 mg/kg IV Granisetron 2 mg PO or 1 mg IV or 0.01 mg/kg IV Ondansetron 24 mg PO or 8 mg IV or 0.15 mg/kg IV Palonosetron 0.25 mg IV and Dexamethasone 12 mg PO (with aprepitant) or 20 mg PO and Aprepitant 125 mg PO	Dexamethasone 8 mg PO days 2 and 3 after chemotherapy Aprepitant 80 mg PO days 2 and 3 after chemotherapy
Moderate	Anthracycline + cyclophosphamide: SSRI: (as above) and Dexamethasone 12 mg PO (with aprepitant) and Aprepitant 125 mg PO All other regimens of moderate emetic risk: SSRI: Dolasetron 100 mg PO or 100 mg IV or 1.8 mg/kg IV Granisetron 2 mg PO or 1 mg IV or 0.01 mg/kg IV Ondansetron 16 mg PO or 8 mg IV or 0.15 mg/kg IV Palonosetron 0.25 mg IV and Dexamethasone 8 mg IV	Aprepitant 80 mg PO days 2 and 3 after chemotherapy SSRI: Dolasetron 100 mg PO daily ^a Granisetron 1 mg PO daily ^a Ondansetron 8 mg PO daily or twice daily ^a or Dexamethasone 8 mg PO daily ^a
Low	Dexamethasone 8 mg PO	None
Minimal	None	None

CINV, chemotherapy-induced nausea and vomiting; SSRI, selective serotonin reuptake inhibitor.
^aFor 2–4 days following chemotherapy.
Doses included in the above table reflect the recommendations from published guidelines (refs. 3, 28, 29). These doses may differ from manufacturer labeling; they reflect the consensus of the guideline participants.

1)—a SSRI (e.g., dolasetron, granisetron, ondansetron, or palonosetron) + dexamethasone + NK₁ inhibitor (e.g., aprepitant). Patients receiving regimens that are classified as being of moderate emetic risk should receive a combination antiemetic regimen containing a SSRI + dexamethasone on day 1. The exception to this is patients who are receiving an anthracycline plus cyclophosphamide; these patients should receive the triple-drug combination described for regimens of high emetic risk. Dexamethasone alone is recommended for prophylaxis prior to regimens of low emetic risk.

SSRIs are considered to be of equivalent efficacy and safety when equivalent doses are used for the prevention of acute emesis. When available in both oral and intravenous dosage forms, oral products are equally effective as intravenous products. The decision as to which SSRI to use should be based on patient-specific factors and cost.

Treatment of CINV

Some patients who are receiving chemotherapy experience nausea and/or vomiting despite the use of multiagent prophylaxis. All patients receiving chemotherapy should have antiemetics available for rescue of breakthrough nausea and vomiting. Chlorpromazine, prochlorperazine, promethazine, methylprednisolone, lorazepam, metoclopramide, dexamethasone, and dronabinol can be used for adult patients. Around-the-clock dosing should be considered

TABLE 37-6 Recommendations for the Use of Antiemetics in Patients Receiving Chemotherapy

Emetic Risk	Prophylaxis of Acute Phase of CINV on Day of Chemotherapy Administration (Day 1)	Prophylaxis of Delayed Phase of CINV
High	SSRI + dexamethasone + aprepitant	Days 2 and 3 after chemotherapy: dexamethasone + aprepitant
Moderate	Anthracycline + cyclophosphamide: SSRI + dexamethasone + aprepitant All other regimens of moderate emetic risk: SSRI + dexamethasone	Days 2 and 3 after chemotherapy: aprepitant Days 2–4 after chemotherapy: dexamethasone or SSRI
Low	Dexamethasone	None
Minimal	None	None

CINV, chemotherapy-induced nausea and vomiting; SSRI, selective serotonin reuptake inhibitor.

TABLE 37-8 Risk Factors for Postoperative Nausea and Vomiting

Patient-specific factors
Female gender
Nonsmoking status
History of motion sickness/postoperative nausea and vomiting
Anesthetic risk factors
Use of volatile anesthetics
Nitrous oxide
Use of opioids (intraoperative or postoperative)
Surgical risk factors
Duration of surgery
Operative procedure (intraabdominal, ear-nose-throat, major gynecologic, orthopedic, or laparoscopic)

From Gan et al.²⁹

rather than as-needed administration. The choice of agent should be based on patient-specific factors, including potential adverse drug reactions, and cost. Granisetron, dolasetron, and ondansetron are effective in the treatment of breakthrough nausea and vomiting, but they are not superior to the less expensive antiemetics listed above. Chlorpromazine, lorazepam, and methylprednisolone (or dexamethasone) are recommended for pediatric patients.

Prophylaxis of Delayed CINV
